For schedule and classifier consumers, combine Definition 459.6 with Definition 459.7. The sign flip remains a displayed dyadic ledger operation, and the inherited limit classifier reaches the real-name boundary only through E.

Thus the public export is a finite BEDC seal handoff. It is not a completed-real inverse theorem, because the carrier has no coordinate from which a quotient stream, host sequence equality, selected limit, or ambient completeness premise could be projected. □

Theorem 459.9 (RegularCauchyNegation apartness non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *apartness, additive-inverse, sum, or difference consumer of an accepted* $\mathsf{RegularCauchyNegation}^{\uparrow}$ *carrier*

$$G = (X, W, D, R, F, E, H, C, P, N)$$

must read the sign-flipped dyadic ledger F, the source classifier row R, and the $\mathsf{Real}^{\uparrow}$ *seal row E through the displayed rows $X, W, D, R, F, E, H, C, P, N$. It cannot replace that route by host sequence equality, quotient-stream equality, selected limits, completed-real inverse laws, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.RegularCauchyNegationUp.RegularCauchyNegationCarrier apartness nonescape`

Proof. Start with the local obligations of Definition 459.2. They expose the source row, window schedule, dyadic observation row, classifier row, sign-flipped ledger, seal handoff, transports, continuation routes, provenance, and local naming row as coordinates of the same packet.

The algebraic handoff theorem Definition 459.4 handles additive-inverse, sum, and difference consumers. Each such route reads the sign-flipped ledger F as the unary negation surface, uses the source classifier row R as the regular rational readback boundary, and reaches the real-facing row only through the seal E.

For apartness consumers, combine sign-flip ledger stability with limit-classifier compatibility. The apartness read can inspect the displayed opposite dyadic observations and their inherited classifier data, but the route to a RealUp boundary still passes through F, R, and E in the same carrier.

Finally apply the public seal export theorem Definition 459.8. Since every public real-facing consumer receives exactly the displayed seal route and the carrier contains no host sequence equality, quotient-stream equality, selected limit, completed-real inverse law, or ambient completeness premise, none of those objects can escape through apartness or additive-inverse use. □

Theorem 459.10 (RegularCauchyNegation additive-inverse boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *additive-inverse, apartness, sum, or difference consumer of an accepted* $\mathsf{RegularCauchyNegation}^{\uparrow}$ *carrier*

$$G = (X, W, D, R, F, E, H, C, P, N)$$

must pass through the sign-flipped dyadic ledger F, the source classifier row R, and the $\mathsf{Real}^{\uparrow}$ *seal row E displayed by G. The consumer may inspect the finite rows $X, W, D, R, F, E, H, C, P, N$ through the stored* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegularCauchyNegation}^{\uparrow}}$ *row, but it cannot replace this boundary by quotient streams, host sequence equality, selected limits, completed-real inverse laws, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.RegularCauchyNegationUp.RegularCauchyNegationCarrier additive inverse boundary`

Proof. Begin with the NameCert obligations of Definition 459.2. Carrier admission and classifier transport place the consumer inside the displayed packet G, with R as the source regular-rational classifier and F as the only sign-flipped dyadic observation ledger.

Next apply the algebraic handoff theorem Definition 459.4. Additive-inverse, sum, and difference consumers all read the negated row as a finite algebraic surface through F and R, not as a completed-real inverse operation.

The sign-flip ledger stability theorem Definition 459.6 and the limit-classifier compatibility theorem Definition 459.7 keep the same finite sign-flipped observations attached to the inherited $\mathsf{RegSeqRat}^{\uparrow}$ classifier. Thus any classifier-facing or apartness-facing read still reaches the real boundary only through F, R, E.

Finally combine the public seal export theorem Definition 459.8 with apartness non-escape Definition 459.9. These results exhaust the public $\mathsf{Real}^{\uparrow}$ route and rule out quotient streams, host sequence equality, selected limits, completed-real inverse laws, and ambient completeness as exported data. □

Theorem 459.11 (RegularCauchyNegation involutive seal boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *algebraic, apartness, sum, or difference consumer of an accepted* $\mathsf{RegularCauchyNegation}^{\uparrow}$ *carrier*

$$G = (X, W, D, R, F, E, H, C, P, N)$$

that applies the displayed sign-flip boundary twice must factor through the original $\mathsf{RegularCauchyName}^{\uparrow}$ *source row* X*, the* $\mathsf{StreamName}^{\uparrow}$ *window schedule* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation row* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* R*, the first sign-flipped ledger* F*, the second displayed sign-flipped ledger, and the same* $\mathsf{Real}^{\uparrow}$ *seal route* E, H, C, P, N*. The double route exports no quotient stream, host sequence equality, selected limit, completed-real inverse law, or ambient completeness premise.*

Lean4 ✓ `BEDC.Derived.RegularCauchyNegationUp.RegularCauchyNegationCarrier involutive seal boundary`

Proof. Start with the NameCert obligations in Definition 459.2. They make $X, W, D, R, F, E, H, C, P, N$ the only available carrier coordinates, and they force any sign-flip read to pass through the source windows, dyadic row, classifier row, displayed transports, continuation routes, provenance, and local naming row.

Apply sign-flip ledger stability Definition 459.6 to the first boundary. The first flip is a finite operation on the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ observations read through W and classified by R, so the consumer obtains only the ledger F and not a host-level negation or completed real name.

Apply the same boundary form to the second displayed sign flip. The second ledger is again reached through the same source row, schedule, dyadic observations, classifier row, transports, routes, package provenance, and naming certificate; it is not an independent quotient object and it does not replace the original source row X by host sequence equality.

For algebraic consumers, use the additive-inverse boundary Definition 459.10. It already restricts additive-inverse, apartness, sum, and difference routes to the finite rows $X, W, D, R, F, E, H, C, P, N$, so a double sign-flip route can only add the second displayed ledger before returning to the same $\mathsf{Real}^{\uparrow}$ seal handoff.

Finally combine public seal export Definition 459.8 with apartness non-escape Definition 459.9. The public real-facing boundary remains the same seal route E, H, C, P, N, and the absence of

quotient streams, host sequence equality, selected limits, completed-real inverse laws, and ambient completeness premises prevents the double route from exporting stronger real-algebra data. □

Theorem 459.12 (RegularCauchyNegation bridge readback scope)**.** *Every bridge-facing consumer of the public sign-flipped* $\mathsf{Real}^{\uparrow}$ *seal exported by an accepted* $\mathsf{RegularCauchyNegation}^{\uparrow}$ *carrier*

$$G = (X, W, D, R, F, E, H, C, P, N)$$

must factor through the displayed $\mathsf{RegularCauchyName}^{\uparrow}$ *source row* X*, the* $\mathsf{StreamName}^{\uparrow}$ *window schedule* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation row* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *pointwise classifier row* R*, the sign-flipped dyadic ledger* F*, the* hsame *transports* H*, the* Cont *routes* C*, the* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyNegation}^{\uparrow}}$ *row* N*. The readback may reach the public seal row* E *only through those rows, and it does not assert quotient equality, selected limits, ambient real completeness, or full additive inverse laws for completed real names.*

Lean4 ✓ `BEDC.Derived.RegularCauchyNegationUp.RegularCauchyNegationCarrier bridge readback scope`

Proof. Begin with carrier transport. The NameCert obligations expose $X, W, D, R, F, E, H, C, P, N$, and transport stability keeps the source row, window schedule, dyadic observation row, classifier row, and seal row in the same displayed packet.

Next apply sign-flip ledger stability. It makes F a pointwise read from the dyadic observation row D under the scheduled windows W, so a bridge-facing consumer cannot replace the sign-flipped observations by a completed-real operation.

Use limit-classifier compatibility for the classifier readback. The inherited $\mathsf{RegSeqRat}^{\uparrow}$ row R is read before the real-facing handoff, and the public seal export theorem routes the handoff to E only after $X, W, D, R, F, H, C, P, N$ have been exposed.

Finally apply apartness non-escape. It rules out quotient streams, host sequence equality, selected limits, completed-real inverse laws, and ambient completeness as exported bridge data, so the bridge-facing readback scope is exactly the displayed finite carrier surface. □

Theorem 459.13 (RegularCauchyNegation real-algebra bridge certificate)**.** *For every accepted* $\mathsf{RegularCauchyNegation}^{\uparrow}$ *carrier*

$$G = (X, W, D, R, F, E, H, C, P, N),$$

the $\mathsf{Real}^{\uparrow}$*-algebra bridge certificate exported by* G *is exactly the finite certificate assembled from the sign-flipped dyadic ledger* F*, the inherited* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* R*, the public* $\mathsf{Real}^{\uparrow}$ *seal row* E*, the displayed* hsame *transports* H*, the displayed* Cont *routes* C*, the* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyNegation}^{\uparrow}}$ *row* N*. This certificate is the bridge-facing handoff for downstream sum, difference, additive-inverse, and apartness consumers; it exports no quotient stream, host sequence equality, selected limit, completed-real inverse law, or ambient completeness premise.*

Lean4 ✓ `BEDC.Derived.RegularCauchyNegationUp.RegularCauchyNegationCarrier real algebra bridge certificate`

Proof. The NameCert obligations of Definition 459.2 identify the carrier and classifier rows inside the single packet G. In particular, R is the inherited $\mathsf{RegSeqRat}^{\uparrow}$ classifier row, while H, C, P, N are the displayed transport, continuation, provenance, and local naming rows available to any certified consumer.

The sign-flip ledger stability theorem Definition 459.6 pins the negated dyadic observations to F, and the algebraic handoff theorem Definition 459.4 is the route by which sum, difference, additive-inverse, and apartness consumers read that ledger. Thus the algebra-facing part of the certificate is the pair (F, R) together with the displayed rows H, C, P, N, not a completed-real inverse operation.

The public seal export theorem Definition 459.8 supplies the real-facing boundary E. The involutive seal boundary Definition 459.11 keeps double sign-flip use inside the same displayed carrier rows, so repeated algebraic reads do not create an additional public object beyond F, R, E, H, C, P, N.

Finally, the bridge readback scope theorem Definition 459.12 describes the bridge-facing consumers of the public sign-flipped seal. Combining that scope with apartness non-escape Definition 459.9 rules out quotient streams, host sequence equality, selected limits, completed-real inverse laws, and ambient completeness, which leaves exactly the stated finite bridge certificate. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyNegation}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyNegation}^{\uparrow}$ packet is generated from a $\mathsf{RegularCauchyName}^{\uparrow}$ source row, a $\mathsf{StreamName}^{\uparrow}$ window schedule, a $\mathsf{DyadicRatCore}^{\uparrow}$ observation row, a $\mathsf{RegSeqRat}^{\uparrow}$ pointwise classifier row, a sign-flipped dyadic ledger, a $\mathsf{Real}^{\uparrow}$ seal handoff, displayed hsame transports, Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyNegation}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The real-algebra bridge certificate theorem Definition 459.13 binds the sign-flipped dyadic ledger, inherited RegSeqRat classifier row, RealUp seal, displayed hsame transports, Cont routes, Pkg provenance, and local NameCert row for bridge-facing algebra consumers.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyNegation}^{\uparrow}}, \mathsf{auditClean})$

Lean target: `BEDC.Derived.RegularCauchyNegationUp.RegularCauchyNegationCarrier\_real\_algebra\_bridge\_certificat`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close quotient equality of streams, host sequence equality, selected limits, ambient real completeness, completed-real additive inverse laws, a StdBridge object, or ambient real algebra.

Upgrade path: No further paper-side theory closure is claimed beyond standard bridge checking for the displayed real-algebra certificate.

Chapter 460

A Concrete Naming Certificate for $\mathsf{CauchyDoubleSequence}^{\uparrow}$

The $\mathsf{CauchyDoubleSequence}^{\uparrow}$ interface names the finite certificate used when a two-parameter regular Cauchy array is read through a diagonal cofinal window and then handed to the constructive real-completion path. It records the array, the selected diagonal schedule, tail tolerance data, regular readback, completion consumer, and $\mathsf{Real}^{\uparrow}$ seal provenance without asserting a quotient limit or host double-sequence convergence theorem.

The two-parameter array route consumes the finite $\mathsf{StreamName}^{\uparrow}$ window surface of chapter 126, the regular-rational readback surface of chapter 301, and the seal-facing $\mathsf{Real}^{\uparrow}$ row of chapter 38 before the $\mathsf{RealCauchyCompletion}^{\uparrow}$ consumer is read.

Definition 460.1 (CauchyDoubleSequence carrier)**.** *A* $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (X, \mu, \tau, D, R, E, H, C, P, N)$$

with the following displayed coordinates:

1. *X is a two-parameter* $\mathsf{RegSeqRat}^{\uparrow}$ *family, read only through finite stream windows and regular rational rows;*
2. *μ is the* $\mathsf{CauchyRate}^{\uparrow}$ *schedule selecting a diagonal cofinal window in the two indices;*
3. *τ is the* $\mathsf{DyadicTailBound}^{\uparrow}$ *tolerance row assigned to the selected diagonal window;*
4. *D is the diagonal* $\mathsf{RegSeqRat}^{\uparrow}$ *readback obtained by applying μ and τ to X;*
5. *R is the* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *consumer row that reads the diagonal regular name;*
6. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row exposed after the completion consumer reads D;*
7. *H stores the componentwise* hsame *transports for the array, schedule, tolerance, diagonal readback, completion consumer, and real seal rows;*
8. *C stores the* Cont *routes for reading the array windows, schedule, tail bound, diagonal readback, completion consumer, and seal;*
9. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyRate}^{\uparrow}$, $\mathsf{RealCauchyCompletion}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyDoubleSequence}^{\uparrow}}$ *row.*

The carrier is a finite diagonal certificate. It contains no coordinate for an ambient double limit, quotient equality of arrays, a selected host limit, or unscoped completeness.

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceTasteGate single carrier alignment`

Theorem 460.2 (CauchyDoubleSequence NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CauchyDoubleSequence}^{\uparrow}}$ *surface for the carrier of Definition 460.1 consists exactly of carrier admission, diagonal schedule admission, tail-bound routing, diagonal* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *consumption,* $\mathsf{Real}^{\uparrow}$ *seal exposure, componentwise* hsame *transport, displayed* Cont *readback, package provenance, and the local naming row.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 460.1. The coordinates $X, \mu, \tau, D, R, E, H, C, P, N$ give the complete accepted packet.

The schedule, tolerance, and readback obligations are then obtained by reading μ, τ, and D in order. The schedule selects the cofinal diagonal window, the tolerance row bounds that selected window, and the diagonal readback repacks the selected rational rows as a regular Cauchy name.

Finally the completion and seal obligations are projections through R and E. The transport, continuation, package, and local naming obligations are the displayed rows H, C, P, N, so the certificate has no remaining source from which to read an external limit or quotient array equality. □

Theorem 460.3 (CauchyDoubleSequence diagonal handoff)**.** *Every* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer read of an accepted* $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *carrier factors through the diagonal route*

$$X, \mu, \tau \longmapsto D \longmapsto R \longmapsto E.$$

The consumer receives only the two-parameter $\mathsf{RegSeqRat}^{\uparrow}$ *family windows selected by* μ*, the* $\mathsf{DyadicTailBound}^{\uparrow}$ *row* τ*, the diagonal* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* D*, the completion consumer row* R*, and the seal row* E *with their displayed* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceCarrier diagonal handoff`

Proof. First project the accepted packet of Definition 460.1. The only array coordinate is X, and the only row capable of selecting a cofinal diagonal window is μ.

Next read the tolerance row τ and the diagonal readback D. These rows convert the selected finite windows of X into the regular Cauchy data consumed downstream.

It remains to route the real-facing consumer. The row R reads D as the completion-facing input, and E is the sole $\mathsf{Real}^{\uparrow}$ seal exposed after that read. Thus every handoff factors through the displayed diagonal route and cannot bypass it through an ambient double-limit object. □

Theorem 460.4 (CauchyDoubleSequence Real seal non-escape)**.** *An accepted* $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *carrier exports no* $\mathsf{Real}^{\uparrow}$*-facing data except the seal row* E *obtained from the diagonal* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* D *through the* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *consumer row* R*. In particular, the carrier has no coordinate for host double-sequence convergence, quotient equality of regular arrays, selected limits, or an unscoped real-completeness principle.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceSealNonEscape`

Proof. Inspect the carrier inventory in Definition 460.1. The only $\mathsf{Real}^{\uparrow}$ coordinate is E, and it appears after the diagonal readback and completion consumer rows.

The preceding handoff theorem fixes the path to E through D and R. Transport and continuation rows move this displayed path componentwise; they do not create an additional seal or an ambient comparison operation.

Therefore every real-facing read is exhausted by $X, \mu, \tau, D, R, E, H, C, P, N$. The excluded host convergence, quotient, selected-limit, and unscoped-completeness data have no coordinate in the packet. □

Theorem 460.5 (CauchyDoubleSequence scoped surface)**.** *The scoped* $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *surface is the finite* BHist *package over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyRate}^{\uparrow}$, $\mathsf{DyadicTailBound}^{\uparrow}$, $\mathsf{RealCauchyCompletion}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *whose only analytic route is the diagonal handoff of Definition 460.3 and whose only real-facing escape boundary is Definition 460.4.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceScopedSurface`

Proof. Combine the carrier and obligation statements. The carrier fixes the ten displayed coordinates, and the NameCert obligations say that accepted consumers read exactly those coordinates.

The diagonal handoff theorem identifies the unique analytic route from the two-parameter array to the completion consumer. The seal non-escape theorem identifies the unique real-facing boundary after that route.

Hence the chapter surface is scoped to the displayed BHist package and its named dependencies. No theorem in this surface claims an independent completeness result for double arrays or a public standard bridge. □

Theorem 460.6 (CauchyDoubleSequence window diagonal exhaustion)**.** *Let* $A = (X, \mu, \tau, D, R, E, H, C, P, N)$ *be an accepted* $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *carrier. Every finite consumer read of the two-parameter array* X *that contributes to the diagonal readback* D *factors through a window selected by the schedule row* μ *and bounded by the tolerance row* τ*. Thus no downstream* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealCauchyCompletion}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *read can inspect an array coordinate outside the visible finite windows recorded by* $X, \mu, \tau, D, H, C, P, N$.

Proof. Project the accepted carrier. The array row is X, the schedule row is μ, and the tolerance row is τ; no other coordinate can select or bound a two-parameter window.

Apply the diagonal handoff of Definition 460.3. The handoff reads X only after μ has selected the cofinal window and τ has supplied the bound used by the diagonal $\mathsf{RegSeqRat}^{\uparrow}$ row D.

The completion consumer and real seal appear only after D. Therefore every finite consumer read contributing to D, R, or E is exhausted by the visible schedule and tolerance windows, and no ambient array coordinate can be read outside the displayed packet. □

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceCarrier window diagonal exhaustion`
Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceWindowDiagonalExhaustion`

Theorem 460.7 (CauchyDoubleSequence two-axis seal factorization)**.** *For an accepted carrier* $A = (X, \mu, \tau, D, R, E, H, C, P, N)$*, every real-facing read factors as a two-axis path*

$$X \xrightarrow{\mu,\tau} D \xrightarrow{R} E.$$

The first axis is finite diagonal-window selection from the array row to the diagonal $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and the second axis is completion-consumer access from* D *to the* $\mathsf{Real}^{\uparrow}$ *seal row. The factorization is stable under the componentwise* hsame *transports and* Cont *routes recorded in* H *and* C.

Proof. Use Definition 460.6 to isolate the first axis. It says that all array information consumed by D is already selected by μ and bounded by τ.

Use the Real seal non-escape theorem Definition 460.4 for the second axis. The only real-facing coordinate is E, and it is exposed through the completion consumer row R after the diagonal readback.

Finally transport the two axes through H and read them through C. These rows preserve the displayed path as BHist data; they do not introduce a host double limit, a quotient of arrays, or a second real seal. □

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceTwoAxisSealFactorization`

Theorem 460.8 (CauchyDoubleSequence schedule-tail exactness)**.** *For every accepted* $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *carrier* $A = (X, \mu, \tau, D, R, E, H, C, P, N)$*, the diagonal schedule row* μ *and the tail-bound row* τ *exactly determine the finite array windows consumed by the diagonal readback* D*. The route uses the* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *array rows, the* $\mathsf{CauchyRate}^{\uparrow}$ *schedule, the* $\mathsf{DyadicTailBound}^{\uparrow}$ *tolerance row, and the displayed* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}_{\mathsf{CauchyDoubleSequence}^{\uparrow}}$ *provenance.*

No completion consumer may inspect an array coordinate outside the scheduled and tail-bounded windows.

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceCarrier schedule tail exactness`

Proof. Begin with window diagonal exhaustion. It says that every array read contributing to D is selected by μ and bounded by τ.

Use the diagonal handoff to align those selected windows with the $\mathsf{RegSeqRat}^{\uparrow}$ readback row. The schedule row is the only $\mathsf{CauchyRate}^{\uparrow}$ coordinate, and the tolerance row is the only $\mathsf{DyadicTailBound}^{\uparrow}$ coordinate.

Transport the route through H and read it through C. Package and naming provenance record the same finite schedule-tail path, so no unscheduled array coordinate is available to the completion side. □

Theorem 460.9 (CauchyDoubleSequence completion consumer scope)**.** *Every* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *packet factors through the schedule-tail route*

$$(X, \mu, \tau) \longmapsto D \longmapsto R \longmapsto E.$$

The first stage is the finite $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *window read controlled by* $\mathsf{CauchyRate}^{\uparrow}$ *and* $\mathsf{DyadicTailBound}^{\uparrow}$ *rows; the second stage is the* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *consumer row; the final stage is the* $\mathsf{Real}^{\uparrow}$ *seal row, transported through* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}_{\mathsf{CauchyDoubleSequence}^{\uparrow}}$*.*

The consumer receives no host double-limit object, quotient equality of arrays, selected limit, or unscoped completeness principle.

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceCarrier completion consumer scope`

Proof. First apply schedule-tail exactness. The completion input D is already exhausted by the scheduled finite windows and their tail-bound row.

Next apply seal non-escape and two-axis seal factorization. They identify R as the only completion consumer row and E as the only real-facing seal available after D.

Finally use the scoped surface. It binds the whole route to the displayed BHist, hsame, Cont, Pkg, and NameCert rows, so every completion consumer remains inside the finite packet. □

Theorem 460.10 (CauchyDoubleSequence real consumer boundary)**.** *Any downstream consumer that reads a* $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *packet as real-completion input receives exactly the diagonal window data, the completion-consumer row, and the seal row displayed by* $X, \mu, \tau, D, R, E, H, C, P, N$*. Its read factors through Definition 460.7 and cannot depend on host double-sequence convergence, quotient equality of arrays, selected limits, or unscoped real completeness.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceCarrier real consumer boundary`

Proof. Begin with the scoped surface of Definition 460.5. It restricts the public package to the named BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

The two-axis factorization then identifies the only real-facing route. A consumer first receives the finite diagonal windows selected from X by μ and τ, then the diagonal readback D, then the completion row R, and finally the seal row E.

The excluded host objects are not coordinates of the carrier and are ruled out again by Definition 460.4. Hence the consumer boundary is exactly the displayed finite packet and its seal row. □

Definition 460.11 (CauchyDoubleSequence scoped route)**.** *The scoped diagonal route for an accepted* $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *carrier*

$$A = (X, \mu, \tau, D, R, E, H, C, P, N)$$

is the finite BHist *route*

$$(X, \mu, \tau, H, C, P, N) \longmapsto D \longmapsto R \longmapsto E.$$

Here X *is the two-parameter* $\mathsf{RegSeqRat}^{\uparrow}$ *family,* μ *is the* $\mathsf{CauchyRate}^{\uparrow}$ *diagonal schedule,* τ *is the* $\mathsf{DyadicTailBound}^{\uparrow}$ *tolerance row,* D *is the scheduled diagonal* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* R *is the* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *consumer, and* E *is the* $\mathsf{Real}^{\uparrow}$ *seal. The route is scoped by the displayed* hsame, Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{CauchyDoubleSequence}^{\uparrow}}$ *rows; it is not an ambient convergence theorem for host double sequences.*

Theorem 460.12 (CauchyDoubleSequence scoped diagonal route)**.** *Every accepted* $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *packet binds the two-parameter* $\mathsf{RegSeqRat}^{\uparrow}$ *family,* $\mathsf{CauchyRate}^{\uparrow}$ *diagonal schedule,* $\mathsf{DyadicTailBound}^{\uparrow}$ *tolerance row,* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *consumer, and* $\mathsf{Real}^{\uparrow}$ *seal into the scoped route of Definition 460.11. Every real-completion read of the packet factors through this route as a* BHist *dependency surface.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceScopedDiagonalRoute`

Proof. Project the accepted carrier $A = (X, \mu, \tau, D, R, E, H, C, P, N)$. The only two-parameter source row is X, the only diagonal selector is μ, and the only tolerance row assigned to the selected windows is τ.

Use schedule-tail exactness to identify the windows consumed by D. The diagonal $\mathsf{RegSeqRat}^{\uparrow}$ readback is therefore already determined by the displayed array, schedule, and tail-bound rows.

Next use completion consumer scope and two-axis seal factorization. They force every real-completion read through D, then through the completion consumer row R, and finally through the $\mathsf{Real}^{\uparrow}$ seal row E.

The transport, continuation, package, and naming rows H, C, P, N scope the whole route as finite BHist evidence. Thus the route is a displayed dependency surface, not a host double-sequence convergence principle. □

Theorem 460.13 (CauchyDoubleSequence cofinal-tail stability)**.** *Let*

$$A = (X, \mu, \tau, D, R, E, H, C, P, N)$$

be an accepted CauchyDoubleSequence$^{\uparrow}$ *carrier. If transported cofinal schedule and tail-bound rows* μ' *and* τ' *select only diagonal windows no earlier than the displayed* μ, τ *route, then the diagonal readback determined by* μ' *and* τ' *has the same* RealCauchyCompletion$^{\uparrow}$ *consumer row and the same* Real$^{\uparrow}$ *seal row, both factoring through the displayed provenance* H, C, P, N*. The statement is only a cofinal-tail stability claim for the finite route; it exports no host double-limit convergence theorem, no quotient equality of arrays, and no selected limit.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceCarrier cofinal tail stability`

Proof. Start with Definition 460.8. The transported rows μ' and τ' are allowed only because their windows lie in the displayed tail selected by μ and bounded by τ. Hence the new diagonal readback reads the same finite source family X through a later scheduled tail, not through a different array object.

Apply Definition 460.7. Once the diagonal readback is fixed by the scheduled tail, the completion-facing consumer must pass through R and the real-facing consumer must pass through E.

Finally use Definition 460.12. The transport, continuation, package, and local naming rows H, C, P, N scope both the original route and the cofinal readback route. Since the route has no coordinates for host double-limit convergence, quotient array equality, or selected limits, the stability result cannot export any of those objects. □

Theorem 460.14 (CauchyDoubleSequence diagonal-tail stability)**.** *Let*

$$A = (X, \mu, \tau, D, R, E, H, C, P, N) \qquad \text{and} \qquad A' = (X', \mu', \tau', D', R', E', H', C', P', N')$$

be accepted CauchyDoubleSequence$^{\uparrow}$ *packets. Suppose the array rows* X *and* X' *are related by componentwise* hsame *on every finite diagonal window consumed by their displayed readback rows, the schedule rows* μ, μ' *are cofinal over those consumed windows, and the tail-bound rows* τ, τ' *agree on each displayed dyadic tolerance window used by the readback rows. Then the diagonal* RegSeqRat$^{\uparrow}$ *readbacks* D, D' *expose the same* RealCauchyCompletion$^{\uparrow}$ *consumer row and the same* Real$^{\uparrow}$ *seal route, both through the scoped dependency surfaces* H, C, P, N *and* H', C', P', N'*. The statement exports no host double-limit convergence theorem, quotient equality of arrays, selected limit, or unscoped real-completeness principle.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceDiagonalTailStability`

Proof. Project both accepted carriers. Their public analytic data are exactly the array, schedule, tail-bound, diagonal readback, completion-consumer, real-seal, transport, replay, provenance, and local naming rows displayed in the statement.

Apply schedule-tail exactness to each packet. The consumed coordinates of D and D' are precisely the finite diagonal windows selected by μ, μ' and bounded by τ, τ'. The hypotheses identify these consumed windows by componentwise hsame and match the dyadic tolerance rows on every displayed window used by the readback.

Use cofinal-tail stability to move later scheduled windows back to the same scoped tail route. Cofinality ensures that neither readback leaves the visible diagonal tail, and the tail-bound agreement keeps the two readbacks within the same tolerance ledger.

Finally apply two-axis seal factorization and the scoped diagonal route theorem. Once the diagonal readbacks expose the same finite tail route, the completion-facing reads must pass through

the corresponding R, R' rows and the real-facing reads through E, E', with both routes scoped by their displayed transport, replay, provenance, and local naming rows. Since neither carrier contains a coordinate for host convergence, quotient array equality, selected limits, or unscoped completeness, the conclusion is only equality of the visible completion-consumer and seal routes. □

Theorem 460.15 (CauchyDoubleSequence scoped non-escape)**.** *The scoped diagonal route of Definition 460.11 exports no host double-sequence convergence theorem, no quotient equality of two-parameter arrays, no selected double limit, and no unscoped real-completeness principle. A downstream* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer receives only the scheduled diagonal windows, the diagonal* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the completion consumer row, the seal row, and the displayed* H, C, P, N *provenance.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceCarrier scoped nonescape`

Proof. Begin with the scoped diagonal route theorem. It says that every real-completion read factors through $X, \mu, \tau, D, R, E, H, C, P, N$.

Apply window diagonal exhaustion to the first stage. No consumer can inspect an array coordinate outside the windows selected by μ and bounded by τ.

Apply real seal non-escape to the final stage. The only real-facing coordinate is E, and it is reached through the completion consumer row R after the diagonal readback D.

Since the scoped route contains no coordinate for host convergence, quotient equality, selected limits, or unscoped completeness, those objects cannot be extracted from the packet. □

Theorem 460.16 (CauchyDoubleSequence seal-route determinacy)**.** *Let*

$$A = (X, \mu, \tau, D, R, E, H, C, P, N)$$

be an accepted $\mathsf{CauchyDoubleSequence}^{\uparrow}$ *packet. Any two* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer reads of* A *that use the same displayed rows* $X, \mu, \tau, D, R, E, H, C, P, N$ *factor through the same scoped diagonal route of Definition 460.11 and classify at the same* $\mathsf{Real}^{\uparrow}$ *seal row* E*. Neither read may use host double-sequence convergence, quotient array equality, selected limits, or unscoped completeness to obtain a different seal classification.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceSealRouteDeterminacy`

Proof. First apply the scoped diagonal route theorem. It sends each accepted real-completion read through the displayed dependency surface

$$(X, \mu, \tau, H, C, P, N) \longmapsto D \longmapsto R \longmapsto E.$$

Next use two-axis seal factorization and completion consumer scope. They identify D as the only diagonal readback, R as the only completion-consumer row after D, and E as the only real-facing seal row after R.

Finally apply scoped non-escape. Since the packet has no coordinate for host convergence, quotient array equality, selected limits, or unscoped completeness, two reads that start from the same displayed rows cannot leave the route to produce different seal classifications. □

Theorem 460.17 (CauchyDoubleSequence diagonal-tail envelope)**.** *Every accepted two-parameter Cauchy array whose diagonal is consumed by a* $\mathsf{Real}^{\uparrow}$*-completion route exposes one finite tail envelope before the* $\mathsf{Real}^{\uparrow}$ *seal is read. The envelope contains the* $\mathsf{StreamName}^{\uparrow}$ *window row, the*

RegSeqRat$^{\uparrow}$ *readback row, the dyadic tail-bound row, the cofinal schedule row, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* NameCert *row. A downstream completion consumer may read the diagonal through that envelope and then through the seal row E, but it cannot bypass the envelope by host double-sequence convergence, quotient array equality, selected limits, or unscoped real completeness.*

Lean4 ✓ `BEDC.Derived.CauchyDoubleSequenceUp.CauchyDoubleSequenceDiagonalTailEnvelope`

Proof. Start with the diagonal handoff and schedule-tail exactness theorems. They force every diagonal read to expose the scheduled window data and the dyadic tail-bound row before any regular rational readback is available.

Next apply cofinal-tail stability. Cofinal schedule changes remain inside the same displayed tail envelope, so the transported schedule row and tail-bound row still feed the same diagonal readback surface.

Use the scoped diagonal route to attach the structural rows. The componentwise hsame transport, displayed Cont replay, Pkg provenance, and local NameCert row scope the stream window, regular rational readback, dyadic tail-bound, and cofinal schedule rows as one finite packet.

Finally apply seal-route determinacy. Once the envelope is fixed, the completion consumer reaches the same Real$^{\uparrow}$ seal row E and has no coordinate for host convergence, quotient equality, selected limits, or unscoped completeness. □

Closure status for NameCert$_{\text{CauchyDoubleSequence}^{\uparrow}}$.

Constructive story: A CauchyDoubleSequence$^{\uparrow}$ packet is generated from a two-parameter RegSeqRat$^{\uparrow}$ family, a CauchyRate$^{\uparrow}$ diagonal schedule, a DyadicTailBound$^{\uparrow}$ tolerance row, a diagonal RegSeqRat$^{\uparrow}$ readback, a RealCauchyCompletion$^{\uparrow}$ consumer, a Real$^{\uparrow}$ seal, componentwise hsame transports, displayed Cont routes, package provenance, and local NameCert evidence.

Theory closure: TheoryGate(NameCert$_{\text{CauchyDoubleSequence}^{\uparrow}}$, publicClosed)

Scope closed: Definition 460.11, Definition 460.12, Definition 460.13, Definition 460.15, and Definition 460.16 export the public StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$ double-sequence route for the finite diagonal-array carrier, schedule, tolerance, readback, completion consumer, real seal, transport, continuation, package, and local naming rows.

Formal verification: FormalStatus(NameCert$_{\text{CauchyDoubleSequence}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not claim Lean verification, bridge checking, host double-sequence convergence, quotient equality of arrays, selected limits, or unscoped real completeness.

Upgrade path: Lean verification and bridge checking require checked targets for the exported StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, CauchyRate$^{\uparrow}$, DyadicTailBound$^{\uparrow}$, and RealCauchyCompletion$^{\uparrow}$ route.

Chapter 461

A Concrete Naming Certificate for $\mathsf{RegularCauchyProduct}^{\uparrow}$

The $\mathsf{RegularCauchyProduct}^{\uparrow}$ interface names the finite pointwise Cauchy-product surface for two regular rational Cauchy names. Bishop-Bridges constructive real arithmetic uses Cauchy products to make multiplication of regular real names visible. BEDC records the finite packet version: two regular source rows, aligned stream windows, dyadic endpoint multiplication, a product-error ledger, regular rational readback, componentwise transport, continuation routes, package provenance, and a local naming row.

The packet sits beside $\mathsf{RegularCauchySum}^{\uparrow}$ and $\mathsf{RegularCauchyDifference}^{\uparrow}$. It is not a completed-real multiplication law, not a quotient of Cauchy streams, not a selected host limit, and not an ambient completeness theorem.

Definition 461.1 (RegularCauchyProduct carrier)**.** *A* $\mathsf{RegularCauchyProduct}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N)$$

with the following displayed rows:

1. *A and B are the two* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows whose scheduled rational observations are multiplied pointwise;*
2. *W_A and W_B are aligned* $\mathsf{StreamName}^{\uparrow}$ *windows for a shared precision request and a shared unary observation index;*
3. *D_A and D_B are the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows read from those windows;*
4. *D is the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *multiplication row obtained from the common-exponent product window for $D_A \cdot D_B$;*
5. *E is the finite* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *product ledger recording the two input tolerances, endpoint magnitude bounds, cross-error terms, and the output tolerance assigned to D;*
6. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row whose scheduled point row is D with the tolerance budget recorded by E;*
7. *H stores componentwise* hsame *transports for both source names, both stream windows, the three dyadic endpoint rows, the product-error ledger, and the readback row;*
8. *C stores the displayed* Cont *routes for reading the two input windows, forming the dyadic endpoint multiplication row, checking the product budget, and exposing the readback;*

9. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{FiniteErrorBudget}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyProduct}^{\uparrow}}$ *row.*

The carrier is a finite multiplication certificate for regular Cauchy names. It stores no quotient stream, no selected limit, no host real equality, and no ambient completeness object.

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductTasteGate single carrier alignment`

Theorem 461.2 (RegularCauchyProduct NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyProduct}^{\uparrow}}$ *surface for the carrier of Definition 461.1 consists of five finite obligations:*

1. *carrier admission: the accepted object is the displayed* BHist *packet M with two* $\mathsf{RegSeqRat}^{\uparrow}$ *sources, aligned* $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic endpoint rows, a product-error ledger, transport rows, continuation rows, provenance, and local naming data;*

2. *classifier transport: classification transports the two source rows, the aligned windows, the endpoint multiplication row, the finite product-error ledger, and the readback row componentwise through the stored* hsame *and* Cont *rows;*

3. *stability: replacing either source by a classified regular name preserves the aligned window and recomputes the same kind of displayed dyadic multiplication row;*

4. *ledger exactness: the output tolerance row is the finite product-error budget recorded in E, including the two input tolerances and the displayed endpoint magnitude bounds;*

5. *downstream handoff: every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of the product first reads R together with A, B, W_A, W_B, D_A, D_B, D, E, H, C, P, and N.*

Proof. Carrier admission is projection from the tuple in Definition 461.1. Each source row, window row, endpoint row, budget row, transport route, continuation route, provenance row, and local naming row is an explicit coordinate of M.

Classifier transport is componentwise. The two $\mathsf{RegSeqRat}^{\uparrow}$ source rows transport their scheduled rational observations, the $\mathsf{StreamName}^{\uparrow}$ rows transport the aligned window reads, and the $\mathsf{DyadicRatCore}^{\uparrow}$ rows transport the endpoint multiplication calculation at the common exponent.

The budget row is finite. It records the two input tolerances, the endpoint magnitude bounds used in the product estimate, the cross-error terms, and the output tolerance before the product readback is exposed. The downstream handoff is then the readback row R, and no omitted coordinate can add quotient streams, selected limits, host real equality, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier namecert obligations`

Theorem 461.3 (RegularCauchyProduct window budget)**.** *Given accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows A and B in a* $\mathsf{RegularCauchyProduct}^{\uparrow}$ *packet and a shared precision request, the aligned* $\mathsf{StreamName}^{\uparrow}$ *windows W_A and W_B display dyadic endpoint rows D_A and D_B. The packet displays a* $\mathsf{DyadicRatCore}^{\uparrow}$ *row D for $D_A \cdot D_B$ and a finite ledger E whose output tolerance is the recorded product-error budget for the two source tolerances and endpoint magnitude bounds.*

Proof. Read the shared precision request through the two stream windows. Since W_A and W_B are aligned coordinates of the same packet, they expose the two endpoint rows at the same requested observation index.

Apply the displayed common-exponent multiplication row of $\mathsf{DyadicRatCore}^{\uparrow}$ to D_A and D_B. The result is the endpoint row D, still inside the carrier.

Finally read the finite budget ledger E. Its entries record the two input tolerances, the visible endpoint bounds, and the product-error terms assigned to the output request. This proves the window budget without invoking any completed real, quotient stream, or hidden limit. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier window budget`

Theorem 461.4 (RegularCauchyProduct RegSeqRat handoff)**.** *The budgeted pointwise-product windows of Definition 461.3 repack as the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R of Definition 461.1. A consumer of R reads only the aligned input windows, the dyadic endpoint multiplication row, the finite product-error ledger, the displayed* hsame *transports, the* Cont *routes, the* Pkg *provenance, and the local* NameCert *row.*

Proof. Start with the finite window budget. For each requested precision, the packet exposes the two source endpoint rows, the dyadic product endpoint, and the product-error row that bounds the output tolerance.

Repack those displayed rows as a regular rational sequence readback. The point row of R is D, and the regularity evidence visible to the consumer is the product ledger E routed through the same aligned windows.

The transport and continuation rows are inherited from the carrier. Since the repacking uses only coordinates already listed in Definition 461.1, it introduces no host sequence quotient, selected limit, or completed-real multiplication object. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier regseqrat handoff`

Theorem 461.5 (RegularCauchyProduct RealUp seal boundary)**.** *Any* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegularCauchyProduct}^{\uparrow}$ *packet reads only the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R together with the visible provenance of the two source names, aligned windows, dyadic endpoint multiplication row, finite product-error ledger,* hsame *transports,* Cont *routes,* Pkg *row, and local* $\mathsf{NameCert}_{\mathsf{RegularCauchyProduct}^{\uparrow}}$ *row.*

Proof. Factor the real-facing read through the regular readback. By Definition 461.4, R is already the repacking of the budgeted pointwise-product windows.

The remaining consumer-visible data are exactly the provenance rows attached to that repacking: the two source names, aligned schedules, dyadic product endpoints, product-error ledger, transports, continuations, package row, and local naming row.

The carrier has no independent $\mathsf{Real}^{\uparrow}$ equality field and no completion witness outside the readback. Therefore the real seal can consume only the displayed regular readback and its visible provenance. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier real seal boundary`

Theorem 461.6 (RegularCauchyProduct source-window transport)**.** *For an accepted* $\mathsf{RegularCauchyProduct}^{\uparrow}$ *packet $M = (A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N)$, classifier transport preserves the two* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows A, B and the aligned* $\mathsf{StreamName}^{\uparrow}$ *windows W_A, W_B through the displayed* hsame *and* Cont *routes. Consequently any transported packet reads the same two regular sources and the same aligned source windows before forming the dyadic product row.*

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier source window transport`

Proof. Project the carrier of Definition 461.1. The two source rows and the two aligned stream windows are explicit coordinates of the same finite packet.

Apply the classifier-transport obligation of Definition 461.2. It transports the source rows and aligned windows componentwise through the stored hsame and Cont rows.

The product endpoint rows D_A, D_B, D are downstream of these transported windows. Since the transport first fixes A, B, W_A, W_B, the dyadic product row can only be read after the same two source rows and the same aligned window positions have been displayed. □

Theorem 461.7 (RegularCauchyProduct error-budget exactness)**.** *For an accepted* RegularCauchyProduct$^{\uparrow}$ *packet, the output tolerance assigned to the readback row R is exactly the finite product-error ledger E computed from the two input tolerances, the endpoint magnitude bounds for D_A and D_B, and the cross-error terms recorded in the packet. No additional tolerance rule is read from a quotient stream, a selected limit, or a completed real multiplication object.*

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier error budget exactness`

Proof. Use the window budget theorem Definition 461.3. It displays D_A and D_B from the aligned source windows and forms the dyadic endpoint product row D.

Read the ledger row E. By the NameCert obligations, E records the two input tolerances, the endpoint magnitude bounds, the cross-error terms, and the output tolerance before R is exposed.

Apply the RegSeqRat$^{\uparrow}$ handoff of Definition 461.4. The readback row R is repacked from D with the tolerance budget already recorded in E, so the output tolerance is exactly that finite ledger and nothing outside the displayed packet. □

Theorem 461.8 (RegularCauchyProduct downstream source lock)**.** *Every downstream* RegSeqRat$^{\uparrow}$ *or* Real$^{\uparrow}$ *consumer of an accepted* RegularCauchyProduct$^{\uparrow}$ *packet factors through*

$$(A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N).$$

Such a consumer can read the two source rows, aligned windows, dyadic endpoint rows, finite product-error ledger, regular readback, transport rows, continuation routes, package provenance, and local naming row, but cannot read quotient streams, selected limits, host real equality, or completed real multiplication.

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier downstream source lock`

Proof. Start with the regular handoff. By Definition 461.4, every RegSeqRat$^{\uparrow}$ readback factors through the aligned input windows, dyadic endpoint multiplication row, finite product-error ledger, transports, continuations, package row, and local naming row.

Use Definition 461.6 to lock the source rows. The aligned windows available to any transported consumer are still the windows attached to A and B.

Finally apply the RealUp seal boundary of Definition 461.5. A real-facing consumer reads only the regular readback and its visible provenance, so neither a quotient stream nor a selected limit nor host real equality nor completed multiplication can enter downstream. □

Theorem 461.9 (RegularCauchyProduct public export certificate)**.** *The carrier, local* NameCert *obligations, window budget,* RegSeqRat$^{\uparrow}$ *handoff,* Real$^{\uparrow}$ *seal boundary, source-window transport, error-budget exactness, and downstream source lock assemble into one public* RegularCauchyProduct$^{\uparrow}$ *export packet. Its exported rows are exactly*

$$A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N.$$

The packet exports no quotient stream, selected limit, host real equality, ambient completeness witness, or completed-real multiplication law.

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier public export certificate`

Proof. Start with the displayed carrier of Definition 461.1. It supplies exactly the two regular source rows, two aligned source-window rows, dyadic endpoint rows, product row, finite error ledger, regular readback, transports, continuations, provenance, and local name.

Add the local acceptance and budget rows. The NameCert obligations of Definition 461.2 bind the accepted packet, while Definition 461.3 computes the endpoint and product rows from the aligned windows.

Next expose the two consumer boundaries. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff is supplied by Definition 461.4, and the $\mathsf{Real}^{\uparrow}$ seal boundary is supplied by Definition 461.5.

Finally use Definition 461.6, Definition 461.7, and Definition 461.8. These results keep every downstream read on the displayed source windows and finite error ledger, and they exclude quotient streams, selected limits, host real equality, ambient completeness, and completed-real multiplication from the public export. □

Theorem 461.10 (RegularCauchyProduct bridge readiness)**.** *The public* $\mathsf{RegularCauchyProduct}^{\uparrow}$ *export packet of Definition 461.9 is bridge-ready for downstream real-algebra consumers. Every such consumer factors through the carrier* $M = (A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N)$*, the local* NameCert *obligations, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row* R*, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, and the public export certificate before it may read product data. The bridge-ready surface exports exactly the regular-Cauchy product boundary and no host multiplication over completed reals, quotient stream equality, selected limit, ambient completeness, or unlisted algebra law.*

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier bridge readiness`

Proof. Start with the public export certificate. It assembles the carrier, local naming obligations, window budget, regular readback handoff, real-seal boundary, source-window transport, error-budget exactness, and downstream source lock into one public packet.

Use the $\mathsf{RegSeqRat}^{\uparrow}$ handoff to identify the product datum read by downstream consumers. The handoff row R is obtained from the aligned windows, dyadic endpoint multiplication row, and finite product-error ledger, so it is already a regular rational product route.

Next apply the $\mathsf{Real}^{\uparrow}$ seal boundary and the real algebra boundary. They force real-facing consumers to read the same regular readback and visible provenance rather than a completed-real multiplication operation.

The public export certificate then supplies the bridge boundary: all product reads pass through $A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N$. Since no excluded algebraic or completion object is a carrier coordinate, the public surface is ready to be the source side of a standard bridge for real-algebra consumers. □

Theorem 461.11 (RegularCauchyProduct real algebra boundary)**.** *Every downstream* $\mathsf{Real}^{\uparrow}$ *algebra consumer of an accepted* $\mathsf{RegularCauchyProduct}^{\uparrow}$ *packet*

$$M = (A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N)$$

must read the source-window rows A, B, W_A, W_B*, the finite error-budget ledger* E*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row* R*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations* D_A, D_B, D*, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, the displayed* hsame *transports* H*, the finite* Cont *routes* C*, the* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyProduct}^{\uparrow}}$

row N. It receives no quotient stream, host multiplication over completed reals, selected limit, ambient completeness, or unlisted algebra law.

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier real algebra boundary`

Proof. Start with the NameCert obligations of Definition 461.2. They admit only the displayed packet M and force every accepted read through the two source rows, aligned windows, endpoint rows, product ledger, transports, routes, provenance, and local name.

Apply the window budget theorem Definition 461.3. It builds the dyadic product row from the two source windows and records the product tolerance in the finite ledger E before any downstream algebra consumer sees the readback.

Next use the $\mathsf{RegSeqRat}^{\uparrow}$ handoff Definition 461.4 together with the $\mathsf{Real}^{\uparrow}$ seal boundary Definition 461.5. The real-facing route is the regular readback R with its visible product provenance, not a host multiplication operation over completed reals.

Finally combine error-budget exactness, downstream source lock, and the public export certificate. These results exhaust the consumer-visible rows and exclude quotient streams, selected limits, ambient completeness, host real equality, completed-real multiplication, and unlisted algebra laws from the product boundary. □

Theorem 461.12 (RegularCauchyProduct bounded-source handoff)**.** *Let*

$$M = (A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyProduct}^{\uparrow}$ *packet. If the two source windows W_A and W_B expose dyadic endpoint magnitude bounds in the finite product-error ledger E, then every* $\mathsf{RegSeqRat}^{\uparrow}$ *readback of the product factors through W_A, W_B, the dyadic product row D, and the same ledger row E. No readback may replace those bounded windows by a quotient stream, selected limit, host real equality, ambient completeness, or completed-real multiplication law.*

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier bounded source handoff`

Proof. Start with Definition 461.3. The product row D is computed from the displayed source windows and the dyadic endpoint rows, and the product tolerance is recorded in the finite ledger E.

Use Definition 461.6. Transported consumers still see the windows attached to the source rows A and B, so the endpoint magnitude bounds remain the bounds supplied by W_A and W_B.

Apply Definition 461.7. The error budget exposed to a readback is exactly the displayed product ledger, with no additional completed-real algebra coordinate.

Finally use Definition 461.8. Any downstream $\mathsf{RegSeqRat}^{\uparrow}$ handoff must keep the same source windows, dyadic product row, and ledger row E, which gives the stated bounded-source factorization. □

Theorem 461.13 (RegularCauchyProduct real seal product budget)**.** *Every* $\mathsf{Real}^{\uparrow}$ *algebra consumer of the product seal in an accepted* $\mathsf{RegularCauchyProduct}^{\uparrow}$ *packet receives the finite product-budget row E before the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row R. The consumer cannot replace this budget by completed-real multiplication, quotient stream equality, selected limits, ambient completeness, host real equality, or any unlisted algebra law.*

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier real seal product budget`

Proof. First apply Definition 461.5. The real-facing endpoint is read through the visible product provenance and regular readback route, not through completed-real multiplication.

Next use Definition 461.11. A $\mathsf{Real}^{\uparrow}$ algebra consumer must read the finite error ledger E, the $\mathsf{RegSeqRat}^{\uparrow}$ handoff R, the dyadic product row, transports, continuations, provenance, and local name.

The public export certificate Definition 461.9 supplies the same row order at the public surface. The packet contains the product ledger and readback row, but no quotient stream, selected limit, ambient completeness, or host real equality.

Finally invoke Definition 461.12. Since every readback factors through the bounded source windows, dyadic product row, and ledger E, the real seal consumer receives the finite product budget before it can consume the regular rational handoff. □

Theorem 461.14 (RegularCauchyProduct window comparison)**.** *Let M be an accepted* $\mathsf{RegularCauchyProduct}^{\uparrow}$ *packet, let S be an accepted* $\mathsf{RegularCauchySum}^{\uparrow}$ *packet, and let Q be an accepted* $\mathsf{RegularCauchyDifference}^{\uparrow}$ *packet. Suppose the three packets share the same two* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows A, B and the same aligned* $\mathsf{StreamName}^{\uparrow}$ *source windows W_A, W_B. Then every product consumer must first read the common finite boundary*

$$(A, B, W_A, W_B)$$

before diverging to the product-error ledger E of M, while the sum and difference consumers diverge from that same boundary to their own finite arithmetic ledgers. The conclusion is a comparison of finite-window routes; it is not a completed-real algebra law.

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier window comparison`

Proof. Start with the product carrier of Definition 461.1. Its first four rows are the two regular source rows and the two aligned source-window rows, so any product read must expose A, B, W_A, W_B before it reaches dyadic endpoint multiplication or the product ledger.

Use the source-window transport theorem Definition 461.6. Transport preserves the same source rows and aligned windows through the displayed hsame and Cont routes, so the shared boundary remains the first visible route segment for every transported product consumer.

Now apply the real algebra boundary and product-budget results, Definition 461.11 and Definition 461.13. They force the product route to diverge from the shared source-window boundary into the finite product-error ledger E before the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and $\mathsf{Real}^{\uparrow}$ seal are consumed.

Finally compare the sibling surfaces chapter 417 and chapter 429. Their accepted packets read the same kind of finite source-window boundary for the same two source rows, but their next arithmetic coordinates are the finite sum and difference ledgers rather than E. Thus the comparison is a route comparison over shared windows and sibling ledgers, with no quotient stream, selected limit, host real equality, ambient completeness, or field multiplication law. □

Theorem 461.15 (RegularCauchyProduct coordinate regularity)**.** *For every accepted* $\mathsf{RegularCauchyProduct}^{\uparrow}$ *packet*

$$M = (A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N),$$

the readback row R is regular by finite coordinates alone. Each requested product endpoint row D is obtained from the aligned $\mathsf{StreamName}^{\uparrow}$ *windows W_A, W_B, and the ledger E records the two source tolerances, the endpoint magnitude bounds for D_A, D_B, and the cross-error terms needed for the output tolerance. Thus the regularity of R is witnessed by the carrier coordinates, the local* $\mathsf{NameCert}$ *obligations, the window budget, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, the* $\mathsf{Real}^{\uparrow}$ *seal boundary, source-window transport, error-budget exactness, and downstream source lock, with no appeal to a quotient stream, selected limit, host real equality, ambient completeness, or completed-real multiplication.*

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier coordinate regularity`

Proof. Project the carrier of Definition 461.1. The coordinates $A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N$ include the two regular sources, the aligned windows, the dyadic endpoint rows, the product row, and the finite budget ledger.

Use the local NameCert obligations and the window budget theorem, Definition 461.2 and Definition 461.3. They force each requested product endpoint to be read from the aligned $\mathsf{StreamName}^{\uparrow}$ windows and place the two source tolerances, endpoint bounds, and cross-error terms in E.

Apply the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the $\mathsf{Real}^{\uparrow}$ seal boundary, Definition 461.4 and Definition 461.5. The row R is the regular rational readback of these finite product windows, while the real-facing boundary exposes only the same finite provenance.

Finally use source-window transport, error-budget exactness, and downstream source lock. These keep every transported consumer on the displayed windows and ledger, so the regularity witness for R is the finite product-coordinate route itself. □

Theorem 461.16 (RegularCauchyProduct classifier stability)**.** *Let*

$$M = (A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyProduct}^{\uparrow}$ *packet. Classifier transport of either source row preserves the aligned source windows, the dyadic endpoint product row, the finite error ledger, and the readback route through the stored* hsame *and* Cont *coordinates. Consequently replacing A or B by a classified regular source does not change the finite product boundary read by R; it only replays the carrier,* NameCert *obligations, window budget,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal boundary, source-window transport, error-budget exactness, and downstream source lock along the displayed transport rows.*

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier classifier stability`

Proof. Start from the classifier-transport clause in Definition 461.2. It transports the two source rows, aligned windows, endpoint rows, finite product-error ledger, and readback row componentwise through the stored hsame and Cont coordinates.

Use Definition 461.6. Transported packets still display the same source-window boundary A, B, W_A, W_B before any dyadic endpoint product row can be consumed.

Next apply the window budget and error-budget exactness results. The product row D and ledger E remain the rows obtained from the transported aligned windows, and the output tolerance is still exactly the displayed product ledger.

Finally combine the $\mathsf{RegSeqRat}^{\uparrow}$ handoff, $\mathsf{Real}^{\uparrow}$ seal boundary, and downstream source lock. They force the transported readback to consume the same finite product boundary, so classifier stability is a stability claim about the displayed coordinates rather than a completed-real algebra law. □

Theorem 461.17 (RegularCauchyProduct RealUp pair seal)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of a product pair sealed by an accepted* $\mathsf{RegularCauchyProduct}^{\uparrow}$ *packet can read only the two source regular names A, B, the regular readback row R, and the finite product provenance carried by $W_A, W_B, D_A, D_B, D, E, H, C, P, N$. The seal exposes the carrier,* NameCert *obligations, window budget,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal boundary, source-window transport, error-budget exactness, and downstream source lock, but it does not expose host real multiplication, a quotient stream, a selected limit, an ambient completeness witness, or any extra algebra law.*

Lean4 ✓ `BEDC.Derived.RegularCauchyProductUp.RegularCauchyProductCarrier real pair seal`

Proof. Begin with the carrier and local NameCert obligations. The accepted packet contains exactly the two source rows, aligned windows, dyadic endpoint rows, product ledger, readback, transports, continuations, package provenance, and local name.

Apply the window budget and $\mathsf{RegSeqRat}^{\uparrow}$ handoff. They show that the product readback R is assembled from the finite endpoint rows and product-error ledger, so the consumer reads a regular rational product route rather than a completed-real multiplication operation.

Use the $\mathsf{Real}^{\uparrow}$ seal boundary together with source-window transport. The real-facing consumer sees the same two source names and aligned windows after transport, and no additional real-valued coordinate is introduced.

Finally invoke error-budget exactness and downstream source lock. They exhaust the visible product provenance and rule out quotient streams, selected limits, host real equality, ambient completeness witnesses, host multiplication, and unlisted algebra laws at the pair seal. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyProduct}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyProduct}^{\uparrow}$ packet is generated from two $\mathsf{RegSeqRat}^{\uparrow}$ source rows, aligned $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint multiplication rows, a finite $\mathsf{FiniteErrorBudget}^{\uparrow}$ product ledger, displayed hsame transports, Cont routes, Pkg provenance, a $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyProduct}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature public export surface records the finite carrier, local naming obligations, shared-window product budget, regular readback handoff, real-seal boundary, source-window transport, error-budget exactness, downstream source lock, public export certificate, and bridge-readiness theorem for pointwise products of regular Cauchy names.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyProduct}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient equality of streams, selected limits, host real equality, ambient completeness, real-field multiplication laws, or bridge checking.

Upgrade path: Verification closure requires Lean synchronization for the mature public regular-Cauchy product boundary and any standard bridge target recorded by the formalization pipeline.

Chapter 462

A Concrete Naming Certificate for $\mathsf{CauchyModulusMeet}^{\uparrow}$

The $\mathsf{CauchyModulusMeet}^{\uparrow}$ interface packages the finite rows needed when two regular rational stream names must be read through one shared Cauchy bound. It is a naming certificate for the shared-modulus packet used by diagonal-limit and uniform Cauchy consumers; it does not assert that a quotient stream, a selected limit, or an ambient completeness principle has already been constructed.

The meet packet consumes $\mathsf{StreamName}^{\uparrow}$ finite-window rows from chapter 126, regular rational readbacks from chapter 301, dyadic tolerance ledgers from chapter 291, and the $\mathsf{Real}^{\uparrow}$ seal surface from chapter 38. Thus $\mathsf{CauchyModulusMeet}^{\uparrow}$ is a shared-bound packet over these sibling carriers, not a kernel-only surface.

Definition 462.1 (CauchyModulusMeet carrier)**.** *A* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N)$$

with the following displayed coordinates:

1. S_0 *and* S_1 *are the two* $\mathsf{StreamName}^{\uparrow}$ *rows whose rational windows are read as* $\mathsf{RegSeqRat}^{\uparrow}$ *data;*
2. μ_0 *and* μ_1 *are the two source* $\mathsf{CauchyModulus}^{\uparrow}$ *rows attached to those regular rational names;*
3. μ *is the shared* $\mathsf{CauchyModulus}^{\uparrow}$ *meet row, displayed with a* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger sufficient for both source rows;*
4. H *stores componentwise* hsame *transports for the two stream names, two source moduli, shared meet modulus, dyadic tolerance rows, real-facing reads, provenance, and local name;*
5. C *stores the displayed* Cont *routes by which consumers inspect stream windows, regular rational rows, source modulus rows, the shared meet bound, and the real-facing handoff;*
6. P *is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$*;*
7. N *is the local* $\mathsf{NameCert}_{\mathsf{CauchyModulusMeet}^{\uparrow}}$ *row.*

The classifier compares accepted packets only after transporting these displayed coordinates to a common stream-name, modulus, and dyadic tolerance surface. The carrier has no coordinate for quotient stream equality, selected limits, host real equality, or ambient completeness.

Theorem 462.2 (CauchyModulusMeet NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CauchyModulusMeet}^{\uparrow}}$ *surface for the carrier of Definition 462.1 consists exactly of five rows:*

1. *carrier admission for the finite packet* $M = (S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N)$*;*
2. *classifier transport to a common displayed* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *surface;*
3. *stability of both source modulus projections and of the shared meet row under componentwise* hsame *transport;*
4. *exactness of the shared dyadic tolerance ledger as a bound readable by both source modulus rows;*
5. *ledger rows for* Cont *routes,* Pkg *provenance,* $\mathsf{Real}^{\uparrow}$ *handoff reads, and the local naming certificate.*

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket namecert obligations`

Proof. Carrier admission is projection from Definition 462.1. The displayed coordinates provide the two source stream names, two source moduli, shared meet modulus, transport rows, continuation rows, provenance, and local name.

Classifier transport uses H to move every coordinate to a common finite surface. Once transported, the routes in C are the only ways to read stream windows, regular rational rows, source moduli, the shared meet bound, and the real-facing handoff.

The dyadic tolerance ledger is stored inside the shared row μ and its associated $\mathsf{DyadicRatCore}^{\uparrow}$ read. Since no carrier coordinate stores quotient streams, selected limits, host real equality, or an ambient completeness proof, the NameCert obligations are exhausted by the five displayed rows. □

Theorem 462.3 (CauchyModulusMeet shared-radius carrier admission)**.** *Carrier admission for a* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet*

$$M = (S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N)$$

exposes exactly the two $\mathsf{StreamName}^{\uparrow}$ *rows* S_0, S_1*, the two source* $\mathsf{CauchyModulus}^{\uparrow}$ *rows* μ_0, μ_1*, the shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance meet carried by* μ*, the componentwise* hsame *rows in* H*, the displayed* Cont *routes in* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{CauchyModulusMeet}^{\uparrow}}$ *row* N*. No carrier-admission route adds quotient stream equality, selected limits, host real equality, or ambient completeness.*

Proof. Start with the carrier of Definition 462.1. Its displayed coordinates are precisely $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$, with S_0, S_1 providing the stream-name rows and μ_0, μ_1, μ providing the two source modulus rows and the shared meet row.

Apply the NameCert obligation surface of Definition 462.2. The carrier-admission row is one of the five local obligations, and the remaining rows only classify, stabilize, bound, route, record provenance, and name the same finite packet.

Projection stability and shared-bound exhaustion identify the readable modulus content. Definition 462.6 keeps the source projections on the displayed transport surface, while Definition 462.9 confines the shared bound to the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger carried by μ. Hence carrier admission exposes exactly the listed BEDC rows and nothing external to the packet. □

Theorem 462.4 (CauchyModulusMeet RegSeqRat classifier transport)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier comparison between accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packets factors through transported stream windows, the two source modulus rows, the shared meet row* μ*, and the displayed* hsame *and* Cont *routes of the carrier in Definition 462.1. The comparison may use the* Pkg *and* NameCert *rows to identify the packet provenance and local name, but it has no access to quotient stream equality, selected limits, host real equality, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket regseqrat classifier transport`

Proof. Read the classifier row from Definition 462.2. It transports the compared packets to a common displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ surface before any classifier read is made.

Now use the carrier coordinates of Definition 462.1. The only stream-window inputs are the windows routed from S_0 and S_1, the only source modulus inputs are μ_0 and μ_1, and the only common bound input is the shared meet row μ with its dyadic ledger.

Finally apply projection stability and the shared-bound exhaustion theorem. Definition 462.6 keeps the two source modulus reads stable under the displayed hsame transports, and Definition 462.9 prevents the classifier from replacing μ by an undisplayed analytic datum. The classifier comparison therefore factors through the listed transported routes. □

Theorem 462.5 (CauchyModulusMeet Real seal consumer obligation)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of a* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet may read only the shared-bound route exposed by*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

Such a consumer cannot extract quotient streams, selected limits, host real equality, ambient completeness, or any real-valued seal beyond the displayed shared modulus handoff.

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket real seal consumer obligation`

Proof. Begin with the carrier in Definition 462.1. The packet contains stream names, regular-rational read routes, source modulus rows, the shared meet row, transport rows, continuation routes, provenance, and a local name, but no host real object or completeness witness.

Use the NameCert obligations to identify the available consumer rows. By Definition 462.2, the real-facing handoff reads are ledger rows over the same finite packet, not extra coordinates.

Apply the Real handoff boundary and shared-bound exhaustion. Definition 462.7 forces each $\mathsf{Real}^{\uparrow}$ read through the stream-name, regular-rational, dyadic-tolerance, transport, route, provenance, and naming rows, while Definition 462.9 identifies the only readable bound as the displayed ledger carried by μ.

Thus the consumer obligation is exactly the shared-bound route. Since neither the carrier nor the cited obligations contain quotient streams, selected limits, host real equality, ambient completeness, or a separate real-valued seal, none can be extracted by a $\mathsf{Real}^{\uparrow}$ consumer. □

Theorem 462.6 (CauchyModulusMeet projection stability)**.** *Let* $M = (S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N)$ *and* $M' = (S'_0, S'_1, \mu'_0, \mu'_1, \mu', H', C', P', N')$ *be accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *carriers whose displayed coordinates are related componentwise by the transport rows in* H *and* H'*. Then the projected source modulus reads* μ_0, μ_1 *and the shared meet read* μ *remain readable through the transported packet, and their* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger is the same displayed ledger seen by both* $\mathsf{RegSeqRat}^{\uparrow}$ *stream-name projections.*

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket projection stability`

Proof. Project both accepted carriers and read the componentwise transport rows. The only modulus coordinates in either packet are the two source rows and the shared meet row.

Use the displayed hsame entries in H and H' to transport $S_0, S_1, \mu_0, \mu_1, \mu$ to the common surface. The continuation rows then read the transported stream windows and regular rational rows before reading the transported source moduli.

It remains to compare the shared bound. The dyadic tolerance ledger is part of the displayed meet row and is routed by C rather than by an external real-completeness object. Hence each projected source modulus remains readable through the meet packet after transport, and both projections see the same displayed shared bound. □

Theorem 462.7 (CauchyModulusMeet Real handoff boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *diagonal consumer of an accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *carrier may read the shared bound only through the displayed* $\mathsf{StreamName}^{\uparrow}$ *rows* S_0, S_1*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *rational readbacks of those rows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger carried by* μ*, the componentwise* hsame *transports, the displayed* Cont *routes, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{CauchyModulusMeet}^{\uparrow}}$ *row.*

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket real handoff boundary`

Proof. Begin with a $\mathsf{Real}^{\uparrow}$ diagonal consumer route. The carrier has no real-facing coordinate other than the handoff reads reached through the stream-name, regular rational, and shared modulus routes.

The consumer first reads S_0 and S_1, then their regular rational windows, and then the shared dyadic tolerance ledger inside μ. The two source moduli μ_0 and μ_1 are available only as displayed projections through the same finite packet.

All remaining movement is supplied by the rows H, C, P, N. These rows transport, route, record provenance, and name the packet; they do not add quotient streams, selected limits, ambient completeness, or host real equality. Therefore the real-facing handoff is bounded by the displayed certificate surface. □

Theorem 462.8 (CauchyModulusMeet swap stability)**.** *Let* $M = (S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N)$ *be an accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *carrier, and let*

$$M^{\mathrm{sw}} = (S_1, S_0, \mu_1, \mu_0, \mu, H^{\mathrm{sw}}, C^{\mathrm{sw}}, P, N)$$

be the packet obtained by exchanging the two displayed source stream/modulus rows and transporting every affected row componentwise by the hsame *entries recorded in* H*. Then* M^{sw} *is accepted by the same carrier surface, and it presents the same shared meet ledger* μ *and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows to every displayed* Cont *route.*

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket swap stability`

Proof. Project the accepted packet through Definition 462.1. The first two stream coordinates and the first two source modulus coordinates are the only ordered source-side entries of the carrier.

Exchange these two pairs and read the corresponding componentwise transport rows from H. The transported packet still has two $\mathsf{StreamName}^{\uparrow}$ rows, two $\mathsf{RegSeqRat}^{\uparrow}$ readbacks, two source $\mathsf{CauchyModulus}^{\uparrow}$ rows, one shared meet row, the same provenance row, and the same local name row.

The shared row μ is not duplicated or replaced by the swap. Its dyadic tolerance ledger remains the displayed ledger routed by C, while H^{sw} and C^{sw} only retarget the source-side reads. Hence the swapped packet is accepted and exposes the same shared meet surface. □

Theorem 462.9 (CauchyModulusMeet shared-bound exhaustion)**.** *For an accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *carrier* $M = (S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N)$*, every readable shared bound exported by the packet is one of the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows carried by* μ*. No exported shared-bound route can use quotient stream equality, a selected limit, host real equality, or an ambient completeness datum.*

Proof. Start from an exported shared-bound route. By the carrier definition, the only bound coordinate common to the two source modulus rows is the meet row μ together with its displayed $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger.

The continuation row C reads source stream windows, regular rational rows, source modulus rows, the shared meet bound, and the real-facing handoff. The transport row H only moves these displayed coordinates to a common surface.

There is no carrier coordinate for quotient streams, selected limits, host real equality, or ambient completeness. Therefore a readable shared bound must be a displayed tolerance row inside μ, recorded through H, C, P, N and nothing outside the finite packet. □

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket shared bound transport`

Theorem 462.10 (CauchyModulusMeet consumer factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer route out of an accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *carrier factors through the ordered rows*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

In particular, such a consumer first reads the displayed stream-name rows, the source modulus rows, and the shared meet row, and then uses only the componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyModulusMeet}^{\uparrow}}$ *row supplied by the packet.*

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket consumer factorization`

Proof. Let a $\mathsf{Real}^{\uparrow}$ or $\mathsf{RegSeqRat}^{\uparrow}$ consumer route be given. Project its source carrier to the tuple of Definition 462.1.

For a $\mathsf{RegSeqRat}^{\uparrow}$ consumer, the stream-name and rational readback surface is reached through S_0 and S_1, with source bounds supplied by μ_0, μ_1 and their common bound supplied by μ. For a $\mathsf{Real}^{\uparrow}$ consumer, Definition 462.7 forces the real-facing read through the same rows before any handoff is visible.

The remaining route data are exactly H, C, P, N. These rows transport, route, record provenance, and name the packet; they do not provide an independent consumer object. Thus every such route factors through the displayed ordered carrier rows. □

Theorem 462.11 (CauchyModulusMeet obligation surface)**.** *The carrier, projection stability, swap stability, shared-bound exhaustion,* $\mathsf{Real}^{\uparrow}$ *handoff boundary, and consumer factorization of the* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet constitute the full obligation surface for meeting two displayed* $\mathsf{CauchyModulus}^{\uparrow}$ *rows over a shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger. Downstream* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *consumers may use only this finite surface.*

The surface exports no quotient stream equality, selected limit, ambient completeness datum, host real equality, or public standard bridge.

Proof. First project the carrier of Definition 462.1. It lists the two $\mathsf{StreamName}^{\uparrow}$ rows, their two source $\mathsf{CauchyModulus}^{\uparrow}$ rows, the shared meet row, the transport row, continuation row, provenance row, and local name.

Projection stability is supplied by Definition 462.6, and source-row exchange is supplied by Definition 462.8. Together these bind the two source moduli and their shared meet row under the permitted componentwise hsame transports.

The shared-bound and consumer-facing parts are then fixed by Definition 462.9, Definition 462.7, and Definition 462.10. These three results force $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance reads, $\mathsf{RegSeqRat}^{\uparrow}$ route reads, and $\mathsf{Real}^{\uparrow}$ handoff reads through the displayed meet packet.

Finally the NameCert obligations in Definition 462.2 record the same rows as the local naming surface. Since none of the cited blocks introduces quotient stream equality, selected limits, ambient completeness, host real equality, or a standard bridge, the listed blocks are the full obligation surface. □

Theorem 462.12 (CauchyModulusMeet public export certificate)**.** *The carrier, projection stability, swap stability, shared-bound exhaustion,* $\mathsf{Real}^{\uparrow}$ *handoff boundary, consumer factorization, and obligation surface assemble one public* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *certificate over* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

This certificate exports exactly the finite rows

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

It does not export quotient stream equality, selected limits, host real equality, ambient completeness, or a standard bridge.

Proof. Begin with the carrier of Definition 462.1. It supplies the two $\mathsf{StreamName}^{\uparrow}$ rows, their $\mathsf{RegSeqRat}^{\uparrow}$ readbacks, the two source $\mathsf{CauchyModulus}^{\uparrow}$ rows, the shared meet row, the transport row, the continuation row, the provenance row, and the local NameCert row.

Add the local stability surface. Projection stability is supplied by Definition 462.6, source-row exchange by Definition 462.8, and shared-bound exhaustion by Definition 462.9.

Add the consumer-facing surface. The $\mathsf{Real}^{\uparrow}$ handoff boundary is supplied by Definition 462.7, consumer factorization by Definition 462.10, and the finite obligation inventory by Definition 462.11.

Each cited block is stated over the same displayed packet and refuses quotient stream equality, selected limits, host real equality, ambient completeness, and bridge content. Therefore the assembled public certificate has exactly the named surface and no additional export. □

Theorem 462.13 (CauchyModulusMeet public export surface)**.** *The* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *public export packet is the finite shared-modulus surface over*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

It assembles the carrier admission, projection stability, $\mathsf{Real}^{\uparrow}$ *handoff boundary, swap stability, shared-bound exhaustion, consumer factorization, and obligation surface into one readable certificate for downstream* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *consumers.*

The export packet carries no quotient stream equality, selected limit, ambient completeness datum, host real equality, or standard bridge.

Proof. Begin with the carrier of Definition 462.1. It supplies exactly the two stream-name rows, two source modulus rows, shared meet row, transport row, continuation row, provenance row, and local naming row.

Add the stability and boundary components. Projection stability comes from Definition 462.6, real-facing access from Definition 462.7, source-row exchange from Definition 462.8, and shared-bound exhaustion from Definition 462.9.

Add consumer routing and local obligations. Consumer factorization is supplied by Definition 462.10, and the complete obligation inventory is supplied by Definition 462.11.

Each cited result is stated over the same finite rows and explicitly refuses quotient streams, selected limits, ambient completeness, host real equality, and a standard bridge. Therefore the public export packet is exactly the assembled shared-modulus surface. □

Theorem 462.14 (CauchyModulusMeet export consumer lock)**.** *Every downstream consumer using the* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *public export packet is locked to the shared modulus rows*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

A $\mathsf{RegSeqRat}^{\uparrow}$ *read,* $\mathsf{Real}^{\uparrow}$ *handoff,* $\mathsf{CauchyModulus}^{\uparrow}$ *projection, or* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance read must factor through the public export surface of Definition 462.13.*

Proof. Start with a downstream consumer of the export packet. By Definition 462.13, the only public rows are $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$.

For $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers, apply Definition 462.10 and Definition 462.7. These force the read through the displayed stream-name, source-modulus, shared-meet, transport, route, provenance, and naming rows.

For $\mathsf{CauchyModulus}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ consumers, apply Definition 462.6 and Definition 462.9. These force modulus projections and tolerance reads through the same shared meet row μ and its displayed dyadic ledger. □

Theorem 462.15 (CauchyModulusMeet tailmeet handoff)**.** *An accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet* $M = (S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N)$ *supplies the shared-bound rows consumed by* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*. The tail-meet consumer may read the two* $\mathsf{StreamName}^{\uparrow}$ *rows, the two source* $\mathsf{CauchyModulus}^{\uparrow}$ *rows, the shared meet row* μ*, the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, componentwise* hsame *transports,* Cont *routes, package provenance, and local* $\mathsf{NameCert}$ *row, and it has no tail oracle outside the public export packet.*

Proof. Start with the public export surface of Definition 462.13. It exposes exactly $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$ for downstream consumers.

Use projection stability and shared-bound exhaustion. Definition 462.6 keeps the two source modulus rows and the shared meet row readable under the displayed transports, while Definition 462.9 identifies the shared-bound read with μ and its dyadic tolerance ledger.

Finally apply the real handoff boundary and export consumer lock. The $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ read is a downstream shared-bound consumer, so it is forced through the same packet and cannot import quotient stream equality, selected limits, host real equality, ambient completeness, or an external tail oracle. □

Theorem 462.16 (CauchyModulusMeet diagonal window route)**.** *For an accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet* $M = (S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N)$*, every diagonal-window consumer that later feeds a* $\mathsf{Real}^{\uparrow}$ *read uses the same* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *rows exposed by the public packet. The route passes through* $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$ *and not through quotient streams, selected limits, host real equality, ambient completeness, or a separate completion witness.*

Proof. Begin with consumer factorization and the real handoff boundary. They route every real-facing read through the displayed stream names, source modulus rows, shared meet row, transports, continuations, provenance, and local naming row.

Then use shared-bound exhaustion. The dyadic tolerance read for the diagonal window is the ledger attached to the same meet row μ, while the source windows remain the public rows S_0 and S_1.

The public export surface and export consumer lock finish the routing claim. They prevent a diagonal-window consumer from choosing independent $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, or $\mathsf{DyadicRatCore}^{\uparrow}$ data outside M. □

Theorem 462.17 (CauchyModulusMeet comparison synchronization)**.** *Every comparison consumer of an accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet* $M = (S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N)$ *synchronizes on the displayed meet row* μ*. In particular, tail-meet consumers and diagonal-window consumers compare source rows through the same shared-bound row, componentwise transports, continuation routes, package provenance, and local naming row, rather than through an external tail oracle.*

Proof. First compose projection stability with swap stability. These results say that either ordering of the source rows reads the same source-modulus projections and the same shared meet row under the displayed transports.

Next use shared-bound exhaustion together with the public export surface. The comparison row available to downstream consumers is the meet row μ and its dyadic tolerance ledger, packaged with H, C, P, N.

Finally apply the tailmeet handoff and diagonal-window route theorems above. Both downstream consumer classes are already locked to M, so their comparison synchronization occurs on the displayed meet row and cannot be delegated to quotient streams, selected limits, host real equality, ambient completeness, or an external tail oracle. □

Theorem 462.18 (CauchyModulusMeet tail-threshold compatibility)**.** *The public export rows*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$$

of a $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet supply the shared tail-threshold route consumed by* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*. The route reads the two source stream rows, the two source modulus rows, the shared meet row, the componentwise transport, continuation routes, package provenance, and local naming row, and it has no independent tail oracle outside the public packet.*

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket tail threshold compatibility`

Proof. Start with the carrier of Definition 462.1. It gives the two stream-name rows, the two source modulus rows, the meet modulus row, the transport row, the continuation row, the provenance row, and the local $\mathsf{NameCert}$ row.

Use the NameCert obligations of Definition 462.2 and the projection stability of Definition 462.6. They make the source moduli and the meet row stable under the displayed hsame transport.

The shared-bound exhaustion theorem Definition 462.9 then supplies the tail-threshold read through μ. By the public export surface and export consumer lock, a $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ consumer must read that threshold through the displayed packet and cannot add a quotient stream, selected limit, host real equality, ambient completeness, or independent tail oracle. □

Theorem 462.19 (CauchyModulusMeet diagonal-window consumer handoff)**.** *The public export rows*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$$

of a $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet supply the selected-window route consumed by* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$*. The selected-window consumer receives only the shared bound, the two source stream/modulus rows,*

the displayed dyadic tolerance ledger, componentwise transport, continuation routes, package provenance, and local naming row.

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket diagonal window consumer handoff`

Proof. Begin with carrier admission and the NameCert obligation surface. These fix the finite packet over the two stream rows, two source modulus rows, shared meet row, transport, continuation, provenance, and naming coordinates.

Apply projection stability and shared-bound exhaustion. The diagonal-window read can choose its window only through the stable source projections and the shared bound supplied by μ.

Now apply consumer factorization, the $\mathsf{Real}^{\uparrow}$ handoff boundary, the public export surface, and the export consumer lock. These route the $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ consumer through the public shared-modulus packet and exclude quotient streams, selected limits, host real equality, ambient completeness, and any independent tail oracle. □

Theorem 462.20 (CauchyModulusMeet downstream unblock package)**.** *The public* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *export is a finite downstream handoff package for the real-completion route*

$$\mathsf{RegularCauchyTailMeet}^{\uparrow}, \quad \mathsf{RealDiagonalWindowCoverage}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

Its rows $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$ *provide the shared tail-threshold route, the selected-window route, and the finite* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *handoff boundary, with no quotient stream equality, selected limit, host real equality, ambient completeness, or independent tail oracle.*

Proof. First assemble the local packet from the carrier, NameCert obligations, and projection stability. This gives the displayed rows and keeps source-modulus reads stable under componentwise transport.

Next attach the tail and window routes. Shared-bound exhaustion gives the tail-threshold route of Definition 462.18, while the same shared meet row supplies the selected-window handoff of Definition 462.19.

Finally add the consumer-facing boundary. The $\mathsf{Real}^{\uparrow}$ handoff boundary and consumer factorization route $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers through the same finite packet, and the public export surface with the export consumer lock prevents any downstream consumer from importing quotient streams, selected limits, host real equality, ambient completeness, or independent tail oracles. □

Theorem 462.21 (CauchyModulusMeet export non-escape)**.** *No consumer of the* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *public export packet can extract quotient stream equality, a selected limit, ambient completeness, host real equality, or a standard bridge. Every public read is exhausted by the carrier rows, projection stability, real handoff boundary, swap stability, shared-bound exhaustion, consumer factorization, and local obligation surface assembled in Definition 462.13.*

Proof. Inspect the export packet given by Definition 462.13. Its coordinates are exactly $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$ together with the cited stability, boundary, routing, and obligation facts.

Apply Definition 462.14. Any downstream consumer is forced through those same displayed rows, so no consumer route can introduce an independent quotient, limit, host-real, completion, or bridge coordinate.

The exclusions then follow from Definition 462.11. That theorem already states that the shared-modulus obligation surface exports none of the forbidden objects, and the public export packet adds no row beyond that surface. □

Theorem 462.22 (CauchyModulusMeet source-pair exposure)**.** *The public* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *export exposes exactly the two source stream/modulus rows and the shared meet row:*

$$(S_0, \mu_0), \quad (S_1, \mu_1), \quad \mu.$$

Every exposed source-pair read is accompanied by the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, componentwise* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row of the packet.*

Proof. Start with Definition 462.1. The only source-side rows in the carrier are S_0, S_1, μ_0, μ_1, and the only shared bound row is μ.

Definition 462.6 preserves the two source modulus projections and the shared meet read under componentwise transport. Definition 462.9 identifies the readable shared bound with the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger carried by μ.

Finally apply Definition 462.13. The public packet adds only the transport, continuation, provenance, and local naming rows, so the exposed source-pair surface is exactly the two source pairs plus the shared meet row. □

Theorem 462.23 (CauchyModulusMeet shared-bound consumer read)**.** *Any downstream shared-bound read from a* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet factors through the public export surface of Definition 462.13. The read may use the two source stream/modulus rows, the shared meet row, the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, componentwise transports, continuation routes, package provenance, and local naming row, and no other route.*

Proof. Let a downstream shared-bound read be given. By Definition 462.14, every downstream consumer is locked to $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$.

Definition 462.22 identifies the source-pair rows and the shared meet row inside that public surface. The dyadic tolerance ledger is therefore read as part of μ, not as a separate completion or quotient object.

Definition 462.21 excludes quotient streams, selected limits, host real equality, ambient completeness, and bridge-checking oracle content. Hence a shared-bound consumer has no route outside the public export packet. □

Theorem 462.24 (CauchyModulusMeet diagonal handoff scope)**.** *A* $\mathsf{Real}^{\uparrow}$ *diagonal handoff consuming a* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet may use only the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the two source stream/modulus rows, the shared meet row,* hsame *transports,* Cont *routes,* Pkg *provenance, and the local* NameCert *row. The handoff does not import quotient stream equality, a selected limit, ambient completeness, host real equality, or a bridge-checking oracle.*

Proof. Begin with a $\mathsf{Real}^{\uparrow}$ diagonal handoff. Definition 462.7 forces the real-facing read through the stream-name rows, regular rational readbacks, shared dyadic tolerance ledger, transports, routes, provenance, and local naming row.

Definition 462.23 then factors the shared-bound part of the handoff through the public export surface. The source-pair exposure theorem identifies the exact source rows and shared meet row available to that surface.

It remains to rule out external analytic data. This is exactly Definition 462.21: the public packet supplies no quotient stream equality, selected limit, ambient completeness, host real equality, or bridge-checking oracle. □

Theorem 462.25 (CauchyModulusMeet common window coherence)**.** *Every* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *or* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *consumer that reads the shared meet row of a* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet must use the same displayed packet*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$$

and the same finite $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *rows. In particular, a diagonal-window read and a regular-Cauchy tail read cannot choose separate source names, separate rational readbacks, or separate dyadic tolerance ledgers while claiming the same shared meet.*

Proof. Start with the carrier and the source-pair exposure theorem. Definition 462.1 gives the displayed coordinates, and Definition 462.22 identifies the two source stream/modulus rows together with the shared meet row.

Next read the shared bound through Definition 462.23. Any downstream shared-bound consumer is already forced through $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$ and through no other route.

Finally apply Definition 462.24. A $\mathsf{Real}^{\uparrow}$ diagonal handoff has the same finite rows available as the public shared-bound read, so a diagonal-window consumer and a regular-Cauchy tail consumer meet on the same source, readback, tolerance, transport, route, provenance, and local naming packet. □

Theorem 462.26 (CauchyModulusMeet paired RegSeqRat readback)**.** *Both* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks attached to* S_0 *and* S_1 *are exposed before any* $\mathsf{Real}^{\uparrow}$ *handoff using a* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet. These readbacks are finite packet rows, not quotient stream equality, selected limits, or host real equality, and no downstream consumer may replace either readback by such an external equality.*

Proof. Use projection stability first. Definition 462.6 preserves the two source modulus projections under the componentwise transport rows, so the source-side readbacks remain attached to the displayed packet.

Now apply consumer factorization and source-pair exposure. Definition 462.10 routes every real-facing or regular-rational-facing read through the finite carrier coordinates, and Definition 462.22 names the paired source rows before the shared meet row is consumed.

The replacement exclusions are exactly the public export boundary. By Definition 462.21, no consumer route can extract quotient stream equality, selected limits, host real equality, ambient completeness, or bridge-checking oracle content from the packet. □

Theorem 462.27 (CauchyModulusMeet diagonal consumer sufficiency)**.** *Definition 462.25, Definition 462.26, and the public export surface of Definition 462.13 are sufficient for downstream diagonal-window consumers to use the shared bound of a* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet. Such consumers need not import selected limits, ambient completeness, host real equality, quotient stream equality, or bridge-checking oracle content.*

Proof. First use common window coherence. It fixes the diagonal-window and regular-Cauchy tail consumers to the same $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$ packet and the same finite stream-name, rational-readback, and dyadic-tolerance rows.

Next use paired readback. The two $\mathsf{RegSeqRat}^{\uparrow}$ rows are already exposed before the $\mathsf{Real}^{\uparrow}$ handoff, so the diagonal consumer can read the source rational data and the shared modulus data from the displayed packet.

Finally apply the public export surface and the export non-escape theorem. Definition 462.13 supplies exactly the finite rows needed by the diagonal consumer, while Definition 462.21 rules

out selected limits, ambient completeness, host real equality, quotient stream equality, and bridge-checking oracle content. □

Theorem 462.28 (CauchyModulusMeet standard bridge certificate)**.** *The public export packet of Definition 462.13 is exactly the standard shared-modulus bridge surface consumed by* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$*. Every bridge read factors through*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

The certificate exports no quotient stream, selected limit, host real equality, ambient completeness row, or bridge-checking oracle.

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetUp StdBridge`

Proof. First read the public export surface. By Definition 462.13, the available packet consists precisely of the two source names, two source modulus rows, the shared modulus row, transport rows, continuation routes, package provenance, and local name.

Next lock the downstream consumers to those rows. Apply Definition 462.14; every $\mathsf{RegSeqRat}^{\uparrow}$ read, $\mathsf{Real}^{\uparrow}$ handoff, source-modulus projection, and dyadic tolerance read must pass through the displayed shared-modulus packet.

The shared-bound content is exhausted by Definition 462.9. Thus the bridge surface has no further analytic coordinate beyond the shared meet row μ and its finite dyadic ledger.

Finally apply Definition 462.21. Since no consumer can extract quotient streams, selected limits, host real equality, ambient completeness, or an independent bridge checker, the public export packet is exactly the standard shared-modulus bridge surface available to $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers. □

Theorem 462.29 (CauchyModulusMeet mature shared-bound readback)**.** *Every mature shared-bound readback of a* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet is exactly the displayed surface*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

The two source stream rows and their source modulus rows provide the only $\mathsf{RegSeqRat}^{\uparrow}$*-facing inputs,* μ *carries the shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, and* H, C, P, N *supply only componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *row.*

Proof. Begin with the carrier of Definition 462.1. It names precisely the two source streams, two source modulus rows, the shared meet row, transport ledger, routes, provenance, and local certificate.

The source-pair exposure and shared-bound exhaustion theorems identify the readable shared-bound data. Definition 462.22 fixes $S_0, S_1, \mu_0, \mu_1, \mu$, while Definition 462.9 binds the tolerance ledger to the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ row carried by μ.

Finally use the public export surface and export consumer lock. They force every mature readback through $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$ and prevent any additional source, tolerance, route, provenance, or naming coordinate from entering the shared-bound read. □

Theorem 462.30 (CauchyModulusMeet mature downstream handoff)**.** *Every downstream* $\mathsf{RegSeqRat}^{\uparrow}$ *read and every downstream* $\mathsf{Real}^{\uparrow}$ *handoff consuming the mature* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *shared-bound package factors through the public export surface of Definition 462.13 and the standard bridge certificate of Definition 462.28. In particular, the downstream consumer receives only the shared-bound readback surface of Definition 462.29.*

Proof. First route the consumer through the public packet. Definition 462.14 already locks $\mathsf{RegSeqRat}^{\uparrow}$ reads, $\mathsf{Real}^{\uparrow}$ handoffs, source-modulus projections, and dyadic tolerance reads to the public export coordinates.

Next apply the diagonal handoff scope. Definition 462.24 and Definition 462.27 show that real-facing diagonal consumers use the same stream, regular-rational, shared-modulus, dyadic, transport, route, provenance, and naming rows as the public shared-bound read.

The standard bridge certificate then identifies that public packet as the bridge surface accepted by $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$. Combining it with the mature shared-bound readback theorem gives the claimed factorization through the displayed package and through no separate downstream route. □

Theorem 462.31 (CauchyModulusMeet mature non-escape)**.** *The mature* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *downstream package exports no quotient stream, no selected limit, no host real equality, no ambient completeness principle, and no independent bridge checker. Its downstream readback,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and* $\mathsf{Real}^{\uparrow}$ *handoff remain confined to the public shared-bound export and the standard bridge certificate.*

Proof. Read the package through the mature shared-bound readback theorem. The only available surface is $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$ with the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger.

Now apply the mature downstream handoff theorem. It factors the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer routes through the public export surface and the standard bridge certificate, so no consumer acquires a second source of analytic data.

Finally use export non-escape. Definition 462.21 already excludes quotient streams, selected limits, host real equality, ambient completeness, and bridge-checking oracle content from the public packet, and the standard bridge certificate repeats the same exclusion at the bridge surface. □

Theorem 462.32 (CauchyModulusMeet modulus-meet associativity)**.** *Let* M_{01}*,* M_{12}*, and* M_{02} *be accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packets whose source rows are respectively* (S_0, S_1)*,* (S_1, S_2)*, and the displayed shared meet row obtained by composing those two packets through the common* S_1 *source. Then every downstream consumer of the three packets reads the same finite shared-bound surface*

$$S_0, S_1, S_2, \mu_0, \mu_1, \mu_2, \mu_{01}, \mu_{12}, \mu_{02}, H, C, P, N$$

as the iterated meet packet. The comparison is only a public readback equality of exported rows; it does not assert quotient stream equality, host real equality, a selected limit, or ambient completeness.

Proof. Begin with the public export surface. Definition 462.13 exposes exactly the source stream rows, source modulus rows, shared meet row, transport rows, displayed routes, provenance, and local name for each packet.

Use source-pair exposure for M_{01} and M_{12}. The shared S_1 row and its modulus row are displayed before either meet row is consumed, so the two packets can be read through the common finite source-pair surface.

Now read the composed shared bound. Definition 462.29 fixes each mature readback to the displayed meet row and its $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and Definition 462.14 keeps downstream consumers on those rows.

Finally apply export non-escape. Since no packet exports quotient streams, selected limits, host real equality, ambient completeness, or a bridge-checking oracle, the two parenthesizations of the three accepted meet packets have the same downstream surface precisely because they display the same finite rows. □

Theorem 462.33 (CauchyModulusMeet meet-projection pair determinacy)**.** *Let M and M' be accepted* CauchyModulusMeet$^{\uparrow}$ *packets. If both packets expose the same two source* StreamName$^{\uparrow}$ *rows, the same two source* CauchyModulus$^{\uparrow}$ *rows, and the same shared meet row up to the displayed* hsame *transport, then their* RegSeqRat$^{\uparrow}$*-facing source-pair reads and their* DyadicRatCore$^{\uparrow}$ *tolerance ledgers have the same public readback surface.*

Proof. First apply projection stability. Definition 462.6 transports the two source modulus projections componentwise, so M and M' retain the same visible source-pair coordinates under the displayed hsame rows.

Next use source-pair exposure. Definition 462.22 identifies the RegSeqRat$^{\uparrow}$-facing reads with the two displayed source stream and modulus rows before the shared meet row is consumed.

The tolerance ledger is then determined by the mature shared-bound readback. Definition 462.29 binds the shared meet row to its DyadicRatCore$^{\uparrow}$ ledger and leaves no second ledger coordinate in the carrier.

Thus the public readback surfaces agree. The conclusion is only determinacy of the displayed source-pair and tolerance rows, not equality of quotient streams, selected limits, host real values, or ambient completeness witnesses. □

Theorem 462.34 (CauchyModulusMeet regular-limit consumer triad)**.** *Every* RealDiagonalWindowCoverage$^{\uparrow}$*,* RegularCauchyTriangleBound$^{\uparrow}$*, or* RegSeqRat$^{\uparrow}$ *consumer of an accepted* CauchyModulusMeet$^{\uparrow}$ *packet factors through the same rows*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

The three consumer kinds may use those rows differently, but none obtains an additional quotient stream, selected limit, host real equality, ambient completeness principle, or bridge-checking oracle.

Proof. Start with common-window coherence. Definition 462.25 places diagonal-window and regular-tail consumers on the same stream, source-modulus, shared-modulus, dyadic-ledger, transport, route, provenance, and naming rows.

Next use paired RegSeqRat$^{\uparrow}$ readback. Definition 462.26 exposes the two source readbacks before the Real$^{\uparrow}$ handoff, so a regular-rational consumer reads the same source pair as a diagonal-window consumer.

Now apply diagonal consumer sufficiency. Definition 462.27 shows that the displayed packet already supplies the shared bound needed by diagonal-window and regular-Cauchy tail consumers.

Finally use mature downstream handoff. Definition 462.30 factors the downstream RegSeqRat$^{\uparrow}$ and Real$^{\uparrow}$ routes through the public export surface and the standard bridge certificate, while the non-escape boundary rules out every undisplayed analytic coordinate. □

Theorem 462.35 (CauchyModulusMeet binary meet projection lock)**.** *Every accepted* CauchyModulusMeet$^{\uparrow}$ *packet exposes the two source modulus projections and the shared meet row exactly through*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

Here S_0, S_1 are the two source StreamName$^{\uparrow}$ *rows, μ_0, μ_1 are the source* CauchyModulus$^{\uparrow}$ *rows, μ is the shared meet row with its* DyadicRatCore$^{\uparrow}$ *ledger, and H, C, P, N are respectively the componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row. The projection lock exports no selected limit, no quotient stream, no host real equality, and no ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket binary projection lock`

Proof. Project the carrier of Definition 462.1. Its visible rows are the two source streams, the two source modulus rows, the shared meet row, the transport and continuation rows, package provenance, and the local certificate.

Apply source-pair exposure and projection stability. Definition 462.22 identifies the two source stream and modulus projections, while Definition 462.6 keeps those projections componentwise under the displayed hsame rows.

Use shared-bound exhaustion to identify the meet row. Definition 462.9 and Definition 462.29 leave the shared dyadic ledger inside μ and expose no second tolerance coordinate.

Finally apply the non-escape boundary. Definition 462.21 rules out selected limits, quotient streams, host real equality, ambient completeness, and any bridge-checking oracle outside the displayed packet. □

Theorem 462.36 (CauchyModulusMeet joint consumer exactness)**.** *Every joint* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet factors through the paired source rows* S_0, S_1, μ_0, μ_1*, the shared dyadic ledger carried by* μ*, componentwise* hsame *transport* H*, displayed* Cont *routes* C*, package provenance* P*, and the local* NameCert *row* N*. No joint consumer may replace this route by a selected stream limit, quotient stream equality, host real equality, or ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket joint consumer exactness`

Proof. Begin with the export consumer lock. Definition 462.14 already forces every $\mathsf{RegSeqRat}^{\uparrow}$ read, $\mathsf{Real}^{\uparrow}$ handoff, source-modulus projection, and dyadic tolerance read through the public export coordinates.

Read the paired source rows next. Definition 462.26 exposes the two source readbacks before the real handoff, and Definition 462.35 fixes the corresponding modulus projections and shared meet row.

The real-facing side is the same finite route. Definition 462.24 and Definition 462.27 show that diagonal and real consumers use the same shared-bound packet and the same displayed transport, continuation, provenance, and naming rows.

Finally use mature downstream handoff and mature non-escape. They identify the downstream route with the public export surface and exclude selected limits, quotient streams, host real equality, ambient completeness, and any external analytic object. □

Theorem 462.37 (CauchyModulusMeet root-unblock export)**.** *The accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet exports the exact shared-bound surface consumed by* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. The export consists of carrier admission, projection stability, swap stability, shared-bound exhaustion, diagonal handoff scope, common-window coherence, paired* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and mature downstream handoff over the single packet*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

It is a root-unblock surface for those consumers only through displayed BEDC rows, not through quotient streams, selected limits, host real values, ambient completeness, or an external bridge checker.

Lean4 ✓ `BEDC.Derived.CauchyModulusMeetUp.CauchyModulusMeetPacket root unblock export`

Proof. First assemble the packet surface. Carrier admission comes from Definition 462.1, and Definition 462.35 fixes the two source rows, the two source modulus rows, the shared meet row, transport, routes, provenance, and local name.

Next close the stability and shared-bound obligations. Definition 462.6 and Definition 462.8 keep the source projections stable, while Definition 462.9 identifies the shared dyadic ledger as the only bound exported by μ.

Now route the diagonal and common-window consumers. Definition 462.24, Definition 462.25, and Definition 462.27 put $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, and RealDiagonalWindowCoverage on the displayed shared-bound packet.

Finally route the rational and real consumers. Definition 462.26, Definition 462.36, and Definition 462.30 put $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ on the same packet, and Definition 462.31 excludes every undisplayed analytic route. □

Theorem 462.38 (CauchyModulusMeet uniform-family tail-threshold factorization)**.** *Let an accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet export its shared meet row to a finite-family* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *ledger and to an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. If both consumers read the shared tail threshold supplied by the meet packet, then both consumer routes factor through the same displayed rows*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

The finite-family ledger and the tail-meet packet may transport the row through their own displayed hsame *and* Cont *routes, but neither consumer may replace μ by an independent tail selector, quotient stream, selected limit, host equality, ambient completeness witness, or any tail-threshold row not read from the displayed* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet.*

Proof. Begin with the exported meet surface. Definition 462.37 fixes the two source stream rows, the two source modulus rows, the shared meet row, transport, continuation, provenance, and local naming rows as the only root-unblock packet available to downstream consumers.

Next attach the regular tail-meet consumer. Definition 560.20 says that a finite-family threshold request absorbed by $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ must pass through the displayed tail-meet route rather than a separate selector or completion object.

Now read the finite-family side. Definition 435.10 keeps the family threshold request on the shared transported threshold row, and Definition 435.47 keeps subfamily tail reads inside the same finite family ledger.

Combining these routes identifies the tail-meet threshold and the finite-family threshold as two consumer views of the same displayed row μ inside

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

The exclusions follow because each cited route is a ledger-read theorem over displayed BEDC rows and none exposes quotient streams, selected limits, host equality, ambient completeness, or an external tail selector. □

Theorem 462.39 (CauchyModulusMeet finite-chain threshold induction)**.** *Let $M_0, \ldots, M_n$ be a finite chain of accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packets such that each adjacent pair shares the displayed source stream row and source modulus row needed to compose the next meet packet. Write the visible rows of the chain as*

$$S_0, \ldots, S_n, \mu_0, \ldots, \mu_n, \mu_{01}, \mu_{12}, \ldots, \mu_{n-1,n}, H, C, P, N$$

with the iterated meet row obtained by repeatedly applying the displayed shared-threshold meet. Then every $\mathsf{UniformCauchyCriterion}^{\uparrow}$*,* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer of the chain factors through a single iterated shared-threshold surface assembled from the rows S_i, the*

modulus rows μ_i, the iterated meet row, componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *rows of the accepted packets.*

The factorization is only a finite BEDC ledger read. It exports no quotient stream, no selected limit, no host real equality, no hidden tail oracle, and no ambient completeness principle.

Proof. The base case is the binary packet. Definition 462.35 fixes the two source rows, two source modulus rows, shared meet row, transports, continuations, provenance, and local name, while Definition 462.36 confines the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer routes to that same packet.

For the induction step, assume the initial segment already reads through its iterated shared-threshold surface. Compose that surface with the next accepted meet packet along the adjacent shared source row and shared modulus row. Definition 462.32 identifies the parenthesized readbacks as the same finite exported surface, so the next packet extends the row list without introducing a second threshold coordinate.

Now route the finite-family consumers. Definition 462.37 exposes the accepted meet packets as the root-unblock surface for $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and Definition 462.38 puts $\mathsf{UniformCauchyCriterion}^{\uparrow}$ and $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold reads on the same displayed meet row.

Finally apply mature non-escape at each accepted packet and at the iterated surface. Definition 462.31 rules out quotient streams, selected limits, host real equality, hidden analytic routes, bridge-checking oracles, and ambient completeness, so the finite chain supplies only the displayed shared-threshold ledger requested by the downstream consumers. □

Theorem 462.40 (CauchyModulusMeet regular-comparison window handoff)**.** *An accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *packet exporting*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$$

supplies the shared window and dyadic tolerance surface consumed by a $\mathsf{RegularCauchyComparison}^{\uparrow}$ *packet. The comparison rows W, D, τ must therefore be read from the displayed meet row μ and its source projections S_0, S_1, μ_0, μ_1, rather than from a second tolerance surface, quotient stream equality, host real equality, selected limit, or ambient completeness principle.*

Proof. First lock the meet projections. Apply Definition 462.35: the two source rows, the two source modulus rows, and the shared meet row are exactly the displayed $S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N$ surface.

Next read joint consumer exactness and the root-unblock export. Definition 462.36 keeps $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers on that same finite route, and Definition 462.37 identifies it as the shared-bound surface exposed to regular comparison consumers.

Now attach the $\mathsf{RegularCauchyComparison}^{\uparrow}$ packet. Its carrier and window exactness rows, Definition 411.1 and Definition 411.4, force the two regular names through one displayed window W before dyadic observations are read.

Finally apply tolerance-row exactness and the real seal boundary, Definition 411.7 and Definition 411.8. They make the comparison's D, τ rows part of the same finite comparison surface and exclude a second tolerance, host real equality, quotient stream, selected limit, or ambient completeness route. □

Theorem 462.41 (CauchyModulusMeet Real seal shared-threshold determinacy)**.** *Any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer that uses the* $\mathsf{RegularCauchyComparison}^{\uparrow}$ *window route and the* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *shared meet row must read the same threshold packet*

$$S_0, S_1, \mu_0, \mu_1, \mu, H, C, P, N.$$

The consumer may pass through the comparison window rows W, D, τ, but those rows are determined by the displayed shared meet packet. It cannot introduce a second tolerance surface, quotient stream equality, selected limit, host real equality, or ambient completeness witness.

Proof. First lock the shared packet. Definition 462.35 fixes the two source rows, the two source modulus rows, the shared meet row, and the transport, continuation, provenance, and naming rows.

Next read the consumer side. Definition 462.36 keeps $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ consumers on that same finite route, while Definition 462.37 exposes it as the shared-bound packet consumed downstream.

Now attach the comparison route. Definition 462.40 forces the $\mathsf{RegularCauchyComparison}^{\uparrow}$ window and dyadic tolerance rows to be read from the displayed meet row μ and its source projections.

The exclusions follow from the same route determinations. Since the cited packet, export, and handoff theorems expose no second tolerance surface, quotient stream equality, selected limit, host real equality, or ambient completeness witness, the Real-seal and regular-rational consumers read one deterministic threshold packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyModulusMeet}^{\uparrow}}$.

Constructive story: A $\mathsf{CauchyModulusMeet}^{\uparrow}$ packet is generated from two $\mathsf{StreamName}^{\uparrow}$ rows, their $\mathsf{RegSeqRat}^{\uparrow}$ rational readbacks, two source $\mathsf{CauchyModulus}^{\uparrow}$ rows, one shared $\mathsf{CauchyModulus}^{\uparrow}$ meet row with a $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyModulusMeet}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 462.1, Definition 462.2, Definition 462.6, Definition 462.7, Definition 462.8, Definition 462.9, Definition 462.10, Definition 462.11, Definition 462.12, Definition 462.13, Definition 462.14, Definition 462.21, Definition 462.25, Definition 462.26, Definition 462.27, Definition 462.28, Definition 462.29, Definition 462.30, and Definition 462.31 bind the finite shared-modulus carrier, source modulus projections, dyadic tolerance ledger, Real and RegSeqRat consumer boundaries, diagonal-window consumer surface, public export certificate, standard bridge surface, mature shared-bound readback, mature downstream handoff, and mature non-escape package over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and NameCert.

Not claimed: This chapter does not close quotient streams, selected limits, ambient completeness, host real equality, or bridge-checking oracle content.

Upgrade path: No further formal-axis upgrade remains for the checked standard bridge.

Chapter 463

A Concrete Naming Certificate for $\mathsf{UniformLimit}^{\uparrow}$

The $\mathsf{UniformLimit}^{\uparrow}$ interface names the constructive-analysis packet for a uniformly convergent family of displayed real-valued windows. Following Bishop–Bridges constructive analysis, the limiting object is read through a uniform tail ledger, a regular rational handoff, and a visible $\mathsf{CauchyLimitSeal}^{\uparrow}$ row. The packet does not select a host function limit, quotient a function space, or appeal to ambient completeness of $\mathsf{Real}^{\uparrow}$.

The endpoint row is available only after the packet consumes the $\mathsf{StreamName}^{\uparrow}$ finite-window surface of chapter 126, the $\mathsf{UniformCauchyCriterion}^{\uparrow}$ tail ledger of chapter 435, the $\mathsf{RegSeqRat}^{\uparrow}$ handoff of chapter 301, and the $\mathsf{CauchyLimitSeal}^{\uparrow}$ seal row of chapter 386. Thus the endpoint is a routed finite seal read, not a host-selected limit.

Definition 463.1 (UniformLimit carrier)**.** *A* $\mathsf{UniformLimit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

with the following displayed coordinates:

1. *F is the displayed function/window family, read only through finite* $\mathsf{StreamName}^{\uparrow}$ *windows and* $\mathsf{Real}^{\uparrow}$ *endpoint rows;*
2. *M is the shared modulus ledger assigning each requested tolerance to one family-wide window threshold;*
3. *T is the* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *tail ledger that records the accepted comparisons beyond the threshold selected by M;*
4. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row obtained from the same windows and tail ledger;*
5. *S is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *seal row attached to the regular handoff;*
6. *E is the exposed* $\mathsf{Real}^{\uparrow}$ *endpoint row read after the seal row;*
7. *H stores componentwise* hsame *transports for the function/window family, modulus ledger, uniform tail ledger, regular handoff, limit seal, endpoint row, package provenance, and local naming row;*
8. *C stores the displayed* Cont *routes for reading the windows, applying the shared threshold, consuming the uniform tail ledger, reaching the regular handoff, and exposing the seal endpoint;*

9. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{UniformCauchyCriterion}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{UniformLimit}^{\uparrow}}$ *row.*

The classifier compares accepted carriers only through these rows, their displayed transports, their continuation routes, package provenance, and local naming provenance.

Theorem 463.2 (UniformLimit NameCert obligations)**.** *For the carrier of Definition 463.1, the local* $\mathsf{NameCert}_{\mathsf{UniformLimit}^{\uparrow}}$ *surface consists exactly of five finite obligations:*

1. *carrier admission for the packet $U = (F, M, T, R, S, E, H, C, P, N)$;*
2. *classifier transport by componentwise* hsame *over the function/window family, modulus ledger, tail ledger, regular handoff, seal row, and endpoint row;*
3. *uniform-tail exactness, requiring each endpoint-facing read to pass through the same threshold row M and the* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *ledger T;*
4. *regular-seal routing, requiring every limit-facing read to pass from F, M, T through R and S before reaching E;*
5. *non-escape from pointwise convergence without a uniform ledger, open-cover compactness, selected host limits, quotient function spaces, and* $\mathsf{Real}^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.UniformLimitUp.UniformLimitCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 463.1. The displayed coordinates name the family windows, shared modulus, uniform tail ledger, regular handoff, seal row, endpoint row, transports, continuations, package provenance, and local certificate.

Classifier transport is componentwise. The rows in H move each named coordinate, and the routes in C replay the same consumer order, so a transported packet remains inside the displayed carrier surface.

For exactness, inspect a requested tolerance. The consumer route first reads M, then reads the corresponding comparisons in T, and only then reaches the regular handoff and seal rows. The packet inventory contains no coordinate for pointwise-only convergence, open-cover compactness, selected host limits, quotient function spaces, or real completeness. □

Theorem 463.3 (UniformLimit seal factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *endpoint read exported by an accepted* $\mathsf{UniformLimit}^{\uparrow}$ *carrier factors through the finite route*

$$F, M, T \longmapsto R \longmapsto S \longmapsto E.$$

Thus the endpoint is exposed only after the displayed function/window family has been read through the shared threshold ledger, the $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *tail row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row, together with the visible* hsame, Cont, Pkg, *and* NameCert *provenance.*

Lean4 ✓ `BEDC.Derived.UniformLimitUp.UniformLimitCarrier seal factorization`

Proof. Begin with an endpoint-facing consumer request. By the carrier definition, the only $\mathsf{Real}^{\uparrow}$ endpoint coordinate is E, and the continuation route to E passes through the named rows of the same finite packet.

Read the family windows through F and the shared threshold through M. The uniform comparisons are then supplied by T, so the request has not used an indexwise or pointwise-only convergence witness.

Next consume the regular rational handoff R and the limit seal S. These rows mediate the passage from the uniform tail ledger to the endpoint row, while H, C, P, N record the transport, route, package, and naming provenance. Hence every endpoint read has the stated factorization. □

Theorem 463.4 (UniformLimit non-escape boundary)**.** *An accepted* $\mathsf{UniformLimit}^{\uparrow}$ *carrier exports only the displayed function/window family, shared modulus ledger,* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *tail ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *seal row,* $\mathsf{Real}^{\uparrow}$ *endpoint, and the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows of Definition 463.1. It exports no pointwise convergence object lacking the uniform ledger, no open-cover compactness principle, no selected host limit, no quotient function space, and no completeness theorem for* $\mathsf{Real}^{\uparrow}$*.*

Proof. Inspect the packet coordinates. Every listed row is a finite display, transport, continuation, provenance, or local naming row, and the only endpoint coordinate is the seal-facing row E.

Apply Definition 463.2. Uniform-tail exactness keeps each read inside F, M, T, and regular-seal routing forces the route through R and S before E is exposed.

The excluded analytic objects would require additional carrier coordinates or a different consumer route. Since neither is present, the public surface is exhausted by the finite BEDC rows listed in the statement. □

Theorem 463.5 (UniformLimit finite endpoint certificate)**.** *The carrier, local* NameCert *obligations, seal factorization, and non-escape boundary assemble a finite endpoint certificate for* $\mathsf{UniformLimit}^{\uparrow}$ *over* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{UniformCauchyCriterion}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. Every downstream completion or real-consumer read is confined to that packet and its factorization route.*

Proof. Start with the carrier of Definition 463.1. It supplies exactly the function/window family, shared modulus, uniform tail ledger, regular handoff, seal row, endpoint row, transports, continuations, package provenance, and local certificate.

Use Definition 463.2 to obtain carrier admission, classifier transport, uniform-tail exactness, regular-seal routing, and the non-escape clauses. Then use Definition 463.3 to identify the endpoint route.

Finally apply Definition 463.4. The route has no coordinate outside the listed BEDC rows, so the finite endpoint certificate is the whole downstream consumer surface. □

Theorem 463.6 (UniformLimit windowwise Cauchy obligation)**.** *Every endpoint-facing read of an accepted* $\mathsf{UniformLimit}^{\uparrow}$ *carrier must pass through the shared threshold ledger* M *and the* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *tail row* T *before it reaches the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff. Thus the read is windowwise uniform: no endpoint row may be obtained from a pointwise-only convergence witness or from a window threshold selected outside the packet.*

Proof. Project the route inventory from Definition 463.1. The only endpoint-facing continuation route reads the family windows through F, then the shared threshold ledger M, then the uniform tail ledger T.

Apply the uniform-tail and regular-seal clauses of Definition 463.2. They force the consumer route to use the same M and T before the handoff row R can be reached.

Finally use Definition 463.3 and Definition 463.5. Both identify the downstream endpoint path as the finite route through F, M, T, R, S, E, so a pointwise-only or externally selected threshold route is not part of the certificate. □

Theorem 463.7 (UniformLimit limit-seal compatibility)**.** *The* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row* R *and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* S *of an accepted* $\mathsf{UniformLimit}^{\uparrow}$ *carrier are compatible with the same window coordinates and the same* hsame *and* Cont *rows used by the uniform tail route. Transporting the window family, shared threshold, or uniform tail ledger therefore transports the handoff and seal route without changing the endpoint surface.*

Proof. Read the carrier coordinates H and C from Definition 463.1. These rows store the componentwise transports and displayed continuations for the function/window family, threshold ledger, uniform tail ledger, handoff row, seal row, and endpoint.

Use Definition 463.3. It factors every endpoint read through the same route from F, M, T to R, then to S, and finally to E.

Apply the classifier-transport clause of Definition 463.2. Since R and S are transported by the same H and replayed by the same C as the tail route, the transported packet keeps the handoff and seal compatible with the original windows and endpoint boundary. □

Theorem 463.8 (UniformLimit ledger exactness obligation)**.** *For an accepted* $\mathsf{UniformLimit}^{\uparrow}$ *carrier, the packet*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

exhausts the visible ledger. It includes the function/window family, shared modulus, uniform tail ledger, regular handoff, limit seal, endpoint row, transports, continuations, package provenance, and local naming row, and it excludes pointwise-only convergence, open-cover compactness, selected host limits, quotient function spaces, and $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Start with Definition 463.1. Its tuple lists every visible coordinate of the carrier and names the dependency rows in P and N.

Use Definition 463.6 for the tail side and Definition 463.7 for the handoff and seal side. Together they show that all endpoint-facing routes are contained in the displayed packet.

Finally apply Definition 463.4 and Definition 463.5. The excluded analytic structures would require additional carrier coordinates or a different consumer route, and neither is present in U. □

Theorem 463.9 (UniformLimit tail-ledger exactness)**.** *For every accepted* $\mathsf{UniformLimit}^{\uparrow}$ *carrier*

$$U = (F, M, T, R, S, E, H, C, P, N),$$

each endpoint-facing read first factors through the displayed function/window family F*, the shared threshold ledger* M*, and the unique* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *tail ledger* T *visible to the packet. No second tail ledger, pointwise-only convergence witness, or independently selected threshold route can be read before the regular handoff row* R*.*

Lean4 ✓ `BEDC.Derived.UniformLimitUp.UniformLimitCarrier tail ledger exactness`

Proof. Project U through Definition 463.1. The only rows before the regular handoff are F, M, T.

Apply Definition 463.2. The local NameCert surface names the function/window family, the shared threshold ledger, and the uniform Cauchy tail ledger as the finite endpoint-facing entrance to the packet.

Use Definition 463.6. Any endpoint-facing read reaches R only after the shared threshold and uniform tail rows have been read.

Finally apply Definition 463.8. Since the visible ledger has exactly one T coordinate and no pointwise-only convergence or second threshold coordinate, the displayed T is the unique tail ledger available to the packet. □

Theorem 463.10 (UniformLimit tail-seal route uniqueness)**.** *Let*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

and

$$U' = (F', M', T', R', S', E', H', C', P', N')$$

be accepted $\mathsf{UniformLimit}^{\uparrow}$ *carriers. If the displayed classifier rows identify* F *with* F'*,* M *with* M'*,* T *with* T'*,* R *with* R'*,* S *with* S'*, and* E *with* E'*, then every endpoint-facing read follows the same finite route*

$$F \longmapsto M \longmapsto T \longmapsto R \longmapsto S \longmapsto E.$$

No pointwise-only convergence witness, second tail ledger, selected host limit, quotient function space, or $\mathsf{Real}^{\uparrow}$ *completeness theorem can provide a competing endpoint route.*

Proof. Project both carriers through Definition 463.1. The classifier hypotheses identify the function/window family, shared threshold ledger, uniform tail ledger, regular handoff, seal row, and endpoint row on the displayed carrier surface.

Apply Definition 463.9. Any endpoint-facing read must enter through F, M, T, and the accepted carrier has no second tail ledger or pointwise-only entrance that could reach R first.

Use Definition 463.3. Once the tail entrance is fixed, the endpoint route factors through the regular handoff R, the seal row S, and the endpoint E, so the displayed route is the only tail-to-seal path available to the consumer.

Finally invoke Definition 463.4. The excluded analytic objects are not carrier coordinates and are not exported by the transport, continuation, provenance, or local naming rows, so they cannot supply a competing endpoint read. □

Theorem 463.11 (UniformLimit seal-route transport)**.** *Let*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

and

$$U' = (F', M', T', R', S', E', H', C', P', N')$$

be accepted $\mathsf{UniformLimit}^{\uparrow}$ *carriers related by the displayed classifier. Componentwise* hsame *transport of* F, M, T *transports the regular handoff, limit seal, and endpoint route* R, S, E *through the same* H, C, P, N *provenance. Thus the seal route remains the same finite route after transport:*

$$F \longmapsto M \longmapsto T \longmapsto R \longmapsto S \longmapsto E.$$

Proof. Start with the compatibility theorem Definition 463.7. It states that the handoff row R and seal row S use the same window coordinates and the same transport and continuation rows as the uniform tail route.

Apply Definition 463.9. Transport of the endpoint-facing entrance is therefore transport of the rows F, M, T, not a change to a different tail ledger.

Use Definition 463.3. The endpoint row E is reached only through R and S, so transporting F, M, T carries the whole route through the same R, S, E boundary.

Finally invoke Definition 463.2 and Definition 463.8. The rows H, C, P, N are the displayed transport, replay, provenance, and local naming rows for this packet, and no additional seal route is present. □

Theorem 463.12 (UniformLimit endpoint readback exhaustion)**.** *Every downstream* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{UniformLimit}^{\uparrow}$ *carrier can read only*

$$F, M, T, R, S, E, H, C, P, N.$$

Such a consumer may read the displayed window family, shared threshold ledger, uniform tail ledger, regular handoff, limit seal, endpoint row, transports, continuations, package provenance, and local naming row. It cannot extract pointwise convergence without the uniform ledger, quotient function spaces, selected host limits, open-cover compactness, or $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Begin with an arbitrary downstream endpoint read. By Definition 463.9, the read first factors through F, M, T.

Apply Definition 463.11 and Definition 463.3. The regular handoff, limit seal, and endpoint route are exactly R, S, E, transported and replayed by the same H, C rows.

Use Definition 463.5. The finite certificate packages the endpoint-facing route together with P and N as the visible provenance and local naming surface.

Finally apply Definition 463.4 and Definition 463.8. The excluded pointwise, quotient, selected-limit, compactness, and completeness objects are not coordinates of the carrier and cannot be recovered by readback. □

Theorem 463.13 (UniformLimit obligation closure package)**.** *For every accepted* $\mathsf{UniformLimit}^{\uparrow}$ *carrier*

$$U = (F, M, T, R, S, E, H, C, P, N),$$

the carrier, local NameCert *obligations, windowwise Cauchy obligation, limit-seal compatibility, tail-ledger exactness, seal-route transport, and endpoint readback exhaustion jointly supply the obligation surface over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{UniformCauchyCriterion}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert.

The package exports exactly the displayed function/window family, shared threshold ledger, uniform tail ledger, regular handoff, limit seal, endpoint row, transport routes, continuation routes, provenance, and local naming data. It exports no pointwise-only convergence object, open-cover compactness principle, selected host limit, quotient function space, or $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Proof. Begin with the carrier and local naming obligations in Definition 463.1 and Definition 463.2. They identify the coordinates $F, M, T, R, S, E, H, C, P, N$ and bind carrier admission, classifier transport, uniform-tail exactness, regular-seal routing, and non-escape to those coordinates.

Use the windowwise Cauchy obligation of Definition 463.6 and the limit-seal compatibility theorem Definition 463.7. These force every endpoint route to read the shared threshold and the same uniform tail ledger before reaching the handoff and seal rows.

Apply tail-ledger exactness from Definition 463.9 and seal-route transport from Definition 463.11. They show that transported endpoint reads remain on the finite route from F, M, T through R, S, E.

Finally use endpoint readback exhaustion in Definition 463.12. Since all downstream consumers can read only the displayed rows and their provenance, the obligation package has no coordinate for pointwise-only convergence, open-cover compactness, selected host limits, quotient function spaces, or real completeness. □

Theorem 463.14 (UniformLimit diagonal-window handoff)**.** *Let*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{UniformLimit}^{\uparrow}$ *carrier, and let*

$$G = (q, w, r, d, e, h, c, p, n)$$

be an accepted $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *carrier. Suppose that the selected window* w *is a displayed window of* F*, and that the readback row* r *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff read through* T*. Then every* $\mathsf{Real}^{\uparrow}$*-facing diagonal-window read determined by* G *and the displayed window of* U *factors simultaneously through the two finite routes*

$$F \longmapsto M \longmapsto T \longmapsto R \longmapsto S \longmapsto E$$

and

$$q \longmapsto w \longmapsto r \longmapsto d \longmapsto e.$$

Consequently the diagonal-window consumer can use the uniform-limit endpoint exposure only through the selected finite window, the uniform tail ledger, the regular rational handoff, the dyadic observation ledger, and the displayed $\mathsf{Real}^{\uparrow}$ *seal; it gains no pointwise-only convergence row, host limit, quotient function space, ambient completeness theorem, or unbounded diagonal stream.*

Proof. Start from the accepted $\mathsf{UniformLimit}^{\uparrow}$ carrier. By Definition 463.3, every endpoint read exported by U reaches the endpoint only along the finite route through F, M, T, R, S, E.

Use the windowwise Cauchy obligation of Definition 463.6 and tail-ledger exactness from Definition 463.9. Since w is one of the displayed windows of F and r is the $\mathsf{RegSeqRat}^{\uparrow}$ handoff read through T, the diagonal read cannot bypass the shared threshold ledger or replace the uniform tail row with a pointwise witness.

Now turn to the accepted $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ carrier. The selected-window coverage theorem Definition 561.7 forces the seal-facing read to expose w and the dyadic ledger d before the seal row is consumed.

Apply the RealUp handoff theorem Definition 561.8. It routes every real-facing completion or continuous-map consumer through q, w, r, d, h, c, p, n before the $\mathsf{Real}^{\uparrow}$ seal row e is read, so the selected-window side is exactly the displayed route from q through e.

Finally combine the non-escape boundary for $\mathsf{UniformLimit}^{\uparrow}$ with the non-escape boundary for $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$. The first boundary excludes host limits, quotient function spaces, pointwise-only convergence, compactness principles, and real completeness from U; the second excludes quotient streams, host real equality, unbounded diagonal streams, ambient completeness, and choice-selected limits from G. Thus the only common consumer route is the paired finite factorization through the uniform-limit endpoint route and the selected diagonal-window route. □

Theorem 463.15 (UniformLimit observation-budget factorization)**.** *Let*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{UniformLimit}^{\uparrow}$ *carrier, and let*

$$B = (e, W, D, R_B, S_B, H_B, C_B, P_B, N_B)$$

be an accepted $\mathsf{RealObservationBudget}^{\uparrow}$ *carrier. Suppose the finite windows in* W *are displayed windows of* F*, the dyadic readbacks in* D *are the endpoint-facing readbacks for those windows, the handoff rows in* R_B *include the same* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff* R *read through* T*, and the seal rows in*

S_B include the same endpoint-facing seal route S, E. Then every $\mathsf{Real}^{\uparrow}$ *endpoint read exported by U factors through the observation-budget route*

$$e \longmapsto W \longmapsto D \longmapsto R_B \longmapsto S_B$$

before exposing the endpoint row E.

Thus a common consumer of the uniform-limit packet and the observation-budget packet reads the shared finite windows, dyadic readbacks, regular handoff, seal rows, transports, and routes before the endpoint is available.

Proof. First identify the uniform-limit entrance. By Definition 463.3, every endpoint read of U reaches E only through F, M, T, R, S.

Next apply the windowwise Cauchy obligation and the diagonal-window handoff, Definition 463.6 and Definition 463.14. Since the windows in W are displayed windows of F and the readbacks in D are tied to those windows, the endpoint-facing read cannot bypass the shared threshold row M or the tail ledger T.

Now read the budget side. The finite-window seal-route totality theorem for $\mathsf{RealObservationBudget}^{\uparrow}$, Definition 611.17, routes every admitted seal read through e, W, D, R_B, S_B with the displayed transports, continuations, provenance, and local name.

Finally combine the two route inventories. The shared handoff hypothesis identifies the uniform-limit R with the budget handoff rows, and the shared seal hypothesis identifies S, E with the budget seal route. Therefore the common endpoint read must pass through the observation-budget route before E is exposed. □

Theorem 463.16 (UniformLimit observation-budget nonchoice boundary)**.** *Under the hypotheses of Definition 463.15, the common endpoint read cannot be replaced by pointwise convergence, a hidden selected limit, quotient function-space equality, an ambient completeness theorem, quotient stream equality, host real equality, or an unbounded observation schedule. Its only admissible route is the shared finite budget route through F, M, T, R, S, E and e, W, D, R_B, S_B with the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Begin with the uniform-limit non-escape boundary. Definition 463.4 removes pointwise-only convergence, open-cover compactness, selected host limits, quotient function spaces, and $\mathsf{Real}^{\uparrow}$ completeness from the $\mathsf{UniformLimit}^{\uparrow}$ packet.

Then apply the observation-budget non-escape theorem, Definition 611.6. It removes quotient stream equality, host real equality, ambient completeness, hidden limit selection, and unbounded observation schedules from the $\mathsf{RealObservationBudget}^{\uparrow}$ packet.

The factorization theorem Definition 463.15 gives the remaining common route. Since both packets expose only their displayed rows and the shared handoff and seal hypotheses identify the overlap, a consumer has no second source from which to select the endpoint. □

Theorem 463.17 (UniformLimit shared threshold regular seal)**.** *For every accepted* $\mathsf{UniformLimit}^{\uparrow}$ *carrier*

$$U = (F, M, T, R, S, E, H, C, P, N),$$

the endpoint-facing route uses one shared threshold ledger M and one $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *tail row T before it reaches the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff R and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row S. Thus the regular handoff and seal are bound to the same windowwise threshold data that generated the uniform tail comparisons.*

Proof. Start with the accepted carrier U. By Definition 463.6, every endpoint-facing read must enter through the displayed windows, the shared threshold ledger M, and the uniform tail row T before it can reach R.

Apply Definition 463.9. The carrier has no second tail ledger and no independently selected threshold route, so the rows M and T used at the entrance are the unique rows available to the regular handoff.

Finally use Definition 463.3. The route from the regular handoff to the endpoint passes through S and then E, so the seal row is attached to the same shared threshold and tail ledger rather than to a separate pointwise or host-level limit route. □

Theorem 463.18 (UniformLimit RegSeq seal classifier scope)**.** *Let*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

and

$$U' = (F', M', T', R', S', E', H', C', P', N')$$

be accepted $\mathsf{UniformLimit}^{\uparrow}$ *carriers related by the displayed classifier. Classifier transport of* F, M, T *transports the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff* R*, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* S*, and the endpoint row* E *through the displayed* hsame *rows and* Cont *routes already recorded in* H *and* C*. It does not create a second seal route.*

Proof. Use Definition 463.7. The handoff row R and seal row S are compatible with the same window coordinates, transport rows, and continuation routes that carry the uniform tail route.

Apply Definition 463.11. Once F, M, T are transported by the displayed classifier, the regular handoff, seal, and endpoint route are transported along the same finite path through R, S, E.

The carrier inventory contains only the transport ledger H and continuation ledger C for this route. Hence classifier transport preserves the displayed seal route and supplies no additional route by which a consumer could bypass the regular handoff. □

Theorem 463.19 (UniformLimit completion consumer boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{UniformLimit}^{\uparrow}$ *carrier factors through*

$$F, M, T, R, S, E, H, C, P, N.$$

Such a consumer cannot read pointwise-only convergence, selected host limits, quotient function spaces, open-cover compactness, or $\mathsf{Real}^{\uparrow}$ *completeness from the packet.*

Proof. Begin with an arbitrary real-facing or completion-facing consumer. By Definition 463.12, the consumer can read only the displayed carrier rows $F, M, T, R, S, E, H, C, P, N$.

Use Definition 463.14 for the boundary handoff. Any diagonal-window read that reaches the endpoint must pass through the finite uniform route and the selected finite window route, so it gains no unbounded stream, host limit, quotient function space, or ambient completeness principle.

Finally apply Definition 463.4. The excluded analytic objects are not carrier coordinates and are not exposed by the continuation or provenance rows. Therefore the Real and completion consumers are confined to the displayed uniform-limit packet. □

Theorem 463.20 (UniformLimit continuous map handoff)**.** *Let*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{UniformLimit}^{\uparrow}$ *carrier. Any* $\mathsf{ContinuousMap}^{\uparrow}$ *consumer, and more generally any continuity-preservation consumer of the limiting endpoint, must factor through the finite route*

$$F \longmapsto M \longmapsto T \longmapsto R \longmapsto S \longmapsto E$$

together with the transport, continuation, provenance, and non-escape rows H, C, P, N*. The shared threshold ledger* M *and uniform tail row* T *supply the only uniform threshold surface before the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff* R *and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* S*. The consumer therefore has no access to pointwise-only convergence, host function limits, quotient function spaces, open-cover compactness, or* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Begin with a $\mathsf{ContinuousMap}^{\uparrow}$ or continuity-preservation consumer of the limiting endpoint. By Definition 463.19, every endpoint-facing consumer is confined to the displayed carrier rows $F, M, T, R, S, E, H, C, P, N$ and cannot read an ambient function-space or completeness object.

Use Definition 463.6. The route into the endpoint is forced to pass through the finite windows, the shared threshold ledger M, and the uniform tail row T. Thus the continuity consumer receives its limiting-endpoint data only after the same uniform threshold surface has been selected.

Finally apply Definition 463.3. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff R and the $\mathsf{CauchyLimitSeal}^{\uparrow}$ row S are downstream of that shared uniform route, so the handoff presented to a continuous-map consumer is exactly the finite completion-facing surface already sealed by the packet. The listed pointwise, host-limit, quotient, compactness, and $\mathsf{Real}^{\uparrow}$-completeness readings are outside the carrier inventory and cannot be consumed here. □

Theorem 463.21 (UniformLimit finite window seal exhaustion)**.** *Let*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{UniformLimit}^{\uparrow}$ *carrier, and let*

$$G = (q, w, r, d, e, h, c, p, n)$$

be an accepted $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *carrier. Suppose* w *is a displayed window of* F*, and suppose* r *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff read through* T*. Then every common* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer read of the two packets is exhausted by the paired finite route*

$$F \longmapsto M \longmapsto T \longmapsto R \longmapsto S \longmapsto E$$

together with

$$q \longmapsto w \longmapsto r \longmapsto d \longmapsto e.$$

Conversely, any read assembled from those two displayed routes, together with the visible hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows of* U *and* G*, is an admissible finite seal read for the common endpoint-facing consumer surface. No such read can escape to pointwise-only convergence, quotient function spaces, selected host limits, open-cover compactness, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or unbounded diagonal streams.*

Proof. First identify the uniform-limit side of the common route. Apply Definition 463.14: because w is a displayed window of F and r is read through T, every diagonal-window endpoint read supplied by U factors through the finite route from F to E. Apply Definition 463.17 to bind that route to the same shared threshold row M, the same tail ledger T, the same regular handoff R, and the same seal row S.

Next transport the route through the displayed classifier surface. By Definition 463.18, classifier transport of F, M, T carries R, S, E along the same hsame and Cont rows already present in H and C. Thus the common consumer cannot obtain a second regular-seal route from a pointwise-only witness, a quotient function space, a selected host limit, or an open-cover compactness principle.

Now identify the selected-window side. The theorem Definition 561.7 forces any $\mathsf{Real}^{\uparrow}$-facing read of G to display w and the dyadic observation ledger d before the seal row e is consumed. The handoff theorem Definition 561.8 then routes every completion or continuous-map consumer through q, w, r, d, e and the visible transport, continuation, provenance, and naming rows.

Combining these two finite routes gives the forward exhaustion claim. Apply Definition 463.19 to the $\mathsf{UniformLimit}^{\uparrow}$ packet and the RealDiagonalWindowCoverage handoff just cited to remove every undisplayed common consumer source, including ambient $\mathsf{Real}^{\uparrow}$ completeness and unbounded diagonal streams.

For the converse direction, start with a read assembled from the displayed rows of the two routes. The uniform route is admissible because the accepted carrier U exposes exactly $F, M, T, R, S, E, H, C, P, N$ to endpoint-facing consumers, and the selected-window route is admissible because the accepted carrier G exposes exactly $q, w, r, d, e, h, c, p, n$ to Real-facing consumers. Since the two routes agree at the displayed window w and the handoff row r, their assembly is a finite seal read on the common endpoint-facing surface and uses no row outside the two accepted packets. □

Theorem 463.22 (UniformLimit finite-window induction)**.** *Let*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{UniformLimit}^{\uparrow}$ *carrier. Induction over the displayed finite windows of F, with the base row read through the shared threshold ledger M and successor rows read through the uniform tail ledger T, generates the finite endpoint route*

$$F \longmapsto M \longmapsto T \longmapsto R \longmapsto S \longmapsto E.$$

Every finite stage of this induction is an admissible carrier read using only the visible hsame*,* Cont*,* Pkg*, and* NameCert *rows of U.*

Proof. The base stage is the displayed threshold row. By Definition 463.6, each finite window of F must be read through the shared threshold ledger M before any endpoint-facing consumer can see a tail estimate.

For the successor stage, apply Definition 463.9. The uniform tail row T supplies the next finite witness without changing the selected threshold surface, so the regular handoff R and the seal row S are appended by the same carrier route rather than by a pointwise side channel.

Iterating these finite stages yields the displayed route from F through E. The exhaustion theorem Definition 463.21 then shows that no additional endpoint read is needed: every common completion-facing read is already accounted for by the finite route and the visible transport, continuation, provenance, and naming rows of U. □

Theorem 463.23 (UniformLimit Real seal nonescape)**.** *Let*

$$U = (F, M, T, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{UniformLimit}^{\uparrow}$ *carrier. The finite-window induction of Definition 463.22 exports only the finite route*

$$F \longmapsto M \longmapsto T \longmapsto R \longmapsto S \longmapsto E$$

and the visible hsame, Cont, Pkg, *and* NameCert *rows of* U. *It does not export pointwise-only convergence, a selected host limit, a quotient function space, open-cover compactness, or* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Apply Definition 463.22. The induction surface is finite at every stage and reaches the endpoint only through M, T, R, S, E and the visible carrier rows.

Now use Definition 463.4. That boundary rules out every read of U that bypasses the shared threshold ledger or treats the seal row as evidence for a pointwise, quotient, compactness, host-limit, or ambient-completeness object.

Finally apply Definition 463.19. Completion-facing consumers are confined to the same finite endpoint surface, so the induction cannot export any $\mathsf{Real}^{\uparrow}$ completeness principle or external function-space limit beyond the rows displayed by the accepted carrier. □

Closure status for $\mathsf{NameCert}_{\mathsf{UniformLimit}^{\uparrow}}$.

Constructive story: A $\mathsf{UniformLimit}^{\uparrow}$ packet is generated from a displayed function/window family, a shared threshold ledger, one $\mathsf{UniformCauchyCriterion}^{\uparrow}$ tail ledger, a $\mathsf{RegSeqRat}^{\uparrow}$ handoff, a $\mathsf{CauchyLimitSeal}^{\uparrow}$ seal row, a $\mathsf{Real}^{\uparrow}$ endpoint, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{UniformLimit}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 463.1, Definition 463.3, Definition 463.5, Definition 463.17, and Definition 463.4 bind the finite carrier, seal factorization, public-facing endpoint certificate, tail-ledger exactness, and non-escape boundary for the displayed uniform-limit packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{UniformLimit}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.UniformLimitUp.UniformLimitCarrier\_seal\_factorization`

Bridge status: none

Origin: human

Not claimed: This chapter does not close pointwise convergence without a uniform ledger, open-cover compactness, selected host limits, quotient function spaces, $\mathsf{Real}^{\uparrow}$ completeness, or a checked Lean certificate.

Upgrade path: Formal audit and bridge checking remain verification-axis work over the same finite uniform-limit endpoint surface.

The $\mathsf{CauchyProduct}^{\uparrow}$ hub binds the product-facing Real route to the sibling rows of chapter 126, chapter 291, chapter 301, and chapter 38.

Chapter 464

A Concrete Naming Certificate for $\mathsf{CauchyProduct}^{\uparrow}$

The $\mathsf{CauchyProduct}^{\uparrow}$ interface names the finite product certificate for two regular Cauchy names. It expresses the Bishop–Bridges constructive product of regular Cauchy sequences as displayed $\mathsf{NameCert}$ rows over scheduled finite windows, dyadic observations, regular rational readback, and the $\mathsf{Real}^{\uparrow}$ seal, without adding quotient streams or an ambient completeness operation.

Definition 464.1 (CauchyProduct NameCert source)**.** *A* $\mathsf{CauchyProduct}^{\uparrow}$ *source is a finite* BHist *packet*

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N)$$

with the following displayed coordinates:

1. *X and Y are the two* $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows;*
2. *W_X and W_Y are the paired* $\mathsf{StreamName}^{\uparrow}$ *finite-window schedules for a shared precision request;*
3. *M_X and M_Y are the paired dyadic-radius rows bounding the two source windows;*
4. *Q_X and Q_Y are the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation rows read from the scheduled windows;*
5. *P is the pointwise product observation row formed from Q_X and Q_Y inside the displayed dyadic rational core;*
6. *E is the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row for the product observation and its finite radius ledger;*
7. *H stores the displayed* hsame *transports for the two source names, both stream windows, both radius rows, both dyadic observations, the product observation, and the regular rational readback;*
8. *C stores the displayed* Cont *routes for reading the source windows, transporting the dyadic product observation, exposing the regular rational classifier, and handing the result to the real seal;*
9. *L is the finite ledger recording the paired input radii, the product-radius row, the* $\mathsf{Real}^{\uparrow}$ *seal handoff, and the* Pkg *provenance over* $\mathsf{RegularCauchyName}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row.*

The packet stores a finite product construction. It contains no quotient stream, host multiplication primitive, selected limit, trichotomy row, independent real carrier, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductTasteGate single carrier alignment`

Theorem 464.2 (CauchyProduct NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^\uparrow}$ *surface for the source packet of Definition 464.1 consists exactly of carrier admission, paired* $\mathsf{RegularCauchyName}^\uparrow$ *source admission, paired* $\mathsf{StreamName}^\uparrow$ *window scheduling, dyadic-radius routing,* $\mathsf{DyadicRatCore}^\uparrow$ *product observation, pointwise* $\mathsf{RegSeqRat}^\uparrow$ *classifier exposure,* $\mathsf{Real}^\uparrow$ *seal handoff, displayed* hsame *and* Cont *transport, package provenance, finite ledger, and the local naming row.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket namecert obligations`

Proof. Carrier admission is projection from the displayed packet Z. Its coordinates list the two regular Cauchy sources, their paired stream windows, the radius rows, dyadic observations, product observation, readback classifier, transport rows, continuation routes, ledger, and local certificate.

The analytic product step is finite. The two window reads expose Q_X and Q_Y inside $\mathsf{DyadicRatCore}^\uparrow$, and the product observation row P is the only row that combines them. The classifier row E then reads this product observation with the radius information stored in the ledger.

The remaining obligations are provenance obligations. The rows H, C, L, N carry transport, continuation, package, seal handoff, and local naming data, so the certificate has no source from which to read host multiplication, quotient equality, selected limits, trichotomy, or completeness. □

Theorem 464.3 (CauchyProduct root window obligations)**.** *For an accepted* $\mathsf{CauchyProduct}^\uparrow$ *packet*

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N),$$

the root-facing paired-window obligation is anchored in the BHist *rows* $X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y$*. The two* $\mathsf{RegularCauchyName}^\uparrow$ *sources may be consumed only through the paired* $\mathsf{StreamName}^\uparrow$ *schedules and the shared finite tail threshold surface used by chapter 560; no consumer may replace those windows by quotient streams, selected limits, host multiplication, or an ambient completeness row.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root window obligations`

Proof. Begin with the carrier and NameCert obligations. Definition 464.1 displays the two source rows and paired window rows, while Definition 464.2 makes those rows part of the local certificate surface.

Use the StreamName handoff of Definition 464.20. It forces every product read to pass through W_X, W_Y before Q_X, Q_Y, M_X, M_Y, P, and E can be inspected.

Finally read the shared-tail consumer through chapter 560. The tail-meet packet consumes the same kind of finite threshold window, so the CauchyProduct root obligation is a paired finite-window row rather than a quotient or completed-real operation. □

Theorem 464.4 (CauchyProduct root budget obligations)**.** *The product-radius budget obligation of an accepted* $\mathsf{CauchyProduct}^\uparrow$ *packet is a finite* BHist *route from the paired radius rows* M_X, M_Y *and dyadic rows* Q_X, Q_Y *through the product observation* P *to the classifier row* E *and ledger row* L*. It is routed only by the displayed* hsame *transports,* Cont *continuations,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^\uparrow}$ *row, and it exposes no radius oracle, host multiplication estimate, quotient stream, selected limit, trichotomy row, or ambient completeness witness.*

Proof. Start with the source packet. The only budget-relevant coordinates are $M_X, M_Y, Q_X, Q_Y, P, E, L$ together with the structural rows H, C, N.

Apply Definition 464.2 and Definition 464.20. These make the dyadic and radius rows visible only after the paired finite windows, and they route the product observation through the same local certificate.

The budget route is then exact by Definition 464.29. Since that theorem binds the product-radius ledger to the displayed path into E, no unrecorded radius oracle or analytic primitive can enter the root obligation. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root budget obligations`

Theorem 464.5 (CauchyProduct root Real seal obligations)**.** *Every root-facing* $\mathsf{Real}^{\uparrow}$ *seal read of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet factors through the finite rows*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and through the shared tail-threshold consumption surface of chapter 560. The seal read cannot escape to host multiplication, RealUp completeness, quotient-stream equality, selected limits, trichotomy, independent real carriers, or an ambient completeness operation.

Proof. First combine the root window obligations with the root budget obligations. The former fixes the paired finite windows, and the latter fixes the product-radius route from those windows through the dyadic observations to the classifier and ledger.

Next apply Definition 464.21. The $\mathsf{Real}^{\uparrow}$ seal reads the product only through the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E together with the displayed ledger, transport, continuation, provenance, and local naming rows.

Finally use Definition 464.30. It exhausts every real-facing consumer route by the same finite inventory, while the sibling tail-meet packet supplies only the shared finite threshold surface. Hence the root seal obligation is finite-row based and has no escape to the excluded analytic objects. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root real seal obligations`

Theorem 464.6 (CauchyProduct root window seal compatibility)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet*

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N),$$

the paired $\mathsf{StreamName}^{\uparrow}$ *windows* W_X, W_Y *and the product-radius budget recorded through* M_X, M_Y, Q_X, Q_Y, P, L *are the only route through which a* $\mathsf{Real}^{\uparrow}$ *seal consumer reaches the classifier row* E*. The route is the one named by the root window obligations, root budget obligations, and root Real seal obligations; it admits no host multiplication, quotient stream, selected limit, trichotomy row, or ambient completeness witness.*

Proof. Begin with Definition 464.3. It places every root-facing product read downstream of the paired finite windows W_X, W_Y.

Apply Definition 464.4. The product-radius route is then fixed through M_X, M_Y, Q_X, Q_Y, P, L before the classifier row can be inspected.

Finally use Definition 464.5. The $\mathsf{Real}^{\uparrow}$ seal reads E only after the paired windows and budget route have been consumed, so none of the excluded analytic objects has a coordinate in the accepted packet. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root window seal compatibility`

Theorem 464.7 (CauchyProduct root obligation package)**.** *Every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet supplies a root-unblock package consisting of carrier admission, paired-window source rows, product-budget exactness, Real seal compatibility,* hsame *and* Cont *transport,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *rows. The package is the finite surface*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

and it excludes host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, and ambient completeness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root obligation package`

Proof. First read carrier admission and NameCert obligations through Definition 464.1 and Definition 464.2. These give the two source names, paired windows, dyadic rows, product observation, classifier row, transport rows, continuation routes, ledger, provenance, and local naming row.

Next assemble the root route. The root window obligations provide the paired-window source surface, the root budget obligations provide the product-radius accounting, and Definition 464.6 identifies the Real seal route through the same rows.

Finally apply the root Real seal obligations. They keep the seal consumer inside the displayed packet and preserve the exclusions on host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, and ambient completeness. The listed rows therefore form the root-unblock package. □

Theorem 464.8 (CauchyProduct root source-pair lock)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet*

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N),$$

the two $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows* X, Y *and their paired* $\mathsf{StreamName}^{\uparrow}$ *window rows* W_X, W_Y *are locked before any product observation row is read. A consumer cannot inspect* P *until the carrier admission, local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *obligations, and the* $\mathsf{StreamName}^{\uparrow}$ *handoff have exposed the two source rows as one paired finite-window route.*

Proof. Read the carrier from Definition 464.1. The first four rows of Z are the two regular Cauchy sources and their paired stream windows, before the radius, dyadic observation, product, classifier, and seal-facing rows.

Apply Definition 464.2. It makes paired source admission and paired window scheduling part of the local certificate surface rather than optional consumer data.

Finally use Definition 464.20. It routes every product read through W_X, W_Y before exposing Q_X, Q_Y, M_X, M_Y, P, or E, so the accepted packet locks the two source rows before any product observation is available. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root window read stability`

Theorem 464.9 (CauchyProduct root product observation route)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, the product observation row* P *is reachable only along the finite route*

$$X, Y \longmapsto W_X, W_Y \longmapsto Q_X, Q_Y \longmapsto M_X, M_Y \longmapsto P.$$

The route reads paired $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic observation rows, and radius rows, and it exposes no host multiplication primitive, quotient stream, selected limit, independent real carrier, or ambient completeness witness.*

Proof. Start from the source-pair lock in Definition 464.8. The consumer has already passed through the two source rows and their paired stream windows before any product-facing row is visible.

Use Definition 464.20. The handoff exposes Q_X, Q_Y and M_X, M_Y from the paired schedules before the product row P is formed.

Now apply Definition 464.4. The product-radius budget keeps P inside the same finite BHist route and rules out any extra radius oracle or analytic multiplication coordinate. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root product observation route`

Theorem 464.10 (CauchyProduct root downstream unblock surface)**.** *The root-unblock surface of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet is the finite union of the source-pair lock, the product-observation route, the root budget obligations, the root* $\mathsf{Real}^{\uparrow}$ *seal obligations, and the displayed* hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *rows. Downstream* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *product consumers read only this union and cannot import quotient streams, host multiplication, selected limits, trichotomy, independent real carriers, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root downstream unblock surface`

Proof. First combine Definition 464.8 and Definition 464.9. These identify the source-window side and the finite product-observation path into P.

Next apply Definition 464.4. The same route is extended through the product-radius ledger toward E and L, with no extra analytic coordinate.

Finally use Definition 464.5 together with Definition 464.2. The seal, transport, continuation, provenance, and local naming rows are already part of the displayed packet, so the downstream unblock surface is exactly the stated finite union. □

Theorem 464.11 (CauchyProduct paired-window source admission)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet*

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N),$$

the rows X, Y, W_X, W_Y *are admitted only as paired* $\mathsf{StreamName}^{\uparrow}$ *finite-window source rows over the two* $\mathsf{RegularCauchyName}^{\uparrow}$ *inputs. The admission route is the one exposed by the sibling surfaces chapter 126 and chapter 301; it has no quotient-stream, selected-limit, host multiplication, or ambient-completeness coordinate.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket paired window source admission`

Proof. Begin with Definition 464.7. It identifies X, Y, W_X, W_Y as the source side of the root package for the product packet.

Apply Definition 464.3. The two source names can be consumed only through the paired finite windows W_X, W_Y, and the route is downstream of the displayed $\mathsf{StreamName}^{\uparrow}$ schedule rows.

The sibling StreamName and RegSeqRat surfaces provide the dependency anchors for the window and source-name reads. Because the root package excludes quotient streams, selected limits, host multiplication, and ambient completeness, no other source-admission route is available. □

Theorem 464.12 (CauchyProduct budget route exactness)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, the rows*

$$M_X, M_Y, Q_X, Q_Y, P, L$$

are the exact finite budget route into the RegSeqRat$^{\uparrow}$ *classifier row* E*. The route reads dyadic observations through chapter 291, records its regular-rational classifier through chapter 301, and admits no radius oracle, quotient stream, selected limit, host multiplication estimate, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget route exactness`

Proof. Start from Definition 464.4. It lists $M_X, M_Y, Q_X, Q_Y, P, E, L$ as the finite product-radius route.

Use Definition 464.7 to keep the same route inside the carrier, transport, continuation, provenance, and local naming rows. The dyadic observation surface comes from the displayed Q_X, Q_Y rows, and the product observation P is the only combining row.

Finally apply Definition 464.6. The classifier row E is reached only after the budget ledger L has consumed those rows, so the sibling DyadicRatCore and RegSeqRat surfaces are the whole classifier-facing budget path. □

Theorem 464.13 (CauchyProduct finite budget composition)**.** *For every accepted* CauchyProduct$^{\uparrow}$ *packet, the paired* StreamName$^{\uparrow}$ *window route, root budget route,* RegSeqRat$^{\uparrow}$ *seal route,* RealObservationBudget$^{\uparrow}$ *seal, and* RealSeries$^{\uparrow}$ *consumer boundary compose into one finite CauchyProduct budget handoff over* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. The composed handoff is the displayed route through*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the budget-facing rows consumed by RealObservationBudget$^{\uparrow}$ *and the terminal* RealSeries$^{\uparrow}$ *consumer row. It exposes no ambient* Real$^{\uparrow}$ *completeness theorem, quotient sequence equality, selected representative, host infinite sum, host multiplication primitive, trichotomy row, or independent real carrier.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket finite budget composition`

Proof. Start with paired-window source admission. By Definition 464.11, the source rows X, Y are read only through the paired finite StreamName$^{\uparrow}$ windows W_X, W_Y.

Next apply budget route exactness. Definition 464.12 fixes the route from M_X, M_Y, Q_X, Q_Y, P, L into the classifier row E, and Definition 464.16 ties that classifier to the same paired windows.

Now use the Real seal boundary. The root RealObservationBudget seal boundary of Definition 464.19 keeps budget-facing reads inside the displayed product and budget rows.

Finally apply the RealSeries consumer boundary of Definition 464.23. It consumes the public CauchyProduct surface only after the finite budget handoff has been assembled, so none of the excluded analytic objects has a coordinate in the composed route. □

Theorem 464.14 (CauchyProduct main surface public handoff)**.** *Every public* CauchyProduct$^{\uparrow}$ *consumer reads the paired* RegularCauchyName$^{\uparrow}$ *sources,* StreamName$^{\uparrow}$ *windows,* DyadicRatCore$^{\uparrow}$ *budget rows,* RegSeqRat$^{\uparrow}$ *classifier,* RealObservationBudget$^{\uparrow}$ *seal, and* RealSeries$^{\uparrow}$ *consumer boundary through one displayed route over* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. For an accepted packet, that route is the finite surface*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the budget-facing rows consumed by RealObservationBudget$^{\uparrow}$ *and the terminal* RealSeries$^{\uparrow}$ *consumer row. It exposes no quotient stream, selected limit, host multiplication primitive, trichotomy row, independent real carrier, or ambient* Real$^{\uparrow}$ *completeness theorem.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket main surface public handoff`

Proof. Begin with paired-window source admission. The theorem Definition 464.11 forces the two $\mathsf{RegularCauchyName}^{\uparrow}$ rows X, Y to be read only through the paired $\mathsf{StreamName}^{\uparrow}$ windows W_X, W_Y.

Next assemble the budget route. By Definition 464.12, the dyadic rows M_X, M_Y, Q_X, Q_Y, P, L are the exact finite route into the classifier row E, and Definition 464.13 composes that route with the public budget handoff.

Now use the root seal and series boundaries. The root $\mathsf{RealObservationBudget}^{\uparrow}$ seal obligations of Definition 464.19 keep budget-facing reads inside the displayed product and budget rows, while Definition 464.23 permits a $\mathsf{RealSeries}^{\uparrow}$ consumer only after the public CauchyProduct surface has been read.

Finally repack the route through the structural rows. The displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows are already part of the accepted packet, so no public consumer has a coordinate for quotient streams, selected limits, host multiplication, trichotomy, independent real carriers, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 464.15 (CauchyProduct budget public handoff)**.** *Every product-facing* $\mathsf{Real}^{\uparrow}$ *or series consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet must factor through the public budget handoff*

$\mathsf{RegularCauchyName}^{\uparrow}$, $\mathsf{CauchySharedTailModulus}^{\uparrow}$, $\mathsf{DiagonalTailSelector}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRa}$

Concretely, the consumer first reads the two regular Cauchy source names, their shared-tail budget and paired $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation and product rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, the* $\mathsf{Real}^{\uparrow}$ *seal, the shared-tail modulus, the diagonal-tail selector rows, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row before reading the product packet.*

The handoff exports no quotient streams, selected limits, host multiplication primitive, trichotomy row, countable-choice schedule, independent real carrier, or ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget public handoff`

Proof. Start with the main surface public handoff of Definition 464.14. It already routes every public product consumer through the paired source names, windows, dyadic budget rows, classifier, real seal, transport, replay, provenance, and local name.

Next use the finite budget composition of Definition 464.13. It composes the paired-window route with the RealObservationBudget seal and RealSeries consumer boundary, so the product-facing Real or series consumer sees one budget route rather than separate local rows.

Finally insert the shared-tail and diagonal-tail surfaces from the root window obligations and the sibling regular Cauchy tail budget. These rows supply the modulus and selector needed before a product packet can be read, while the accepted carrier has no coordinate for quotient streams, selected limits, trichotomy, countable choice, host multiplication, or ambient completeness. □

Theorem 464.16 (CauchyProduct paired-window ledger classifier)**.** *The paired window rows* W_X, W_Y *together with the ledger route* M_X, M_Y, Q_X, Q_Y, P, L *determine the classifier-facing product row* E *consumed by the* $\mathsf{Real}^{\uparrow}$ *seal. This determination is routed through the sibling surfaces chapter 126, chapter 291, chapter 301, and chapter 38, and it exposes no independent real carrier, selected limit, quotient stream, trichotomy row, host multiplication primitive, or ambient completeness operation.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket paired window ledger classifier`

Proof. First combine Definition 464.11 with Definition 464.12. The paired windows provide the source reads, and the budget route provides the dyadic product observation and ledger feeding E.

Next use Definition 464.5. The $\mathsf{Real}^{\uparrow}$ seal consumes the product only after the classifier row E has been reached through the same finite windows, dyadic observations, product row, ledger, transport, continuation, provenance, and local naming rows.

The sibling surfaces account for each dependency edge: StreamName for finite windows, DyadicRatCore for observations and product rows, RegSeqRat for the classifier readback, and RealUp for the seal. Therefore the classifier-facing product row is determined by the paired-window ledger route and by no excluded analytic object. □

Theorem 464.17 (CauchyProduct root window seal stability)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet*

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N),$$

the paired window rows W_X, W_Y *remain the unique route to every seal-facing product row under componentwise* hsame *transport and displayed* Cont *replay. A seal consumer reaches* P*,* E*, and the ledger row* L *only through the route fixed by the paired* $\mathsf{StreamName}^{\uparrow}$ *windows, the dyadic observations, the product-radius ledger, package provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root window seal stability`

Proof. Start with the root window obligations. They force every root-facing product read through the paired finite windows W_X, W_Y before the dyadic rows, radius rows, product row, classifier row, or seal-facing ledger can be inspected.

Now apply the StreamName handoff and window product stability. The handoff fixes the route from W_X, W_Y to Q_X, Q_Y, M_X, M_Y, P, E, while stability keeps that route invariant under the componentwise transport row H and the continuation replay row C.

Finally use the root Real seal obligations. Since the $\mathsf{Real}^{\uparrow}$ seal can read the product only after the same window and ledger route has been consumed, no second path to a seal-facing row is available inside the accepted packet. □

Theorem 464.18 (CauchyProduct root RegSeqRat seal stability)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet*

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N),$$

the product observation row P *and the product-radius ledger row* L *determine the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E *before any* $\mathsf{Real}^{\uparrow}$ *seal read is available. The determining route is the finite path through the paired windows, dyadic observations, radius rows, displayed* hsame *transports, displayed* Cont *routes, package provenance, and local NameCert row.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root regseq seal stability`

Proof. First apply the root budget obligations. They bind $M_X, M_Y, Q_X, Q_Y, P, E, L$ as the finite product-radius route downstream of the paired windows.

Use radius ledger exactness to identify L with the displayed route from the input-radius rows and dyadic observations through the product observation P. Then apply radius product regularity to recover the classifier row E from exactly that ledgered product route.

The root Real seal obligations place every real-facing read after this classifier. Hence the $\mathsf{RegSeqRat}^{\uparrow}$ row is determined before the seal is consumed, and the seal cannot supply an independent classifier, quotient stream, selected limit, trichotomy row, host multiplication row, or ambient completeness coordinate. □

Theorem 464.19 (CauchyProduct root RealObservationBudget seal boundary)**.** *Every* $\mathsf{RealObservationBudget}^{\uparrow}$ *consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet reads the product only through the union of the CauchyProduct rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and the budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

The boundary exposes no quotient stream, selected limit, trichotomy row, host multiplication primitive, independent real carrier, ambient completeness coordinate, or additional real-facing product route.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root real budget seal boundary`

Proof. Begin with root window seal stability and root RegSeqRat seal stability. These place the product route through the paired windows, the product observation, the radius ledger, and the classifier row before any real-facing budget consumer can read the seal.

Now compose with the Real observation budget handoff. It routes the product seal through the accepted budget packet before the consumer reaches its real-facing rows.

Use the observation budget RegSeq handoff to identify the classifier read with the budgeted regular-sequence row. Finally apply the budgeted product consumer boundary; it exhausts the joined interface by the displayed product rows and budget rows, leaving no coordinate for any excluded analytic object. □

Theorem 464.20 (CauchyProduct StreamName handoff)**.** *Every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet routes a product read through the paired* $\mathsf{StreamName}^{\uparrow}$ *windows* W_X, W_Y *before exposing the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations* Q_X, Q_Y*, the dyadic-radius rows* M_X, M_Y*, the product observation* P*, and the pointwise* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E*. No consumer can read a product row without first reading those finite schedules and their displayed provenance.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket streamname handoff`

Proof. Start with the two source rows X and Y. Each is read only through its displayed $\mathsf{RegularCauchyName}^{\uparrow}$ source row and the matching finite $\mathsf{StreamName}^{\uparrow}$ schedule.

The dyadic product row is downstream of the schedules. Once W_X and W_Y have exposed Q_X, Q_Y and M_X, M_Y, the row P records the finite dyadic product observation and E repacks it as a pointwise regular rational classifier.

The transport and continuation rows preserve this order. Since H, C, L, N are attached to the same paired windows, a consumer has no alternate route to a host sequence, quotient product, selected limit, or ambient real operation. □

Theorem 464.21 (CauchyProduct Real seal boundary)**.** *Any* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet reads only the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E *built from the paired* $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic-radius rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *product observation, displayed* hsame *transports,* Cont *routes, finite ledger, package provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row. The seal boundary exports no RealUp completeness theorem, quotient stream, selected limit, trichotomy row, independent real carrier, or host multiplication primitive.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal boundary`

Proof. Factor the real-facing read through the pointwise regular classifier. By Definition 464.20, the classifier is already downstream of the two finite stream windows and their dyadic product observation.

The real seal is recorded in the ledger row rather than supplied by an ambient carrier. Thus a $\mathsf{Real}^{\uparrow}$ consumer receives E together with H, C, L, N, which are exactly the displayed transport, continuation, ledger, package, and naming rows.

No other coordinate in Definition 464.1 can supply completeness, quotient equality, a selected limit, trichotomy, or host multiplication. The real-facing boundary is therefore exhausted by the finite product packet. □

Theorem 464.22 (CauchyProduct public interface export)**.** *Every public consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet reads the product through the paired-window source rows, the finite budget route, the ledger classifier, the* $\mathsf{StreamName}^{\uparrow}$ *handoff, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary. Equivalently, the public export surface is the finite route through* $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$ *together with the displayed source, budget, provenance, continuation, and naming rows; it exports no quotient stream equality, selected infinite sum, host multiplication primitive, trichotomy row, independent real carrier, or ambient completeness claim.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket public interface export`

Proof. First use the paired-window source surface. The StreamName handoff, Definition 464.20, places every product read behind the two finite windows W_X, W_Y and the dyadic observation rows Q_X, Q_Y, M_X, M_Y.

Next compose the budget route with the classifier route. The root RealObservationBudget seal boundary identifies the budget-facing rows, while the root RegSeqRat seal stability theorem makes the classifier row E downstream of the product observation and ledger.

Finally apply the Real seal boundary, Definition 464.21. It exhausts the public read through the displayed finite rows and excludes quotient streams, selected limits, trichotomy, host multiplication, independent real carriers, and ambient completeness. This is exactly the stated export surface. □

Theorem 464.23 (CauchyProduct RealSeries consumer boundary)**.** *Every* $\mathsf{RealSeries}^{\uparrow}$ *consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet factors through* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{RealAlgOrder}^{\uparrow}$, $\mathsf{RealSeries}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows. The consumer may read the product only through the public interface of Definition 464.22; it receives no selected infinite sum, quotient stream equality, host multiplication primitive, order trichotomy, independent real carrier, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real series consumer boundary`

Proof. Begin with a RealSeries-facing read. The public interface export theorem routes the read through the paired finite windows, dyadic ledgers, product observation, classifier, transports, continuations, provenance, and local name.

The series consumer can then inspect only the named BEDC rows. Its stream access is through $\mathsf{StreamName}^{\uparrow}$, its rational readback is through $\mathsf{RegSeqRat}^{\uparrow}$, its real-facing seal is through $\mathsf{Real}^{\uparrow}$, and its order-facing comparison surface is through $\mathsf{RealAlgOrder}^{\uparrow}$ before the $\mathsf{RealSeries}^{\uparrow}$ row is consumed.

The structural rows BHist, hsame, Cont, Pkg, and NameCert preserve that route without adding analytic data. Applying Definition 464.21 removes any remaining path to a selected infinite sum,

quotient stream equality, host multiplication primitive, order trichotomy, independent real carrier, or ambient completeness witness. □

Theorem 464.24 (CauchyProduct public RealSeries budget export)**.** *Every public* $\mathsf{RealSeries}^{\uparrow}$*-facing* $\mathsf{CauchyProduct}^{\uparrow}$ *consumer exports a product claim only after the finite budget route through the* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, dyadic product rows,* $\mathsf{Real}^{\uparrow}$ *seal, and* $\mathsf{RealSeries}^{\uparrow}$ *partial-sum ledger has been displayed. For an accepted packet, the export route is*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the terminal $\mathsf{RealSeries}^{\uparrow}$ *consumer row.*

The public export surface supplies no quotient stream equality, selected infinite sum, host multiplication primitive, order trichotomy, independent real carrier, or ambient completeness witness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket public real series budget export`

Proof. Begin with the root budget obligations of Definition 464.4. They bind $M_X, M_Y, Q_X, Q_Y, P, E, L$ as the product-radius route downstream of the paired windows.

Next use the StreamName handoff and the public interface export, Definition 464.20 and Definition 464.22. These force the stream windows and regular-rational classifier to be consumed before any public product claim is named.

Finally apply Definition 464.23. The $\mathsf{RealSeries}^{\uparrow}$ row reads the product only after the $\mathsf{Real}^{\uparrow}$ seal and the displayed public CauchyProduct surface, so the partial-sum ledger cannot import an untracked analytic object. □

Theorem 464.25 (CauchyProduct public observation budget export)**.** *Every public* $\mathsf{RealObservationBudget}^{\uparrow}$ *handoff from an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet exports the product through the same paired-window, regular-readback, dyadic-budget, and real-seal route as the RealSeries consumer. The handoff is the finite route through*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

plus the accepted $\mathsf{RealObservationBudget}^{\uparrow}$ *budget row; it exports no radius oracle, quotient stream, selected limit, host multiplication primitive, trichotomy row, independent real carrier, or ambient completeness claim.*

Proof. Use the root RealObservationBudget seal boundary of Definition 464.19. It identifies the budget-facing consumer as downstream of the product rows and the observation-budget rows.

Compose this with Definition 464.4. The dyadic product observation and radius ledger are fixed before the classifier row E and ledger row L can be inspected.

The StreamName handoff and Real seal boundary, Definition 464.20 and Definition 464.21, keep the public observation-budget route inside the displayed finite rows. Therefore the handoff cannot export any excluded analytic or host-side object. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket public observation budget export`

Theorem 464.26 (CauchyProduct public RealSeries export)**.** *Every public* $\mathsf{RealSeries}^{\uparrow}$*-facing export of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet is the composition of paired-window source admission, budget route exactness, paired-window ledger classification, public interface export, and the RealSeries consumer boundary. The exported surface is exactly the finite route through*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the $\mathsf{RealSeries}^{\uparrow}$ *row. It supplies no quotient stream, selected infinite sum, host multiplication, order trichotomy, independent real carrier, or ambient completeness.*

Proof. Start with paired-window source admission and budget route exactness. The source rows X, Y, W_X, W_Y and the budget rows M_X, M_Y, Q_X, Q_Y, P, L are fixed by Definition 464.11 and Definition 464.12.

Next apply the paired-window ledger classifier. Definition 464.16 places the classifier row E downstream of those windows, dyadic observations, product row, and ledger.

Now use the public interface export. Definition 464.22 packages the same finite route with the displayed transport, continuation, provenance, and local naming rows H, C, N.

Finally apply the RealSeries consumer boundary. It attaches the $\mathsf{RealSeries}^{\uparrow}$ consumer row only after the public CauchyProduct surface has been read, and it rules out the excluded quotient, sum-selection, host-multiplication, trichotomy, independent-carrier, and completeness objects. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket public real series export`

Theorem 464.27 (CauchyProduct ledger exhaustion)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, every consumer route is exhausted by the rows named in Definition 464.1 together with the obligations of Definition 464.2, the* $\mathsf{StreamName}^{\uparrow}$ *handoff of Definition 464.20, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary of Definition 464.21. The ledger contains exactly the paired input radii, product-radius row, regular rational readback route, seal handoff, displayed transports, continuations, package provenance, and local certificate.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket ledger exhaustion`

Proof. Inspect the source packet. Its only product-facing data are the two regular names, paired windows, paired radius rows, dyadic observations, product observation, classifier row, transports, continuations, ledger, and local naming row.

The NameCert obligations attach every accepted read to those displayed rows. The StreamName handoff fixes the order from source windows to dyadic product observation to regular classifier, while the Real seal boundary places each real-facing read downstream of the same classifier and ledger.

Therefore the listed rows exhaust the certificate. A route seeking quotient streams, host multiplication, selected limits, trichotomy, an independent real carrier, or ambient completeness has no coordinate in the accepted packet. □

Theorem 464.28 (CauchyProduct window product stability)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet*

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N),$$

the paired $\mathsf{StreamName}^{\uparrow}$ *windows* W_X, W_Y *stably determine the dyadic product observation* P*. Componentwise* hsame *transport of the two source names, both windows, both radius rows, and both dyadic observations preserves the product row and keeps every read inside the displayed window route.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket window product stability`

Proof. Project the source packet of Definition 464.1. The product row P is downstream of the paired window rows and the dyadic observations Q_X, Q_Y.

Apply the StreamName handoff theorem. It forces a product read to pass through W_X, W_Y before exposing Q_X, Q_Y, the radius rows, and the product observation.

The transport coordinate H compares exactly those rows componentwise, and the continuation coordinate C replays the displayed route from windows to product observation. Hence stable transport preserves the paired-window product route without adding host multiplication or a quotient product. □

Theorem 464.29 (CauchyProduct radius ledger exactness)**.** *The product-radius ledger of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet is exact for the displayed route from paired input radii* M_X, M_Y *through the dyadic product observation* P *to the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E*. The ledger records no independent radius oracle, selected limit, trichotomy row, host multiplication primitive, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket radius ledger exactness`

Proof. Use window product stability to bind the product observation to the paired windows, input radii, and dyadic observations. This places the product-radius read downstream of $W_X, W_Y, M_X, M_Y, Q_X, Q_Y$.

The NameCert obligations identify E as the pointwise regular rational classifier exposed from the product observation together with its finite radius information. The finite ledger L records the paired input radii, product-radius row, seal handoff, and package provenance.

Finally apply ledger exhaustion. Since every consumer route is exhausted by the source packet and its displayed obligations, the radius ledger is exact for that route and contains no unlisted analytic primitive. □

Theorem 464.30 (CauchyProduct Real seal consumer exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet factors through the paired windows, dyadic product observation, product-radius ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, displayed transport and continuation rows, finite ledger, package provenance, and local naming row. It has no access to host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal consumer exhaustion`

Proof. Start with the Real seal boundary. It places each real-facing read downstream of the classifier row E, which is built from the paired windows, dyadic observations, and displayed ledger.

Use radius ledger exactness to identify the classifier input with the product-radius route recorded by L. The transport and continuation rows H, C are the only allowed movement from source windows to the product observation and then to the regular rational readback.

Apply ledger exhaustion at the end. The rows named in the source packet exhaust every consumer route, so the real seal cannot import host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, or ambient completeness. □

Theorem 464.31 (CauchyProduct paired-window closure)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet*

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N),$$

the two $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows* X, Y *close their product read only through the paired* $\mathsf{StreamName}^{\uparrow}$ *windows* W_X, W_Y*. Those windows expose the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations* Q_X, Q_Y*, the paired radius rows* M_X, M_Y*, the product observation* P*, the product-radius ledger in* L*, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E*; no quotient stream, selected limit, trichotomy row, ambient completeness witness, or host multiplication primitive is admitted.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket paired window closure`

Proof. Begin with the StreamName handoff. It forces every product read from X, Y to pass through the paired finite windows before the dyadic observations and radius rows are visible.

Use window product stability next. The product observation P is stably determined by $W_X, W_Y, Q_X, Q_Y, M_X, M_Y$ under componentwise transport.

Finally apply radius ledger exactness and ledger exhaustion. The product-radius row and classifier exposure are exactly the rows recorded in L and E, so the paired-window closure has no coordinate for quotient streams, selected limits, trichotomy, ambient completeness, or host multiplication. □

Theorem 464.32 (CauchyProduct radius product regularity)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, the product-radius ledger turns the paired* $\mathsf{RegularCauchyName}^{\uparrow}$ *source windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations, and product observation P into the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row E. The regularity evidence is exactly the finite radius route recorded by L and transported by H, C; it is not a host multiplication theorem, quotient stream construction, selected limit, trichotomy decision, or ambient completeness argument.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket radius product regularity`

Proof. Use radius ledger exactness to bind the product-radius route to the displayed path from M_X, M_Y and Q_X, Q_Y through P to E.

The paired-window closure identifies the source of those rows with the two regular Cauchy names and their finite windows. Window product stability keeps the product observation invariant under the displayed transport rows.

Ledger exhaustion then prevents any further regularity source. The regular sequence classifier is therefore certified by the finite radius ledger alone, not by host multiplication, quotient streams, selected limits, trichotomy, or completeness. □

Theorem 464.33 (CauchyProduct Real multiplication seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *handoff of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet reads multiplication only as the sealed* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row E built from paired* $\mathsf{RegularCauchyName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations, the product-radius ledger, displayed* hsame *transports,* Cont *routes, package provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *evidence. The handoff exports no host multiplication primitive, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real multiplication seal handoff`

Proof. Start with Real seal consumer exhaustion. It already factors every real-facing read through the paired windows, product observation, radius ledger, classifier row, transports, continuations, provenance, and local naming data.

Apply radius product regularity to identify the classifier input. The row E is supplied by the finite product-radius ledger over the dyadic observations and product row, not by an ambient multiplication operation.

Use the Real seal boundary at the end. Since the seal sees only the classifier and its finite ledger, the multiplication handoff cannot expose host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, or completeness. □

Theorem 464.34 (CauchyProduct product-observation seal obligations)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, the paired* $\mathsf{RegularCauchyName}^{\uparrow}$ *windows, paired* $\mathsf{StreamName}^{\uparrow}$ *schedules, dyadic-radius rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *product observation P,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier E,* $\mathsf{Real}^{\uparrow}$ *seal handoff, displayed* hsame *transports,* Cont *routes, finite ledger,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row*

jointly supply the seed-to-obligation package for product observation. The package admits no host multiplication primitive, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness witness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket product observation seal obligations`

Proof. Begin with the NameCert obligations. They expose the carrier, paired regular Cauchy sources, finite stream schedules, dyadic-radius routing, product observation P, regular rational classifier E, seal handoff, transport rows, continuation rows, package provenance, ledger, and local naming row.

Use the StreamName handoff to bind the order of observation. A product read must pass through W_X, W_Y before Q_X, Q_Y, the radius rows, P, and then E are visible.

The radius ledger exactness theorem identifies the product-radius row with that displayed route, and radius product regularity turns the route into the regular classifier row. Thus the observation supplied to the seal is the finite dyadic product packet, not an external multiplication rule.

Finally apply the Real multiplication seal handoff. Since every real-facing consumer reads multiplication only through E and the recorded ledger, the listed rows form the obligation package and no unlisted analytic primitive can enter. □

Theorem 464.35 (CauchyProduct RealCompleteness diagonal seal route)**.** *Let an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet be consumed by a* $\mathsf{RealCompleteness}^{\uparrow}$ *diagonal-limit packet through the real-facing seal route. The contribution from* $\mathsf{CauchyProduct}^{\uparrow}$ *is only the finite product-observation surface*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

These rows supply the paired $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic observations, product-radius ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, componentwise* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row. The diagonal seal route receives no host multiplication primitive, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness witness from the product packet.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real completeness diagonal seal route`

Proof. Start with the StreamName handoff of Definition 464.20. It places the product observation downstream of the paired finite windows and their dyadic observation rows, so a diagonal-limit consumer first sees $W_X, W_Y, M_X, M_Y, Q_X, Q_Y$ before it can read P.

Next apply radius ledger exactness and radius product regularity, Definition 464.29 and Definition 464.32. These identify the product-radius ledger as the only route from the dyadic product observation to the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E.

Use the product-observation seal obligations and Real multiplication seal handoff, Definition 464.34 and Definition 464.33. They make the real-facing multiplication read consume only the displayed ledger, classifier, transports, continuations, package provenance, and local certificate.

Finally pull this finite surface back along the RealCompleteness scoped seal discipline of Definition 450.18. Since the pullback receives only the displayed product rows, the diagonal seal route cannot acquire host multiplication, quotient streams, selected limits, trichotomy, an independent real carrier, or ambient completeness from $\mathsf{CauchyProduct}^{\uparrow}$. □

Theorem 464.36 (CauchyProduct constant left factor)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet whose left source row X is read as a constant regular Cauchy name through the displayed* $\mathsf{RegularCauchyName}^{\uparrow}$

and StreamName$^{\uparrow}$ *schedules, multiplication by that left factor is certified only by the existing product packet. The consumer route factors through the paired windows, dyadic product observation P, product-radius ledger,* RegSeqRat$^{\uparrow}$ *classifier E, and* Real$^{\uparrow}$ *multiplication seal handoff, and it introduces no host scalar multiplication primitive or quotient equality.*

Proof. Begin with the StreamName handoff. Even when the left source is constant, the packet still reads X through its displayed RegularCauchyName$^{\uparrow}$ row and the window W_X before the dyadic observation Q_X is available.

Use paired-window closure and radius product regularity. These force the product observation P and the classifier row E through the same finite route from $W_X, W_Y, M_X, M_Y, Q_X, Q_Y$ to the product-radius ledger.

Finally apply the Real multiplication seal handoff. The seal receives only E with its recorded ledger and transports, so the constant left factor is a specialization of the displayed product packet rather than a host scalar operation. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket constant left factor`

Theorem 464.37 (CauchyProduct constant right factor)**.** *For an accepted* CauchyProduct$^{\uparrow}$ *packet whose right source row Y is read as a constant regular Cauchy name through the displayed* RegularCauchyName$^{\uparrow}$ *and* StreamName$^{\uparrow}$ *schedules, multiplication by that right factor is certified only by the existing product packet. The consumer route factors through the paired windows, dyadic product observation P, product-radius ledger,* RegSeqRat$^{\uparrow}$ *classifier E, and* Real$^{\uparrow}$ *multiplication seal handoff, and it introduces no host scalar multiplication primitive or quotient equality.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket constant right factor`

Proof. Start with the right source row. The StreamName handoff makes W_Y the only route by which the constant right input exposes its dyadic observation Q_Y and radius row M_Y.

Apply paired-window closure and radius product regularity. The right constant read is paired with the left window through the product observation P, and the classifier row E is supplied by the finite product-radius ledger.

The Real multiplication seal handoff then exhausts the real-facing route. Since the seal sees only the displayed classifier and ledger, the right constant factor does not add host scalar multiplication, quotient streams, selected limits, or ambient completeness. □

Theorem 464.38 (CauchyProduct bilinear tail window)**.** *For an accepted* CauchyProduct$^{\uparrow}$ *packet and any shared tail read admitted by its paired* StreamName$^{\uparrow}$ *windows, the two one-sided constant-factor routes and the product route are all witnessed by the same finite window surface*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

The bilinear tail window is therefore a NameCert obligation over the displayed product-radius ledger and Real$^{\uparrow}$ *seal handoff, not a field law, quotient equality, selected-limit argument, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket bilinear tail window`

Proof. First bind the shared tail read to the paired-window closure. The windows W_X, W_Y expose the two source observations, their radius rows, the dyadic product observation, and the regular rational classifier through one finite route.

Next use the two constant-factor obligations. The left and right constant reads are not new operations; each is a specialization of the same displayed product packet and therefore uses the same product observation P and classifier row E.

Finally use radius product regularity and the Real multiplication seal handoff. These identify the product-radius ledger as the only regularity evidence visible to the seal, so the bilinear tail window is exactly the finite NameCert surface and not an external algebraic law. □

Theorem 464.39 (CauchyProduct constant-factor bilinear seal)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, the left constant-factor route, the right constant-factor route, and the bilinear tail window are all specializations of the same finite product packet. Every* $\mathsf{Real}^{\uparrow}$ *seal-facing multiplication read therefore factors through the paired windows, dyadic product observation, product-radius ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row:*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

The shared seal boundary asserts only this finite packet route. It asserts no host multiplication, quotient equality, selected limit, trichotomy, independent real carrier, or ambient completeness principle.

Proof. Start with Definition 464.36 and Definition 464.37. Each constant-factor read passes through the displayed $\mathsf{RegularCauchyName}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ rows before exposing the dyadic observations and product-radius ledger.

Use Definition 464.38. The bilinear tail window states that the two one-sided constant-factor routes and the product route share the same finite surface $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$.

Apply radius product regularity to identify the product-radius ledger with the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E. Then apply the $\mathsf{Real}^{\uparrow}$ multiplication seal handoff to make the seal-facing consumer read only E together with the recorded ledger, transports, continuations, provenance, and local naming row.

The assembled route is therefore one product-packet seal boundary. Since none of its rows is a host multiplication primitive, quotient stream, selected limit, trichotomy row, independent real carrier, or completeness witness, the listed exclusions remain in force. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket constant factor bilinear seal`

Theorem 464.40 (CauchyProduct left-factor classifier congruence)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet with product route*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

replace the left $\mathsf{RegularCauchyName}^{\uparrow}$ *source by another source whose* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier is equivalent through the displayed* $\mathsf{StreamName}^{\uparrow}$ *handoff,* hsame *transports,* Cont *routes, package provenance, finite radius ledger, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row. Then the product observation route descends to the same displayed classifier row* E *and the same* $\mathsf{Real}^{\uparrow}$ *multiplication seal handoff. The descent introduces no host multiplication primitive, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket left factor classifier congruence`

Proof. Begin with the left StreamName handoff. Classifier-equivalence of the replacement source is read only through the displayed window W_X, radius row M_X, dyadic observation Q_X, transport row H, continuation route C, provenance row L, and local naming row N.

Next pair this transported left read with the unchanged right window. Window product stability keeps the dyadic product observation P on the same finite route, so the product packet has no additional coordinate from which a host product could be read.

Finally apply radius ledger exactness, radius product regularity, and the Real multiplication seal handoff. These identify the classifier row as the same E and make the real-facing seal consume only the recorded ledger, so the left-factor replacement is a classifier descent inside the packet surface. □

Theorem 464.41 (CauchyProduct right-factor classifier congruence)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet with product route*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

replace the right $\mathsf{RegularCauchyName}^{\uparrow}$ *source by another source whose* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier is equivalent through the displayed* $\mathsf{StreamName}^{\uparrow}$ *handoff,* hsame *transports,* Cont *routes, package provenance, finite radius ledger, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row. Then the product observation route descends to the same displayed classifier row E and the same* $\mathsf{Real}^{\uparrow}$ *multiplication seal handoff. The descent introduces no host multiplication primitive, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket right factor classifier congruence`

Proof. Start with the right StreamName handoff. The replacement source can expose its classifier only through W_Y, M_Y, Q_Y, the displayed transport and continuation rows, the package row, and the local naming evidence.

Now pair that transported right read with the unchanged left window. Window product stability preserves the dyadic product observation P over the same finite product surface and leaves the packet with the original radius ledger.

Use radius ledger exactness and radius product regularity to recover the same regular rational classifier row E. The Real multiplication seal handoff then reads only that row and its ledger, excluding host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, and ambient completeness. □

Theorem 464.42 (CauchyProduct two-factor classifier descent)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet with product route*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

simultaneously replace the left and right $\mathsf{RegularCauchyName}^{\uparrow}$ *sources by classifier-equivalent sources witnessed through the displayed* $\mathsf{StreamName}^{\uparrow}$ *handoffs,* hsame *transports,* Cont *routes, package provenance, finite product-radius ledger, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *evidence. The paired replacement descends to the same* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row E and therefore to the same* $\mathsf{Real}^{\uparrow}$ *multiplication seal handoff. The resulting multiplication surface contains no host multiplication primitive, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket two factor classifier descent`

Proof. First transport the two source reads separately. The left congruence supplies the route through $W_X, M_X, Q_X, H, C, L, N$, and the right congruence supplies the route through $W_Y, M_Y, Q_Y, H, C, L, N$.

Next recombine the transported reads at the product observation. Window product stability keeps P on the displayed paired-window surface, while ledger exactness keeps the radius evidence tied to the same finite product-radius row.

It remains to pass from the product row to the real-facing consumer. Radius product regularity recovers the same $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E, and the Real multiplication seal handoff reads only E with its recorded ledger. Thus the simultaneous two-factor descent is a classifier-level handoff, not an appeal to host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, or ambient completeness. □

Theorem 464.43 (CauchyProduct swapped-window classifier symmetry)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet with product route*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

the swapped finite route

$$W_Y, W_X, M_Y, M_X, Q_Y, Q_X$$

reaches the same displayed $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E *and the same* $\mathsf{Real}^{\uparrow}$ *multiplication seal after the dyadic product observation is replayed through the displayed* hsame *transports,* Cont *continuations,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row. This symmetry is internal to the packet surface and contains no host multiplication primitive, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket swapped window classifier symmetry certificate`

Proof. Start with the two one-factor classifier congruences. The left-factor congruence transports the first source read through W_X, M_X, Q_X, and the right-factor congruence transports the second source read through W_Y, M_Y, Q_Y, always along the displayed hsame, Cont, Pkg, and local NameCert rows.

Now read the same two transported sources in the opposite finite window order. The two-factor classifier descent applies to the paired replacement and keeps the product route at the displayed classifier row E rather than exposing a new classifier field.

It remains to replay the product observation through the real-facing seal. Radius product regularity identifies the radius ledger with the same $\mathsf{RegSeqRat}^{\uparrow}$ row E, and the Real multiplication seal handoff consumes that row together with H, C, L, N.

Thus the swapped window route has the same classifier and seal as the original route. Since every step was made through the packet rows, no host multiplication, quotient stream, selected limit, trichotomy, independent real carrier, or ambient completeness witness is introduced. □

Theorem 464.44 (CauchyProduct factor-swap observation surface)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet with product route*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

swapping the two $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows swaps only the displayed source-window and radius-observation rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y.$$

The dyadic product observation route P*, classifier row* E*,* hsame *transports* H*,* Cont *continuations* C*, finite ledger* L*, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row* N *remain on the same product surface.*

The swapped read therefore preserves the $\mathsf{Real}^{\uparrow}$ *multiplication seal handoff and introduces no host multiplication primitive, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket factor swap observation surface`

Proof. Begin with the two StreamName handoffs for the source rows. Swapping the source order exchanges the displayed finite windows and their radius-observation rows, so the only rows whose names change are $W_X, W_Y, M_X, M_Y, Q_X, Q_Y$.

Next use window product stability. The paired window route still reaches the same dyadic product observation P, because the product packet records the observation through the finite paired-window surface rather than through a host multiplication operation.

The radius ledger exactness theorem keeps the ledger L tied to that same product observation route. Radius product regularity then recovers the same $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E from the recorded ledger.

Finally use the two-factor classifier descent together with the Real multiplication seal handoff. The transports H, continuations C, package provenance, and local naming row N are carried along the displayed packet route, so the factor swap changes only the factor-side rows and not the public product observation surface or any forbidden ambient resource. □

Theorem 464.45 (CauchyProduct public multiplication consumer boundary)**.** *Every public multiplication consumer supplied by the* $\mathsf{CauchyProduct}^{\uparrow}$ *packet and read through the* $\mathsf{Real}^{\uparrow}$ *seal can inspect only the finite rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

It cannot inspect host multiplication, quotient streams, selected limits, trichotomy rows, independent real carriers, or ambient completeness. Thus the public multiplication boundary is exactly the displayed NameCert product packet and not any external algebraic or order-theoretic resource.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket public multiplication consumer boundary`

Proof. Start from the Real multiplication seal handoff. A seal-facing consumer receives the product only through the recorded $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E and the finite ledger, not through a host product or an independently chosen real representative.

Trace that classifier row backward through the packet. Radius product regularity, radius ledger exactness, and the product-observation seal obligations force every access to E to pass through P and then through the paired window and dyadic observation rows $W_X, W_Y, M_X, M_Y, Q_X, Q_Y$.

The remaining rows are administrative rather than ambient. The transports H, continuations C, package provenance, ledger L, and local naming evidence N exhaust the public consumer interface recorded by the product packet.

Since this exhaustion lists every row visible through the $\mathsf{Real}^{\uparrow}$ seal, there is no remaining coordinate from which a public consumer could read quotient streams, selected limits, trichotomy, an independent carrier, ambient completeness, or host multiplication. □

Theorem 464.46 (CauchyProduct RealAlgOrder multiplication export)**.** *The source packet of Definition 464.1, together with the factor-swap observation surface of Definition 464.44 and the public multiplication consumer boundary of Definition 464.45, supplies the RealAlgOrder-facing multiplication export for* $\mathsf{CauchyProduct}^{\uparrow}$*. The export is the finite product packet*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

read through the Real$^{\uparrow}$ *seal, with factor congruence, factor swap, and public consumer exhaustion all internal to the displayed* RegularCauchyName$^{\uparrow}$, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket realalgorder multiplication export`

Proof. First assemble the source packet. The carrier source and local NameCert obligations provide the two regular Cauchy source rows, paired StreamName windows, dyadic observations, product observation, classifier row, transports, continuations, ledger, provenance, and naming evidence.

Next add factor congruence and descent. The left-factor, right-factor, and two-factor classifier congruence theorems show that changing either source by an equivalent displayed classifier leaves the product route at the same classifier row E and the same Real multiplication seal handoff.

The factor-swap surface records the symmetric product read visible to downstream algebra consumers. It preserves P, E, H, C, L, N and swaps only the source-side window and radius-observation rows.

Finally use the public multiplication consumer boundary. Since every public consumer reads only the listed packet through the Real$^{\uparrow}$ seal, the RealAlgOrder-facing export has exactly the finite multiplication surface required here and carries no host multiplication, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness witness. □

Theorem 464.47 (CauchyProduct obligation closure)**.** *For every accepted* CauchyProduct$^{\uparrow}$ *packet, the carrier source of Definition 464.1, the StreamName handoff, the* Real$^{\uparrow}$ *seal boundary, ledger exhaustion, radius product regularity, and product-observation seal obligations jointly supply the full* obligation *surface for* CauchyProduct$^{\uparrow}$ *over* RegularCauchyName$^{\uparrow}$, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert.

This closure surface preserves the exclusions on quotient streams, selected limits, trichotomy, host multiplication, independent real carriers, and ambient completeness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket obligation closure`

Proof. First collect the carrier source and NameCert obligations. They list the two RegularCauchyName$^{\uparrow}$ sources, paired StreamName$^{\uparrow}$ windows, dyadic-radius rows, DyadicRatCore$^{\uparrow}$ observations, product observation, RegSeqRat$^{\uparrow}$ classifier, Real$^{\uparrow}$ seal handoff, transport, continuation, ledger, provenance, and local naming rows.

Next apply the StreamName handoff and Real seal boundary. These theorems fix the route from the source names through paired finite windows to the dyadic product observation and then to the real-facing classifier row.

Use ledger exhaustion and radius product regularity to identify the finite regularity evidence. The product-radius ledger is the only route turning the paired observations and product row into the displayed RegSeqRat$^{\uparrow}$ classifier.

Finally apply the product-observation seal obligations. They assemble the same rows into the product-observation package and exclude any coordinate for quotient streams, selected limits, trichotomy, host multiplication, independent real carriers, or ambient completeness. The named rows therefore supply the full obligation-closure surface. □

Theorem 464.48 (CauchyProduct Real observation budget handoff)**.** *For every accepted* CauchyProduct$^{\uparrow}$ *packet, any* RealObservationBudget$^{\uparrow}$ *consumer that reads the product through the* Real$^{\uparrow}$ *seal must first route the paired windows, dyadic product observation, product-radius ledger,* RegSeqRat$^{\uparrow}$ *classifier, and seal row through the finite budget packet*

$$B = (E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B).$$

The rows W_B, D_B, R_B, S_B cover the product-side windows W_X, W_Y, dyadic observations Q_X, Q_Y, product observation P, radius ledger L, classifier row E, and Real$^\uparrow$ *seal handoff before the product consumer reads the seal.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real observation budget handoff`

Proof. Begin with the CauchyProduct obligation closure. It already binds the product route to the paired StreamName$^\uparrow$ windows, dyadic observations, product-radius ledger, RegSeqRat$^\uparrow$ classifier, Real$^\uparrow$ seal boundary, displayed transports, continuations, provenance, and local naming rows.

Route that surface through the observation budget. The readiness theorem Definition 611.18 requires carrier admission for $B = (E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B)$ before a later consumer may use the finite windows, dyadic rows, regular handoff, or real seal.

Finally align the product rows with the budget rows. The StreamName handoff supplies the paired windows, ledger exhaustion and radius product regularity supply the product-radius and classifier route, and the Real seal boundary supplies the seal row. Thus the budget packet is read before the product seal is consumed. □

Theorem 464.49 (CauchyProduct observation budget RegSeq handoff)**.** *An accepted* CauchyProduct$^\uparrow$ *packet hands its product* RegSeqRat$^\uparrow$ *classifier to a* RealObservationBudget$^\uparrow$ *consumer only through the budget rows $E_B, W_B, D_B, R_B, H_B, C_B, P_B, N_B$. The classifier row E is reached from the paired source windows and the product observation by the CauchyProduct StreamName handoff, ledger exhaustion, radius product regularity, and the* RealObservationBudget$^\uparrow$ *regular-sequence handoff; no consumer may read E from a quotient stream, selected limit, host multiplication row, trichotomy row, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket observation budget regseq handoff`

Proof. First build the product classifier route. The StreamName handoff places P downstream of $W_X, W_Y, Q_X, Q_Y, M_X, M_Y$, while ledger exhaustion and radius product regularity identify the finite radius ledger as the route from P to the classifier row E.

Next pass through the observation budget. By Definition 611.4, every regular-sequence handoff in an accepted budget packet is downstream of the precision request, finite windows, dyadic readbacks and radii, transports, continuation routes, provenance, and local naming row.

Combining the two routes gives the required handoff. The product classifier can be consumed only as the budgeted regular-sequence row R_B, carried by H_B, C_B, P_B, N_B, and all forbidden analytic objects remain outside both packets. □

Theorem 464.50 (CauchyProduct window-budget composition surface)**.** *For every accepted* CauchyProduct$^\uparrow$ *packet and every accepted* RealObservationBudget$^\uparrow$ *packet reading its product, the paired windows W_X, W_Y, radius rows M_X, M_Y, dyadic rows Q_X, Q_Y, product row P, ledger L, and budget rows $E_B, W_B, D_B, R_B, H_B, C_B, P_B, N_B$ form one finite composition surface from* StreamName$^\uparrow$ *through* DyadicRatCore$^\uparrow$ *to the* RegSeqRat$^\uparrow$ *classifier row E. The surface is obtained by the CauchyProduct StreamName handoff of Definition 464.20, the budget route exactness surface of Definition 464.12, and radius product regularity of Definition 464.32, and it exposes no quotient stream, selected limit, host multiplication primitive, trichotomy row, independent real carrier, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket window budget composition surface`

Proof. First unfold the paired-window rows of the accepted product packet. The StreamName handoff of Definition 464.20 sends the two source names through W_X, W_Y to the dyadic-radius and observation rows M_X, M_Y, Q_X, Q_Y, so the first part of the surface is already finite.

Next route the same rows through the observation budget. The budget route exactness surface of Definition 464.12 identifies the consumer-visible rows $E_B, W_B, D_B, R_B, H_B, C_B, P_B, N_B$ with the finite precision, window, dyadic readback, regular-sequence, transport, continuation, provenance, and naming rows of the budget packet.

Finally compose with radius product regularity of Definition 464.32. The product row P and ledger L carry the paired dyadic observations to the classifier row E, so the combined route is a single finite surface from $\mathsf{StreamName}^{\uparrow}$ through $\mathsf{DyadicRatCore}^{\uparrow}$ to $\mathsf{RegSeqRat}^{\uparrow}$.

Every displayed coordinate belongs to one of the two packets, and both packets exclude unlisted analytic resources. Hence the composition surface contains no quotient stream, selected limit, host multiplication primitive, trichotomy row, independent real carrier, or ambient completeness witness. □

Theorem 464.51 (CauchyProduct budget Real seal compatibility)**.** *The window-budget composition surface of Definition 464.50 is exactly the route that a* $\mathsf{Real}^{\uparrow}$ *seal and a* $\mathsf{RealObservationBudget}^{\uparrow}$ *consumer may read. The* $\mathsf{Real}^{\uparrow}$ *side reads the classifier and seal rows supplied by the CauchyProduct Real seal boundary of Definition 464.21; the budget side reads the same classifier only through the Real observation budget handoff of Definition 464.48 and the observation-budget* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 464.49. No additional quotient stream, selected limit, host multiplication primitive, trichotomy row, independent real carrier, or ambient completeness witness is available at the join.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget real seal compatibility`

Proof. Begin at the Real seal boundary of Definition 464.21. It permits the product to reach a $\mathsf{Real}^{\uparrow}$ consumer only through the recorded $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E, the finite ledger, the displayed transports, continuations, provenance, and local naming evidence.

Now read the same route through the observation budget. The Real observation budget handoff of Definition 464.48 requires the budget packet before the seal is consumed, and the observation-budget $\mathsf{RegSeqRat}^{\uparrow}$ handoff of Definition 464.49 places the classifier row downstream of $E_B, W_B, D_B, R_B, H_B, C_B, P_B, N_B$.

The two readings therefore meet on the composition surface and nowhere else. The seal-facing route supplies the product classifier, while the budget-facing route supplies the permitted consumer access to that classifier.

Since the cited boundaries are exhaustive on both sides, there is no remaining coordinate for quotient streams, selected limits, host multiplication primitives, trichotomy rows, independent real carriers, or ambient completeness witnesses. □

Theorem 464.52 (CauchyProduct root product readiness package)**.** *The window-budget composition surface of Definition 464.50, the budget Real seal compatibility of Definition 464.51, and the budgeted product consumer boundary of Definition 464.53 supply the root product readiness package for downstream* $\mathsf{RealAlgOrder}^{\uparrow}$, $\mathsf{RealCompleteness}^{\uparrow}$*, and budgeted product consumers. The package consists exactly of the finite product rows* $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$ *together with the finite budget rows* $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$*, read through* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *evidence.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root product readiness package`

Proof. First collect the composition surface. It gives downstream readers the finite route from paired $\mathsf{StreamName}^{\uparrow}$ windows and $\mathsf{DyadicRatCore}^{\uparrow}$ observations to the $\mathsf{RegSeqRat}^{\uparrow}$ product classifier.

Next attach the Real seal compatibility. This identifies the same finite route as the only route a $\mathsf{Real}^{\uparrow}$ seal and a $\mathsf{RealObservationBudget}^{\uparrow}$ consumer may jointly read.

Finally add the budgeted product consumer boundary. That theorem lists the complete product and budget inventories visible to product consumers, including the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

The three surfaces therefore form the advertised readiness package. It is suitable for $\mathsf{RealAlgOrder}^{\uparrow}$, $\mathsf{RealCompleteness}^{\uparrow}$, and budgeted product consumers precisely because it exports a finite product-read interface and excludes quotient streams, selected limits, trichotomy, host multiplication primitives, independent real carriers, and ambient completeness witnesses. □

Theorem 464.53 (CauchyProduct budgeted product consumer boundary)**.** *Every product consumer that enters through an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet and exits through an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet reads exactly the union of the product rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and the budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

The shared route exposes finite windows, dyadic observations, product-radius accounting, regular-rational classification, the $\mathsf{Real}^{\uparrow}$ *seal boundary, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It exposes no quotient stream, host multiplication primitive, selected limit, trichotomy decision, independent real carrier, or ambient completeness coordinate.*

Proof. Start from the product side. CauchyProduct obligation closure, the StreamName handoff, the Real seal boundary, ledger exhaustion, and radius product regularity exhaust the product-facing rows before the seal is read.

Now add the observation-budget side. The budget readiness theorem, together with budget consumer exactness and non-escape, says that $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers read only $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$.

The consumer boundary is therefore the displayed union of rows. Since both packets list their complete inventories and both non-escape clauses exclude unlisted analytic objects, the joined consumer route has no coordinate for quotient streams, host multiplication, selected limits, trichotomy, independent real carriers, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget product consumer boundary`

Theorem 464.54 (CauchyProduct budget RegSeq classifier lock)**.** *Before the product row* E *of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet is read as a* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier by a* $\mathsf{RealObservationBudget}^{\uparrow}$ *consumer, the finite rows* $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, L$ *have already locked the route from the two source names to the product observation. The lock is the route supplied by the CauchyProduct StreamName handoff, the paired-window ledger classifier, the budget route exactness surface, and the budgeted product consumer boundary.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget regseq classifier lock`

Proof. The StreamName handoff fixes the source reads through W_X, W_Y and the radius rows M_X, M_Y before the dyadic rows Q_X, Q_Y and product observation P are visible.

The paired-window ledger classifier then routes P through L to the classifier row E. Budget route exactness and the budgeted product consumer boundary say that a consumer can read this row only through the displayed budget route, so E cannot be reached before the listed product rows have been exposed. □

Theorem 464.55 (CauchyProduct Real seal budget gate)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet that is consumed through a* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet factors through the finite budget rows* $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$*. The gate is the Real observation budget handoff joined with the CauchyProduct budget Real seal compatibility and the budgeted product consumer boundary.*

Proof. First use the Real observation budget handoff. It requires the consumer to expose the precision request, window, dyadic, regular-sequence, seal, transport, continuation, provenance, and local naming rows of B.

The CauchyProduct budget Real seal compatibility identifies that budget route with the product classifier and seal route. The budgeted product consumer boundary exhausts the joined inventory, so every seal read through the budget passes through exactly $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal budget gate`

Theorem 464.56 (CauchyProduct window product nonescape)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, the paired windows* W_X, W_Y *are the only route from the two source names to the product observation* P*. The route proceeds through* M_X, M_Y, Q_X, Q_Y *and the product ledger surface, and it excludes quotient streams, host multiplication, selected limits, trichotomy, independent real carriers, and ambient completeness.*

Proof. The CauchyProduct StreamName handoff sends each source name to its finite window and dyadic observation row. The paired-window ledger classifier then supplies the product observation route through the displayed dyadic and ledger rows.

Budget route exactness, the Real observation budget handoff, and the budgeted product consumer boundary exhaust all rows available to downstream readers. Since none of those rows is a quotient stream, host multiplication primitive, selected limit, trichotomy decision, independent real carrier, or ambient completeness theorem, there is no alternate route from the source names to P. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket window product nonescape`

Theorem 464.57 (CauchyProduct shared-window root admission)**.** *Every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet admits a root-facing product route only through the paired* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{Real}^{\uparrow}$ *seal, and the support rows* hsame*,* Cont*,* Pkg*, and* NameCert*. The admitted root surface is*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

It exposes no product before those paired finite windows and their dyadic observations have been read.

Proof. Begin with the CauchyProduct StreamName handoff. It places the product route downstream of the paired source-window rows W_X, W_Y and their modulus rows M_X, M_Y.

Next use the product-observation seal obligations and ledger exhaustion. These rows force the dyadic observations Q_X, Q_Y, the product observation P, and the product-radius ledger L to be read before the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E is available.

Finally pass through the Real multiplication seal handoff and the public consumer boundary. The rows H, C, L, N preserve, route, account for, and name the same packet, so a root-facing consumer receives the product only through the displayed finite window inventory. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket shared window root admission`

Theorem 464.58 (CauchyProduct root window RegSeqRat seal route)**.** *Every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *root route that reaches a* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer reads the paired* $\mathsf{StreamName}^{\uparrow}$ *windows, the paired* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the* $\mathsf{Real}^{\uparrow}$ *seal in that order. The route is the finite inventory*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and it exposes no product-facing seal before the paired windows and dyadic observations have been recorded.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root window regseqrat seal route`

Proof. Begin with Definition 464.57. It admits a root-facing product route only after the paired window rows W_X, W_Y, source-radius rows M_X, M_Y, and dyadic observation rows Q_X, Q_Y have entered the product packet.

Next use the product-observation and ledger rows later in this chapter. The paired-window regularity exhaustion, root factor-source exhaustion, and root budget classifier coverage keep the product row P, classifier row E, and ledger row L downstream of the same finite window and dyadic observation route.

Finally apply the Real seal root surface and seal-ledger exactness. These rows place the $\mathsf{Real}^{\uparrow}$ seal after the $\mathsf{RegSeqRat}^{\uparrow}$ readback and preserve the same hsame, Cont, Pkg, and NameCert evidence, giving the stated order with no additional analytic coordinate. □

Theorem 464.59 (CauchyProduct root budget non-escape)**.** *An accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *root formation packet cannot export quotient streams, host real multiplication, ambient completeness, selected limits, trichotomy rows, independent real carriers, or unbounded selector rows. Every exported product route is confined to paired finite windows, dyadic observations, product-observation rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, the* $\mathsf{Real}^{\uparrow}$ *seal, displayed transport, displayed continuation, package provenance, local naming, and any explicitly displayed* $\mathsf{RealObservationBudget}^{\uparrow}$ *rows.*

Proof. Start from the shared-window root admission route. It places the product behind the paired finite windows, dyadic observations, classifier row, seal row, and local support rows.

Use the later product-observation and budget rows to account for all consumers. The budgeted readback root boundary and budgeted product consumer boundary add only displayed $\mathsf{RealObservationBudget}^{\uparrow}$ rows, while paired-window regularity exhaustion and root budget classifier coverage keep every product read inside the same finite ledger.

The excluded objects have no coordinate in this inventory. Since quotient streams, host real multiplication, ambient completeness, selected limits, trichotomy rows, independent real carriers, and unbounded selector rows are absent from the packet and absent from the budget handoff, root formation cannot export them. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root budget nonescape`

Theorem 464.60 (CauchyProduct root selector-ledger exactness)**.** *Every selector or budget row used by a downstream* CauchyProduct$^{\uparrow}$ *product consumer is recorded in the local ledger before the consumer reads the* Real$^{\uparrow}$ *seal. The recorded route includes the paired* StreamName$^{\uparrow}$ *windows,* DyadicRatCore$^{\uparrow}$ *observations, product row,* RegSeqRat$^{\uparrow}$ *readback,* Real$^{\uparrow}$ *seal, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, local* NameCert *evidence, and any displayed* RealObservationBudget$^{\uparrow}$ *rows.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root selector ledger exactness`

Proof. First apply shared-window root admission. It fixes the product route as a finite sequence through paired windows, dyadic observations, product formation, classifier readback, transport, continuation, ledger, provenance, and local naming rows.

Next attach the downstream consumer. The budgeted readback root boundary, root seal-ledger exactness, and budgeted product consumer boundary require any budget-facing read to carry its displayed observation-budget rows with the same product ledger.

Finally read the seal. The Real seal root surface and Real seal multiplication non-escape rows leave the consumer no route around the local ledger, so each selector or budget row has already been recorded before the Real$^{\uparrow}$ seal is consumed. □

Theorem 464.61 (CauchyProduct budgeted readback root boundary)**.** *For an accepted* CauchyProduct$^{\uparrow}$ *packet feeding an accepted* RealObservationBudget$^{\uparrow}$ *packet, every root-facing readback of the product factors through the product inventory*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and the budget inventory

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

The readback reaches the RegSeqRat$^{\uparrow}$ *and* Real$^{\uparrow}$ *rows only after the paired* StreamName$^{\uparrow}$ *windows,* DyadicRatCore$^{\uparrow}$ *observations,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows have been consumed.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budgeted readback root boundary`

Proof. First apply the shared-window root admission theorem. It binds the product route to the paired finite windows, dyadic observations, product observation, classifier row, Real seal, transport, continuation, ledger, provenance, and local naming rows.

Now enter the observation budget. The Real observation budget handoff and observation-budget RegSeq handoff require the budget rows $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$ before a downstream consumer may read the regular-sequence or real-facing product.

The budgeted product consumer boundary then identifies the complete readback interface. Since both inventories are finite packet rows, there is no coordinate for reading the product through a quotient stream, host multiplication primitive, selected limit, trichotomy row, independent real carrier, or ambient completeness witness. □

Theorem 464.62 (CauchyProduct Real seal root surface)**.** *The* Real$^{\uparrow}$ *seal surface of an accepted* CauchyProduct$^{\uparrow}$ *packet is root-visible only as the finite route composed from paired* StreamName$^{\uparrow}$ *windows,* DyadicRatCore$^{\uparrow}$ *observations,* RegSeqRat$^{\uparrow}$ *readback, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *evidence. When the packet feeds an accepted* RealObservationBudget$^{\uparrow}$ *packet, the same route is read through the budgeted boundary of Definition 464.61.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal root unblock surface`
↪ variant `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal root surface`

Proof. Start with the Real multiplication seal handoff. It makes the real-facing product row depend on the RegSeqRat$^{\uparrow}$ classifier E rather than on host multiplication or a selected real representative.

Trace E back through the finite product route. The CauchyProduct StreamName handoff, product-observation seal obligations, radius ledger, and radius product regularity force the route through $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, L$.

Finally compose with the budgeted readback root boundary. The budget packet reads the same real seal through $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$, while the support rows preserve the product route as hsame, Cont, Pkg, and NameCert data. Thus the root-visible Real seal is exactly the finite packet route. □

Theorem 464.63 (CauchyProduct RealAlgOrder product-observation export)**.** *Every* RealAlgOrder$^{\uparrow}$ *multiplication export that reads an accepted* CauchyProduct$^{\uparrow}$ *packet factors through the paired* StreamName$^{\uparrow}$ *windows, the* DyadicRatCore$^{\uparrow}$ *observations, the* RegSeqRat$^{\uparrow}$ *classifier, the* Real$^{\uparrow}$ *seal, the* RealObservationBudget$^{\uparrow}$ *rows when a budget packet serves the read, and the visible* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. The export reads multiplication only as the finite product-observation route*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$$

when they are present. It exports no host multiplication, quotient stream, selected limit, trichotomy, independent real carrier, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket realalgorder product observation export`

Proof. First compose root-window admission with the budgeted readback boundary. The paired StreamName$^{\uparrow}$ windows and DyadicRatCore$^{\uparrow}$ observations must be read before the product row, classifier row, and seal row are visible to any downstream multiplication consumer.

Next apply the Real seal root surface. It keeps the real-facing product on the finite route through RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, displayed hsame transports, displayed Cont routes, Pkg provenance, and the local NameCert row.

Finally route the same surface through the observation-budget rows when the budget packet serves the read. Since the product and budget inventories contain no host multiplication primitive, quotient stream, selected limit, trichotomy branch, independent real carrier, or ambient completeness witness, the RealAlgOrder$^{\uparrow}$ export can read only the displayed product-observation route. □

Theorem 464.64 (CauchyProduct dyadic-radius ledger handoff)**.** *For an accepted* CauchyProduct$^{\uparrow}$ *packet feeding an accepted* RealObservationBudget$^{\uparrow}$ *packet, the input-radius rows and the product-radius ledger rows are preserved when the product packet hands off to the observation-budget packet. The handoff carries*

$$M_X, M_Y, Q_X, Q_Y, L$$

through the product route

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and into the budget route

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

It preserves the displayed dyadic-radius accounting and exports no host multiplication, quotient stream, selected limit, trichotomy, independent real carrier, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket dyadic radius ledger handoff`

Proof. Start with root-window admission. The input-radius rows and dyadic observations enter the product packet together with the paired finite windows, so the product route cannot reach P or E without first reading M_X, M_Y, Q_X, Q_Y.

Use radius budget conservation for the product side. It identifies L as the finite ledger that carries the input-radius and product-radius accounting through componentwise hsame and displayed Cont routes.

Now pass through the Real seal root surface and the budgeted readback boundary. The observation-budget packet reads the same classifier and seal route through its displayed rows $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$, preserving the dyadic-radius ledger rather than replacing it by any excluded analytic object. □

Theorem 464.65 (CauchyProduct root-window factorization)**.** *Every accepted product consumer that enters through a* $\mathsf{CauchyProduct}^{\uparrow}$ *packet factors through the root-window rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

before any $\mathsf{RealObservationBudget}^{\uparrow}$ *row is read. The factorization route first reads the two* $\mathsf{StreamName}^{\uparrow}$ *window schedules, then the paired dyadic observations and radius ledgers, then the product row* P*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E*, the displayed* hsame *transports, the* Cont *routes, the ledger row* L*, and the local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row* N*. It exposes no quotient stream, selected limit, trichotomy, host multiplication primitive, independent real carrier, or ambient completeness coordinate before the budget packet is entered.*

Proof. Start with the StreamName handoff. It makes the product consumer read the paired finite windows W_X, W_Y, moduli M_X, M_Y, and dyadic observations Q_X, Q_Y as displayed packet rows rather than as ambient streams.

Next use paired-window closure and the product ledger. The pointwise product row P and classifier row E are reached only through the paired finite windows, radius accounting, and regular-rational route; the displayed hsame and Cont rows carry the same route without adding another analytic carrier.

Finally apply Definition 464.53. That boundary places every later observation-budget read downstream of the product inventory, so the root window has already factored through $W_X, W_Y, M_X, M_Y, Q_X, Q_Y$, before any budget row is available. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root window factorization`

Theorem 464.66 (CauchyProduct radius budget conservation)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet feeding an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet, the paired input-radius rows and the product-radius row are conserved under componentwise* hsame *and displayed* Cont *routes through the budget packet. Thus the route from*

$$M_X, M_Y, Q_X, Q_Y, L$$

to the budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$$

preserves the same finite radius ledger, the same product-radius witness, and the same regular-sequence classifier handoff; it cannot replace them by a selected limit, quotient-stream equality, host multiplication estimate, trichotomy branch, independent real carrier, or ambient completeness statement.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket radius budget conservation`

Proof. First read the radius ledger on the product side. Ledger exhaustion and radius product regularity identify the input radii, the dyadic product observation, and the product-radius row as the exact finite accounting surface for the $\mathsf{RegSeqRat}^{\uparrow}$ classifier.

Now transport that surface componentwise. The displayed hsame rows preserve the left and right input-radius rows, while the displayed Cont routes preserve the product-radius route and package provenance inside the finite packet.

Pass the conserved ledger through the observation budget. The observation-budget RegSeq handoff reads the same classifier route as R_B together with H_B, C_B, P_B, N_B, and Definition 464.53 leaves no coordinate by which an analytic replacement could enter. □

Theorem 464.67 (CauchyProduct shared-tail budget consumer)**.** *Let an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet be consumed by an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet, and suppose the paired source windows are admitted through the shared threshold surface of chapter 560. Then every seal-facing product consumer factors through the paired* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, the product-radius budget rows, the shared RegularCauchyTailMeet threshold, and the* $\mathsf{Real}^{\uparrow}$ *seal rows before any product consumer may read the seal.*

The complete consumer route is the product inventory

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the budget inventory

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

It exposes no quotient stream, selected limit, host multiplication, trichotomy, independent real carrier, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket shared tail budget consumer`

Proof. First compose the root-window factorization with the shared tail surface. The factorization forces every product read through $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$, while chapter 560 supplies the common finite threshold used by the paired source windows.

Next apply radius budget conservation. The rows M_X, M_Y, Q_X, Q_Y, L remain the same finite radius ledger when the product route is transported through the observation-budget packet.

Now use the budgeted readback root boundary. It attaches $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$ to the same product route and makes the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and $\mathsf{Real}^{\uparrow}$ seal readable only after the paired windows, dyadic observations, budget rows, and shared threshold have been displayed.

Finally apply the sibling tail-meet threshold surface together with the budgeted product consumer boundary. The resulting route has no remaining coordinate for a quotient stream, selected limit, host multiplication, trichotomy, independent real carrier, or ambient completeness principle, so the seal consumer is exactly the shared-tail budget consumer described above. □

Theorem 464.68 (CauchyProduct tail-fusion budget route)**.** *Every accepted* CauchyProduct$^{\uparrow}$ *product consumer that also consumes* RegularCauchyTailFusion$^{\uparrow}$ *and* RegularCauchyTailBudget$^{\uparrow}$ *factors through the paired* StreamName$^{\uparrow}$ *windows, the* DyadicRatCore$^{\uparrow}$ *observations, the* RegSeqRat$^{\uparrow}$ *readback, the fusion shared-threshold row, and the tail-budget row before the* Real$^{\uparrow}$ *seal is read. The root-visible route is the product inventory*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the observation-budget inventory

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$$

and the displayed tail-fusion and tail-budget rows supplied by the sibling certificates. Its support is carried only by hsame*,* Cont*,* Pkg*, and* NameCert *rows; it exports no quotient stream, host multiplication, selected limit, trichotomy row, independent real carrier, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket tail fusion budget route`

Proof. First use shared-window root admission. The accepted product consumer must read the paired StreamName$^{\uparrow}$ windows and DyadicRatCore$^{\uparrow}$ observations before the product row, classifier row, ledger row, or seal row can be visible.

Next attach the tail-fusion surface. The RegularCauchyTailFusion$^{\uparrow}$ consumer contributes its shared-threshold row as a displayed finite route over the same source windows, so the product read cannot fork into an independent stream or carrier.

Finally compose with Definition 464.67. The tail-budget packet reads the same product inventory and observation-budget inventory, while hsame, Cont, Pkg, and NameCert preserve and name the route. The listed excluded objects have no coordinate in any of the composed packets. □

Theorem 464.69 (CauchyProduct root budget-fusion non-escape)**.** *For an accepted* CauchyProduct$^{\uparrow}$ *product consumer served through* RegularCauchyTailFusion$^{\uparrow}$ *and* RegularCauchyTailBudget$^{\uparrow}$*, the root-visible budget-fusion route is exhausted by the paired* StreamName$^{\uparrow}$ *windows,* DyadicRatCore$^{\uparrow}$ *observations,* RegSeqRat$^{\uparrow}$ *readback, fusion shared-threshold row, tail-budget row,* Real$^{\uparrow}$ *seal,* hsame*,* Cont*,* Pkg*, and* NameCert*. No consumer of this route can recover a quotient stream, host multiplication primitive, selected limit, trichotomy row, independent real carrier, or ambient completeness coordinate.*

Proof. Begin with Definition 464.68. It gives the complete product, observation-budget, tail-fusion, and tail-budget inventory seen by the root-facing consumer.

Now apply radius budget conservation. The input-radius rows, dyadic observations, product-radius ledger, and regular readback row remain the same finite accounting surface when the route enters the tail-budget consumer.

The non-escape conclusion is then coordinate exhaustion. The composed packets expose only the displayed windows, observations, readback, threshold, budget, seal, transport, route, provenance, and local naming rows, so none of the excluded analytic objects can be read from the root-visible route. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root budget fusion nonescape`

Theorem 464.70 (CauchyProduct RealAlgOrder root handoff)**.** *Every* RealAlgOrder$^{\uparrow}$ *product consumer that reads an accepted* CauchyProduct$^{\uparrow}$ *packet through* RegularCauchyTailFusion$^{\uparrow}$ *and* RegularCauchyTailBudget$^{\uparrow}$ *receives only the root-visible budget-fusion route of Definition 464.68. Thus the RealAlgOrder multiplication observation is consumed through paired* StreamName$^{\uparrow}$ *windows,* DyadicRatCore$^{\uparrow}$ *observations,* RegSeqRat$^{\uparrow}$ *readback, the fusion shared-threshold row, the tail-budget row, the* Real$^{\uparrow}$ *seal,* hsame*,* Cont*,* Pkg*, and* NameCert*, with no host multiplication, quotient stream, selected limit, trichotomy, independent real carrier, or ambient completeness coordinate exported.*

Proof. First apply Definition 464.63. The RealAlgOrder$^{\uparrow}$ multiplication export reads multiplication only as the finite product-observation route, with observation-budget rows when the budget packet serves the read.

Next compose the export with Definition 464.68. This inserts the shared tail-fusion threshold and tail-budget rows before the seal-facing RealAlgOrder read without adding a second multiplication carrier.

Finally use Definition 464.69. Since the composed route has no coordinate for host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, or ambient completeness, the RealAlgOrder handoff is exactly the displayed root-visible budget-fusion route. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket realalgorder root handoff`

Theorem 464.71 (CauchyProduct RegSeq seal non-escape)**.** *A* RegSeqRat$^{\uparrow}$ *or* Real$^{\uparrow}$ *seal consumer that is reached from an accepted* CauchyProduct$^{\uparrow}$ *packet and an accepted* RealObservationBudget$^{\uparrow}$ *packet cannot replace the finite product classifier by host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, or ambient completeness. The only available seal-facing route is the product inventory*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the observation-budget inventory

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket regseq seal nonescape`

Proof. Begin at the product seal. The Real multiplication seal handoff reads the product classifier E through the StreamName windows, dyadic observations, radius ledger, displayed transports, continuations, provenance, and local NameCert row.

Next enter the observation budget. The Real observation budget handoff and the observation-budget RegSeq handoff make the budget consumer read the classifier only as a finite budget row, with the same transports, routes, provenance, and local naming evidence.

The budgeted product consumer boundary then seals the route. Since the displayed product and budget inventories are complete, there is no remaining packet coordinate for host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, or ambient completeness. □

Theorem 464.72 (CauchyProduct budgeted product associative route)**.** *Let two accepted* CauchyProduct$^{\uparrow}$ *packets feed a common accepted* RealObservationBudget$^{\uparrow}$ *packet, and suppose the displayed source windows, dyadic observations, product-radius ledgers,* RegSeqRat$^{\uparrow}$ *classifier rows,* Real$^{\uparrow}$ *seal rows, budget rows, transports, routes, provenance, and local naming rows are the same:*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

Then the finite seal-facing route seen by the budgeted product consumer is the same whether the product observation is grouped as first-left-then-right or first-right-then-left. The comparison is a route-composition equality inside the displayed row inventory; it does not introduce quotient streams, host multiplication primitives, selected limits, trichotomy rows, independent real carriers, or ambient completeness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget product associative route`

Proof. Begin with the common product inventory. The CauchyProduct StreamName handoff fixes the paired source-window reads, while ledger exhaustion and radius product regularity fix the product-radius and classifier route from the same displayed dyadic observations.

Pass both groupings through the Real-facing rows. The Real multiplication seal handoff and the Real observation budget handoff read the same $\mathsf{Real}^{\uparrow}$ seal rows and the same budget packet before any consumer-facing seal is exposed.

Finally compare the two composites. The observation budget RegSeq handoff and Definition 464.53 leave only the displayed product rows and budget rows available to the consumer. Since both groupings use exactly those rows with the same transports, routes, provenance, and local names, their seal-facing finite routes coincide within the packet inventory. □

Theorem 464.73 (CauchyProduct budgeted product symmetric route)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet feeding an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet, swapping the two source-window families swaps only*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y$$

between the two product inputs. The budget rows $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$*, classifier row* E*, Real seal handoff, displayed transports, routes, provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *row are preserved as the same finite consumer surface. No symmetric route exports quotient streams, host multiplication primitives, selected limits, trichotomy rows, independent real carriers, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget product symmetric route`

Proof. Read the two source families through the CauchyProduct StreamName handoff. Swapping the sources exchanges only the displayed left and right window, modulus, and dyadic observation rows.

The product-radius ledger and radius product regularity are then replayed with the exchanged source rows. They still produce the same classifier-facing product ledger and route to E, because no additional analytic coordinate is available in the packet.

Route the result through the Real multiplication seal handoff, the Real observation budget handoff, and the observation budget RegSeq handoff. The budget packet, seal handoff, transports, continuations, provenance, and local naming rows are unchanged, so Definition 464.53 gives the same consumer boundary with only the two source families exchanged. □

Theorem 464.74 (CauchyProduct budgeted product unit route)**.** *If one displayed source of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet is the regular-Cauchy unit source, then inserting that unit source contributes only its unit source rows to the finite packet. The budgeted product consumer still reads the same product boundary*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the same observation-budget boundary

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B,$$

with the unit source occupying the corresponding source-window, modulus, and dyadic observation coordinates. The route does not export quotient streams, host multiplication primitives, selected limits, trichotomy rows, independent real carriers, or ambient completeness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget product unit route`

Proof. Insert the displayed unit source as one regular-Cauchy input. Its contribution is read through the same CauchyProduct StreamName handoff as any other source: one window family, one modulus row, and one dyadic observation family.

Ledger exhaustion and radius product regularity then place the unit rows in the product-radius ledger. The route still reaches the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and $\mathsf{Real}^{\uparrow}$ seal through the existing product packet rather than through a host multiplication primitive or selected limit.

The Real observation budget handoff and observation budget RegSeq handoff carry the result into the same budget packet. By Definition 464.53, the consumer boundary is unchanged except for the displayed unit rows occupying their source slots, and all excluded analytic objects remain outside the finite inventory. □

Theorem 464.75 (CauchyProduct paired-window regularity exhaustion)**.** *Every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet whose product read is consumed by a* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *route factors through exactly the finite rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

The factorization first binds the paired source windows W_X, W_Y*, the source-radius rows* M_X, M_Y*, and the dyadic observations* Q_X, Q_Y*; then it reads the product row* P *and the product-radius route that supplies the classifier row* E*; finally it transports the sealed product through* H, C, L, N *to the consumer boundary. The route excludes host multiplication, quotient streams, selected limits, trichotomy, independent real carriers, and ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket paired window regularity exhaustion`

Proof. Start with paired-window closure. It forces any accepted product read to pass through W_X, W_Y before exposing M_X, M_Y, Q_X, Q_Y, the product row P, and the downstream classifier route.

Next use radius product regularity. The product-radius ledger is the only route from the displayed dyadic product observation to the $\mathsf{RegSeqRat}^{\uparrow}$ classifier E, so the regularity witness is part of the finite packet rather than an external multiplication or completeness claim.

Now pass to the seal-facing boundary. The Real multiplication seal handoff and the RealCompleteness diagonal seal route make every $\mathsf{Real}^{\uparrow}$ or diagonal consumer read only the displayed classifier, transports, continuation rows, ledger, package provenance, and local $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ evidence.

Finally apply ledger exhaustion. Since the named rows exhaust the accepted packet, there is no remaining coordinate for quotient streams, selected limits, trichotomy, independent real carriers, ambient completeness, or a host multiplication primitive. □

Theorem 464.76 (CauchyProduct root factor-source exhaustion)**.** *Every accepted* CauchyProduct$^{\uparrow}$ *route that exposes the product row P to a downstream* RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, *or* RealObservationBudget$^{\uparrow}$ *consumer first exhausts the two factor sources through*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y.$$

The packet therefore reads the left and right StreamName$^{\uparrow}$ *windows, the two source-radius rows, and the two* DyadicRatCore$^{\uparrow}$ *observation rows before P is visible. The product route has no source-facing coordinate for quotient streams, selected limits, host multiplication, trichotomy, independent real carriers, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root factor source exhaustion`

Proof. Start from the paired-window regularity exhaustion theorem. It orders every accepted product read by the displayed rows $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$, with the source windows and dyadic observations preceding the product row.

Next apply the root-window factorization and budgeted readback boundary. These keep the same source rows when the product is read through a budget packet, so P cannot be inspected before the two factor windows, radius rows, and dyadic observations have been consumed.

Finally pass through the Real seal root surface. The seal handoff reads the product only after the classifier and transport rows have inherited the exhausted source inventory, leaving no separate analytic object from which P could be imported. □

Theorem 464.77 (CauchyProduct root budget classifier coverage)**.** *The product observation P, the product-radius ledger L, and the* RegSeqRat$^{\uparrow}$ *classifier row E of an accepted* CauchyProduct$^{\uparrow}$ *packet are covered only by the dyadic-radius budget route through* DyadicRatCore$^{\uparrow}$ *and* RegSeqRat$^{\uparrow}$*. More explicitly, any consumer that reaches one of P, L, E must read the finite product inventory*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and, when an observation budget is present, the finite budget inventory

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

No independent classifier, host multiplication estimate, quotient-stream comparison, selected limit, trichotomy row, independent real carrier, or ambient completeness witness covers P, L, E.

Proof. First use radius budget conservation. It identifies the route from the two dyadic source observations to the product-radius ledger and then to the regular-sequence classifier, so P, L, E stay on the same dyadic-radius accounting path.

Next combine this with paired-window regularity exhaustion. The product row P is reached only after the paired windows, source-radius rows, and dyadic observations have been read, and the classifier row E is supplied by the product-radius route rather than by an external real carrier.

When the read is budgeted, apply the budgeted readback root boundary and the budgeted product consumer boundary. They add exactly the displayed RealObservationBudget$^{\uparrow}$ rows and do not add a second route for P, L, E. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root budget classifier coverage`

Theorem 464.78 (CauchyProduct root seal-ledger exactness)**.** *Any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealObservationBudget}^{\uparrow}$ *seal consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet reads exactly the joined product and budget ledger rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and, when a budget packet is present,

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

The seal consumer cannot import quotient streams, selected limits, host multiplication, trichotomy, independent real carriers, ambient completeness, or any row outside this joined ledger.

Proof. Begin with the Real seal root surface. It routes the real-facing product through paired windows, dyadic observations, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, displayed transports, displayed continuations, package provenance, and local $\mathsf{NameCert}$ evidence.

Next apply root factor-source exhaustion and root budget classifier coverage. The first fixes the factor-source rows before P can be read; the second fixes the only dyadic-radius route covering P, L, E and, when present, the exact budget rows.

Finally use the budgeted product consumer boundary. Since the product ledger and the observation-budget ledger are already the complete finite inventories, a $\mathsf{Real}^{\uparrow}$ or $\mathsf{RealObservationBudget}^{\uparrow}$ seal consumer has no remaining row from which to import quotient streams, selected limits, host multiplication, trichotomy, independent real carriers, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root seal ledger exactness`

Theorem 464.79 (CauchyProduct budgeted bilinear diagonal)**.** *Let two accepted* $\mathsf{RegSeqRat}^{\uparrow}$*-backed* $\mathsf{CauchyProduct}^{\uparrow}$ *factors share a* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet and a* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius ledger. Then the diagonal product window is determined by the existing paired-window and budgeted product routes over*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and the observation-budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

The resulting diagonal read is bilinear only as a finite product-observation certificate: it exposes the two regular source windows, the dyadic radius rows, the pointwise product row, the shared budget ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, and the* $\mathsf{Real}^{\uparrow}$ *seal handoff, and it exports no host multiplication primitive, quotient stream equality, selected limit, independent real carrier, or ambient completeness.*

Proof. Start with Definition 464.75. It forces the product read through the two source windows, source-radius rows, dyadic observations, product row, classifier row, transports, continuations, ledger, package provenance, and local naming row.

Next apply the budgeted product route supplied by Definition 464.53. The shared observation budget contributes exactly $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$, so the product read and the budget read meet on the same diagonal request rather than on a host arithmetic operation.

Use the radius budget conservation route of Definition 464.66. The dyadic radius ledger records the bound consumed by the product window, so the diagonal product observation is determined by the displayed source windows and the displayed budget rows.

Finally use the Real multiplication seal handoff. The seal receives only the finite product and budget rows already listed, giving the stated bilinear diagonal certificate without quotient streams, selected limits, independent real carriers, host multiplication, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budgeted bilinear diagonal`

Theorem 464.80 (CauchyProduct shared-radius product coverage)**.** *Every displayed product-observation request consumed by the* RealAlgOrder$^{\uparrow}$ *multiplication export is covered by paired-window regularity plus radius-budget conservation. Concretely, a multiplication consumer can read a* CauchyProduct$^{\uparrow}$ *product observation only through the two* RegularCauchyName$^{\uparrow}$ *source rows, their shared* StreamName$^{\uparrow}$ *windows, the displayed* DyadicRatCore$^{\uparrow}$ *radius observations, the* RealObservationBudget$^{\uparrow}$ *budget rows, the* RegSeqRat$^{\uparrow}$ *classifier, the* Real$^{\uparrow}$ *seal handoff, and the visible* BHist, hsame, Cont, Pkg, *and* NameCert *rows.*

Proof. Apply Definition 464.75. Any product read reaching a regular-sequence or real-facing consumer already passes through the paired windows and the dyadic product-radius rows.

Apply Definition 464.79. The shared observation budget aligns the product request with the same finite diagonal window and the same radius ledger, so a multiplication export receives a covered product observation rather than an implicit arithmetic operation.

Now use the Real seal handoff and the RegSeq seal non-escape route recorded earlier in this chapter. These rows keep the public consumer inside the product packet, budget packet, classifier row, seal row, transports, continuations, package provenance, and local naming certificate.

Thus every product-observation request displayed to the RealAlgOrder$^{\uparrow}$ multiplication export is accounted for by paired-window regularity and radius-budget conservation, with no hidden multiplication or ambient completeness route. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket shared radius product coverage`

Theorem 464.81 (CauchyProduct Real seal multiplication non-escape)**.** *The public multiplication consumer of a* CauchyProduct$^{\uparrow}$ *packet receives only the finite* CauchyProduct$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RealObservationBudget$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows displayed by the product and budget certificates. It receives no host multiplication primitive, quotient stream equality, selected limit, trichotomy row, independent real carrier, ambient completeness principle, or unrecorded radius witness.*

Proof. Begin with Definition 464.80. It says that every multiplication-facing product observation is covered by the paired source windows, dyadic radius rows, shared observation budget, classifier route, and real seal handoff.

Use Definition 464.53 to identify the public budget boundary. The consumer can inspect the product packet and the observation-budget packet, but only through their displayed rows and the recorded transport, continuation, provenance, and local naming routes.

Finally apply the paired-window exhaustion theorem and the RegSeq seal non-escape route. They leave no coordinate for host multiplication, quotient stream equality, selected limits, trichotomy, independent real carriers, ambient completeness, or unrecorded radius witnesses, so the multiplication seal is exactly the finite public certificate stated above. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal multiplication nonescape`

Theorem 464.82 (CauchyProduct root source admission)**.** *For every accepted* CauchyProduct$^{\uparrow}$ *packet, the source rows*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y$$

admit a finite BHist *root surface over* RegularCauchyName$^{\uparrow}$, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert. *The surface is generated by the two regular-Cauchy source rows, the paired finite-window schedules, the paired radius rows, and the dyadic observation rows,*

and it exposes no quotient stream, selected limit, host multiplication primitive, ambient completeness row, trichotomy row, or independent real carrier.

Proof. Start with the packet source of Definition 464.1. Its displayed coordinates put $X, Y, W_X, W_Y, M_X, M_Y, Q_X,$ inside the same finite BHist packet as the product row, classifier row, transports, continuations, ledger, package provenance, and local naming row.

The sibling carriers supply the admissible readings. Use chapter 126 for the finite window schedules, chapter 291 for the dyadic observations and radius rows, chapter 301 for the classifier route, and chapter 38 for the real seal boundary.

Finally apply Definition 464.3, Definition 464.4, and Definition 464.5. These three obligations bind the source rows to finite windows, radius accounting, and the real-seal route, leaving no coordinate for any excluded analytic object. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root source admission`

Theorem 464.83 (CauchyProduct root classifier stability)**.** *Componentwise classifier transport of the two source rows, paired windows, radius rows, dyadic observations, product observation, and* RegSeqRat$^{\uparrow}$ *classifier preserves the same* CauchyProduct$^{\uparrow}$ *root packet*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

The transported packet is again routed only through the displayed BHist, hsame, Cont, Pkg, *and* NameCert *rows over* RegularCauchyName$^{\uparrow}$, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *and* Real$^{\uparrow}$*; it admits no quotient stream and no host multiplication primitive.*

Proof. First read the source and window rows through Definition 464.82. The theorem fixes the root source surface as a finite BHist packet over the listed sibling carriers.

Next transport the classifier componentwise. The StreamName and DyadicRatCore rows from chapter 126 and chapter 291 preserve the paired windows, radius rows, dyadic observations, and product observation through the displayed hsame and Cont data.

Now read the classifier and seal. The RegSeqRat$^{\uparrow}$ and Real$^{\uparrow}$ rows from chapter 301 and chapter 38, together with Definition 464.75, Definition 464.66, and Definition 464.71, keep the transported packet on the same finite route. Since the route is exhausted by the displayed packet, quotient streams and host multiplication primitives have no source row. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root classifier stability`

Theorem 464.84 (CauchyProduct root product-row determinacy)**.** *For any two accepted* CauchyProduct$^{\uparrow}$ *root packets over the same displayed rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, H, C, L, N,$$

the product row P and classifier-facing row E are determined by the paired finite-window route and the dyadic-observation route before the RegSeqRat$^{\uparrow}$ *readback and the* Real$^{\uparrow}$ *seal are consumed. No host multiplication primitive, quotient stream, selected limit, trichotomy branch, independent real carrier, or ambient completeness coordinate can change P or E once those finite rows are fixed.*

Proof. First read the common source surface through Definition 464.82. The accepted packets expose the paired windows, radius rows, and dyadic observations as one finite BHist route over StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, hsame, Cont, Pkg, and NameCert.

Next apply Definition 464.75. It forces every product read toward a regular-rational or real-facing consumer through

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

Thus the rows preceding P and E already determine the multiplication-facing packet route.

Finally use Definition 464.83 together with the StreamName, DyadicRatCore, RegSeqRat, and Real carrier chapters chapter 126, chapter 291, chapter 301, and chapter 38. These routes preserve the same finite packet through componentwise transport, so the later $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{Real}^{\uparrow}$ seal can only consume the determined product and classifier-facing rows. The excluded analytic objects have no coordinate in the packet and cannot alter them. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root product row determinacy`

Theorem 464.85 (CauchyProduct root phase handoff)**.** *Every downstream L10 consumer of the* $\mathsf{CauchyProduct}^{\uparrow}$ *root surface factors through the displayed paired windows, dyadic product route, radius ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal row, and local* NameCert *rows. Equivalently, the consumer boundary is the finite route through*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and, when a budget packet is present, through the displayed budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

No downstream consumer receives a quotient stream, selected limit, host multiplication primitive, unrecorded radius witness, trichotomy branch, independent real carrier, or ambient completeness principle.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root phase handoff`

Proof. Begin with the root packet. The source admission and classifier stability theorems keep $X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$ as one finite BHist surface over the sibling carriers named in chapter 126, chapter 291, chapter 301, and chapter 38.

Next factor the product-facing consumer. Apply Definition 464.57, Definition 464.61, Definition 464.62, and Definition 464.65; these route the consumer through paired windows, dyadic observations, the product row, the classifier row, and the seal boundary.

Finally pass through the public multiplication surface when it is requested. The diagonal, coverage, and non-escape results Definition 464.79, Definition 464.80, and Definition 464.81 identify the exact downstream boundary. Since all routes are already finite packet rows, no excluded analytic object can be handed to an L10 consumer. □

Theorem 464.86 (CauchyProduct product-window consumer handoff)**.** *Every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *product-window consumer factors through the displayed* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular readbacks, the* $\mathsf{Real}^{\uparrow}$ *seal, and the* $\mathsf{RealAlgOrder}^{\uparrow}$ *multiplication boundary before exporting any product read. Its consumer-facing route is the finite surface*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the displayed observation-budget rows when a budget packet serves the read. It exports no product coordinate outside those rows, and no host multiplication, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness principle.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket product window consumer handoff`

Proof. Start with the paired product windows. The shared-window root admission and root-window factorization results place every product read behind $W_X, W_Y, M_X, M_Y, Q_X, Q_Y$, so the consumer first receives the two finite $\mathsf{StreamName}^{\uparrow}$ schedules and the dyadic tolerance observations.

Next compose the readback route. The budgeted readback boundary and radius budget conservation carry P, L through the displayed $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E, while the structural rows H, C, N preserve the same packet under hsame, Cont, and local NameCert replay.

Finally pass to the order-facing export. The Real seal root surface, the RealAlgOrder product-observation export, and the Real seal multiplication non-escape theorem route the same packet through the $\mathsf{Real}^{\uparrow}$ seal and the $\mathsf{RealAlgOrder}^{\uparrow}$ multiplication boundary. Since every step projects or composes rows already present in the displayed obligations, the exported product read has exactly the stated finite surface and no excluded analytic coordinate. □

Theorem 464.87 (CauchyProduct stream seal obligation)**.** *Every* $\mathsf{CauchyProduct}^{\uparrow}$ *root consumer that reads a product seal must first read the paired* $\mathsf{StreamName}^{\uparrow}$ *windows*

$$W_X, W_Y$$

together with the source-radius rows M_X, M_Y*, the dyadic observation rows* Q_X, Q_Y*, the product row* P*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E*, and the* $\mathsf{Real}^{\uparrow}$ *seal route. The obligation binds the stream windows to the regular-rational and real-seal reads through the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows, and it exports no host multiplication, quotient stream, selected limit, trichotomy row, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket stream seal obligation`

Proof. Begin with Definition 464.82. It places the two $\mathsf{RegularCauchyName}^{\uparrow}$ source rows, their $\mathsf{StreamName}^{\uparrow}$ windows, and the $\mathsf{DyadicRatCore}^{\uparrow}$ observations inside the same finite root surface.

Next apply Definition 464.75. The theorem forces the product read through $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H$ before any regular-rational or real-facing consumer can inspect the product.

Finally use the sibling seal boundaries from chapter 301 and chapter 38. These chapters name the classifier and seal rows reached by the product packet, while chapter 126 and chapter 291 name the upstream finite-window and dyadic inputs. The displayed packet has no row for any excluded analytic object. □

Theorem 464.88 (CauchyProduct real classifier obligation)**.** *The product observation* P *of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet reaches the real-facing classifier only through the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E*. The classifier route is determined by the paired* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations, product-radius ledger, componentwise* hsame *transports, displayed* Cont *routes, package provenance, and local naming row; it is not a host multiplication primitive, quotient-stream comparison, selected limit, trichotomy branch, independent real carrier, or ambient completeness statement.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real classifier obligation`

Proof. Start with the product observation row P. By Definition 464.83, transporting the paired source rows, windows, radius rows, dyadic observations, product observation, and classifier preserves the same finite root packet.

Now read the regular-rational classifier. The $\mathsf{RegSeqRat}^{\uparrow}$ boundary of chapter 301 is reached only after the displayed window and dyadic rows have been consumed, and the radius conservation result Definition 464.66 keeps the ledger attached to the same packet.

The real-facing read follows through the $\mathsf{Real}^{\uparrow}$ seal boundary, not through an external multiplication or completeness principle. Since the carrier exposes only the displayed classifier route, the excluded analytic objects cannot serve as alternative classifier evidence. □

Theorem 464.89 (CauchyProduct ledger obligation)**.** *The* $\mathsf{CauchyProduct}^{\uparrow}$ *root ledger binds the radius rows, product row, transport rows, continuation rows, package provenance, and local NameCert row as one finite accounting surface:*

$$M_X, M_Y, Q_X, Q_Y, P, H, C, L, N.$$

Every product-seal read must preserve this ledger when it passes to $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{RealAlgOrder}^{\uparrow}$, *or* $\mathsf{RealCompleteness}^{\uparrow}$ *consumers. The ledger contains no host multiplication estimate, quotient-stream equality, selected limit, trichotomy witness, independent real carrier, or ambient completeness coordinate.*

Proof. First apply Definition 464.66. It identifies the input radii, dyadic product observations, product-radius witness, and classifier handoff as one conserved finite ledger.

Next combine the ledger with Definition 464.80. The multiplication-facing consumer can read the product only through the paired source windows, dyadic radius observations, budget rows, classifier row, real-seal handoff, and visible structural rows.

Finally route the same ledger to the completion side through chapter 450. That chapter may consume the finite product-observation surface, while the ledger obligation keeps radius, product, transport, Cont, Pkg, and $\mathsf{NameCert}$ rows displayed and leaves all excluded analytic objects outside the packet. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket ledger obligation`

Theorem 464.90 (CauchyProduct root observation-budget totality)**.** *Let an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet feed an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet. The observation-budget rows are total for the product read precisely on the finite route where every displayed product read carries the paired* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, the* $\mathsf{Real}^{\uparrow}$ *seal, the componentwise* hsame *transports, the displayed* Cont *replays, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *rows:*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, S, H, C, L, N.$$

Equivalently as a certificate condition internal to the packet, a budget row may be read by a $\mathsf{RealObservationBudget}^{\uparrow}$ *consumer only when the product ledger of Definition 464.89 and the budgeted readback boundary of Definition 464.61 display the same product route. The budget contributes no host multiplication, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root observation budget totality`

Proof. First read the product side. The stream seal obligation places the paired $\mathsf{StreamName}^{\uparrow}$ windows, dyadic observations, regular-rational classifier, real seal, transport, replay, provenance, and local naming rows on one displayed product route.

Next read the accounting side. The ledger obligation keeps the radius rows, product row, classifier row, transport rows, continuation rows, provenance, and local NameCert row as one finite surface, so a budget-facing read cannot detach one row and still claim to read the product packet.

Now pass to the budget packet. The budgeted readback root boundary says that a $\mathsf{RealObservationBudget}^{\uparrow}$ consumer reads the same product route through its displayed budget rows. It does not add a second product witness or a hidden real carrier.

Finally use the real classifier obligation. Since the classifier and seal are reached only through the finite product route, totality of the budget rows is exactly coverage of every displayed product read by those same rows. The excluded analytic objects have no coordinate in either packet. □

Theorem 464.91 (CauchyProduct downstream unblock)**.** *Downstream* $\mathsf{RealAlgOrder}^{\uparrow}$ *and* $\mathsf{RealCompleteness}^{\uparrow}$ *consumers of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet receive only the finite product-observation surface*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

When an observation-budget packet is present, they may also read the displayed budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

They receive no host multiplication, quotient stream, selected limit, trichotomy row, independent real carrier, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket downstream unblock`

Proof. Begin with Definition 464.85. It states that every downstream L10 consumer factors through the paired windows, dyadic product route, radius ledger, regular-rational readback, real seal row, and local naming rows.

For the order-facing side, apply Definition 464.80 and Definition 464.81. The $\mathsf{RealAlgOrder}^{\uparrow}$ consumer sees a covered finite product observation, not a host multiplication primitive or quotient-stream comparison.

For the completion-facing side, read chapter 450 through the same product surface. The completion route may consume the finite product rows and, when present, the observation-budget rows named by Definition 464.61; it has no coordinate for selected limits, trichotomy, independent real carriers, or ambient completeness beyond the displayed packet. □

Corollary 464.92 (CauchyProduct shared-window root strict local obstruction)**.** *Let* $Z = (X, Y, W_X, W_Y, M_X, M_Y$ *be an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *root formation packet. Suppose a displayed failure, refusal, separation, or countermodel row in the root-unblock obligations is cited against a named converse or reuse route for the shared-window root admission surface of Definition 464.57. Then the cited row is a strict local obstruction. It blocks only the named route whose consumer-facing read tries to omit, replace, detach, or bypass one of the displayed root coordinates*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

or one of the displayed support rows hsame, Cont, Pkg, NameCert, *together with any explicitly displayed* $\mathsf{RealObservationBudget}^{\uparrow}$ *rows serving the same read. Every permitted consumer-facing use factors through those rows and rejects unlisted coordinates. The same cited row cannot be reinterpreted as a global impossibility statement for* $\mathsf{CauchyProduct}^{\uparrow}$*, as a host theorem about multiplication or completion, as hidden external validation, as a quotient-stream argument, as a selected-limit argument, as a trichotomy row, as an independent real carrier, as an ambient completeness principle, or as an unbounded selector route.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket shared window root strict obstruction`

Proof. First apply Definition 464.57. It admits a root-facing product route only through the paired $\mathsf{StreamName}^{\uparrow}$ windows, the $\mathsf{DyadicRatCore}^{\uparrow}$ observations, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, the $\mathsf{Real}^{\uparrow}$ seal, and the support rows hsame, Cont, Pkg, and $\mathsf{NameCert}$. Thus any consumer-facing use of a cited obstruction must first be located on the finite admitted root surface

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

In particular, a route that still factors through these displayed rows is not rejected by the corollary; only a named converse or reuse request that leaves the displayed surface has a challenged coordinate.

Next apply Definition 464.59. It states that every exported product route is confined to paired finite windows, dyadic observations, product-observation rows, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier, the $\mathsf{Real}^{\uparrow}$ seal, displayed transport, displayed continuation, package provenance, local naming, and any explicitly displayed $\mathsf{RealObservationBudget}^{\uparrow}$ rows. It also excludes quotient streams, host real multiplication, ambient completeness, selected limits, trichotomy rows, independent real carriers, and unbounded selector rows from the exported root formation packet.

Now inspect the cited failure, refusal, separation, or countermodel row. If the named converse or reuse route tries to omit the paired windows, replace the dyadic observations, detach the product row from the classifier and seal, bypass H, C, L, N, or reuse the support rows away from hsame, Cont, Pkg, and $\mathsf{NameCert}$, the cited row blocks exactly that local request. If the same row is read instead as a global impossibility, a host theorem, hidden external validation, a quotient-stream route, a selected-limit route, a trichotomy route, an independent real carrier, an ambient completeness principle, or an unbounded selector route, then Definition 464.59 supplies no coordinate through which that reading can be exported.

Therefore the obstruction has exactly the force of a strict local block against the named converse or reuse route. It factors every permitted consumer-facing use through the displayed shared-window root inventory and rejects every unlisted coordinate without asserting any global, host-level, or hidden validation claim. □

Theorem 464.93 (CauchyProduct observation-budget triangle)**.** *Any accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *product observation consumed through a* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet factors through the triangle whose sides are the paired* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, the* $\mathsf{Real}^{\uparrow}$ *seal row, and the product and budget rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

The source side is the admission route of Definition 464.82; the classifier side is the stability route of Definition 464.83; and the budget side is the finite readback boundary of Definition 464.61.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket observation budget triangle`

Proof. First read the product packet through Definition 464.82. The two $\mathsf{RegularCauchyName}^{\uparrow}$ source rows are visible only through the paired $\mathsf{StreamName}^{\uparrow}$ windows and the $\mathsf{DyadicRatCore}^{\uparrow}$ observation rows, so the product row P has no source-facing route outside the displayed finite window surface.

Next transport that surface through Definition 464.83. The classifier row E, the $\mathsf{Real}^{\uparrow}$ seal row, and the displayed hsame, Cont, Pkg, and NameCert rows preserve the same finite product packet rather than replacing it by a quotient stream or host product.

Finally enter the observation budget through Definition 464.61. The budget rows $E_B, W_B, D_B, R_B, S_B, H_B, C_B$, read the same product packet, so the accepted observation is routed through the stated triangle of source windows, dyadic observations, classifier and seal rows, and budget rows. □

Theorem 464.94 (CauchyProduct RealAlgOrder Completion handoff)**.** *Every* $\mathsf{RealAlgOrder}^{\uparrow}$ *multiplication consumer and every* $\mathsf{RealCompleteness}^{\uparrow}$ *completion-facing consumer that reads an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet receives the same finite product-budget route. The shared route is the phase handoff of Definition 464.85 with the ledger obligation of Definition 464.89, read by the downstream chapters chapter 766 and chapter 450.*

Proof. Begin with Definition 464.85. It places every downstream L10 product consumer behind the paired source windows, dyadic observations, product row, classifier row, real seal row, displayed transports, continuations, package provenance, and local naming evidence.

Now apply Definition 464.89. The ledger route keeps the radius rows, product-radius accounting, and product classifier visible as finite packet data, so the handoff does not create a second multiplication surface for $\mathsf{RealAlgOrder}^{\uparrow}$ or a selected limit surface for $\mathsf{RealCompleteness}^{\uparrow}$.

The two downstream chapters then consume the same row inventory. The $\mathsf{RealAlgOrder}^{\uparrow}$ chapter may use the packet as its multiplication-facing product route, while the $\mathsf{RealCompleteness}^{\uparrow}$ chapter may use the same route as a completion-facing finite seal input; neither receives any coordinate beyond the displayed product and budget rows. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket realalgorder completion handoff`

Theorem 464.95 (CauchyProduct finite product-budget exhaustion)**.** *The union of the product rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and the budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$$

exhausts the downstream L10 consumer surface of an accepted $\mathsf{CauchyProduct}^{\uparrow}$ *packet consumed through* $\mathsf{RealObservationBudget}^{\uparrow}$*. That surface excludes quotient streams, selected limits, host multiplication primitives, trichotomy rows, independent real carriers, and ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket finite product budget exhaustion`

Proof. Read the product side first. The root source admission, classifier stability, and phase handoff theorems make every product-facing consumer pass through $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$ before any downstream real-facing read is available.

Read the budget side next. The observation-budget boundary supplies exactly $E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B$ as the finite consumer rows through which a $\mathsf{RealObservationBudget}^{\uparrow}$ packet may inspect the product.

Combining the two inventories leaves no unused coordinate in the L10 consumer surface. Since quotient streams, selected limits, host multiplication primitives, trichotomy rows, independent real carriers, and ambient completeness are not rows of either packet, they cannot be exported by the accepted product-budget route. □

Theorem 464.96 (CauchyProduct budget-triangle Real seal exhaustion)**.** *Any Real-facing consumer that reads an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet through the observation-budget triangle reaches the* $\mathsf{Real}^{\uparrow}$ *seal only after the paired* $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic observations, product row, classifier row, product ledger, and* $\mathsf{RealObservationBudget}^{\uparrow}$ *rows have all been displayed. The exhausted route is the finite union*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

It exports no quotient stream, selected limit, host multiplication primitive, trichotomy row, independent real carrier, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget triangle real seal exhaustion`

Proof. First compose the triangle of Definition 464.93. It routes the product read through paired source windows, dyadic observations, the product row, classifier row, seal row, and the displayed observation-budget rows.

Next apply the RealAlgOrder and completion handoff of Definition 464.94. The downstream $\mathsf{RealAlgOrder}^{\uparrow}$ and $\mathsf{RealCompleteness}^{\uparrow}$ consumers receive the same finite product-budget route, so the seal is not reached through a separate multiplication or completion surface.

Finally use finite product-budget exhaustion from Definition 464.95. That row inventory accounts for every product and budget coordinate available to the consumer; because quotient streams, selected limits, host multiplication, trichotomy, independent real carriers, and ambient completeness are absent from the inventory, none can be exported by the Real-facing seal route. □

Theorem 464.97 (CauchyProduct budget-triangle selector compatibility)**.** *Any Real-facing consumer that reads an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet through the observation-budget triangle and then through a* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *route factors through the shared finite product rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

the $\mathsf{RealObservationBudget}^{\uparrow}$ *rows*

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B,$$

and the selector rows

$$R, n, \mu, k, W, D, T, S, H, C, P, N.$$

The common seal route is read through the displayed $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows, and it exports no quotient stream, selected host limit, countable-choice row, trichotomy row, host multiplication primitive, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget triangle selector compatibility`

Proof. Start with the observation-budget triangle of Definition 464.93. It identifies the product-facing read with the paired $\mathsf{StreamName}^{\uparrow}$ windows, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation rows, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row, the $\mathsf{Real}^{\uparrow}$ seal row, and the displayed product and budget rows.

Next apply finite product-budget exhaustion from Definition 464.95. This accounts for every product and $\mathsf{RealObservationBudget}^{\uparrow}$ coordinate visible to the Real-facing consumer before any selector handoff occurs.

Finally pass to the $\mathsf{DiagonalTailSelector}^{\uparrow}$ route by Definition 697.6. The selector read contributes only the rows $R, n, \mu, k, W, D, T, S, H, C, P, N$ and uses the same $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surface already identified by the product-budget triangle.

Combining the three row inventories gives the stated factorization. Since none of the product, budget, or selector rows contains a quotient stream, selected host limit, countable-choice row, trichotomy row, host multiplication primitive, or ambient completeness coordinate, the common Real seal route cannot export any of those objects. □

Theorem 464.98 (CauchyProduct shared-tail selector factorization)**.** *Let an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet be consumed by a Real-facing route whose paired source windows are served by an accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet and whose seal route then passes through a* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. Then the consumer factors through the product rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

the shared-tail rows

$$R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N,$$

and the selector rows

$$R, n, \mu, k, W, D, T, S, H, C, P, N.$$

The combined route exports no quotient stream, selected host limit, countable-choice row, trichotomy row, host multiplication primitive, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket shared tail selector factorization`

Proof. Start with the product side. Apply Definition 464.97; the Real-facing product read is already confined to the displayed product rows, the observation-budget route, and the $\mathsf{DiagonalTailSelector}^{\uparrow}$ rows.

Next identify the paired source windows used by that product read. The diagonal-consistency route of Definition 464.117 keeps the two source windows on the same finite product packet, so the shared-tail packet may serve the read without replacing it by a host product or a quotient stream.

Now insert the shared-tail modulus surface. By Definition 983.4, every completion-facing Real seal read factors through $M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N$. The paired-window readback and route replay rows keep the sources R_0, R_1 on the same displayed route, so the full shared-tail inventory is $R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N$.

Finally use Definition 983.9 together with the diagonal selector boundary Definition 697.6. The shared threshold cannot be replaced by private thresholds, and the selector contributes only $R, n, \mu, k, W, D, T, S, H, C, P, N$.

Combining the product, shared-tail, and selector inventories gives the stated factorization. Since none of the three finite row lists contains quotient streams, selected host limits, countable-choice rows, trichotomy, host multiplication, or ambient completeness, no Real or completion consumer can obtain such a coordinate from the combined route. □

Lemma 464.99 (CauchyProduct observation-budget downstream coverage)**.** *Every accepted local consumer downstream of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet read through the* $\mathsf{RealObservationBudget}^{\uparrow}$ *observation-budget triangle is exhausted by the finite alternatives, ledgers, and coverage rows already displayed in the triangle file. Concretely, the consumer can read only the product-side rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

the observation-budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B,$$

or the downstream $\mathsf{RealAlgOrder}^{\uparrow}$ *and* $\mathsf{RealCompleteness}^{\uparrow}$ *handoff route carried by the same finite product-budget inventory. Quotient streams, selected product limits, host multiplication primitives, trichotomy rows, independent regular-sequence or real carriers, and ambient completeness witnesses remain outside the accepted BEDC packet.*

Proof. Start with the observation-budget triangle of Definition 464.93. It says that any accepted product observation consumed through $\mathsf{RealObservationBudget}^{\uparrow}$ factors through the paired $\mathsf{StreamName}^{\uparrow}$ windows, the $\mathsf{DyadicRatCore}^{\uparrow}$ observations, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row, the $\mathsf{Real}^{\uparrow}$ seal row, and exactly the displayed product and budget row lists. Thus every local product-facing alternative has already entered one of the listed source-window, dyadic, classifier, seal, product-ledger, or budget-ledger coordinates.

Now pass to downstream consumers by Definition 464.94. A $\mathsf{RealAlgOrder}^{\uparrow}$ multiplication consumer and a $\mathsf{RealCompleteness}^{\uparrow}$ completion-facing consumer receive the same finite product-budget route, namely the phase handoff together with the ledger obligation. Therefore the downstream read does not add a second multiplication surface, a selected completion surface, or an independent real carrier; it only reuses the rows already supplied by the triangle.

Finally apply the finite product-budget exhaustion of Definition 464.95 and the Real seal exhaustion of Definition 464.96. These two coverage statements account for every product, budget, and seal-facing coordinate available to a local consumer. Since quotient streams, selected product limits, host multiplication primitives, trichotomy rows, independent regular-sequence or real carriers, and ambient completeness witnesses occur in none of those inventories, there is no row from which such an excluded alternative can be exported by the accepted BEDC packet. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket observation budget downstream coverage`

Theorem 464.100 (CauchyProduct root source window totality)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, each product read first exposes the two* $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows through the paired* $\mathsf{StreamName}^{\uparrow}$ *windows* W_X, W_Y*. The exposed rows are exactly the finite source-window route named by the carrier, the local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *obligations, the StreamName handoff, the root window obligations, and the shared tail-window surface of chapter 560.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root source window totality`

Proof. Read the carrier of Definition 464.1. Its first source coordinates are X, Y, W_X, W_Y, with the two source rows displayed before the dyadic observations and before the product row.

Apply the NameCert obligations and the StreamName handoff. These force any consumer of the product packet to enter the two sources through W_X, W_Y before it can inspect M_X, M_Y, Q_X, Q_Y, P, or E.

Finally use the root window obligations together with chapter 560. The sibling tail-meet chapter supplies the same finite tail-window consumption pattern, so the product read has no alternate source route outside the paired StreamName windows. □

Theorem 464.101 (CauchyProduct root budget product lock)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, the dyadic product row* P *is locked by the two source modulus rows* M_X, M_Y *and the product budget ledger* L *before the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E *is read. The lock is the finite route supplied by the carrier, the local NameCert obligations, the StreamName handoff, the root window obligations, the root budget obligations, and the budget triangle package.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root budget product lock`

Proof. Start from the paired source-window route. By source-window totality, W_X, W_Y expose the two regular Cauchy sources before the dyadic observations and product row are available.

The root budget obligations then read M_X, M_Y, Q_X, Q_Y, P, L as the budget route into the product classifier. The budget triangle package keeps that route compatible with the downstream product and observation-budget consumers.

Thus E is reached only after P has been formed inside the displayed dyadic core and after L has recorded the two source modulus rows. No consumer can read the classifier through a separate product estimate, radius oracle, quotient stream, selected limit, host multiplication row, or ambient completeness coordinate. □

Theorem 464.102 (CauchyProduct root source-window unblock certificate)**.** *The source-window totality row, the budget product lock row, and the existing root budget triangle rows form the root-unblock certificate consumed by* $\mathsf{Real}^{\uparrow}$*-facing product consumers. The certificate is the finite* $\mathsf{CauchyProduct}^{\uparrow}$ *route from* X, Y *through* $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, L$ *to* E *and then to the displayed* $\mathsf{Real}^{\uparrow}$ *seal handoff; it exports no quotient stream, host multiplication primitive, selected limit, trichotomy row, independent real carrier, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root unblock certificate`

Proof. First assemble the source side. The carrier, NameCert obligations, StreamName handoff, and source-window totality theorem expose the two $\mathsf{RegularCauchyName}^{\uparrow}$ rows only through the paired StreamName windows.

Next assemble the product side. The root window obligations, root budget obligations, and budget product lock route the dyadic product row through the two source modulus rows and the product ledger before the classifier row is read.

Finally hand the joined route to the existing root budget triangle rows and the sibling finite-tail surface of chapter 560. A $\mathsf{Real}^{\uparrow}$-facing product consumer therefore receives exactly the displayed finite route and has no coordinate for any excluded analytic object. □

Theorem 464.103 (CauchyProduct source-window seal consumer exactness)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, any consumer that exports the product as a* $\mathsf{Real}^{\uparrow}$ *seal factors through the finite route*

$$X, Y \to W_X, W_Y \to M_X, M_Y, Q_X, Q_Y, P, L \to E.$$

The factorization is forced by the source-window totality row, the budget product lock row, and the root-unblock certificate. Such a consumer exports no quotient stream, host multiplication primitive, selected limit, trichotomy row, independent real carrier, or ambient completeness witness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket source window seal consumer exactness`

Proof. First apply Definition 464.100. Every product read reaches the two source rows only through the paired $\mathsf{StreamName}^{\uparrow}$ windows W_X, W_Y, so the consumer has no direct source coordinate outside the displayed window route.

Next apply Definition 464.101. The dyadic product row is read through M_X, M_Y, Q_X, Q_Y, P, L before the classifier row E, so the source modulus rows and product ledger are the only budgeted path into the $\mathsf{RegSeqRat}^{\uparrow}$ classifier.

Finally apply Definition 464.102 together with the sibling finite-tail surface of chapter 560. The downstream $\mathsf{Real}^{\uparrow}$-facing seal therefore receives exactly the stated finite route, and the excluded analytic objects have no exported coordinate in the accepted packet. □

Theorem 464.104 (CauchyProduct root source-window admission)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, every product read admits the two source rows* X, Y *only through the paired windows* W_X, W_Y *and the displayed* $\mathsf{StreamName}^{\uparrow}/\mathsf{DyadicRatCore}^{\uparrow}$ *route. The read cannot inspect either source before the window rows, and it cannot replace the window route by a quotient stream, selected product limit, host multiplication primitive, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root source window admission`

Proof. First apply Definition 464.100. It exposes the two $\mathsf{RegularCauchyName}^{\uparrow}$ source rows exactly through the paired $\mathsf{StreamName}^{\uparrow}$ windows W_X, W_Y.

Next apply Definition 464.107. The route from the source rows to the classifier must pass through the displayed dyadic and regular-rational rows, so no source read can enter after the windows have been skipped.

Finally use Definition 464.102. The root certificate excludes quotient streams, selected limits, host multiplication, and ambient completeness from the product route, leaving the paired source-window admission as the only source entry. □

Theorem 464.105 (CauchyProduct window product readback)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, the product row* P *is read back from* M_X, M_Y, Q_X, Q_Y *before the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E *is consumed. The readback is the finite product route through* $X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, L, E$*, not a route through host multiplication or a selected product limit.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductWindowProductReadback`

Proof. Begin with source-window admission. It fixes the source rows behind W_X, W_Y before any modulus, dyadic, product, or classifier row can be read.

Apply Definition 464.101. The dyadic product row P is locked by the source modulus rows M_X, M_Y and the product ledger L before the classifier E is available.

The source-window seal consumer exactness theorem then gives the complete order of the readback into E. Thus P is read from M_X, M_Y, Q_X, Q_Y inside the finite BEDC route, with no host product primitive or selected limit coordinate. □

Theorem 464.106 (CauchyProduct product seal non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet receives only the finite route*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

The consumer obtains no quotient stream, host multiplication primitive, selected limit, trichotomy row, independent real carrier, or ambient completeness witness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket product seal nonescape`

Proof. First use Definition 464.104. It confines the two source rows to the paired StreamName windows and the displayed dyadic route.

Next use Definition 464.105. The product row and classifier are read only after the source modulus and dyadic readback rows have been fixed.

Finally apply Definition 464.103 and Definition 464.102. These results hand the product route to a $\mathsf{Real}^{\uparrow}$-facing seal consumer and exclude quotient streams, host multiplication, selected limits, trichotomy rows, independent real carriers, and ambient completeness from the exported surface. □

Theorem 464.107 (CauchyProduct StreamName-RegSeqRat source lock)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, every product read locks both source rows through the paired* $\mathsf{StreamName}^{\uparrow}$ *windows* W_X, W_Y *before any* $\mathsf{RegSeqRat}^{\uparrow}$ *or dyadic product row is read. The locked route is the finite path*

$$X, Y \to W_X, W_Y \to M_X, M_Y, Q_X, Q_Y, P, L \to E.$$

It exports no unpaired source row, quotient stream, selected product limit, host multiplication primitive, or ambient completeness witness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket streamname regseqrat source lock`

Proof. First use Definition 464.100. It places the two source rows behind the paired $\mathsf{StreamName}^{\uparrow}$ windows, so a product read cannot inspect X or Y independently of W_X, W_Y.

Next apply Definition 464.101. The dyadic product rows and product ledger are read only after the source modulus and dyadic observation rows, and the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E is downstream of that product ledger.

Finally combine the root-unblock certificate with the StreamName-RegSeqRat consumer surfaces of chapter 126 and chapter 301. The route reaching E is exactly the displayed paired-window route, with no coordinate for an alternate source or host product object. □

Theorem 464.108 (CauchyProduct RealTailAgreementSeal handoff)**.** *Any* $\mathsf{Real}^{\uparrow}$*-facing product consumer that compares product tails of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet must pass through the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *route of chapter 699. The comparison consumes the paired source-window lock, the product budget lock, and the root-unblock certificate before it reaches a RealUp seal; it cannot replace that route by a selected host limit, quotient stream, host equality, or ambient completeness row.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real tail agreement handoff`

Proof. Begin with Definition 464.103. A RealUp-facing product seal already factors through the finite route from the two source rows through the paired windows, dyadic observations, product row, ledger, and classifier.

Use Definition 464.107 to make the source side rigid. Both sources are locked through W_X, W_Y before RegSeqRat readback or product rows can be consumed.

Now read the sibling $\mathsf{RealTailAgreementSeal}^{\uparrow}$ chapter. Its paired-window route compares tails only through displayed StreamName windows, dyadic readbacks, agreement rows, and the RealUp handoff. Composing that route with the product root-unblock certificate gives the required product-tail comparison surface.

The excluded alternatives are absent from both packets. Therefore a product-tail consumer reaches the RealUp seal through $\mathsf{RealTailAgreementSeal}^{\uparrow}$ and receives no selected limit, quotient stream, host equality, host multiplication primitive, or ambient completeness witness. □

Theorem 464.109 (CauchyProduct paired-window tail-agreement exhaustion)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, if a product-tail consumer reaches a* $\mathsf{Real}^{\uparrow}$ *seal, then its paired tail-agreement comparison is exhausted by the finite route through* W_X, W_Y*,* M_X, M_Y, Q_X, Q_Y, P, L*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E*, and the sibling* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet. The route is the one supplied by the* $\mathsf{StreamName}^{\uparrow}$ *source lock, the product budget lock, the RealTailAgreementSeal handoff, and the sibling surfaces of chapter 126, chapter 301, and chapter 699. It exports no quotient stream, host multiplication primitive, host equality, selected limit, trichotomy row, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket source window tail agreement exhaustion`

Proof. First apply Definition 464.107. This fixes the two source rows behind the paired $\mathsf{StreamName}^{\uparrow}$ windows W_X, W_Y before any $\mathsf{RegSeqRat}^{\uparrow}$ classifier or product read is available.

Next apply Definition 464.101. The product-tail consumer can reach E only through M_X, M_Y, Q_X, Q_Y, P, L, so the product comparison has no separate budget, product, or classifier route.

Now apply Definition 464.108. The Real-facing tail comparison is handed to the sibling $\mathsf{RealTailAgreementSeal}^{\uparrow}$ packet, whose chapter supplies the displayed paired-window agreement surface.

Finally read the sibling chapters chapter 126, chapter 301, and chapter 699 as the three consumer boundaries. Their surfaces account for the StreamName windows, the regular-rational classifier row, and the RealTailAgreementSeal packet, leaving no coordinate for quotient streams, host multiplication, host equality, selected limits, trichotomy, or ambient completeness. □

Corollary 464.110 (CauchyProduct root source-window strict obstruction)**.** *Let a displayed failure, refusal, separation, or countermodel row be cited against a named root source-window converse or reuse route for an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet. Then that row is a strict local obstruction: it blocks only the named route whose consumer-facing read omits, replaces, detaches, or bypasses one of the displayed finite coordinates*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

Every permitted consumer-facing use of the obstruction factors first through the paired $\mathsf{StreamName}^{\uparrow}$ *source windows* W_X, W_Y *and then through the finite product-seal route named in Definition 464.106. The obstruction has no force as a global impossibility theorem, no force as a host theorem about products or completion, and no force as hidden external validation for any route not displayed by the accepted packet.*

Proof. Start with Definition 464.100. It makes the two $\mathsf{RegularCauchyName}^{\uparrow}$ source rows visible only through the paired $\mathsf{StreamName}^{\uparrow}$ windows W_X, W_Y, and it identifies the exposed source rows with the carrier route, the local $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ obligations, the StreamName handoff, the root window obligations, and the shared finite tail-window surface. Thus any consumer-facing converse or reuse route for root source-window totality must first ask for those paired windows before it can read any downstream product coordinate.

Now apply Definition 464.106. A $\mathsf{Real}^{\uparrow}$ seal consumer receives only the finite route

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

It receives no quotient stream, host multiplication primitive, selected limit, trichotomy row, independent real carrier, or ambient completeness witness. Therefore every consumer-facing use of a displayed failure, refusal, separation, or countermodel row factors through the same finite route: the source part is forced by W_X, W_Y, and the product-seal part is exhausted by $M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$.

Consider the named converse or reuse route against which the displayed row is cited. If the route omits, replaces, detaches, or bypasses one of the listed coordinates, the row blocks that named route exactly at the missing finite coordinate. If the proposed reading instead asks for a quotient stream, host multiplication theorem, selected product limit, trichotomy row, independent real carrier, ambient completeness witness, or external validation channel, the two cited theorems supply no coordinate through which that request can be consumed. Such a request is rejected

because it is unlisted in the accepted packet, not because the displayed row proves a stronger global impossibility.

Hence the obstruction remains local to the named root source-window converse or reuse route. It is a negative certificate for a failed finite packet read, while global impossibility statements, host product theorems, completion principles, and hidden external validation remain outside the exported $\mathsf{CauchyProduct}^{\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root source window strict obstruction`

Theorem 464.111 (CauchyProduct budgeted root source triple)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, the two* $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows, the paired* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius and observation rows form the admitted root source triple for the product classifier. The triple is the finite* BHist *route*

$$(X, Y), \quad (W_X, W_Y), \quad (M_X, M_Y, Q_X, Q_Y)$$

inside the packet

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N),$$

and it reaches the product row and $\mathsf{RegSeqRat}^{\uparrow}$ *classifier only through the displayed* hsame, Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *rows.*

Proof. Project the carrier of Definition 464.1. Its displayed coordinates put the two regular Cauchy source rows, the paired windows, and the dyadic radius and observation rows in one finite packet before the product row P and classifier row E are read.

Apply the root source admission of Definition 464.82 and the root source window totality of Definition 464.100. These rows force every product read to enter through the two source rows and the paired StreamName windows.

Now use the root budget product lock of Definition 464.101. The dyadic observations and radius rows are the budgeted route into P and E, while H, C, L, N carry the displayed transport, continuation, package, and local naming evidence. Coordinate exhaustion leaves no second source route. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budgeted root source triple`

Theorem 464.112 (CauchyProduct window-budget NameCert ledger)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet feeding a product observation into* $\mathsf{RegSeqRat}^{\uparrow}$*, the finite window-budget ledger is the only* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *ledger available to that observation. It is the displayed inventory*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, L, H, C, N$$

together with the $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E *and, when a* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet consumes the read, the budget rows*

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

No separate ledger can feed the product observation into $\mathsf{RegSeqRat}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket window budget namecert ledger`

Proof. First read the product ledger through Definition 464.89. It binds the radius rows, product row, transport rows, continuation rows, package provenance, and local naming row as one finite accounting surface.

Next apply the window-budget composition surface of Definition 464.50. This identifies the path from paired StreamName windows and DyadicRatCore rows to the $\mathsf{RegSeqRat}^{\uparrow}$ classifier E as a single finite route.

Finally use the budgeted product consumer boundary of Definition 464.53. If a budget packet is present, it adds only the displayed budget rows, and those rows read the same product ledger. Thus the NameCert ledger feeding the RegSeqRat observation is exactly the stated inventory. □

Theorem 464.113 (CauchyProduct Real seal root consumer boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing product seal read of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet factors through the displayed* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows of the root package. The consumer boundary is the finite route from the two source rows through the paired windows, dyadic radius and observation rows, product row, ledger, classifier row, and seal handoff; it does not pass through host multiplication, quotient streams, selected limits, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal root consumer boundary`

Proof. Begin with the budgeted root source triple of Definition 464.111. It fixes the source, window, radius, and dyadic observation rows before the product row and classifier can be inspected.

Use the window-budget NameCert ledger of Definition 464.112. The ledger identifies the exact route through P, L, H, C, N and, when present, through the observation-budget rows feeding the same classifier.

Finally apply the Real seal root surface of Definition 464.62 together with the budget-triangle Real seal exhaustion of Definition 464.96. These theorems place every real-facing product seal behind the same finite product and budget rows, so host multiplication, quotient streams, selected limits, and ambient completeness have no consumer coordinate. □

Theorem 464.114 (CauchyProduct root Real seal factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read that consumes an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet factors through the two* $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows, the paired* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows, the dyadic radius and readback rows, the product row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, and the local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *rows. In* BHist *coordinates the read is routed through*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

with each transport witnessed by the displayed hsame *rows, each admissible continuation witnessed by the displayed* Cont *rows, and each package handoff witnessed by the displayed* Pkg *and* NameCert *rows. No* $\mathsf{Real}^{\uparrow}$ *consumer obtains a separate seal factor outside this finite route.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root real seal factorization`

Proof. Start from the budgeted root source triple of Definition 464.111. It supplies the two regular Cauchy sources, the paired finite windows, and the dyadic budget rows before the product and classifier rows can be inspected.

Use the window-budget NameCert ledger of Definition 464.112. The ledger binds P, E, H, C, L, N to the same finite route and records the local NameCert evidence for the product observation.

Finally apply the Real seal root consumer boundary of Definition 464.113. Since that boundary admits only the displayed root package rows for real-facing seal reads, the factorization is exactly the stated BHist, hsame, Cont, Pkg, and NameCert route. □

Theorem 464.115 (CauchyProduct root RegSeqRat classifier lock)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier input used by a product consumer is locked to the paired-window and dyadic-budget route*

$$(W_X, W_Y, M_X, M_Y, Q_X, Q_Y) \longrightarrow P \longrightarrow E.$$

The classifier row E may read the two regular Cauchy source rows only through the displayed paired $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic radius rows, dyadic readback rows, product row,* hsame *transports,* Cont *continuations,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *ledger. It cannot be fed by an alternate product stream, quotient representative, ambient multiplication operation, or selected limit.*

Proof. The budgeted root source triple in Definition 464.111 identifies the only source, window, and dyadic budget coordinates available before P and E are formed.

The window-budget NameCert ledger of Definition 464.112 then ties those coordinates to the product row and classifier row as one local accounting surface. Any classifier input that omits this ledger has no $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ row in the packet.

The Real seal root consumer boundary of Definition 464.113 excludes all non-root analytic routes at the consumer edge. Therefore the $\mathsf{RegSeqRat}^{\uparrow}$ classifier input is locked to the displayed paired-window and dyadic-budget route. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root regseqrat classifier lock`

Theorem 464.116 (CauchyProduct root completion non-escape)**.** *Every completion-facing product consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet remains inside the finite root package route. In particular, the consumer may use only the two regular Cauchy source rows, paired windows, dyadic radius and readback rows, product row,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row,* BHist *route,* hsame *transports,* Cont *continuations,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *rows displayed in the packet. Host multiplication, quotient streams, selected limits, and ambient completeness are not available as consumer witnesses for the product seal.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root completion nonescape certificate`

Proof. Apply the budgeted root source triple of Definition 464.111. It places every product consumer behind the two source rows, paired windows, and dyadic budget rows.

Apply the window-budget NameCert ledger of Definition 464.112. The ledger shows that the product observation and $\mathsf{RegSeqRat}^{\uparrow}$ classifier share the same finite BHist route, transport rows, continuation rows, package provenance, and local naming row.

Apply the Real seal root consumer boundary of Definition 464.113. That boundary already denies host multiplication, quotient streams, selected limits, and ambient completeness at the real-facing seal edge, so a completion-facing consumer has no remaining route by which to escape the displayed root package. □

Theorem 464.117 (CauchyProduct root source diagonal consistency)**.** *Every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *root package presents one diagonal-consistent source route from the two* $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows through the paired* $\mathsf{StreamName}^{\uparrow}$ *finite windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier input, and the* $\mathsf{Real}^{\uparrow}$ *seal. The route is the finite handoff*

$$(X, Y) \to (W_X, W_Y) \to (M_X, M_Y, Q_X, Q_Y) \to P \to E \to \mathsf{Real}^{\uparrow}$$

inside the displayed BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ *rows. It denies host multiplication, quotient streams, selected limits, and ambient completeness as source witnesses for the product seal.*

Proof. Begin with Definition 464.111. It fixes the two source rows, paired StreamName windows, and dyadic budget rows as the only root source triple feeding the product classifier.

Use Definition 464.112. The ledger ties the windows, dyadic observations, product row, classifier row, transport rows, continuation rows, package provenance, and local naming row into one finite accounting surface.

Next apply Definition 464.113 and Definition 464.115. These rows place the Real-facing seal behind the same root package and lock the $\mathsf{RegSeqRat}^{\uparrow}$ classifier input to the paired-window and dyadic-budget route.

Finally use Definition 464.116. Since completion-facing consumers cannot leave the displayed root package, the preceding rows form one diagonal-consistent Real/Completion handoff and no host multiplication, quotient stream, selected limit, or ambient completeness coordinate remains available. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root source diagonal consistency`

Theorem 464.118 (CauchyProduct source-window budget compatibility)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *root package, the source-window route and the product-budget route are compatible on the single finite consumer path*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, L, E, H, C, N.$$

The compatibility composes the root source-window totality, budget product lock, StreamName-RegSeqRat source lock, RealTailAgreementSeal handoff, and root source diagonal consistency. It leaves no route through quotient streams, host multiplication, selected limits, trichotomy, or ambient completeness.

Proof. Start with Definition 464.100. It exposes the two $\mathsf{RegularCauchyName}^{\uparrow}$ source rows only through the paired $\mathsf{StreamName}^{\uparrow}$ windows W_X, W_Y.

Apply Definition 464.101. This places the dyadic rows M_X, M_Y, Q_X, Q_Y, product row P, and budget ledger L before the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row E is read.

Now use Definition 464.107 and Definition 464.117. The source windows and budget rows feed one diagonal-consistent route to E and then to the $\mathsf{Real}^{\uparrow}$ seal.

Finally apply Definition 464.108. The Real-facing handoff consumes the same finite route, so the excluded analytic resources have no coordinate from which to enter the product seal. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket source window budget compatibility`

Theorem 464.119 (CauchyProduct RegSeqRat product budget exhaustion)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier read used by an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *product seal is exhausted by the displayed rows* $X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, L, E, H, C, N$*. In particular, the classifier input is obtained from the paired source windows, dyadic radius and observation rows, product row, and budget ledger, rather than from a quotient stream, a host multiplication primitive, a selected product limit, trichotomy, or ambient completeness.*

Proof. Read the classifier lock in Definition 464.107. It fixes both source rows behind W_X, W_Y before any $\mathsf{RegSeqRat}^{\uparrow}$ or product row can be consumed.

Use Definition 464.101. The lock makes M_X, M_Y, Q_X, Q_Y, P, L the only budget route into E.

Apply Definition 464.118. The compatibility theorem joins the source windows, budget rows, classifier row, and structural rows into one route.

The non-escape part follows from Definition 464.116. Since completion-facing consumers cannot leave the root package, the classifier read is exhausted by the displayed budget route. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket regseqrat product budget exhaustion`

Theorem 464.120 (CauchyProduct Real seal source-budget non-escape)**.** *Any* $\mathsf{Real}^{\uparrow}$*-facing product seal consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet must pass through*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, L, E, H, C, N$$

before exporting the product seal. The route composes the source-window totality, product-budget exhaustion, StreamName-RegSeqRat lock, RealTailAgreementSeal handoff, and root source diagonal consistency; no quotient stream, host multiplication primitive, selected limit, trichotomy row, or ambient completeness witness is exported with the seal.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal source budget nonescape`

Proof. Begin with Definition 464.118. It gives the single finite source-budget path from the two source rows through the paired windows, dyadic rows, product row, budget ledger, classifier row, and structural rows.

Apply Definition 464.119. This exhausts the $\mathsf{RegSeqRat}^{\uparrow}$ classifier input by the same product-budget path.

Next use Definition 464.108. The Real-facing seal comparison consumes the paired-window and product-budget route before reaching the sibling $\mathsf{RealTailAgreementSeal}^{\uparrow}$ surface.

Finally apply Definition 464.117. The Real/Completion handoff is diagonal-consistent inside the displayed root package, so no excluded analytic object can be repacked as a source-budget witness. □

Corollary 464.121 (CauchyProduct budgeted root source strict obstruction)**.** *For an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, any displayed failure, refusal, separation, or countermodel row attached to the budgeted root source triple is a strict local obstruction. It blocks only a proposed converse or reuse route that tries to feed the product classifier, the completion-facing consumer, or the product seal through a coordinate outside the displayed root package*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

Equivalently, the obstructed route is local to the named missing coordinate: an unlisted source reuse, an unlisted window transport, an unlisted dyadic readback, an unlisted classifier handoff, or an unlisted completion consumer witness. The same row cannot be read as a global impossibility theorem, a host multiplication theorem, a quotient-stream theorem, a selected-limit theorem, an ambient-completeness theorem, or hidden external validation of the product construction.

Proof. Start with the budgeted root source triple of Definition 464.111. It identifies the only admitted source data before the product classifier is read: the two $\mathsf{RegularCauchyName}^{\uparrow}$ source rows, the paired $\mathsf{StreamName}^{\uparrow}$ finite-window rows, and the $\mathsf{DyadicRatCore}^{\uparrow}$ radius and observation rows. In packet coordinates this is the finite route

$$(X, Y), \quad (W_X, W_Y), \quad (M_X, M_Y, Q_X, Q_Y)$$

inside

$$Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N).$$

The theorem also fixes the available handoff rows to the displayed hsame, Cont, Pkg, and local $\mathsf{NameCert}_{\mathsf{CauchyProduct}^{\uparrow}}$ data. Thus a proposed converse or reuse route has a consumer-facing coordinate only when it factors through one of those rows.

Now apply Definition 464.116. Every completion-facing product consumer remains inside the same finite root package, and the theorem explicitly denies host multiplication, quotient streams, selected limits, and ambient completeness as consumer witnesses for the product seal. Therefore a displayed failure, refusal, separation, or countermodel row can obstruct only the attempted escape from that package: it marks that the named converse or reuse route has no listed source, transport, readback, classifier, or completion-consumer coordinate.

The obstruction is strict because the accepted packet still retains the admitted root source triple and the finite classifier route supplied by Definition 464.111. The obstruction is local because Definition 464.116 exhausts the consumer surface by the displayed rows and rejects only unlisted coordinates. Reading the same row as a global impossibility, host theorem, quotient-stream theorem, selected-limit theorem, ambient-completeness theorem, or hidden external validation would add a witness outside the packet inventory, contradicting the non-escape boundary just cited. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budgeted root source strict obstruction`

Theorem 464.122 (CauchyProduct source-window bilinear synchronization)**.** *For every accepted* CauchyProduct$^{\uparrow}$ *packet, the paired source windows from* StreamName$^{\uparrow}$ *synchronize the two* RegularCauchyName$^{\uparrow}$ *inputs before any product row is read. Concretely, every product observation must first factor through the finite source route*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y$$

over the sibling carriers of chapter 126 and chapter 291. The row P is therefore a bilinear readback from the displayed pair of regular-Cauchy source windows, not a host multiplication primitive, selected limit, quotient stream, or ambient product operation.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket source window bilinear synchronization`

Proof. Start with the root source admission theorem Definition 464.82. It places the two RegularCauchyName$^{\uparrow}$ source rows and the paired StreamName$^{\uparrow}$ windows inside the same finite BHist surface.

Next use the radius budget conservation theorem Definition 464.66. The dyadic rows from chapter 291 attach the source windows to the product-radius ledger before P can be inspected.

The sibling regular-rational and real chapters, chapter 301 and chapter 38, then consume only that displayed route. Since the route has no coordinate for host multiplication or quotient streams, the product row is synchronized by the paired windows before any downstream read. □

Theorem 464.123 (CauchyProduct shared budget radius exhaustion)**.** *For every accepted* CauchyProduct$^{\uparrow}$ *packet and every product observation requested by a downstream reader, the shared dyadic radius and budget rows exhaust the product observation before the* RegSeqRat$^{\uparrow}$ *classifier and* Real$^{\uparrow}$ *seal are consumed. The only available route is the finite ledger*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the displayed observation-budget rows when such a budget packet is present. No second radius source, hidden selector, selected limit, quotient stream, host multiplication estimate, or ambient completeness row can feed the classifier after this ledger has been consumed.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket shared budget radius exhaustion`

Proof. Read the conservation surface through Definition 464.66. It identifies the paired source radii, dyadic product observations, product row, and classifier handoff as one finite accounting route.

Apply Definition 464.71. The $\mathsf{RegSeqRat}^{\uparrow}$ classifier is reached only after the displayed product route has been read, and the $\mathsf{Real}^{\uparrow}$ seal is downstream of the same classifier boundary.

Finally combine this with the handoff row Definition 464.94. The order and completion consumers receive the same exhausted ledger rather than a fresh analytic source, so the radius and budget rows close the product observation before the classifier and seal are consumed. □

Theorem 464.124 (CauchyProduct Real-completion consumer lock)**.** *Every* $\mathsf{RealCompleteness}^{\uparrow}$ *or* $\mathsf{RealAlgOrder}^{\uparrow}$ *product consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet is locked to the same finite route*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and, when present, to the same finite observation-budget rows. Such a consumer cannot import quotient streams, selected limits, host multiplication, trichotomy, independent real carriers, or ambient completeness as an alternative source for the product seal.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real completion consumer lock`

Proof. First use source-window synchronization from Definition 464.122. It fixes the paired $\mathsf{RegularCauchyName}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ source surface before the product row is read.

Next apply shared budget radius exhaustion from Definition 464.123. The $\mathsf{RegSeqRat}^{\uparrow}$ classifier and $\mathsf{Real}^{\uparrow}$ seal are reached only through the conserved dyadic radius and product-budget ledger.

Now read the consumer handoff through Definition 464.94 together with the sibling surfaces chapter 301 and chapter 38. The $\mathsf{RealAlgOrder}^{\uparrow}$ and $\mathsf{RealCompleteness}^{\uparrow}$ consumers therefore receive exactly the finite route already displayed by the product packet, and no excluded analytic object has a coordinate from which it could be imported. □

Theorem 464.125 (CauchyProduct finite-window real-seal factorization)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet consumed through an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet, the resulting* $\mathsf{Real}^{\uparrow}$ *seal factors through exactly the paired source windows* W_X, W_Y*, dyadic rows* Q_X, Q_Y*, radius rows* M_X, M_Y*, product row* P*, classifier row* E*, product ledger* L*, and the budget rows*

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

The factorization also contains the two source rows X, Y *that feed the paired windows. No quotient stream, selected limit, host multiplication, trichotomy row, independent real carrier, or ambient completeness coordinate can enter the product seal.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket finite window real seal factorization`

Proof. Start with source-window synchronization from Definition 464.122. It fixes the source rows X, Y and the paired finite windows W_X, W_Y before the product row is read.

Apply shared budget radius exhaustion from Definition 464.123. The only product-side route to the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and $\mathsf{Real}^{\uparrow}$ seal passes through $M_X, M_Y, Q_X, Q_Y, P, E, L$, so the product packet supplies no separate selector, quotient stream, or host multiplication coordinate.

Now attach the observation-budget carrier. Window coverage in Definition 611.3 sends every budget dyadic readback and displayed radius through E_B, W_B, D_B, while the real-seal boundary theorem Definition 611.5 makes S_B the completion-facing boundary reached through R_B, H_B, C_B, P_B, N_B.

Finally combine the consumer lock Definition 464.124 with budget non-escape Definition 611.6. The consumer receives the product seal only through the two displayed finite ledgers, and every excluded analytic object lacks a row on either side of the factorization. □

Theorem 464.126 (CauchyProduct synchronized source-window downstream coverage)**.** *For every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, every accepted local downstream consumer of its product observation is covered by the finite source-window and budget surface displayed in this file. More explicitly, before such a consumer can read the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, the* $\mathsf{Real}^{\uparrow}$ *seal, a* $\mathsf{RealAlgOrder}^{\uparrow}$ *product-order row, a* $\mathsf{RealCompleteness}^{\uparrow}$ *completion row, or an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *observation row, its route has been exhausted by the source rows*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y,$$

the product ledger

$$P, E, H, C, L, N,$$

and, when a budget packet is present, the budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

Consequently the local consumer has no remaining BEDC coordinate for a second radius source, hidden selector, selected limit, quotient stream, host multiplication estimate, trichotomy branch, independent real carrier, or ambient completeness row.

Proof. Start with source-window bilinear synchronization from Definition 464.122. It forces every product observation to enter through the two source rows X, Y, the paired finite windows W_X, W_Y, the paired radius rows M_X, M_Y, and the dyadic observation rows Q_X, Q_Y before the product row P is read. Thus no downstream consumer can begin from host multiplication, quotient-stream comparison, a selected limit, or an ambient product operation.

Next apply shared budget radius exhaustion from Definition 464.123. Once the product observation is requested, the finite ledger

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

exhausts the route to the $\mathsf{RegSeqRat}^{\uparrow}$ classifier and the $\mathsf{Real}^{\uparrow}$ seal, with the displayed observation-budget rows attached when such a budget packet is present. This accounts for the possible local alternatives: the classifier-facing read, the seal-facing read, and the budget-facing read are all rows of the same finite packet.

Now read the local completion and budget consumers through Definition 464.124 and Definition 464.125. The first theorem locks every $\mathsf{RealAlgOrder}^{\uparrow}$ or $\mathsf{RealCompleteness}^{\uparrow}$ product consumer to the displayed product ledger, and the second theorem identifies the budgeted seal factorization through

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B.$$

Therefore every accepted local downstream consumer is exhausted by one of the enumerated source, ledger, or budget rows. The excluded alternatives are not delayed choices inside the packet; they have no row in the synchronized source surface, no row in the shared radius ledger, and no row in the budgeted seal factorization, so they remain outside the BEDC packet. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket source window downstream coverage`

Theorem 464.127 (CauchyProduct budget route package)**.** *Let* $Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C$ *be an accepted* CauchyProduct$^{\uparrow}$ *packet. Suppose its product is read together with an accepted* FiniteCauchyApproximation$^{\uparrow}$ *finite-approximation packet and an accepted* RealObservationBudget$^{\uparrow}$ *observation-budget packet over the displayed* StreamName$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*,* DyadicRatCore$^{\uparrow}$*,* Real$^{\uparrow}$*, and* CauchyLimitSeal$^{\uparrow}$ *rows. Then these packets assemble one finite product budget route*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

with the finite approximation rows and the observation-budget rows

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$$

over BHist*,* hsame*,* Cont*,* Pkg*, and the local* NameCert *evidence. The assembled route is the one consumed by* Real$^{\uparrow}$ *and completion-facing Cauchy readers; it is not a loose union of separate budget lemmas.*

Proof. Begin with the CauchyProduct side. The obligation closure of Definition 464.47, the window-budget composition surface of Definition 464.50, and the root product readiness package of Definition 464.52 bind the paired StreamName$^{\uparrow}$ windows, DyadicRatCore$^{\uparrow}$ observations, product row, classifier row, Real seal row, transport rows, continuation rows, package provenance, ledger row, and local certificate row into one finite packet.

Attach the root-unblock and triangle rows next. The source-window unblock certificate of Definition 464.102, the observation-budget triangle of Definition 464.93, and the RealAlgOrder Completion handoff of Definition 464.94 identify the same product route as the route read by downstream Real and completion-facing consumers.

Now add the finite approximation and observation-budget chapters. The accepted FiniteCauchyApproximation$^{\uparrow}$ packet is read through chapter 601, and the accepted RealObservationBudget$^{\uparrow}$ packet is read through chapter 611. These chapters supply the finite approximation, precision, finite-window, dyadic-readback, regular-sequence, real-seal, transport, continuation, provenance, and local naming rows that match the product route.

The joined package is therefore a single route over the displayed kernel objects. Since every cited surface is finite and row-exhaustive, the assembled package exports only the listed product, finite-approximation, observation-budget, transport, continuation, provenance, and certificate rows. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget route package`

Theorem 464.128 (CauchyProduct componentwise window admission)**.** *For an accepted* CauchyProduct$^{\uparrow}$ *packet* Z*, the left and right product windows are admitted componentwise through the displayed* StreamName$^{\uparrow}$ *rows* W_X, W_Y *and the displayed* RegSeqRat$^{\uparrow}$ *route to* E *before any product seal is read. The admission proceeds through the finite window rows, dyadic rows, product row, product-radius ledger,* hsame *transports,* Cont *continuations,* Pkg *provenance, and local* NameCert$_{\text{CauchyProduct}^{\uparrow}}$ *row, with the observation-budget rows attached only after the componentwise source windows have been exposed.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket componentwise window admission`

Proof. First read the source windows. The paired-window source admission of Definition 464.11, the StreamName handoff of Definition 464.20, and the root source window totality of Definition 464.100 expose W_X, W_Y componentwise before the dyadic observations and product row are visible.

Next route the componentwise windows into the classifier. The budget product lock of Definition 464.101, the root RegSeqRat classifier lock of Definition 464.115, and the budget RegSeq classifier lock of Definition 464.54 send the displayed window, dyadic, product, and ledger rows to E as a finite $\mathsf{RegSeqRat}^{\uparrow}$ route.

Finally attach the real-facing boundary. The Real seal root consumer boundary of Definition 464.113 and the finite-window real-seal factorization of Definition 464.125 place every seal read after the componentwise window route. Thus the product seal can read only after the left and right windows have already entered through the displayed $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ rows. □

Theorem 464.129 (CauchyProduct Real handoff non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of the product budget route assembled in Definition 464.127 receives only the displayed product rows, finite-approximation rows, observation-budget rows, transport rows, continuation rows, provenance rows, and local* NameCert *rows. The handoff supplies no quotient stream, selected real value, host metric, host multiplication primitive, trichotomy row, independent real carrier, ambient completeness principle, or external Cauchy-limit principle.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real handoff nonescape`

Proof. Start from the product non-escape rows. The window product nonescape of Definition 464.56, the RegSeq seal non-escape of Definition 464.71, and the root completion non-escape of Definition 464.116 rule out quotient streams, selected limits, host multiplication, independent real carriers, and ambient completeness inside the accepted $\mathsf{CauchyProduct}^{\uparrow}$ packet.

Read the budget and real-facing handoff through the route package. The finite product-budget exhaustion of Definition 464.95, the budget-triangle Real seal exhaustion of Definition 464.96, and the finite-window real-seal factorization of Definition 464.125 list every product and observation-budget row visible to the consumer.

Finally compose with the completion-facing sibling surfaces. The finite approximation chapter chapter 601 and the CauchyLimitSeal chapter chapter 386 consume the same displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows. Because neither side contributes a quotient stream, selected real value, host metric, ambient completeness principle, or external Cauchy-limit principle, the Real and seal handoff remains inside the displayed finite route. □

Theorem 464.130 (CauchyProduct public budget route export)**.** *Every public* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, or completion-facing read of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *budget route factors through the assembled* $\mathsf{CauchyProduct}^{\uparrow}$ *rows, the* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet, the* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet, and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary named by Definition 464.127, Definition 464.128, and Definition 464.129. The public export supplies the finite product route and its admitted componentwise windows, but it exports no quotient stream, selected real value, host multiplication primitive, trichotomy row, or independent completeness principle.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket public budget route export`

Proof. Use the budget route package first. Definition 464.127 assembles the product rows with the finite-approximation and observation-budget packets over the displayed BHist, hsame, Cont, Pkg, and local NameCert evidence.

Next expose the componentwise admission surface. Definition 464.128 forces the $\mathsf{StreamName}^{\uparrow}$ rows and the $\mathsf{RegSeqRat}^{\uparrow}$ entry into the route before any product seal is read, so a public reader receives the product boundary through those displayed windows.

Finally apply the handoff non-escape row. Definition 464.129 states that the $\mathsf{Real}^{\uparrow}$ and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumers of the assembled route receive only the listed product, finite-approximation, observation-budget, transport, continuation, provenance, and certificate rows. The same exclusions rule out quotient streams, selected real values, host multiplication primitives, trichotomy rows, and independent completeness principles from the public export. □

Corollary 464.131 (CauchyProduct budget route strict local obstruction)**.** *Let $Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X$ be an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet. Let $F = (R_F, n_F, k_F, W_F, D_F, E_F, S_F, H_F, C_F, P_F, N_F)$ be the accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet serving the same finite product read, and let $B = (E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B)$ be the accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet on the same route. Suppose a displayed failure, refusal, separation, or countermodel row is cited against a named converse or reuse route for the product budget package of Definition 464.127. Then that row is a strict local obstruction: it blocks only the named route whose consumer-facing read tries to omit, replace, detach, or bypass one of the displayed coordinates*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

$$R_F, n_F, k_F, W_F, D_F, E_F, S_F, H_F, C_F, P_F, N_F,$$

$$E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B,$$

together with the displayed BHist, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *support rows. The same row cannot be reinterpreted as a global impossibility statement for* $\mathsf{CauchyProduct}^{\uparrow}$, *as a host theorem about multiplication or completion, as an external validation channel, as a quotient-stream argument, as a selected real value, as a host metric, as a trichotomy row, as an independent real carrier, as an ambient completeness principle, or as an external Cauchy-limit principle.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget route strict obstruction`

Proof. First apply the budget route package of Definition 464.127. It assembles the accepted $\mathsf{CauchyProduct}^{\uparrow}$ packet with the accepted finite-approximation and observation-budget packets into one finite product budget route. On the product side the route displays the source rows, paired windows, modulus rows, dyadic readbacks, product row, classifier row, real-seal support, transports, continuations, ledger, provenance, and local naming evidence. On the auxiliary sides it displays the finite approximation rows of F and the observation-budget rows of B. Thus a consumer-facing converse or reuse route has no first read except through these displayed packet coordinates.

Next apply the Real handoff non-escape theorem, Definition 464.129. Every $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer of the assembled route receives only the displayed product rows, finite-approximation rows, observation-budget rows, transport rows, continuation rows, provenance rows, and local $\mathsf{NameCert}$ rows. In particular, quotient streams, selected real values, host metrics, host multiplication primitives, trichotomy rows, independent real carriers, ambient completeness principles, and external Cauchy-limit principles are not exported coordinates of the handoff.

Now consider the cited failure, refusal, separation, or countermodel row. If the named converse or reuse route asks to omit, replace, detach, or bypass one of the displayed product, finite-approximation, observation-budget, transport, continuation, provenance, ledger, or local naming coordinates, the cited row blocks exactly that request at the challenged coordinate of the accepted package. If the route instead asks for a global impossibility statement, a host theorem, an external validation channel, a quotient stream, a selected real value, a host metric, a trichotomy row, an

independent real carrier, an ambient completeness principle, or an external Cauchy-limit principle, Definition 464.129 gives no coordinate through which such a request can be read.

Therefore every permitted consumer-facing use of the obstruction factors through the displayed finite route, and every unlisted coordinate is rejected as outside the accepted $\mathsf{CauchyProduct}^{\uparrow}$ budget route package. The obstruction is strict and local to the named converse or reuse route, and it asserts nothing beyond the displayed package. □

Theorem 464.132 (CauchyProduct budget-selector distributive lock)**.** *Let $Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y$ be an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet. Suppose the two factor-window reads W_X and W_Y are consumed through the same accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *finite observation-budget selector from chapter 782. Then the product read has a single displayed budget route*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the selector rows

$$B, S, W, D, R, E_B, H_B, C_B, P_B, N_B.$$

The route is distributive only as a finite BHist *product-route certificate: it distributes the same selector window over the two displayed factor windows and then reads the product through the existing* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and local* NameCert *rows. It does not expose host multiplication, quotient stream equality, selected limits, independent real carriers, trichotomy rows, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget selector distributive lock`

Proof. Begin with the two source windows. By Definition 464.56, the only route from the source names to the product observation passes through $W_X, W_Y, M_X, M_Y, Q_X, Q_Y$ and the product ledger before P is visible.

Now read both factor windows through the common finite observation-budget selector of chapter 782. The selector contributes one finite schedule, one finite window family, one dyadic ledger, one regular handoff, one seal row, and one set of transport, continuation, provenance, and local naming rows; it does not create separate selector routes for the two factors.

Finally apply Definition 464.53. The product consumer can inspect exactly the displayed product rows together with the displayed budget rows, so the two factor-window reads and the product read are locked to one finite route. The excluded analytic objects are absent from both accepted packets, hence they cannot enter the distributive product-route certificate. □

Theorem 464.133 (CauchyProduct commuted-budget route)**.** *Let $Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H$ be an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet whose two factor-window reads are accepted by the same finite observation-budget selector from chapter 782. If the packet is read after swapping W_X with W_Y and swapping the dyadic product inputs, then the same finite product-budget route reaches the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row and the* $\mathsf{Real}^{\uparrow}$ *seal. The commuted route is preserved by componentwise* $\mathsf{StreamName}^{\uparrow}$ *handoff,* $\mathsf{DyadicRatCore}^{\uparrow}$ *product-row symmetry,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and* $\mathsf{Real}^{\uparrow}$ *seal non-escape; it does not claim host multiplication or completed-real commutativity.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket commuted budget route`

Proof. First expose the original finite route. The root source-window totality and Definition 464.132 bind both factor windows to the same displayed selector route before the product row is available.

Next commute the source read. Swapping the two factor windows only exchanges the componentwise $\mathsf{StreamName}^{\uparrow}$ handoffs, and the dyadic product row is read through the symmetric $\mathsf{DyadicRatCore}^{\uparrow}$ product observation rather than through host multiplication.

Finally reuse the downstream budget boundary. The root budget product lock and Definition 464.134 keep the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and $\mathsf{Real}^{\uparrow}$ seal downstream of the same finite budget rows. Thus the commuted packet reaches the same classifier and seal route while excluding host multiplication and completed-real commutativity. □

Theorem 464.134 (CauchyProduct Real budget multiplication boundary)**.** *A* $\mathsf{Real}^{\uparrow}$ *multiplication-facing seal for an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet is reached only after the shared* $\mathsf{StreamName}^{\uparrow}$ *factor windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and the local* $\mathsf{CauchyProduct}^{\uparrow}$ $\mathsf{NameCert}$ *rows have all been displayed. If the factor windows are read through the finite observation-budget selector of chapter 782, then the multiplication-facing route additionally passes through the selector budget rows before the* $\mathsf{Real}^{\uparrow}$ *seal is consumed. No seal-facing consumer receives a host multiplication primitive, a quotient-stream product, a selected real value, an independent real carrier, or an ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real budget multiplication boundary`

Proof. First expose the CauchyProduct product route. The non-escape statement Definition 464.56 fixes the source-window route, and Definition 464.132 binds any shared selector read to the same finite product-route certificate.

Next pass to the real-facing seal. By Definition 464.55, every $\mathsf{Real}^{\uparrow}$ seal read consumed through a budget packet factors through the displayed budget rows before the seal is available.

The boundary follows by joining that gate with Definition 464.53. The consumer sees the shared $\mathsf{StreamName}^{\uparrow}$ windows, the dyadic radius ledger, the regular-rational handoff, the selector rows, the displayed transports and continuations, the provenance rows, and the local $\mathsf{NameCert}$ rows. There is no remaining coordinate from which a host multiplication primitive or ambient completion principle could be read. □

Theorem 464.135 (CauchyProduct RegSeqRat product seal coverage)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$*-facing product consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet whose factor windows are read through the finite observation-budget selector of chapter 782 is exhausted by the rows displayed in Definition 464.132 and Definition 464.134. In particular, the consumer reads the same source windows, dyadic radius rows, product row, classifier handoff, selector rows, transports, continuations, provenance, and local naming rows before any product seal is exposed, and it receives no additional regular-sequence carrier, quotient stream, selected limit, host multiplication, trichotomy row, independent real carrier, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket regseqrat product seal coverage`

Proof. Start with the RegSeqRat side of the product packet. The window product non-escape theorem Definition 464.56 and the budgeted product consumer boundary Definition 464.53 leave only the displayed product rows and budget rows available to a regular-rational consumer.

Now attach the shared selector route. The distributive lock Definition 464.132 shows that both factor-window reads pass through one selector route rather than two unrelated budget routes.

Finally use the real budget multiplication boundary of Definition 464.134. Any product seal read occurs after the same window, dyadic, classifier, selector, transport, continuation, provenance, and local naming rows. Thus the listed rows exhaust every $\mathsf{RegSeqRat}^{\uparrow}$-facing product consumer, and no unlisted analytic or host-level object remains available. □

Lemma 464.136 (CauchyProduct budget-selector downstream coverage)**.** *Let an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet read its factor windows through the same accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *selector. Every accepted local consumer downstream of the budget-selector distributive route is exhausted by the finite product rows*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and by the selector and coverage rows already displayed in Definition 464.132 and Definition 464.135. Thus a downstream consumer may read only a factor-window alternative, the product ledger and classifier route, the selector schedule and budget ledger, or the transport, continuation, provenance, and local NameCert *coverage rows. Quotient streams, selected product limits, host multiplication primitives, trichotomy rows, independent regular-sequence or real carriers, and ambient completeness witnesses remain outside the accepted BEDC packet.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket budget selector downstream coverage`

Proof. Start with the distributive route. The budget-selector distributive lock of Definition 464.132 says that the two factor-window reads do not create two independent budget paths. They are consumed through one finite selector route, and the product read is therefore carried by the displayed product rows together with the displayed selector rows.

Now pass to downstream consumers. The RegSeqRat product seal coverage theorem Definition 464.135 exhausts every $\mathsf{RegSeqRat}^{\uparrow}$-facing product consumer by the same source windows, dyadic radius rows, product row, classifier handoff, selector rows, transports, continuations, provenance, and local naming rows before any product seal is exposed.

These two cited statements cover the local alternatives. A factor-window consumer is already on the shared selector route, a ledger or classifier consumer is on the displayed product route, and a seal-facing consumer is on the coverage route of Definition 464.135. No fourth coordinate is exported by either packet inventory. Hence every accepted local consumer is exhausted by the enumerated alternatives, ledgers, and coverage rows, while each excluded analytic alternative remains outside the accepted BEDC packet. □

Theorem 464.137 (CauchyProduct root-selector Real-seal exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing product seal read of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet whose factor windows pass through the shared finite observation-budget selector factors through the existing distributive lock, real budget multiplication boundary,* $\mathsf{RegSeqRat}^{\uparrow}$ *product seal coverage,* $\mathsf{DyadicRatCore}^{\uparrow}$ *product rows,* $\mathsf{StreamName}^{\uparrow}$ *windows,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. In particular, the seal-facing route is exhausted by the displayed source windows, dyadic product observations, selector budget rows, regular-sequence handoff rows, componentwise transports, continuation replays, provenance rows, and local names; it exposes no host multiplication primitive, quotient stream equality, selected real value, independent real carrier, trichotomy row, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root selector real seal exhaustion`

Proof. First read the shared selector route. The distributive lock of Definition 464.132 binds both factor windows to one finite observation-budget selector before a product-facing consumer sees the product rows.

Next pass through the real-facing boundary. The real budget multiplication boundary of Definition 464.134 forces every seal-facing read through the stream windows, dyadic radius and product rows, selector budget rows, regular handoff, transports, continuations, provenance, and local naming.

Finally use the RegSeqRat product seal coverage of Definition 464.135. The regular-sequence side and the real-seal side therefore name the same finite route, so a root-selector consumer has no unlisted coordinate from which to read host multiplication, quotient equality, selected limits, order trichotomy, separate real carriers, or ambient completeness. □

Theorem 464.138 (CauchyProduct shared-selector RegSeqRat–Real seal commutation)**.** *Let* $Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N)$ *be an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet whose two factor windows are read through the same* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *route. Then the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier handoff and the* $\mathsf{Real}^{\uparrow}$ *seal handoff commute through one displayed route*

$$\mathsf{StreamName}^{\uparrow},\ \mathsf{DyadicRatCore}^{\uparrow},\ \mathsf{FiniteObservationBudgetSelector}^{\uparrow},\ \mathsf{hsame},\ \mathsf{Cont},\ \mathsf{Pkg},\ \mathsf{NameCert}.$$

Equivalently, every product-facing consumer first sees the same stream names, dyadic product rows, selector budget rows, componentwise transports, continuation replays, provenance rows, and local naming row before either the regular-sequence classifier or the real seal is consumed. The commutation exposes no host multiplication, quotient stream equality, selected limits, trichotomy, independent real carriers, or ambient completeness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket shared selector regseqrat real seal commutation`

Proof. Start from the shared selector route. By Definition 464.132, the two factor windows are not read by unrelated budget packets: they are displayed through the same finite selector rows and the same product-route certificate.

Now pass to the two downstream handoffs. The real-facing side is bounded by Definition 464.134, while the regular-sequence side is exhausted by Definition 464.135. Both statements name the same stream-window, dyadic, selector, transport, continuation, provenance, and local NameCert rows.

Composing these two readings gives the commutation claim. Whichever handoff a consumer cites first, the other handoff is reached only by replaying the same finite rows, so no unlisted host-level product, quotient equality, selected limit, order trichotomy, separate real carrier, or completeness principle can enter the route. □

Theorem 464.139 (CauchyProduct RealSeries shared-selector handoff)**.** *Let* $Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q$ *be an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet, and let* $K = (T, S, W, Q, D, M, E_R, H_R, C_R, P_R, N_R)$ *be an accepted* $\mathsf{RealSeries}^{\uparrow}$ *packet. Suppose the product factor windows of* Z *and the series tail windows of* K *are consumed through the same finite observation-budget selector from chapter 782. Then the product-facing* $\mathsf{Real}^{\uparrow}$ *seal of* Z *and the series endpoint seal of* K *read the same* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, selector budget rows,* hsame *transports,* Cont *replay,* Pkg *provenance, and local* NameCert *rows before either handoff is exposed.*

The handoff is a finite shared-selector route. It excludes host multiplication, selected infinite sums, quotient stream equality, countable choice, detached real carriers, and ambient $\mathsf{Real}^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket realseries shared selector handoff`

Proof. Start with the CauchyProduct side. The shared-selector commutation theorem Definition 464.138 places the product-facing regular handoff and real seal on one route through the stream windows, dyadic product rows, selector rows, transports, continuations, provenance, and local names.

Now read the RealSeries side through Definition 1581.13 and Definition 1581.37. These results make the finite-tail consumer surface visible only through partial-sum windows, selected $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{RegSeqRat}^{\uparrow}$ readback, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, the shared tail threshold, the endpoint seal, and the structural rows.

The common selector hypothesis identifies the selector budget rows used by the product windows with the selector budget rows used by the series tail windows. Apply Definition 464.132 to lock the product windows to that selector, Definition 464.135 to keep the regular product handoff on the same route, and Definition 464.134 to place the product seal after the same budget ledger.

Finally use the RealSeries endpoint route Definition 1581.40. The endpoint seal of K is downstream of the same finite tail windows, regular readback, dyadic ledger, threshold, transports, continuations, provenance, and local names. Since neither accepted packet contains host multiplication, an infinite-sum selector, quotient stream equality, countable choice, a detached real carrier, or ambient completeness data, the shared-selector handoff exposes none of those objects. □

Theorem 464.140 (CauchyProduct shared-selector budget totality)**.** *Let $Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y,$ be an accepted $\mathsf{CauchyProduct}^{\uparrow}$ packet, and let $K = (T, S, W, Q, D, M, E_R, H_R, C_R, P_R, N_R)$ be an accepted $\mathsf{RealSeries}^{\uparrow}$ packet. Suppose the product factor windows of Z and the series tail windows of K are consumed through one accepted $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ route*

$$B, S_B, W_B, D_B, R_B, E_B, H_B, C_B, P_B, N_B.$$

Then every product-facing or series-facing consumer that reaches a $\mathsf{Real}^{\uparrow}$ endpoint must read the displayed CauchyProduct rows, the selector rows, the $\mathsf{StreamName}^{\uparrow}$ window rows, the $\mathsf{DyadicRatCore}^{\uparrow}$ product and tolerance observations, the $\mathsf{RegSeqRat}^{\uparrow}$ handoff rows, the RealSeries endpoint route, the componentwise hsame *transports, displayed* Cont *replays,* Pkg *provenance rows, and local* NameCert *rows. No remaining endpoint route is available outside this finite budget.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket shared selector budget totality`

Proof. First use the distributive lock Definition 464.132. It binds the two CauchyProduct factor windows to the single selector route before the dyadic product row and regular handoff can be consumed.

Next use the real budget multiplication boundary Definition 464.134. This places every product-facing $\mathsf{Real}^{\uparrow}$ seal downstream of the same stream windows, dyadic product rows, selector ledger, regular handoff, transport, replay, provenance, and local naming rows.

Finally apply the RealSeries shared-selector handoff Definition 464.139. The series endpoint reads the same finite selector route and therefore has no second budget, selected infinite-sum route, quotient stream equality, detached real carrier, or ambient completeness witness. The listed rows exhaust the shared-selector product route. □

Theorem 464.141 (CauchyProduct dyadic product-window inversion)**.** *For an accepted $\mathsf{CauchyProduct}^{\uparrow}$ packet $Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N)$ whose factor windows are consumed through a shared $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ route, any accepted read of the $\mathsf{DyadicRatCore}^{\uparrow}$ product observations Q_X, Q_Y determines the preceding product-window route*

$$W_X, W_Y, M_X, M_Y, Q_X, Q_Y$$

inside the same selector budget. The inversion is only the BEDC packet readback: it recovers the displayed $\mathsf{StreamName}^{\uparrow}$ windows, dyadic product observations, selector rows, $\mathsf{RegSeqRat}^{\uparrow}$ handoff, hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *rows. It does not recover host factors, a quotient stream equality, selected real values, or a parameter-equivalence transport.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket dyadic product window selector certificate`
↪ variant `BEDC.Derived.CauchyProductUp.CauchyProductPacket dyadic product window inversion`

Proof. Start with the window product non-escape theorem used by Definition 464.132. A dyadic product observation in an accepted packet is downstream of the displayed factor windows and radius rows; it is not a detached product token.

Now attach the shared selector. The distributive lock places the factor windows and product observations inside one finite observation-budget selector route. Reading Q_X, Q_Y therefore also reads the selector rows and the same componentwise transports, continuations, provenance, and local names.

Finally use Definition 464.135. The regular-sequence product seal is downstream of exactly these rows, so the inversion recovers only the finite BEDC product-window route. No host factorization, quotient equality, selected real value, or parametric carrier transport is part of the recovered data. □

Theorem 464.142 (CauchyProduct RealSeries budget exhaustion)**.** *Let $Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P$ be an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet and $K = (T, S, W, Q, D, M, E_R, H_R, C_R, P_R, N_R)$ an accepted* $\mathsf{RealSeries}^{\uparrow}$ *packet whose windows are read through the same finite observation-budget selector. The combined product-and-series endpoint route is exhausted by the CauchyProduct displayed rows, the RealSeries tail and endpoint rows, the selector rows,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *product and tolerance observations,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *endpoint seals,* hsame, Cont, Pkg*, and local* NameCert *data. In particular, no consumer can add a second selector, an infinite-sum choice row, host multiplication, quotient stream equality, detached real carrier, trichotomy, or ambient completeness after the shared budget is spent.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real series budget exhaustion`

Proof. First build the product side from the shared-selector budget totality of Definition 464.140. The product-facing route already contains the displayed CauchyProduct rows, selector rows, stream windows, dyadic product observations, regular handoff, and real seal.

Next read the product-window inversion of Definition 464.141. Any dyadic product observation consumed by the route points back to the same factor-window and selector budget, so there is no hidden second window family.

Finally compose with the RealSeries handoff Definition 464.139. The series endpoint seal is downstream of the same finite tail windows, dyadic tolerance ledger, regular readback, transports, continuations, provenance, and local names. Thus the combined route has no coordinate left for a second selector, chosen infinite sum, host multiplication, quotient equality, detached real carrier, order trichotomy, or ambient completeness principle. □

Theorem 464.143 (CauchyProduct root-budget public export)**.** *Let $Z = (X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E,$ be an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet and $K = (T, S, W, Q, D, M, E_R, H_R, C_R, P_R, N_R)$ an accepted* $\mathsf{RealSeries}^{\uparrow}$ *packet whose windows are read through the same finite observation-budget selector. The public export consumed by* $\mathsf{RealSeries}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *seal readers is the single shared-selector route obtained by composing the budget-selector distributive lock, the shared-selector* $\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ *seal commutation, the shared-selector budget totality, and the RealSeries budget exhaustion route. Thus every seal-facing read passes through the displayed CauchyProduct rows, RealSeries tail rows, selector budget rows,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *product and tolerance observations,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *endpoint seals,* hsame, Cont, Pkg*, and local* NameCert *data, with no second selector, host multiplication, quotient stream equality, detached real carrier, trichotomy, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root budget public export`

Proof. First expose the CauchyProduct side. The budget-selector distributive lock of Definition 464.132 binds both factor-window reads to one finite selector route before any product-facing consumer reaches the product rows.

Next pass through the regular and real seal interface. The shared-selector commutation theorem Definition 464.138 places the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and $\mathsf{Real}^{\uparrow}$ seal on the same displayed route.

Now apply shared-selector budget totality from Definition 464.140. It states that product-facing and series-facing endpoint consumers spend the same selector budget and read the same stream, dyadic, transport, replay, provenance, and naming rows.

Finally use Definition 464.142. The RealSeries endpoint route is exhausted by those same rows, so the public export is exactly the shared root-budget route and no unlisted analytic coordinate remains available. □

Theorem 464.144 (CauchyProduct RealSeries selector refinement boundary)**.** *Let $Z = (X, Y, W_X, W_Y, M_X, M_Y,$ be an accepted $\mathsf{CauchyProduct}^{\uparrow}$ packet and $K = (T, S, W, Q, D, M, E_R, H_R, C_R, P_R, N_R)$ an accepted $\mathsf{RealSeries}^{\uparrow}$ packet whose windows pass through one accepted $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ route. Any refinement of the selector budget that preserves the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows preserves both the product-facing $\mathsf{Real}^{\uparrow}$ seal and the series endpoint seal. The refinement exposes no second selector, quotient stream equality, selected infinite sum, host multiplication, detached real carrier, trichotomy, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket realseries selector refinement boundary`

Proof. Start with the budget-selector distributive lock of Definition 464.132. It binds the CauchyProduct factor windows and dyadic product observations to the same finite selector route before either endpoint can be read.

Next use the shared-selector $\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ seal commutation of Definition 464.138. Preserving the displayed stream, dyadic, regular-sequence, real, transport, replay, provenance, and naming rows therefore preserves the product-facing real seal.

Now apply the RealSeries shared-selector handoff of Definition 464.139. The series endpoint consumes the same selector route, so the preserved rows also preserve the series endpoint seal.

Finally use the root-budget public export of Definition 464.143. A selector refinement only replays the same finite rows before either endpoint handoff is consumed, so it has no coordinate for a second selector, quotient stream equality, selected infinite sum, host multiplication, detached real carrier, trichotomy, or ambient completeness. □

Theorem 464.145 (CauchyProduct root regular product carrier row)**.** *For every accepted $\mathsf{CauchyProduct}^{\uparrow}$ packet, the paired $\mathsf{RegularCauchyName}^{\uparrow}$ source rows, paired $\mathsf{StreamName}^{\uparrow}$ finite-window rows, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger rows, and $\mathsf{RegSeqRat}^{\uparrow}$ product classifier row form one finite BHist product carrier row. In displayed coordinates the carrier route is*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

where X, Y are the two regular Cauchy source rows, W_X, W_Y are the paired finite windows, M_X, M_Y, Q_X, Q_Y are the dyadic radius and observation rows, P is the product row, and E is the regular-rational classifier row. The row is local to the product packet and carries no host multiplication, quotient stream, selected limit, independent real carrier, or ambient completeness witness. The windows W_X, W_Y are read through chapter 126, the rows M_X, M_Y, Q_X, Q_Y through chapter 291, the classifier row E through chapter 301, and the seal boundary through chapter 38.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root regular product carrier row`

Proof. Project the accepted carrier of Definition 464.1. Its source coordinates expose X, Y before the paired finite windows W_X, W_Y, and the dyadic rows M_X, M_Y, Q_X, Q_Y are read before the product row.

Use the StreamName handoff and the product-observation seal obligations. They place the product observation P and the classifier E downstream of the displayed finite windows and dyadic ledger rows.

Finally read the support rows. The componentwise hsame rows, displayed Cont routes, Pkg provenance, and local NameCert row keep the whole product route inside one finite BHist carrier row, so none of the excluded analytic objects has an exported coordinate. □

Theorem 464.146 (CauchyProduct root shared-window product classifier)**.** *For every accepted* CauchyProduct$^{\uparrow}$ *packet, the product classifier row E is locked to the paired finite windows W_X, W_Y and to the displayed* hsame *and* Cont *route*

$$W_X, W_Y \to M_X, M_Y, Q_X, Q_Y \to P \to E.$$

Any consumer that reads E must first read the two StreamName$^{\uparrow}$ *windows, the* DyadicRatCore$^{\uparrow}$ *radius and observation rows, and the local support rows H, C, L, N. It cannot feed the classifier from a host multiplication operation, quotient stream product, selected limit, independent real carrier, or ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root shared window product classifier certificate`

Proof. Begin with the carrier row of Definition 464.145. The row lists $W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E$ in the order needed by the product read.

Apply the root source window totality and root budget product lock. These statements force the two finite windows and the dyadic budget rows to be consumed before the product row P and classifier row E are visible.

The displayed hsame and Cont rows then transport the same product route to the local naming surface. Since the accepted packet contains no host multiplication row, quotient stream, selected limit, independent real carrier, or ambient completeness coordinate, the classifier is locked to the finite windows and the displayed route. □

Theorem 464.147 (CauchyProduct root Real seal product ledger)**.** *Any* Real$^{\uparrow}$*-facing product seal read of an accepted* CauchyProduct$^{\uparrow}$ *packet consumes the local* Pkg *and* NameCert *ledger before it reaches the seal. The read factors through*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

uses the product classifier route of Definition 464.146, and then reaches the Real$^{\uparrow}$ *seal only through the displayed product ledger. It cannot use host multiplication, quotient streams, selected limits, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root real seal product ledger certificate`

Proof. First build the product carrier row using Definition 464.145. This supplies the two regular Cauchy sources, paired windows, dyadic ledger rows, product row, classifier row, and support rows as one finite inventory.

Next apply the shared-window product classifier theorem. The classifier row E is already downstream of the paired windows, dyadic observations, product row, and displayed hsame and Cont route.

Finally route the classifier to the Real-facing seal. The local Pkg and NameCert ledger rows L, N are part of the displayed packet before the seal is consumed, and the existing Real seal root boundary excludes host multiplication, quotient streams, selected limits, and ambient completeness from the consumer surface. □

Theorem 464.148 (CauchyProduct root regular product budget seal exhaustion)**.** *Any* Real$^{\uparrow}$*-facing product consumer that uses the root regular product carrier of an accepted* CauchyProduct$^{\uparrow}$ *packet must pass through*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and through the displayed RealObservationBudget$^{\uparrow}$ *and* RegSeqRat$^{\uparrow}$ *seal route before a* Real$^{\uparrow}$ *seal is exposed. The consumer cannot reach the seal from host multiplication, quotient streams, selected limits, an independent real carrier, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root regular product budget seal inventory certificate`

Proof. Begin with the root regular product carrier row. It places the paired regular Cauchy sources, finite windows, dyadic budget rows, product observation, classifier row, transport rows, route rows, package ledger, and local naming row in one finite inventory.

Apply the shared-window product classifier. The classifier E is visible only after the paired windows W_X, W_Y, the dyadic radius and observation rows M_X, M_Y, Q_X, Q_Y, and the product row P have been consumed along the displayed route.

Use the Real seal product ledger for the final boundary. It sends the Real$^{\uparrow}$-facing consumer through the local Pkg and NameCert ledger rows L, N before the seal is visible, and it identifies the exposed seal as the displayed RealObservationBudget$^{\uparrow}$ and RegSeqRat$^{\uparrow}$ route rather than an ambient real object.

The excluded sources have no coordinate in the carrier row. Therefore the Real-facing product seal is exhausted by the displayed budgeted product route. □

Lemma 464.149 (CauchyProduct root regular product downstream coverage)**.** *Every accepted local consumer downstream of the root regular product route of an accepted* CauchyProduct$^{\uparrow}$ *packet is exhausted by the finite alternatives, ledgers, and coverage rows displayed in this file. Concretely, the consumer can read only the carrier and classifier rows*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

the Real$^{\uparrow}$*-facing product ledger through* L, N*, or the displayed* RealObservationBudget$^{\uparrow}$ *and* RegSeqRat$^{\uparrow}$ *seal route attached to the same product inventory. Host multiplication, quotient streams, selected product limits, independent regular-sequence or real carriers, and ambient completeness witnesses remain outside the accepted BEDC packet.*

Proof. Start with the carrier row of Definition 464.145. It displays the whole root regular product packet as one finite BHist inventory: the two RegularCauchyName$^{\uparrow}$ source rows, the paired StreamName$^{\uparrow}$ windows, the dyadic radius and observation rows, the product row, the RegSeqRat$^{\uparrow}$ classifier, and the support rows H, C, L, N. Hence every local consumer first meets one of the listed carrier, window, dyadic, product, classifier, transport, continuation, ledger, or naming coordinates.

The classifier alternatives are then fixed by Definition 464.146. Any read of E must pass through the paired windows, the dyadic rows, the product row P, and the displayed hsame and Cont route. Thus a downstream consumer cannot introduce a second classifier input, a host multiplication operation, a quotient-stream product, or a selected product limit at the classifier stage.

For a seal-facing read, apply Definition 464.147. The $\mathsf{Real}^{\uparrow}$ boundary consumes the local Pkg and NameCert ledger rows before the seal is visible, so the downstream route is still the same finite inventory with L, N as the product ledger.

Finally apply Definition 464.148. It identifies every $\mathsf{Real}^{\uparrow}$-facing product consumer using the root regular product carrier with the displayed $\mathsf{RealObservationBudget}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ seal route, and it excludes host multiplication, quotient streams, selected limits, an independent real carrier, and ambient completeness from the seal surface. Combining the carrier, classifier, ledger, and budget-seal rows accounts for all accepted local downstream reads, while the excluded alternatives occur in no coordinate of the accepted BEDC packet. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root regular product downstream coverage`

Theorem 464.150 (CauchyProduct regular product window exhaustion)**.** *Any* $\mathsf{Real}^{\uparrow}$*-facing product consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet must consume both* $\mathsf{StreamName}^{\uparrow}$ *windows, both* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation and budget rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *product classifier, the local* Pkg *and* NameCert *ledger, and the displayed* $\mathsf{RealObservationBudget}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *seal route before any product read is exported. Equivalently, the consumer factors through*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and then through the budgeted Real seal route. The packet provides no host multiplication, quotient stream product, selected limit, independent real carrier, or ambient completeness coordinate from which a product read could be exported earlier.

Proof. First apply the root regular product carrier row. It supplies the two regular Cauchy sources, the two finite windows, the two dyadic observation and budget pairs, the product row, the classifier row, and the local support rows as one finite inventory.

Next apply the shared-window product classifier. The classifier E is downstream of both windows W_X, W_Y and both dyadic rows M_X, M_Y, Q_X, Q_Y, so no product read can use E before the displayed finite-window route has been consumed.

Finally apply the budget seal exhaustion theorem. That theorem routes every $\mathsf{Real}^{\uparrow}$-facing product consumer through the local Pkg and NameCert ledger and through the displayed $\mathsf{RealObservationBudget}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ seal boundary before the Real seal is visible.

The excluded sources have no coordinate in the carrier row. Hence host multiplication, quotient streams, selected limits, independent real carriers, and ambient completeness are unavailable to the consumer, and the regular product window route is exhaustive. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket regular product window exhaustion`

Theorem 464.151 (Cauchy product regular-tail diagonal window lock)**.** *Let an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet be read by a product-facing consumer through two regular product tails whose finite observations are served by shared* $\mathsf{StreamName}^{\uparrow}$ *windows. Before the consumer can inspect the local* NameCert *row, the read must pass through the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance budget, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the same diagonal-tail selector row, and the same terminal* $\mathsf{Real}^{\uparrow}$ *seal:*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N \longmapsto \mathsf{DiagonalTailSelector}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}.$$

The packet has no alternate route through quotient streams, a selected product limit, host equality, host multiplication, choice, or ambient Real completeness.

Proof. Start with the regular product window exhaustion theorem. It forces every Real-facing product consumer through the paired $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{DyadicRatCore}^{\uparrow}$ observation and budget rows, $\mathsf{RegSeqRat}^{\uparrow}$ classifier, local Pkg and $\mathsf{NameCert}$ ledger, and the displayed Real seal route before any product read is exported.

Next use the root regular product budget separation theorem. The two product tails share the same displayed tolerance budget and readback route, so the consumer cannot split one tail through a second dyadic ledger or an independent regular-rational classifier.

Attach the diagonal selector route using the product budget-triangle selector compatibility and shared-tail selector factorization rows. Those sibling rows identify the $\mathsf{DiagonalTailSelector}^{\uparrow}$ contribution with the same finite StreamName, DyadicRatCore, RegSeqRat, and Real surface already present in the product packet.

Finally compare the route with the $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ seal boundaries. The seal-facing consumer reaches the local $\mathsf{NameCert}$ only after the displayed product inventory, diagonal-tail selector, and Real seal have been read. Since none of the cited rows contains quotient streams, selected limits, host equality, host multiplication, choice data, or ambient completeness, no such coordinate can feed the product-facing consumer. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductRegularTailDiagonalWindowLock`

Theorem 464.152 (CauchyProduct root RealSeries handoff exhaustion)**.** *Every* $\mathsf{CauchyProduct}^{\uparrow}$ *consumer fed by a* $\mathsf{RealSeries}^{\uparrow}$ *root series surface consumes paired* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *budget rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows, the* $\mathsf{RealSeries}^{\uparrow}$ *shared tail threshold, and the local* Pkg *and* $\mathsf{NameCert}$ *ledger before any Real-facing product seal is exported. The visible route factors through the local product inventory*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and through the RealSeries rows

$$T, S, W, Q, D, M, E, H, C, P, N$$

from Definition 1581.19. It has no coordinate for host multiplication, quotient stream product, selected infinite sums, independent real carriers, or ambient completeness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root series handoff exhaustion`

Proof. Begin with the root regular product carrier row. It supplies $X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L,$ as the only product inventory visible to the consumer.

Apply the shared-window product classifier. The classifier row E is downstream of both $\mathsf{StreamName}^{\uparrow}$ windows, the $\mathsf{DyadicRatCore}^{\uparrow}$ budget and observation rows, and the product observation row, so a product read cannot be fed by a host multiplication operation or quotient stream product.

Use the budget seal exhaustion theorem for the Real-facing boundary. It sends every seal read through the local Pkg and $\mathsf{NameCert}$ rows before any $\mathsf{Real}^{\uparrow}$ seal is exported.

Finally apply Definition 1581.19. The RealSeries handoff supplies only the finite rows $T, S, W, Q, D, M, E, H, C,$ with the shared threshold row M already fixed before endpoint sealing. Thus the product consumer receives a finite paired-window route, not a selected infinite sum, independent real carrier, or ambient completeness coordinate. □

Theorem 464.153 (CauchyProduct root regular product public export)**.** *Every public* CauchyProduct$^{\uparrow}$ *export over the root regular-product packet factors through paired* RegularCauchyName$^{\uparrow}$ *sources, paired* StreamName$^{\uparrow}$ *windows,* DyadicRatCore$^{\uparrow}$ *budget rows, the* RegSeqRat$^{\uparrow}$ *product classifier,* RealSeries$^{\uparrow}$ *shared-tail rows, the local* Pkg *and* NameCert *ledger, and the terminal* Real$^{\uparrow}$ *seal route. In displayed coordinates the export consumes*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and the RealSeries$^{\uparrow}$ *rows*

$$T, S, W, Q, D, M, E, H, C, P, N$$

before any public product read is available. The export has no coordinate for host multiplication, quotient streams, selected product limits, independent real carriers, or ambient completeness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root regular product public export`

Proof. First apply the root regular product carrier row. It places the paired RegularCauchyName$^{\uparrow}$ sources, paired finite windows, dyadic budget rows, product observation, classifier row, transport, replay, provenance, and local naming in one finite carrier inventory.

Next use the shared-window product classifier. The classifier row E can be read only after the two StreamName$^{\uparrow}$ windows and the DyadicRatCore$^{\uparrow}$ radius and observation rows have been consumed, so no host multiplication or quotient-stream product can feed the public export.

Then apply the regular product budget seal exhaustion and the Real seal product ledger. Together they route the public read through L, N and through the displayed RegSeqRat$^{\uparrow}$ and Real$^{\uparrow}$ seal boundary before any Real-facing product value is exposed.

Finally use the root RealSeries handoff exhaustion. The shared-tail rows $T, S, W, Q, D, M, E, H, C, P, N$ are the only series-facing input to the product packet, and their threshold row is fixed before endpoint sealing. Combining these carrier, classifier, budget, ledger, and handoff rows gives the public export route and excludes the stated analytic alternatives by field exhaustion. □

Theorem 464.154 (CauchyProduct root regular product budget separation)**.** *Any accepted* CauchyProduct$^{\uparrow}$ *root regular product consumer that reaches a* Real$^{\uparrow}$*-facing seal factors first through the paired* StreamName$^{\uparrow}$ *windows, the* DyadicRatCore$^{\uparrow}$ *budget rows, the* RegSeqRat$^{\uparrow}$ *classifier row, the* RealObservationBudget$^{\uparrow}$ *rows, the displayed* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *evidence. The Real seal is consumed only after that route has exposed*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

No host multiplication, quotient stream product, selected limit, independent real carrier, or ambient completeness coordinate is available to the consumer before the seal is read.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket root regular product budget separation certificate`

↪ variant `BEDC.Derived.CauchyProductUp.CauchyProductPacket root regular product budget separation`

Proof. First apply the root regular product carrier row. It supplies the paired regular Cauchy sources, finite windows, dyadic budget rows, product observation row, classifier row, and structural support rows as one finite carrier inventory.

Next apply the shared-window product classifier. This locks E behind the two StreamName$^{\uparrow}$ windows and the DyadicRatCore$^{\uparrow}$ radius and observation rows, so the classifier cannot be fed by a host multiplication operation or a quotient stream product.

Then apply the Real seal product ledger. The Pkg and NameCert rows are consumed before the seal, and the route passes through the displayed RealObservationBudget$^{\uparrow}$ and RegSeqRat$^{\uparrow}$ handoff rather than through an independent real carrier.

Finally apply budget seal exhaustion. The exhausted route has no coordinate for selected limits or ambient completeness, so every accepted Real-facing product consumer remains separated from the excluded sources until the displayed finite budget route reaches the seal. □

Theorem 464.155 (CauchyProduct regular factor source minimality)**.** *Any* Real$^{\uparrow}$*-facing product consumer over the root regular product packet of an accepted* CauchyProduct$^{\uparrow}$ *carrier must display both* RegularCauchyName$^{\uparrow}$ *source rows, both* StreamName$^{\uparrow}$ *windows, all* DyadicRatCore$^{\uparrow}$ *budget and observation rows, the* RegSeqRat$^{\uparrow}$ *product classifier, the* RealObservationBudget$^{\uparrow}$ *seal rows, local* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *support before a* Real$^{\uparrow}$ *seal is exported. In coordinates the required source surface is*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N.$$

No proper subroute omitting either regular factor, either finite window, any dyadic budget row, the classifier row, the RealObservationBudget rows, or the local support rows can export the product seal.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket regular factor source minimality certificate`

Proof. Begin with the carrier row of Definition 464.145. It displays $X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L,$ as one finite product inventory, with both regular factors and both finite windows present before the product observation and classifier rows.

Apply Definition 464.146. The classifier E is locked behind the paired StreamName$^{\uparrow}$ windows, the dyadic budget and observation rows, the product row P, and the displayed hsame and Cont route, so omitting any of those rows destroys the classifier input rather than producing a smaller product read.

Next use Definition 464.148. Every Real-facing product consumer passes through the displayed RealObservationBudget$^{\uparrow}$ and RegSeqRat$^{\uparrow}$ seal route before the Real$^{\uparrow}$ boundary is visible.

Finally combine Definition 464.152 with Definition 464.153. The RealSeries handoff and public export consume the same paired-factor inventory and the local Pkg and NameCert rows before exposing any public product seal. Since the accepted carrier contains no host multiplication, quotient stream product, selected limit, independent real carrier, or ambient completeness coordinate, the displayed route is source-minimal for regular-factor Real-facing product reads. □

Theorem 464.156 (CauchyProduct mature public factorization)**.** *Every public* CauchyProduct$^{\uparrow}$ *read over an accepted root regular product packet factors through regular product source rows, shared-tail modulus rows, finite dyadic product budgets,* RegSeqRat$^{\uparrow}$ *readback,* RealSeries$^{\uparrow}$ *handoff, and* Real$^{\uparrow}$ *seal rows before any consumer can read a product claim. In displayed coordinates the public route consumes*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

from the product packet, then the RealSeries$^{\uparrow}$ *handoff rows*

$$T, S, W, Q, D, M, E, H, C, P, N$$

from the shared-tail surface, and finally the local Pkg *and* NameCert *ledger at the seal boundary. No public product claim is available from host multiplication, quotient stream product, selected limits, independent real carriers, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket mature public factorization`

Proof. First build the regular product source surface. The root carrier theorem supplies the paired regular Cauchy source rows, shared finite windows, dyadic radius and observation rows, product row, classifier row, transport, replay, provenance, and local naming as one finite product inventory.

Next apply the shared-window classifier and the Real seal product ledger. These route any read of the product classifier through the paired windows and dyadic budgets, then through the local Pkg and NameCert rows before a Real-facing seal is visible.

Use budget exhaustion and downstream coverage for the consumer boundary. They identify every accepted Real-facing product consumer with the same finite dyadic product budget route and exclude host multiplication, quotient streams, selected limits, independent real carriers, and ambient completeness from the carrier surface.

Finally apply the RealSeries handoff and source-minimality theorems. The shared-tail rows $T, S, W, Q, D, M, E, H, C, P, N$ are consumed before the public product export, and the two regular factors, finite windows, dyadic budget rows, readback, ledger, and seal rows cannot be omitted without destroying the displayed product route. Therefore every public $\mathsf{CauchyProduct}^{\uparrow}$ read factors through exactly the stated finite source, budget, handoff, and seal surfaces. □

RegSeqRat–Real sibling route. The $\mathsf{CauchyProduct}^{\uparrow}$ carrier consumes the $\mathsf{RegSeqRat}^{\uparrow}$ regular-sequence carrier of chapter 301 and sends its product readback to the $\mathsf{Real}^{\uparrow}$ seal surface of chapter 38. This dependency is the finite product route through scheduled windows and dyadic ledgers, not an imported series convergence theorem.

Theorem 464.157 (CauchyProduct Real seal upstream dependency)**.** *Every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *Real-seal read consumed by a completion-facing downstream chapter first consumes the paired* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations, the product budget ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, and the* $\mathsf{Real}^{\uparrow}$ *seal surface. In displayed coordinates, the upstream route is the finite packet*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with any accepted observation-budget rows when the consumer uses a budget packet. The route exports no quotient stream, selected product limit, host multiplication primitive, trichotomy row, independent real carrier, or ambient completeness witness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal upstream dependency`

Proof. Start with paired-window source admission from Definition 464.100 and Definition 464.82. These rows force the two source names X, Y to enter the product packet through the paired $\mathsf{StreamName}^{\uparrow}$ windows W_X, W_Y.

Next use budget route exactness from Definition 464.101 and Definition 464.66. The dyadic observations Q_X, Q_Y, source-radius rows M_X, M_Y, product row P, and ledger row L form the budget route before the classifier can be read.

Apply the paired-window ledger classifier results Definition 464.146 and Definition 464.88. They identify the $\mathsf{RegSeqRat}^{\uparrow}$ row E as downstream of the same finite windows, dyadic observations, and product ledger.

Finally use the root Real seal obligations and consumer exhaustion supplied by Definition 464.147, Definition 464.124, and Definition 464.85. The completion-facing consumer therefore reaches the $\mathsf{Real}^{\uparrow}$ seal only through the displayed upstream route and cannot import any excluded analytic object. □

Theorem 464.158 (CauchyProduct Real seal budget factorization)**.** *Every completion-facing product read of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *Real-seal packet factors through the paired* $\mathsf{StreamName}^{\uparrow}$ *windows* W_X, W_Y*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations* Q_X, Q_Y*, the product budget rows* M_X, M_Y, P, L*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* E*, the* $\mathsf{Real}^{\uparrow}$ *seal, and any accepted observation-budget rows when such rows are present. In displayed coordinates the factorization is exhausted by*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with those accepted budget rows. No quotient stream, selected product limit, host multiplication primitive, trichotomy row, independent real carrier, or ambient completeness row can bypass this finite factorization route.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal upstream budget factorization`

Proof. First apply Definition 464.157. It already places every completion-facing Real-seal read downstream of the paired StreamName windows, dyadic observations, product budget ledger, RegSeqRat classifier, Real seal surface, and accepted observation-budget rows when the consumer asks for such rows.

Next use the Real–RegSeqRat–StreamName handoff of Definition 464.159. That handoff identifies the same rows as the ordered visibility chain seen by Real-completion-facing consumers, so the factorization has the displayed source windows, observation rows, product rows, classifier row, transport rows, replay rows, ledger row, and local naming row as its whole public surface.

Finally combine the local budget locks used in the upstream proof: Definition 464.101, Definition 464.66, and Definition 464.132. These locks prevent a consumer from reading a product seal before the product budget rows and accepted observation-budget rows have been displayed.

The cited upstream dependency and handoff theorems already exclude quotient streams, selected product limits, host multiplication primitives, trichotomy rows, independent real carriers, and ambient completeness data. Therefore no completion-facing product read can bypass the finite budget factorization route stated above. □

Theorem 464.159 (Real RegSeqRat StreamName CauchyProduct handoff)**.** *An accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *route consumed by a Real-completion-facing chapter is equivalent, as a finite BEDC handoff surface, to the ordered visibility chain consisting of paired* $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic observations, the product budget ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, and the* $\mathsf{Real}^{\uparrow}$ *seal. In coordinates, the handoff surface is exhausted by*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the accepted observation-budget rows when a budget consumer asks for them. It exports no quotient stream, host multiplication primitive, trichotomy row, or ambient completeness witness.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real regseqrat streamname handoff`

Proof. First read the ordered source surface. The paired-window totality of Definition 464.100 forces the two source names X, Y to be visible only through the paired $\mathsf{StreamName}^{\uparrow}$ windows W_X, W_Y before any product consumer can inspect the downstream rows.

Next read the budget and classifier surface. The budget product lock of Definition 464.101 places the dyadic observations, source-radius rows, product row, and ledger row before the classifier, and Definition 464.88 identifies the resulting E row as the finite $\mathsf{RegSeqRat}^{\uparrow}$ classifier consumed by the Real route.

Finally apply the upstream dependency theorem Definition 464.157. It states that a completion-facing Real-seal read reaches the $\mathsf{Real}^{\uparrow}$ seal only through exactly those prior rows, so the ordered chain is both sufficient for the handoff and exhaustive for accepted consumers. Coordinate exhaustion gives the exclusions: no quotient stream, host multiplication, trichotomy, or ambient completeness coordinate is present. □

Theorem 464.160 (CauchyProduct LimitSeal sibling dependency)**.** *Every accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *Real-seal route that reaches the* $\mathsf{Real}^{\uparrow}$ *seal passes through the same finite rows consumed by the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *compatibility boundary of chapter 386: paired* $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic observations, the product budget ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier, transport rows, route rows, package provenance, and local* $\mathsf{NameCert}$ *rows. The sibling dependency supplies a horizontal handoff edge only; it imports no selected product limit, quotient stream, host multiplication primitive, or ambient completeness row.*

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket limitseal sibling dependency`

Proof. Begin with the upstream dependency theorem. It places every completion-facing Real-seal read of a $\mathsf{CauchyProduct}^{\uparrow}$ packet on the paired windows, dyadic observations, product budget ledger, classifier row, and displayed structural rows before the $\mathsf{Real}^{\uparrow}$ seal is consumed.

Next use the Real–RegSeqRat–StreamName handoff. That handoff identifies the same finite ordered surface as the route seen by a downstream Real-completion consumer.

Read this finite surface against the $\mathsf{CauchyLimitSeal}^{\uparrow}$ compatibility boundary named in chapter 386. That boundary consumes $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, dyadic observation, $\mathsf{Real}^{\uparrow}$, transport, route, package, and local naming rows, so the product route and the limit-seal route meet on those rows.

The conclusion is only a sibling dependency. Since neither cited product theorem exports a quotient stream, selected product limit, host multiplication primitive, or ambient completeness row, the horizontal edge adds no analytic coordinate beyond the displayed finite BEDC surface. □

Theorem 464.161 (CauchyProduct shared-selector Real seal stability)**.** *Let two accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packets read their factor windows through the same* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *route. Suppose the displayed* $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic radius rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, and* $\mathsf{Real}^{\uparrow}$ *seal boundary agree componentwise on the public packet rows. Then every multiplication-facing* $\mathsf{Real}^{\uparrow}$ *seal consumer of the two packets reads the same finite product-route surface*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the shared selector rows. The shared selector can be reused without changing the product seal surface, and the route exports no host multiplication, quotient-stream product, selected limit, trichotomy row, or ambient completeness datum.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket shared selector real seal stability`

Proof. First apply the budget-selector distributive lock Definition 464.132. It identifies both factor-window reads with one finite selector route and one displayed product-route certificate.

Next use the Real budget multiplication boundary Definition 464.134. A multiplication-facing $\mathsf{Real}^{\uparrow}$ seal read is available only after the shared windows, dyadic radius rows, regular-rational handoff, selector rows, transports, continuations, provenance, and local naming rows have been displayed.

Finally apply the RegSeqRat product seal coverage theorem Definition 464.135. Agreement on the displayed StreamName, dyadic, classifier, and Real seal boundary rows therefore forces both consumers to inspect the same finite product-route surface. The cited coverage theorem also lists the missing coordinates, so no host multiplication, quotient product, selected limit, trichotomy row, or ambient completeness object can be introduced by reusing the selector. □

Theorem 464.162 (CauchyProduct Real seal selector coherence)**.** *Let two accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packets use the same finite observation-budget selector. Suppose their paired* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius and observation rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, and* $\mathsf{Real}^{\uparrow}$ *seal boundary agree componentwise on the public packet rows. Then every Real-seal consumer and every* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *sibling-seal consumer reads the same finite route*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the shared selector rows. Selector reuse is coherent with the full L10 sibling seal route, and it exports no host multiplication, quotient stream, selected limit, trichotomy row, choice witness, or ambient completeness datum.

Proof. First read the Real-seal side through Definition 464.157. That theorem exhausts every completion-facing Real-seal read by the displayed route, together with accepted observation-budget rows, before the $\mathsf{Real}^{\uparrow}$ boundary can be consumed.

Next read the sibling-seal side through Definition 464.160. It identifies the $\mathsf{CauchyLimitSeal}^{\uparrow}$ compatibility boundary as a horizontal consumer of the same StreamName, dyadic, classifier, Real, transport, route, package, and local naming rows, so the sibling edge has no independent analytic coordinate.

Finally apply Definition 464.161. Since the two accepted packets share one selector and agree on the public window, radius, observation, classifier, and Real boundary rows, selector reuse fixes the finite product-route surface for both packets. Combining the three cited theorems gives the same route for Real-seal and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumers, with no host multiplication, quotient streams, selected limits, trichotomy, choice, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal selector coherence`

Theorem 464.163 (CauchyProduct limit-seal selector coherence)**.** *Let an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *packet reuse the same finite observation-budget selector for its Real-seal route and for the sibling route consumed through chapter 386. Then the selector remains coherent on the displayed product route*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

and on the shared StreamName, dyadic, RegSeqRat, Real-boundary, transport, route, package, and local NameCert rows. The sibling edge adds no quotient stream, selected product limit, host multiplication coordinate, choice witness, or ambient completeness datum.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket limitseal selector coherence`

Proof. Read the Real-seal route through Definition 464.162. The selector already fixes the finite product-route surface for every Real-seal consumer that agrees on the public StreamName, dyadic, classifier, and Real-boundary rows.

Now read the sibling consumer through chapter 386. The CauchyLimitSeal boundary consumes the same finite stream windows, dyadic observations, regular classifier row, Real boundary, transports, routes, package provenance, and local naming rows.

Thus the reused selector is not a new analytic coordinate. It is a shared finite witness for the same displayed product-route surface, and the sibling handoff cannot export quotient streams, selected product limits, host multiplication, choice, or ambient completeness because none of those rows is present in either route. □

Lemma 464.164 (CauchyProduct Real seal selector minimal witness)**.** *For a completion-facing consumer of an accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *Real-seal packet, the local admission and consumption claim is witnessed by the single displayed product route*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N$$

together with the shared $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *rows when the consumer asks for a selector. If a consumer presents a larger reading of the same Real-seal claim, then its accepted part factors through this displayed witness: the source admission uses only* X, Y, W_X, W_Y*, the budget and product admission uses only* M_X, M_Y, Q_X, Q_Y, P, L*, the classifier admission uses only* E*, and the seal consumption uses only* H, C, N *with the displayed Real boundary. No unlisted quotient stream, selected product limit, host multiplication primitive, trichotomy row, independent real carrier, ambient choice object, or ambient completeness witness can serve as an additional admission coordinate.*

Proof. Start with the upstream dependency theorem Definition 464.157. It states that every completion-facing Real-seal read first consumes the paired $\mathsf{StreamName}^{\uparrow}$ windows, the $\mathsf{DyadicRatCore}^{\uparrow}$ observations, the product budget ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row, and the $\mathsf{Real}^{\uparrow}$ seal surface. In coordinates this is exactly the displayed packet, with accepted observation-budget rows only when a budget consumer asks for them.

Now apply the shared-selector Real-seal stability theorem Definition 464.161. When two accepted product packets read their factor windows through the same $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ route and agree on the public window, radius, classifier, and Real-boundary rows, every multiplication-facing Real-seal consumer reads the same finite product-route surface together with the shared selector rows. Thus selector reuse does not create a second product seal surface; it only names the finite selector rows already attached to the displayed route.

Combine the two readings by sorting the consumer-facing coordinates by their role in the displayed packet. The source part is forced to factor through X, Y, W_X, W_Y by the upstream source admission. The budget and product part is forced to factor through M_X, M_Y, Q_X, Q_Y, P, L before the classifier is visible. The classifier part is forced to factor through E, and the final seal handoff is carried by H, C, N together with the Real boundary already listed by the two cited theorems. The shared selector rows may be consumed as witness rows for the common observation-budget route, but they do not add any unlisted analytic object.

Therefore any larger accepted reading has the same consumer-facing content after projection to the displayed product route and the shared selector rows. Since both cited theorems explicitly exclude quotient streams, selected limits, host multiplication primitives, trichotomy rows, independent real carriers, ambient choice objects, and ambient completeness witnesses from the exported route, none of those objects can be used as an additional admission or consumption coordinate. □

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket real seal selector minimal witness`

Theorem 464.165 (CauchyProduct L10 dependency lattice)**.** *Every accepted* CauchyProduct$^{\uparrow}$ *packet that reaches the* Real$^{\uparrow}$ *seal factors through the displayed L10 dependency lattice: the paired* StreamName$^{\uparrow}$ *windows of chapter 126, the* DyadicRatCore$^{\uparrow}$ *observation and radius rows of chapter 291, the* RegSeqRat$^{\uparrow}$ *classifier row of chapter 301, the* Real$^{\uparrow}$ *seal of chapter 38, and the local* BHist, hsame, Cont, Pkg, *and* NameCert *support rows. In coordinates the product-facing lattice is*

$$X, Y, W_X, W_Y, M_X, M_Y, Q_X, Q_Y, P, E, H, C, L, N,$$

with any accepted observation-budget selector rows attached only as finite budget witnesses. The lattice exports no quotient streams, host multiplication primitives, selected limits, independent real carriers, trichotomy rows, countable-choice witnesses, or ambient completeness principles.

Lean4 ✓ `BEDC.Derived.CauchyProductUp.CauchyProductPacket l10 dependency lattice`

Proof. Start from the product carrier row of Definition 464.145. It puts the two source names, paired finite windows, dyadic radius and observation rows, product observation, classifier row, transport rows, continuation rows, provenance row, and local naming row into one finite BHist carrier.

Next pass to the Real seal by Definition 464.157. The seal-facing consumer can reach Real$^{\uparrow}$ only after the displayed StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and local support rows have already been read.

Use Definition 464.135 for the regular-rational side. It shows that any product-seal consumer using a finite observation-budget selector remains on the same windows, dyadic rows, classifier row, selector rows, transports, continuations, provenance, and local NameCert rows, rather than acquiring an additional carrier.

Combining these three rows gives the stated L10 lattice. The cited carrier, Real-seal, and RegSeqRat coverage theorems list exactly the available coordinates, so quotient streams, host multiplication primitives, selected limits, independent real carriers, trichotomy rows, countable choice, and ambient completeness have no coordinate from which they could enter the accepted packet. □

Closure status for NameCert$_{\text{CauchyProduct}^{\uparrow}}$**.**

Constructive story: A CauchyProduct$^{\uparrow}$ packet is generated from two RegularCauchyName$^{\uparrow}$ source rows, paired StreamName$^{\uparrow}$ finite-window schedules, dyadic-radius rows, DyadicRatCore$^{\uparrow}$ observations, a pointwise product row, a RegSeqRat$^{\uparrow}$ classifier, displayed hsame transports, Cont routes, a finite ledger, Real$^{\uparrow}$ seal handoff, package provenance, and local NameCert evidence.

Theory closure: TheoryGate(NameCert$_{\text{CauchyProduct}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 464.47, Definition 464.139, Definition 464.138, and Definition 464.140 bind the product-observation surface to its shared-selector RealSeries handoff, RegSeqRat–Real seal commutation, and budget-totality consumers.

Formal verification: FormalStatus(NameCert$_{\text{CauchyProduct}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close RealUp completeness, quotient streams, selected limits, trichotomy, host multiplication as a primitive, independent real carriers, or bridge checking.

Upgrade path: Bridge checking remains the verification-side step; the theory-side route already includes the shared-selector RealSeries handoff, RegSeqRat–Real seal commutation, and budget-totality rows.

Chapter 465

A Concrete Naming Certificate for $\mathsf{RegularCauchyScale}^{\uparrow}$

The $\mathsf{RegularCauchyScale}^{\uparrow}$ interface names the finite rational-scaling surface for a regular rational Cauchy name. It sits with $\mathsf{RegularCauchySum}^{\uparrow}$, $\mathsf{RegularCauchyNegation}^{\uparrow}$, and $\mathsf{RegularCauchyProduct}^{\uparrow}$: the packet displays a rational scalar row, one regular source name, aligned stream windows, dyadic endpoint rows for the scalar and source, a scaled dyadic endpoint row, a finite error-budget ledger, regular rational readback, transports, continuations, package provenance, and local naming data.

The packet is a constructive arithmetic certificate. It is not a quotient of streams, not a selected host limit, not a host real equality assertion, and not an ambient completeness theorem.

The $\mathsf{RegularCauchyScale}^{\uparrow}$ packet consumes the same finite arithmetic route as chapter 417, chapter 459, and chapter 461. Its scalar endpoint tolerance is recorded through chapter 385 before any $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ handoff.

Definition 465.1 (RegularCauchyScale carrier)**.** *A* $\mathsf{RegularCauchyScale}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N)$$

with the following displayed rows:

1. *Q is the* $\mathsf{Rat}^{\uparrow}$ *scalar row whose rational value is used in every scaled endpoint;*
2. *A is the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row whose scheduled rational observations are scaled by Q;*
3. *W is the aligned* $\mathsf{StreamName}^{\uparrow}$ *window used to read the source observation at the requested precision and index;*
4. *D_Q is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row for the scalar Q at the common exponent used by the packet;*
5. *D_A is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row read from the source window W;*
6. *D is the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint row for the scaled value $D_Q \cdot D_A$;*
7. *E is the finite* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *ledger recording the scalar endpoint, source tolerance, scalar magnitude bound, scaled endpoint error, and output tolerance assigned to D;*
8. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row whose scheduled point row is D with regularity evidence supplied by E;*

9. *H stores componentwise* hsame *transports for the scalar, source name, stream window, dyadic endpoint rows, finite budget ledger, and readback row;*
10. *C stores the displayed* Cont *routes for reading the scalar, reading the source window, forming the dyadic scaled endpoint, checking the budget, and exposing the readback;*
11. *P is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{FiniteErrorBudget}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyScale}^{\uparrow}}$ *row.*

The carrier is finite rational-scaling data for regular Cauchy names. It stores no quotient stream, no selected limit, no host real equality, and no ambient completeness object.

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleTasteGate single carrier alignment`

Theorem 465.2 (RegularCauchyScale NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyScale}^{\uparrow}}$ *surface for the carrier of Definition 465.1 consists of five finite obligations:*

1. *carrier admission: the accepted object is the displayed* BHist *packet S with a* $\mathsf{Rat}^{\uparrow}$ *scalar, one* $\mathsf{RegSeqRat}^{\uparrow}$ *source, an aligned* $\mathsf{StreamName}^{\uparrow}$ *window, dyadic endpoint rows, a finite scale-error ledger, transports, continuations, provenance, and local naming data;*
2. *classifier transport: classification transports the scalar row, source row, window row, endpoint rows, finite budget ledger, and readback row componentwise through the stored* hsame *and* Cont *rows;*
3. *stability: replacing the scalar or source by a classified row preserves the displayed window route and recomputes the same kind of dyadic scaled endpoint row;*
4. *ledger exactness: the output tolerance row is the finite scale-error budget recorded in E, including the scalar endpoint, source tolerance, scalar magnitude bound, and scaled endpoint error;*
5. *downstream handoff: every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer first reads R together with Q, A, W, D_Q, D_A, D, E, H, C, P, and N.*

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier namecert obligations`

Proof. Carrier admission is projection from the tuple in Definition 465.1. The rational scalar, regular source, stream window, endpoint rows, finite ledger, transport rows, continuation routes, provenance row, and local naming row are explicit coordinates of S.

Classifier transport is componentwise. The $\mathsf{Rat}^{\uparrow}$ scalar row transports the rational coefficient, the $\mathsf{RegSeqRat}^{\uparrow}$ source row transports its scheduled observations, the $\mathsf{StreamName}^{\uparrow}$ row transports the source window read, and the $\mathsf{DyadicRatCore}^{\uparrow}$ rows transport the scalar endpoint, source endpoint, and scaled endpoint calculation.

The finite ledger records the scalar endpoint, the source tolerance, the scalar magnitude bound, the scaled endpoint error, and the output tolerance before the readback is exposed. Since the downstream handoff is the readback row R and its displayed provenance, no omitted coordinate can add quotient streams, selected limits, host real equality, or ambient completeness. □

Theorem 465.3 (RegularCauchyScale source factorization)**.** *For an accepted* $\mathsf{RegularCauchyScale}^{\uparrow}$ *carrier $S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N)$, every scale read factors through the* $\mathsf{Rat}^{\uparrow}$ *scalar row Q, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row A, the* $\mathsf{StreamName}^{\uparrow}$ *window W, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows D_Q, D_A, and D, and the* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *row E before the readback row R is exposed.*

Thus the packet presents rational scaling as a finite source factorization: scalar, source schedule, window, endpoint calculation, and budget row are all visible before any $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer reads the scaled name.*

Proof. Project the carrier of Definition 465.1. The scalar row Q, source row A, stream window W, endpoint rows D_Q, D_A, D, and ledger row E are explicit coordinates of the finite packet.

Read a scale request through those coordinates in order. The scalar endpoint is supplied by Q through D_Q, the source observation is supplied by A through W and D_A, and the scaled endpoint is the displayed dyadic row D.

The budget row E then records the scalar endpoint, source tolerance, scalar magnitude bound, scaled endpoint error, and output tolerance. Only after this finite ledger is present does the packet expose the regular readback row R.

Consequently every consumer-facing scale read is factored through the displayed rational source data and finite budget rows rather than through a completed real scalar action or a quotient stream. □

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier source factorization`

Theorem 465.4 (RegularCauchyScale classifier route exhaustion)**.** *Classifier transport for* $\mathsf{RegularCauchyScale}^{\uparrow}$ *is exhausted by componentwise* hsame *transport and* Cont *replay over the displayed tuple*

$$(Q, A, W, D_Q, D_A, D, E, R, H, C, P, N).$$

There is no classifier route for a hidden scalar, an unrecorded source stream, a quotient representative, a selected limit, or an ambient completion object.

Proof. Start with the tuple in Definition 465.1. The visible classifier inputs are the scalar, source, window, endpoint rows, ledger, readback, transport row, continuation row, provenance row, and local naming row.

Apply the classifier transport clause of Definition 465.2. It moves those rows componentwise through the stored hsame data and replays consumer access only through the displayed Cont routes.

The source factorization of Definition 465.3 leaves no remaining coordinate to classify. Every scale read has already passed through Q, A, W, D_Q, D_A, D, E before reaching R.

Thus classifier routing is exhausted by componentwise transport and continuation replay over the displayed tuple, with no hidden stream, selected limit, quotient representative, or completion object available to inspect. □

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier classifier route exhaustion`

Theorem 465.5 (RegularCauchyScale RealUp scalar non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *scalar consumer of an accepted* $\mathsf{RegularCauchyScale}^{\uparrow}$ *packet sees only the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R *and the finite scale ledger* E *together with the visible scalar, source, window, endpoint, transport, continuation, provenance, and naming rows. It does not receive a completed real scalar multiplication, a quotient stream equality, a selected limit, or an ambient vector-space operation.*

Proof. Factor the real-facing read through Definition 465.3. Before R is exposed, the packet displays the rational scalar, source row, aligned window, dyadic endpoint rows, and finite budget ledger.

Use Definition 465.4 to control transport. A classified replacement can replay only the displayed hsame and Cont routes over the same tuple.

Finally apply the existing real seal boundary in Definition 465.11. A $\mathsf{Real}^{\uparrow}$ consumer reads the regular rational sequence surface and its visible provenance, not a separate completed-real scalar field.

Therefore the scalar operation does not escape the finite $\mathsf{RegSeqRat}^{\uparrow}$ readback and budget ledger into quotient equality, selected limits, ambient completeness, or a host vector-space operation. □

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier real scalar non escape`

Theorem 465.6 (RegularCauchyScale carrier admission obligation)**.** *For an accepted* $\mathsf{RegularCauchyScale}^{\uparrow}$ *carrier* $S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N)$*, carrier admission is exactly the displayed finite* BHist *packet of Definition 465.1. The admitted rows are the* $\mathsf{Rat}^{\uparrow}$ *scalar row* Q*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source* A*, the* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *scalar endpoint* D_Q*, source endpoint* D_A*, and scaled endpoint* D*, the* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *scale ledger* E*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R*, componentwise* hsame *transport* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and the local* NameCert *row* N*.*

No admitted coordinate is a quotient stream, host real equality, selected limit, or ambient completeness principle.

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier scale carrier obligation`

Proof. Project the tuple in Definition 465.1. The scalar, source, stream window, endpoint rows, scale ledger, readback, transport, continuation, provenance, and naming rows are all explicit coordinates.

The $\mathsf{Rat}^{\uparrow}$ scalar row and $\mathsf{RegSeqRat}^{\uparrow}$ source row are read through the aligned $\mathsf{StreamName}^{\uparrow}$ window. The $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint rows display the scalar endpoint, source endpoint, and scaled endpoint used by the finite budget ledger.

The rows H, C, P, and N only transport and expose those displayed coordinates. Thus carrier admission has no coordinate for quotient streams, host real equality, selected limits, or ambient completeness. □

Theorem 465.7 (RegularCauchyScale classifier stability obligation)**.** *Classifier stability for* $\mathsf{RegularCauchyScale}^{\uparrow}$ *transports the* $\mathsf{Rat}^{\uparrow}$ *scalar row,* $\mathsf{RegSeqRat}^{\uparrow}$ *source row,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows,* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *scale ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row,* Pkg *provenance, and local* NameCert *row componentwise through the displayed* hsame *and* Cont *data.*

The transported packet remains the same kind of finite rational-scaling surface: scalar row, source window, dyadic scaled endpoint, finite scale ledger, and regular readback. It introduces no quotient stream, host real equality, selected limit, or ambient completeness.

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier classifier stability obligation`

Proof. Start with the transport ledger H. It relates the scalar, source name, stream window, dyadic endpoint rows, finite budget ledger, and readback row componentwise.

Read those transported rows through the continuation routes C. The scalar endpoint and source endpoint still form the displayed scaled endpoint row, and the finite scale ledger still records the tolerance budget consumed by the readback.

The package provenance P and local naming row N bound the transported surface. Since the classifier sees only these finite rows, it cannot add quotient streams, host real equality, selected limits, or ambient completeness. □

Theorem 465.8 (RegularCauchyScale scale ledger exactness obligation)**.** *The scale ledger exactness obligation for* $\mathsf{RegularCauchyScale}^{\uparrow}$ *says that every read of the output row* R *must pass through the* $\mathsf{Rat}^{\uparrow}$ *scalar row* Q*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source* A*, the* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows* D_Q*,* D_A*, and* D*, the* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *ledger* E*, componentwise* hsame *transport* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* NameCert *row* N*.*

The ledger must account for the scalar endpoint, source tolerance, scalar magnitude bound, scaled endpoint error, and output tolerance before any $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer reads the scaled regular Cauchy name.*

Proof. Read the scalar and source rows first. The $\mathsf{Rat}^{\uparrow}$ scalar supplies D_Q, and the $\mathsf{RegSeqRat}^{\uparrow}$ source is observed through the $\mathsf{StreamName}^{\uparrow}$ window to supply D_A.

Use the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ row D for the scaled endpoint. The finite ledger E records the scalar endpoint, source tolerance, scalar magnitude bound, scaled endpoint error, and output tolerance assigned to that endpoint.

Finally route the readback through H, C, P, and N. Because the ledger exactness route is fully displayed before R reaches a downstream consumer, no quotient stream, host real equality, selected limit, or ambient completeness can be used in its place. □

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier ledger exactness obligation`

Theorem 465.9 (RegularCauchyScale window budget)**.** *Given an accepted* $\mathsf{Rat}^{\uparrow}$ *scalar row* Q *and an accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *source row* A *in a* $\mathsf{RegularCauchyScale}^{\uparrow}$ *packet, every precision request reads the aligned* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the scalar endpoint row* D_Q*, and the source endpoint row* D_A*. The packet displays a* $\mathsf{DyadicRatCore}^{\uparrow}$ *row* D *for* $D_Q \cdot D_A$ *and a finite ledger* E *whose output tolerance is the recorded scale-error budget for the source tolerance and scalar magnitude bound.*

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier window budget`

Proof. Read the precision request through the scalar and source coordinates. The scalar row Q supplies the rational endpoint D_Q, while the source row A is observed through the aligned stream window W to produce D_A.

Apply the displayed dyadic multiplication row of $\mathsf{DyadicRatCore}^{\uparrow}$ to D_Q and D_A. The result is the scaled endpoint row D, still inside the same finite carrier.

Finally read the finite budget ledger E. Its entries record the source tolerance, the scalar magnitude bound, and the endpoint error assigned to the output request, so the budget is a finite BEDC ledger rather than an appeal to a completed real scalar action. □

Theorem 465.10 (RegularCauchyScale RegSeqRat handoff)**.** *The budgeted rational-scaling windows of Definition 465.9 repack as the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R *of Definition 465.1. A consumer of* R *reads only the scalar row, source window, dyadic scaled endpoint row, finite scale-error ledger, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row.*

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier regseqrat handoff`

Proof. Start with the finite window budget. For each requested precision, the packet exposes the scalar endpoint, the source endpoint, the scaled dyadic endpoint, and the scale-error row that bounds the output tolerance.

Repack those displayed rows as a regular rational sequence readback. The point row of R is D, and the regularity evidence visible to the consumer is the scale ledger E routed through the same scalar and source windows.

The transport and continuation rows are inherited from the carrier. Because the repacking uses only coordinates already listed in Definition 465.1, it introduces no host sequence quotient, selected limit, host real equality, or completed-real scalar operation. □

Theorem 465.11 (RegularCauchyScale RealUp seal boundary)**.** *Any* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegularCauchyScale}^{\uparrow}$ *packet reads only the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R *together with the visible provenance of the scalar, source name, aligned window, dyadic endpoint rows, finite scale-error ledger,* hsame *transports,* Cont *routes,* Pkg *row, and local* $\mathsf{NameCert}_{\mathsf{RegularCauchyScale}^{\uparrow}}$ *row.*

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier realup seal boundary`

Proof. Factor the real-facing read through the regular readback. By Definition 465.10, R is already the repacking of the budgeted rational-scaling windows.

The remaining consumer-visible data are exactly the provenance rows attached to that repacking: the scalar row, source name, source schedule, dyadic endpoint rows, scale-error ledger, transports, continuations, package row, and local naming row.

The carrier has no independent $\mathsf{Real}^{\uparrow}$ equality field and no completion witness outside the readback. Therefore the real seal can consume only the displayed regular readback and its visible provenance. □

Theorem 465.12 (RegularCauchyScale obligation scope package)**.** *For every accepted* $\mathsf{RegularCauchyScale}^{\uparrow}$ *carrier*

$$S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N),$$

the carrier admission, classifier stability, scale ledger exactness, window budget, $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and* $\mathsf{Real}^{\uparrow}$ *seal boundary jointly supply the obligation surface over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{FiniteErrorBudget}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert.

The package exports exactly the rational scalar row, source row, aligned window, dyadic endpoint rows, finite scale-error ledger, regular readback, transport routes, continuation routes, provenance, and local naming data. It exports no quotient stream, host real equality, selected limit, ambient completeness object, or completed real scalar operation.

Proof. Start with carrier admission in Definition 465.6. It identifies every coordinate of the accepted packet and fixes the dependency surface over the scalar, source, window, endpoint, ledger, readback, transport, continuation, provenance, and naming rows.

Use classifier stability from Definition 465.7 and scale ledger exactness from Definition 465.8. These clauses keep transported packets componentwise inside the same finite surface and require every output read to pass through $Q, A, W, D_Q, D_A, D, E, H, C, P, N$.

Apply the window budget theorem Definition 465.9 and the $\mathsf{RegSeqRat}^{\uparrow}$ handoff theorem Definition 465.10. They package the scaled dyadic endpoint and finite budget as the readback row R.

Finally use the $\mathsf{Real}^{\uparrow}$ seal boundary in Definition 465.11. A real-facing consumer receives only R and the displayed provenance rows, so the obligation package has no coordinate from which quotient streams, host equality, selected limits, ambient completeness, or a completed real scalar operation could be read. □

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier obligation scope package`

Theorem 465.13 (RegularCauchyScale scoped Real-consumer boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of a scaled regular Cauchy packet*

$$S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N)$$

factors through the scalar row Q*, source row* A*,* $\mathsf{StreamName}^{\uparrow}$ *window* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows* D_Q, D_A, D*,* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *ledger* E*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R*, componentwise* hsame *transports* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and the local* $\mathsf{NameCert}$ *row* N*. The scoped consumer boundary exports no quotient stream, selected limit, host real equality, ambient completeness object, or completed real scalar multiplication.*

Proof. Begin with source factorization from Definition 465.3. It routes every scaled read through the scalar row Q, source row A, aligned window W, endpoint rows D_Q, D_A, D, and finite budget ledger E.

Use classifier route exhaustion from Definition 465.4 and ledger exactness from Definition 465.8. These results keep the transported classifier route inside the same finite packet and require the budget ledger before any output read is exported.

Apply the $\mathsf{RegSeqRat}^{\uparrow}$ handoff theorem Definition 465.10. The scaled dyadic endpoints and finite ledger are repacked as the readback row R under the displayed transport, continuation, provenance, and local naming rows.

Finally use the $\mathsf{Real}^{\uparrow}$ seal boundary in Definition 465.11. The real-facing consumer receives only R and its visible provenance, so the scoped boundary cannot export quotient streams, selected limits, host real equality, ambient completeness, or a completed real scalar operation. □

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier scoped real consumer boundary`

Theorem 465.14 (RegularCauchyScale cofinal budget refinement)**.** *Let*

$$S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyScale}^{\uparrow}$ *packet. Suppose a refined finite scale ledger* E' *is displayed over the same scalar row* Q*, source row* A*, stream window* W*, dyadic endpoint rows* D_Q, D_A, D*, and dyadic endpoint route, and suppose the refined output tolerance is transported by the same componentwise* hsame *rows* H *and displayed* Cont *routes* C*. Then every* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer of the refined packet factors through*

$$(Q, A, W, D_Q, D_A, D, E', R, H, C, P, N).$$

The refinement introduces no completed real scalar multiplication, quotient stream, selected limit, host real equality, or ambient completeness object.

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier cofinal budget refinement`

Proof. Start with source factorization from Definition 465.3. The refined ledger is displayed over the same scalar row, source row, stream window, dyadic endpoint rows, and endpoint route, so the read still begins with Q, A, W, D_Q, D_A, D and the finite budget row now named E'.

Use classifier route exhaustion and ledger exactness from Definition 465.4 and Definition 465.8. These clauses keep the refined tolerance inside the same componentwise hsame and Cont rows, so no classifier route can replace the finite ledger by an ambient estimate.

Apply the window budget theorem Definition 465.9. The refined ledger is cofinal for the same finite window surface, hence every displayed scale-tail read has the same source, endpoint, and transport coordinates with E' in the budget coordinate.

Finally use the $\mathsf{RegSeqRat}^{\uparrow}$ handoff in Definition 465.10 and the $\mathsf{Real}^{\uparrow}$ seal boundary in Definition 465.11. The regular consumer receives the refined finite readback surface, and the real-facing consumer factors through that readback and its visible provenance, leaving no coordinate for quotient streams, selected limits, host equality, ambient completeness, or completed real scalar multiplication. □

Theorem 465.15 (RegularCauchyScale tail-window carrier obligation)**.** *For every accepted* $\mathsf{RegularCauchyScale}^{\uparrow}$ *carrier*

$$S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N),$$

scale-tail admission is exactly the displayed tail-window budget of the packet. The admitted scale tail reads the $\mathsf{Rat}^{\uparrow}$ *scalar* Q*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source* A*, the aligned* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows* D_Q*,* D_A*, and* D*, and the* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *ledger* E *before exposing the readback row* R*.*

No scale-tail row is admitted without the source factorization, classifier route exhaustion, window budget, and $\mathsf{RegSeqRat}^{\uparrow}$ *handoff displayed by Definition 465.3, Definition 465.4, Definition 465.9, and Definition 465.10.*

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier tail window carrier obligation`

Proof. Project the carrier tuple. Its scalar, source, window, endpoint, budget, and readback rows are precisely the coordinates needed for a scale-tail read.

Use source factorization to order the read: Q and A are read through W, the dyadic endpoint rows D_Q and D_A form the scaled endpoint D, and the finite budget E records the output tolerance.

The RegSeqRat handoff then exposes R only after this budget is present. Since classifier route exhaustion leaves no hidden stream or selected limit to inspect, scale-tail admission is exactly the displayed tail-window budget. □

Theorem 465.16 (RegularCauchyScale scalar classifier stability obligation)**.** *Scalar classifier stability for* $\mathsf{RegularCauchyScale}^{\uparrow}$ *is inherited through the* $\mathsf{RegSeqRat}^{\uparrow}$ *scalar route. If a classified packet transports the scalar row* Q*, source row* A*, window* W*, endpoint rows* D_Q, D_A, D*, budget ledger* E*, and readback row* R*, then the transported packet remains a finite rational-scaling carrier with the same source factorization, classifier route exhaustion, window budget, and* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff shape.*

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier scalar classifier stability obligation`

Proof. Begin with classifier route exhaustion. It says that classified packets can move only by the componentwise hsame ledger and the displayed Cont routes over the tuple $Q, A, W, D_Q, D_A, D, E, R, H, C, P, N$.

The source factorization and window budget are stable under that route because the scalar endpoint, source endpoint, scaled endpoint, and finite error ledger are all transported as named rows. No classified replacement can bypass W or replace E by an ambient real estimate.

Finally the $\mathsf{RegSeqRat}^{\uparrow}$ handoff consumes the transported budgeted windows in the same way as the original packet. The resulting readback remains a finite regular rational sequence surface, not a quotient stream or selected host limit. □

Theorem 465.17 (RegularCauchyScale unit-scalar boundary)**.** *For an accepted* $\mathsf{RegularCauchyScale}^{\uparrow}$ *packet*

$$S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N),$$

suppose the $\mathsf{Rat}^{\uparrow}$ *scalar row* Q *is the displayed unit row and* D_Q *is the unit dyadic endpoint on the same denominator ledger as the source endpoint row* D_A*. Then every displayed scale read exposes the same source endpoint route as* D_A *before the finite budget ledger* E *and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R *are exposed.*

Thus the packet supplies the identity-scalar boundary through the finite BHist *packet, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row. It does not use a host vector-space law, quotient stream equality, selected limit, or* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Begin with the source factorization in Definition 465.3. Every scale read already factors through Q, A, W, D_Q, D_A, D, E before it exposes R.

Use the window budget theorem Definition 465.9. Since Q is the displayed unit scalar row and D_Q is the unit endpoint on the same denominator ledger as D_A, the dyadic scaled endpoint route records the same source endpoint route that supplied D_A.

Classifier stability from Definition 465.16 keeps this route inside the componentwise hsame ledger and the displayed Cont rows. No classified replacement can replace the unit endpoint ledger by a host scalar action.

Finally apply the $\mathsf{RegSeqRat}^{\uparrow}$ handoff in Definition 465.10 and the real seal boundary in Definition 465.11. The readback R and any $\mathsf{Real}^{\uparrow}$ consumer see only the displayed budgeted route and its provenance, so the identity-scalar boundary is a finite naming boundary rather than a quotient, selected-limit, completeness, or vector-space assertion. □

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier unit scalar boundary`

Theorem 465.18 (RegularCauchyScale RealUp seal handoff obligation)**.** *The* $\mathsf{Real}^{\uparrow}$ *seal handoff for* $\mathsf{RegularCauchyScale}^{\uparrow}$ *consumes no row outside the displayed surface*

$$\mathsf{DyadicRatCore}^{\uparrow},\ \mathsf{StreamName}^{\uparrow},\ \mathsf{RegSeqRat}^{\uparrow},\ \mathsf{Real}^{\uparrow},\ \mathsf{hsame},\ \mathsf{Cont},\ \mathsf{Pkg},\ \mathsf{NameCert}$$

together with the scalar row Q*, finite budget* E*, and carrier history in* BHist*. In particular, every real-facing consumer factors through the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R *and the visible provenance of Definition 465.1.*

Proof. Read the real-facing route through the RealUp seal boundary. The consumer receives R together with the scalar, source window, dyadic endpoint rows, finite budget ledger, transports, continuations, provenance, and naming row.

The tail-window carrier obligation supplies the admitted budgeted windows, and scalar classifier stability shows that classified packets preserve the same handoff shape. Thus the seal receives the displayed $\mathsf{RegSeqRat}^{\uparrow}$ route rather than a host-level scalar action.

Every coordinate consumed by the seal is named in the carrier or in the listed dependency surface. There is no row for quotient stream equality, selected limit, ambient completeness, or a real-vector-space law outside $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, and NameCert. □

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier real seal handoff obligation`

Theorem 465.19 (RegularCauchyScale rational scalar bridge boundary)**.** *Every bridge-facing consumer of a scaled regular Cauchy packet*

$$S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N)$$

must expose the $\mathsf{Rat}^{\uparrow}$ *scalar row* Q*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row* A*, the* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint rows* D_Q, D_A, D*, the* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *ledger* E*, the* $\mathsf{RegSeqRat}^{\uparrow}$

readback R, the componentwise hsame *transport H, the displayed* Cont *replay C, the* Pkg *provenance P, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyScale}^{\uparrow}}$ *row N before it reads the* $\mathsf{Real}^{\uparrow}$ *seal. The bridge boundary therefore exports rational scaling only through the displayed finite packet, not through quotient streams, selected limits, host real equality, ambient completeness, or an external real-scalar law.*

Proof. Start with source factorization in Definition 465.3. It orders every scaled read through the scalar row Q, the source row A, the aligned stream window W, and the dyadic endpoint rows D_Q, D_A, D.

Next apply the window budget theorem Definition 465.9. The finite error ledger E is exposed before the scale read is admitted, so the bridge-facing consumer receives a displayed tolerance account rather than a hidden real estimate.

Use the $\mathsf{RegSeqRat}^{\uparrow}$ handoff in Definition 465.10. The readback row R is available only after the scalar, source, window, endpoint, and budget rows have been read, and classifier stability keeps the same route under componentwise hsame transport and displayed Cont replay.

Finally apply the $\mathsf{Real}^{\uparrow}$ seal boundary Definition 465.11. The seal can be consumed only through R, H, C, P, N, so the rational-scalar bridge boundary is exactly the displayed carrier route and no quotient, selected-limit, ambient-completeness, or host scalar-action coordinate remains. □

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier rational scalar bridge boundary`

Theorem 465.20 (RegularCauchyScale shared-tail normalization)**.** *Let*

$$S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyScale}^{\uparrow}$ *packet. Suppose two real-facing consumer reads use the same* $\mathsf{RegSeqRat}^{\uparrow}$ *source row A, the same* $\mathsf{StreamName}^{\uparrow}$ *tail-window row W, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *scale ledger D_Q, D_A, D, the same unit-scalar boundary when Q is the displayed unit row, and the same* $\mathsf{Real}^{\uparrow}$ *seal route through the readback row R. Then the two reads normalize to the same displayed shared-tail route through*

$$A,\ W,\ D_Q,\ D_A,\ D,\ E,\ R,\ H,\ C,\ P,\ N.$$

The normalization is internal to the finite carrier history, componentwise hsame *transport, displayed* Cont *rows,* Pkg *provenance, and local* NameCert *row. It does not appeal to quotient streams, host real equality, hidden limits, ambient completeness, or any unlisted real-scalar law.*

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier shared tail normalization`

Proof. First use the tail-window carrier obligation in Definition 465.15. Since both consumers read the same source row, tail-window row, dyadic scale ledger, and finite budget ledger, their admitted scale-tail routes have the same displayed carrier coordinates before readback.

Next apply scalar classifier stability from Definition 465.16. Any classified transport of either read remains inside the same componentwise hsame ledger and the same displayed Cont rows, so no consumer can replace the shared tail by an ambient stream quotient or by a host-level scalar action.

When the scalar row is the displayed unit row, use the unit-scalar boundary in Definition 465.17. It identifies the unit read with the source endpoint route already present in D_A, before the budget ledger and readback row are exposed.

Finally apply the $\mathsf{Real}^{\uparrow}$ seal handoff obligation in Definition 465.18. The real-facing surface consumes only the displayed $\mathsf{RegSeqRat}^{\uparrow}$ readback R and the visible provenance of the same packet,

hence both consumer reads present one shared-tail route and no hidden limit, host real equality, ambient completeness, quotient stream equality, or external real-scalar law is available to distinguish them. □

Theorem 465.21 (RegularCauchyScale scoped closure route)**.** *Every accepted* $\mathsf{RegularCauchyScale}^{\uparrow}$ *carrier*

$$S = (Q, A, W, D_Q, D_A, D, E, R, H, C, P, N)$$

is scoped by the displayed dependency tuple over $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{FiniteErrorBudget}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert. *Every scale read factors through the scalar row Q, source row A, window row W, scalar endpoint D_Q, source endpoint D_A, scaled endpoint D, finite budget E, regular readback R, componentwise transport H, continuation replay C, provenance P, and local naming row N. The scoped route exports no quotient stream, selected limit, host real equality, ambient completeness object, or real-vector-space law.*

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier scoped closure route`

Proof. First use the window budget theorem Definition 465.9. It binds every precision request to the scalar row, source row, stream window, dyadic scalar endpoint, dyadic source endpoint, scaled dyadic endpoint, and finite error-budget ledger.

Next apply the $\mathsf{RegSeqRat}^{\uparrow}$ handoff theorem Definition 465.10. The budgeted endpoint rows repack as the readback row R under the same displayed transport, continuation, provenance, and local naming rows.

Use the $\mathsf{Real}^{\uparrow}$ seal boundary Definition 465.11 together with shared-tail normalization Definition 465.20. These results keep real-facing consumers on the same readback route and normalize common tails through the finite carrier history rather than through quotient equality or host-level limits.

Finally apply the NameCert obligations theorem Definition 465.2. Its carrier admission, classifier transport, ledger exactness, and downstream handoff rows exhaust the visible dependency surface, so no quotient stream, selected limit, host real equality, ambient completeness, or real-vector-space law remains outside the scoped tuple. □

Theorem 465.22 (RegularCauchyScale public consumer boundary)**.** *The named public consumer boundary of an accepted* $\mathsf{RegularCauchyScale}^{\uparrow}$ *packet is the finite route*

$$Q, A, W, D_Q, D_A, D, E, R, H, C, P, N.$$

Every $\mathsf{RegSeqRat}^{\uparrow}$ *consumer reads the same source row A, aligned* $\mathsf{StreamName}^{\uparrow}$ *window W, dyadic endpoint rows D_Q, D_A, D, finite budget E, and regular readback R before exporting scale data. Every* $\mathsf{Real}^{\uparrow}$ *consumer then reads the same readback row, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *row before the terminal seal is visible. Thus the public interface is the displayed scale packet itself, not quotient stream equality, selected limits, host real equality, ambient completeness, or an external real-vector-space law.*

Proof. Project the accepted carrier and apply Definition 465.21. It already orders the scalar, source, window, dyadic endpoint, finite-budget, regular-readback, transport, replay, provenance, and local naming rows.

For $\mathsf{RegSeqRat}^{\uparrow}$ consumers, use Definition 465.10. The readback row R can be consumed only after the displayed source, window, endpoint, and budget rows have been preserved.

For $\mathsf{Real}^{\uparrow}$ consumers, use Definition 465.11. The terminal seal reads the same R, H, C, P, N rows and adds no coordinate for quotient streams, selected limits, host equality, ambient completeness, or external scalar laws. □

Lean4 ✓ `BEDC.Derived.RegularCauchyScaleUp.RegularCauchyScaleCarrier public consumer boundary`

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyScale}\uparrow}$.

Constructive story: A $\mathsf{RegularCauchyScale}^{\uparrow}$ packet is generated from a $\mathsf{Rat}^{\uparrow}$ scalar row, a $\mathsf{RegSeqRat}^{\uparrow}$ source row, an aligned $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ scalar/source/scaled endpoint rows, a finite $\mathsf{FiniteErrorBudget}^{\uparrow}$ scale ledger, displayed hsame transports, Cont routes, Pkg provenance, a $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyScale}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 465.21 binds the finite scalar, window, dyadic endpoint, finite-budget, regular-readback, transport, continuation, provenance, Real seal, and NameCert rows for rational scaling of regular Cauchy names.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyScale}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient equality of streams, selected limits, host real equality, ambient completeness, real-vector-space laws, or bridge checking.

Upgrade path: No further paper-theory closure is claimed before Lean formalization or bridge checking for the displayed scalar, window, dyadic endpoint, finite-budget, regular-readback, and Real seal rows.

Chapter 466

A Concrete Naming Certificate for RegularCauchyTriangleBound$^{\uparrow}$

The RegularCauchyTriangleBound$^{\uparrow}$ interface packages the finite three-leg estimate used by the diagonal regularity step in the Real completeness capstone. It keeps the two diagonal observations, the shared intermediate observation, the two regular-sequence tail bounds, and the middle Cauchy-modulus bound in one NameCert packet. The packet is a displayed estimate surface; it is not a quotient stream, not a selected limit, and not an ambient completeness principle.

The triangle packet consumes the finite windows of chapter 126, the regular readbacks of chapter 301, the dyadic tolerance rows of chapter 291, and the downstream diagonal consumer surface of chapter 646. These four rows determine the L10 dependency route on which the three-leg estimate is later read by completion-facing consumers.

The packet consumes the shared-threshold and middle-meet surfaces of chapter 560 and chapter 462 before handing a finite three-leg bound to Real$^{\uparrow}$ consumers. Those sibling rows supply the L10 threshold lattice used by the triangle route; the present carrier only synchronizes their reads into one diagonal estimate packet.

Definition 466.1 (RegularCauchyTriangleBound carrier)**.** *A* RegularCauchyTriangleBound$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N)$$

with the following displayed rows:

1. *D_m and D_n are the two* StreamName$^{\uparrow}$ *diagonal observation rows for the requested indices m and n;*
2. *I_m and I_n are the two intermediate* StreamName$^{\uparrow}$ *rows used to compare the diagonal observations through a common Cauchy-modulus surface;*
3. *Q is the* DyadicRatCore$^{\uparrow}$ *tolerance ledger carrying the two endpoint tolerances $1/(m+1)$ and $1/(n+1)$ and the summed output bound;*
4. *A stores the two* RegSeqRat$^{\uparrow}$ *regularity reads that bound the first and third triangle legs;*
5. *B stores the middle* CauchyModulusMeet$^{\uparrow}$ *read that bounds the comparison between the two intermediate observations;*
6. *H stores componentwise* hsame *transports for diagonal rows, intermediate rows, tolerance rows, regularity reads, middle-modulus reads, provenance, and the local name;*

7. *C stores the displayed* Cont *routes for diagonal inspection, intermediate-point selection, regularity reads, middle-modulus reads, dyadic tolerance addition, and local NameCert comparison;*
8. *P is the* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyModulusMeet}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTriangleBound}^{\uparrow}}$ *row.*

The classifier compares accepted packets only after transporting every displayed row to a common diagonal, intermediate-point, and dyadic tolerance surface. The carrier has no coordinate for quotient stream equality, selected limits, host real equality, or ambient completeness.

Lean4 ✓ `BEDC.Derived.RegularCauchyTriangleBoundUp.RegularCauchyTriangleBoundTasteGate single carrier alignment decode encode`

Theorem 466.2 (RegularCauchyTriangleBound NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTriangleBound}}$ *surface for the carrier of Definition 466.1 consists exactly of five finite obligations:*

1. *carrier admission for the displayed packet $T = (D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N)$;*
2. *classifier transport to a common* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *surface;*
3. *regular-leg stability for the two endpoint triangle legs stored in A;*
4. *middle-leg exactness for the shared Cauchy-modulus comparison stored in B;*
5. *ledger rows for dyadic tolerance addition,* Cont *routes,* Pkg *provenance,* $\mathsf{Real}^{\uparrow}$ *handoff reads, and the local naming certificate.*

Proof. Carrier admission is projection from Definition 466.1. The rows display the two diagonal observations, two intermediate observations, dyadic tolerance ledger, endpoint regularity reads, middle-modulus read, transports, continuations, provenance, and local name.

Classifier transport uses H to move those rows to a common finite surface. Once transported, the routes in C are the only ways to inspect diagonal rows, choose intermediate rows, read endpoint regularity, read the middle modulus, and add dyadic tolerances.

The two endpoint estimates are stored in A, while the middle comparison is stored in B. Since the carrier has no coordinate for quotient streams, selected limits, host real equality, or ambient completeness, the obligations are exhausted by the five displayed rows. □

Theorem 466.3 (RegularCauchyTriangleBound diagonal regularity)**.** *For an accepted* RegularCauchyTriangleBound *carrier $T = (D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N)$, the two diagonal observations D_m and D_n are compared by the displayed three-leg route*

$$D_m \longrightarrow I_m \longrightarrow I_n \longrightarrow D_n$$

and the output tolerance is the dyadic sum recorded in Q from the two regular endpoint bounds in A and the middle Cauchy-modulus bound in B. Every $\mathsf{Real}^{\uparrow}$ *diagonal-regularity consumer reads this finite route before receiving the bound.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTriangleBoundUp.RegularCauchyTriangleBoundCarrier diagonal regular route`

Proof. Read the accepted carrier and project the four observation rows. The continuation row C supplies the route from D_m to I_m, from I_m to I_n, and from I_n to D_n.

The first and third legs are bounded by the two $\mathsf{RegSeqRat}^{\uparrow}$ regularity reads in A. The middle leg is bounded by the shared $\mathsf{CauchyModulusMeet}^{\uparrow}$ read in B, transported to the same intermediate surface by H.

Finally read the dyadic ledger Q. It records the two endpoint tolerances and the summed output tolerance, so the consumer receives exactly the three-leg diagonal estimate and no separate completed-real object. □

Theorem 466.4 (RegularCauchyTriangleBound endpoint-leg scope)**.** *For an accepted* RegularCauchyTriangleBound *carrier* $T = (D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N)$*, the first comparison leg* $D_m \longrightarrow I_m$ *and the third comparison leg* $I_n \longrightarrow D_n$ *are exactly the two* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity reads stored in row* A*. No additional endpoint estimate, quotient-stream comparison, selected limit, host real equality, or ambient completeness datum participates in either endpoint leg.*

Proof. Project the carrier of Definition 466.1. Its row A is defined as the pair of $\mathsf{RegSeqRat}^{\uparrow}$ regularity reads, one for the m endpoint and one for the n endpoint, while the surrounding rows only transport, route, add tolerances, record provenance, and name the packet.

Apply the diagonal route of Definition 466.3. The route reads the first triangle leg from D_m to I_m and the third triangle leg from I_n to D_n before the dyadic output bound is reported, so the only endpoint estimates available to that route are the two reads already displayed in A.

The non-escape boundary of Definition 466.7 prevents any consumer-facing route from exporting quotient streams, selected limits, host real equality, ambient completeness, or completion witnesses. Thus the endpoint-leg scope is exactly row A. □

Theorem 466.5 (RegularCauchyTriangleBound middle-meet exactness)**.** *For an accepted* RegularCauchyTriangleBo *carrier* $T = (D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N)$*, the middle comparison* $I_m \longrightarrow I_n$ *is exactly the* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *read stored in row* B*, transported by the displayed* hsame *rows in* H *to the common intermediate surface. No quotient stream, selected limit, host real equality, or ambient completeness datum supplies a second middle comparison.*

Proof. Project the carrier of Definition 466.1. Row B is the middle $\mathsf{CauchyModulusMeet}^{\uparrow}$ read, and row H is the componentwise transport surface that aligns the intermediate observations and middle-modulus read.

Use Definition 466.3 to inspect the route $D_m \longrightarrow I_m \longrightarrow I_n \longrightarrow D_n$. The central arrow is the only place in the route where the two intermediate rows are compared, and the theorem identifies that bound as the shared middle Cauchy-modulus read in B.

By Definition 466.7, every consumer-facing route is exhausted by the finite displayed rows. Since the carrier has no coordinate for quotient streams, selected limits, host real equality, or ambient completeness, row B is the exact middle-meet obligation. □

Theorem 466.6 (RegularCauchyTriangleBound tolerance-addition ledger)**.** *For an accepted* RegularCauchyTriangle *carrier* $T = (D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N)$*, the output tolerance read by the diagonal-regularity consumer is precisely the* $\mathsf{DyadicRatCore}^{\uparrow}$ *sum row in* Q*, formed from the two endpoint tolerances certified by* A *and the middle tolerance certified by* B*. No selected limit, quotient-stream equality, host real equality, or ambient completeness datum changes the reported tolerance.*

Proof. Project the carrier of Definition 466.1. Row Q is the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, row A supplies the two endpoint regularity tolerances, and row B supplies the middle Cauchy-modulus tolerance.

The diagonal-regularity statement in Definition 466.3 reads the three legs in order and then reads the dyadic sum recorded in Q. Therefore the reported output tolerance is not recomputed by a hidden completion object; it is the displayed ledger row attached to the finite packet.

The non-escape boundary of Definition 466.7 rules out exported quotient streams, selected limits, host real equality, ambient completeness proofs, and host completion witnesses. Hence the tolerance-addition obligation is precisely the $\mathsf{DyadicRatCore}^{\uparrow}$ row Q. □

Theorem 466.7 (RegularCauchyTriangleBound non-escape)**.** *Every consumer-facing route out of an accepted* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *carrier factors through the finite rows* $D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N$. *No route exports a quotient stream, selected limit, ambient completeness proof, host real equality, or host completion witness.*

Proof. Take any consumer-facing route and project the carrier. The only mathematical rows are the diagonal observations, intermediate observations, dyadic tolerance ledger, endpoint regularity reads, and middle-modulus read.

The remaining rows transport, route, record provenance, and name the packet. Thus any read by a $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer is exhausted by the displayed finite packet.

Because the carrier omits quotient streams, selected limits, ambient completeness proofs, host real equality, and host completion witnesses, none of those objects can be exported by a continuation route. □

Theorem 466.8 (RegularCauchyTriangleBound phase handoff)**.** *The* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *packet is the finite handoff surface from* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *into the Real completeness diagonal-regularity argument. A downstream* $\mathsf{Real}^{\uparrow}$ *consumer receives the transported three-leg route, the endpoint regularity reads, the middle-modulus read, the dyadic tolerance ledger, provenance, and the local* $\mathsf{NameCert}$ *row, and receives no additional limit-selection data.*

Proof. The dependency anchors in P name the dyadic arithmetic, stream schedule, regular rational readback, and shared-modulus rows consumed by the packet. Projecting the carrier exposes exactly those rows together with transports, continuations, provenance, and local naming.

The handoff to $\mathsf{Real}^{\uparrow}$ is through the diagonal-regularity route of Definition 466.3. That route first displays the three triangle legs and then reads the summed dyadic bound.

No downstream row is available for a selected limit, quotient stream, host real equality, or ambient completeness object. Therefore the phase handoff is precisely the finite three-leg estimate surface. □

Theorem 466.9 (RegularCauchyTriangleBound Real consumer route)**.** *Every* $\mathsf{Real}^{\uparrow}$ *completion consumer that uses a* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *packet reads the two endpoint regularity legs, the middle* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *meet, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance-addition ledger before the* $\mathsf{Real}^{\uparrow}$ *seal handoff. The consumer route exports no quotient-stream equality, selected limits, host equality, or ambient completeness row.*

Proof. Start with Definition 466.3. It fixes the three-leg route through the two endpoint observations and the two intermediate rows.

Apply Definition 466.4 and Definition 466.5. These identify the endpoint regularity reads with row A and the middle modulus meet with row B after the displayed transports.

The tolerance row is supplied by Definition 466.6. Use Definition 466.7 to exclude quotient-stream equality, selected limits, host equality, and ambient completeness, then apply Definition 466.8 to present the finite packet to the $\mathsf{Real}^{\uparrow}$ seal handoff. □

Theorem 466.10 (RegularCauchyTriangleBound transported assembly)**.** *For an accepted* RegularCauchyTriangleB *carrier*

$$T = (D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N),$$

any transported consumer route over T is exhausted by the endpoint-leg reads in A, the middle-meet read in B, the dyadic sum ledger Q, the transport and continuation routes H, C, and the package and naming rows P, N. The assembled route is the finite transported packet that a $\mathsf{Real}^{\uparrow}$ *diagonal-regularity or completion-seal consumer receives; it is not a single-theorem variant of one leg obligation, because it combines both endpoint legs, the middle leg, tolerance addition, non-escape, and the Real-phase handoff into one consumer package.*

Proof. Start with diagonal regularity from Definition 466.3. It fixes the visible route $D_m \longrightarrow I_m \longrightarrow I_n \longrightarrow D_n$ and makes the dyadic output bound a read from the same packet.

Apply endpoint-leg scope from Definition 466.4. The first and third legs of the route are exactly the two $\mathsf{RegSeqRat}^{\uparrow}$ regularity reads stored in A after the displayed transports.

Next apply middle-meet exactness from Definition 466.5. The central comparison is exactly the $\mathsf{CauchyModulusMeet}^{\uparrow}$ read stored in B, transported by H to the same intermediate surface.

The tolerance-addition ledger of Definition 466.6 supplies the summed dyadic output row Q. Non-escape from Definition 466.7 prevents quotient streams, selected limits, host real equality, ambient completeness, and completion witnesses from entering the transported route.

Finally use the phase handoff of Definition 466.8. The $\mathsf{Real}^{\uparrow}$ consumer receives the assembled finite packet through H, C, P, N, so the transported assembly is exactly the union of the three leg obligations, the dyadic ledger, and the Real-phase handoff. □

Theorem 466.11 (RegularCauchyTriangleBound completion-seal consumer exactness)**.** *For an accepted* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *carrier*

$$T = (D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N),$$

every $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *completion-seal consumer that invokes the triangle-bound packet factors through the diagonal route theorem, endpoint-leg scope, middle-meet exactness, tolerance-addition ledger, non-escape boundary, and phase handoff. The consumer receives exactly the displayed rows $D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N$ and receives no selected limit, quotient stream, host real equality, ambient completeness proof, or completion witness.*

Proof. First apply Definition 466.3. It fixes the route from D_m through I_m and I_n to D_n as the only diagonal comparison available to a completion-seal consumer.

Next apply Definition 466.4 and Definition 466.5. These identify the two endpoint legs with row A and the middle leg with row B after the displayed transports.

The tolerance read is then forced by Definition 466.6. Apply Definition 466.7 to exclude selected limits, quotient streams, host real equality, ambient completeness proofs, and completion witnesses.

Finally use Definition 466.8. The handoff row presents exactly $D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N$ to the $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ reader, so the consumer boundary is exact for the finite triangle-bound packet. □

Theorem 466.12 (RegularCauchyTriangleBound finite induction scope)**.** *For an accepted* RegularCauchyTriangleB *carrier*

$$T = (D_m, D_n, I_m, I_n, Q, A, B, H, C, P, N),$$

the three-leg estimate is obtained by finite induction over the displayed $\mathsf{StreamName}^{\uparrow}$ *windows and the* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *rows visible to the packet. The induction step preserves the two endpoint*

$\mathsf{RegSeqRat}^{\uparrow}$ *regularity reads in A, the middle-meet read in B, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance-addition ledger Q, so every completion-facing consumer receives the same transported triangle route recorded by Definition 466.10.*

Proof. The base window is the diagonal regularity route of Definition 466.3. It displays the route $D_m \longrightarrow I_m \longrightarrow I_n \longrightarrow D_n$ and binds the output tolerance to the dyadic sum in Q.

For the induction step, extend only the displayed $\mathsf{StreamName}^{\uparrow}$ window rows and the visible $\mathsf{CauchyModulusMeet}^{\uparrow}$ row. Endpoint-leg scope from Definition 466.4 keeps the first and third legs inside A, while middle-meet exactness from Definition 466.5 keeps the central comparison inside B.

The tolerance-addition ledger of Definition 466.6 carries the dyadic sum through the same finite step. Non-escape from Definition 466.7 prevents quotient streams, selected limits, host real equality, ambient completeness, or completion witnesses from entering the induction.

Finally apply the phase handoff of Definition 466.8 and the transported assembly of Definition 466.10. The resulting consumer route is exactly the finite induction over displayed windows and meet rows, with no additional completion object. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyTriangleBound}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ packet is generated from two diagonal observation rows, two intermediate observation rows, a $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, two $\mathsf{RegSeqRat}^{\uparrow}$ regularity reads, one $\mathsf{CauchyModulusMeet}^{\uparrow}$ middle read, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyTriangleBound}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The scoped dependency surface consists exactly of $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyModulusMeet}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows supporting the finite triangle-bound carrier, diagonal route, endpoint legs, middle meet, tolerance ledger, handoff, and non-escape boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyTriangleBound}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.RegularCauchyTriangleBoundUp.RegularCauchyTriangleBoundCarrier\_diagonal\_regular\_rout`

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient equality of streams, selected limits, host real equality, ambient completeness, completion witnesses, or bridge checking.

Upgrade path: No further paper-side closure grade remains; bridge checking is recorded only on the separate formal bridge axis.

Chapter 467

A Concrete Naming Certificate for $\mathsf{DyadicEmbedding}^{\uparrow}$

Following the Bishop–Bridges constructive-analysis treatment of rational and dyadic numbers inside real names, the $\mathsf{DyadicEmbedding}^{\uparrow}$ interface records a constant dyadic real name as a finite route from a dyadic row to a constant stream, a stationary regular rational readback, and a real seal. The packet below exposes the embedding path without quotienting regular sequences, selecting a host real limit, invoking real completeness, or comparing completed real representatives by ambient equality.

The constant dyadic route depends on the finite-window surface of chapter 126, the stationary readback surface of chapter 301, the dyadic source row of chapter 291, and the seal boundary of chapter 38. The $\mathsf{StationaryRationalDiagonal}^{\uparrow}$ row is therefore not a separate analytic shortcut; it is the named sibling route that reads the same dyadic row as a constant stream, then as a stationary regular rational row, and finally as a finite $\mathsf{Real}^{\uparrow}$ seal.

Definition 467.1 (DyadicEmbedding carrier)**.** *A* $\mathsf{DyadicEmbedding}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (d, S, R, Q, H, C, P, N)$$

with the following visible coordinates:

1. *d is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *source row naming the dyadic rational observation;*
2. *S is the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule whose every admitted read returns the same dyadic row d;*
3. *R is the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *readback obtained from the constant stream schedule;*
4. *Q is the* $\mathsf{Real}^{\uparrow}$ *seal row reached from the stationary regular readback;*
5. *H stores componentwise* hsame *transports for the dyadic source, constant stream, stationary readback, real seal, package provenance, and local naming row;*
6. *C stores the displayed* Cont *routes from the dyadic row to the constant stream, from the stream to the stationary regular readback, and from the readback to the real seal;*
7. *P names* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{StationaryRationalDiagonal}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{DyadicEmbedding}^{\uparrow}}$ *row.*

The carrier is a finite naming certificate for constant dyadic real names. It contains no quotient stream, no selected limit, no host real equality test, and no completeness theorem for arbitrary regular sequences.

Lean4 ✓ `BEDC.Derived.DyadicEmbeddingUp.DyadicEmbeddingTasteGate single carrier alignment`

Theorem 467.2 (DyadicEmbedding NameCert obligations)**.** *For the carrier of Definition 467.1, the local* $\mathsf{NameCert}_{\mathsf{DyadicEmbedding}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission for the displayed packet* $D = (d, S, R, Q, H, C, P, N)$*;*
2. *classifier transport by componentwise* hsame *over the dyadic source, constant stream schedule, stationary readback, and real seal;*
3. *constant-stream readback, which requires every stream window to return the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *row before it is read as a* $\mathsf{RegSeqRat}^{\uparrow}$ *row;*
4. *real-seal handoff, which routes any* $\mathsf{Real}^{\uparrow}$ *consumer through the stationary readback* R *and the package rows* P, N*;*
5. *non-escape, which excludes quotient regular streams, chosen limits, host equality of real representatives, trichotomy, and ambient completeness.*

Lean4 ✓ `BEDC.Derived.DyadicEmbeddingUp.DyadicEmbeddingCarrier namecert obligations`

Proof. Carrier admission is the direct projection of the tuple in Definition 467.1. The coordinates name the dyadic source, stream schedule, regular readback, real seal, transports, routes, package provenance, and local certificate row in one finite BHist packet.

Classifier transport is componentwise. The rows d, S, R, Q are compared only through the stored hsame entries in H, and each accepted route is replayed through the displayed Cont entries in C.

For the constant-stream and real-seal obligations, first read d into the constant stream schedule S, then read the stationary regular row R through the same schedule, and finally expose Q only through R. This proves that all downstream real-name consumers receive the displayed finite route.

The non-escape clause follows from the carrier inventory. Since the tuple contains no coordinate for quotient streams, selected limits, host real equality, trichotomy, or completeness, no projected certificate route can export one. □

Theorem 467.3 (DyadicEmbedding constant stream readback)**.** *Every accepted* $\mathsf{DyadicEmbedding}^{\uparrow}$ *carrier reads its* $\mathsf{StreamName}^{\uparrow}$ *coordinate as a constant schedule over the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *row* d*. The resulting* $\mathsf{RegSeqRat}^{\uparrow}$ *row is the stationary rational diagonal named by* $\mathsf{StationaryRationalDiagonal}^{\uparrow}$*, and no separate rational stream or unrecorded convergence witness participates in the readback.*

Lean4 ✓ `BEDC.Derived.DyadicEmbeddingUp.DyadicEmbeddingCarrier constant stream readback`

Proof. Project the dyadic source and stream coordinates from D. The route from d to S is displayed in C, so every admitted window of the stream schedule is read through the same source row.

The stationary readback is then the route from S to R. Because S has no coordinate other than the constant dyadic row and its finite window ledger, R is the regular rational readback of that stationary schedule.

The package row P names $\mathsf{StationaryRationalDiagonal}^{\uparrow}$ as the readback shape. Thus the readback is a named stationary diagonal over d, not a separate rational stream or a convergence object chosen outside the packet. □

Theorem 467.4 (DyadicEmbedding real seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer exported by a* $\mathsf{DyadicEmbedding}^{\uparrow}$ *packet factors through the same dyadic source row* d*, constant* $\mathsf{StreamName}^{\uparrow}$ *schedule* S*, and stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R *before it reaches the real seal* Q*. The seal is therefore a finite handoff from the dyadic row to a constant real name, not a proof of completeness for arbitrary regular sequences.*

Proof. Start with a consumer route to Q. The carrier definition records this route in C as downstream of the regular readback coordinate R.

Apply Definition 467.3. It identifies R as the stationary rational diagonal read from the constant schedule S, and identifies S as the schedule produced from the same dyadic row d.

Composing the displayed routes gives the handoff d to S to R to Q. The packet has no row for arbitrary completeness or a selected limit, so the exported real seal is exactly the constant-name handoff. □

Theorem 467.5 (DyadicEmbedding ledger non-escape)**.** *The dependency ledger of a* $\mathsf{DyadicEmbedding}^{\uparrow}$ *carrier is exhausted by* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{StationaryRationalDiagonal}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. No consumer may add a quotient of streams, a selected real value, host equality of completed representatives, trichotomy, or a completeness principle as an implicit dependency.*

Proof. Inspect the package coordinate P and the local naming coordinate N. Together they name exactly the dependency list displayed in Definition 467.1.

The readback theorem accounts for $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{StationaryRationalDiagonal}^{\uparrow}$ through the rows d, S, R. The real-seal theorem accounts for the $\mathsf{Real}^{\uparrow}$ consumer through Q and the same route inventory.

No further coordinate remains in D. Therefore any extra quotient, selected host value, equality test, trichotomy, or completeness theorem would have to be supplied from outside the accepted packet, which the local $\mathsf{NameCert}_{\mathsf{DyadicEmbedding}^{\uparrow}}$ surface does not permit. □

Theorem 467.6 (DyadicEmbedding public scope)**.** *The public surface of a* $\mathsf{DyadicEmbedding}^{\uparrow}$ *seed packet is precisely the finite constant-name route through* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{StationaryRationalDiagonal}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *named in Definition 467.1. It exports constant dyadic real names and excludes quotient-real construction, arbitrary Cauchy completion, selected limits, host real equality, and real-order trichotomy.*

Proof. Project the public rows of the carrier. They are exactly the dyadic source, constant stream schedule, stationary regular readback, real seal, componentwise transports, continuation routes, package provenance, and local naming row.

Use Definition 467.2 for carrier admission and local classifier transport. Use Definition 467.3 for the stationary readback and Definition 467.4 for the real-name consumer route.

Finally apply Definition 467.5. The ledger admits only the displayed dependency rows, so the public scope is exactly the constant dyadic real-name interface and none of the excluded completion or host-real structure. □

Theorem 467.7 (DyadicEmbedding constant schedule transport)**.** *For an accepted* $\mathsf{DyadicEmbedding}^{\uparrow}$ *carrier*

$$D = (d, S, R, Q, H, C, P, N),$$

componentwise hsame *transport preserving the dyadic source row* d *preserves the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule* S*: every admitted transported stream window still reads the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *row and uses only the displayed route from* d *to* S*.*

Proof. Project the transport coordinate H from Definition 467.1. Its entries compare the dyadic source, constant stream schedule, stationary readback, real seal, package row, and local naming row componentwise.

The constant-stream readback theorem identifies S as a schedule whose admitted windows all return the same dyadic source row d. Transport of d along H therefore transports the single source read used by every stream window.

The continuation coordinate C contains the displayed route from d to S. Replaying that route after the componentwise transport gives the same constant schedule shape and adds no separate stream or convergence witness. □

Theorem 467.8 (DyadicEmbedding stationary readback exactness)**.** *The* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R of an accepted* $\mathsf{DyadicEmbedding}^{\uparrow}$ *carrier is exactly the stationary diagonal over the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *row d. Its exactness is witnessed by the route $d \to S \to R$ and by the* $\mathsf{StationaryRationalDiagonal}^{\uparrow}$ *provenance row in P.*

Proof. Use Definition 467.7 to keep the stream coordinate S constant under the allowed componentwise transports. Thus every read entering the regular rational row starts from the same dyadic source d.

Apply the constant-stream readback theorem. It identifies R with the stationary readback produced from S and names $\mathsf{StationaryRationalDiagonal}^{\uparrow}$ as the readback shape.

The package row P records that stationary diagonal provenance, while C records the route $d \to S \to R$. Hence the readback is exact for the displayed dyadic row and is not an arbitrary regular sequence chosen outside the carrier. □

Theorem 467.9 (DyadicEmbedding Real seal consumer non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{DyadicEmbedding}^{\uparrow}$ *carrier factors through the rows d, S, R, Q, H, C, P, N. It may read the dyadic source, constant stream schedule, stationary readback, real seal, transports, continuations, package provenance, and local naming row, but it has no quotient stream, selected limit, host equality, trichotomy, or completeness datum.*

Proof. Start with the real-seal handoff theorem. It already factors any $\mathsf{Real}^{\uparrow}$ read through d, then S, then R, and finally the real seal row Q.

Use stationary readback exactness to identify the regular rational row consumed by the seal with the stationary diagonal over d. The only transport and continuation data available for that route are the displayed rows H and C.

Finally apply the ledger non-escape theorem. The package and local naming rows P, N exhaust the dependency list, so a consumer cannot obtain quotient streams, selected limits, host real equality, trichotomy, or ambient completeness from the carrier. □

Theorem 467.10 (DyadicEmbedding stationary source obligation)**.** *Every accepted* $\mathsf{DyadicEmbedding}^{\uparrow}$ *packet reads the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *row d through the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule and the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *readback. No accepted read may replace that source by a varying stream coordinate or by a regular sequence selected outside the carrier.*

Proof. Begin with the carrier of Definition 467.1. Its source row is d, its stream schedule is S, and its regular rational readback is R.

Apply Definition 467.3. It identifies every admitted stream window with the same dyadic source row and reads the resulting regular rational row as the stationary diagonal named by $\mathsf{StationaryRationalDiagonal}^{\uparrow}$.

Use Definition 467.7 and Definition 467.8. Transport preserves the constant schedule, and exactness identifies R with the stationary readback over d, so no varying or externally selected source remains available. □

Theorem 467.11 (DyadicEmbedding Real seal obligation)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{DyadicEmbedding}^{\uparrow}$ *packet factors through the rows* d, S, R, Q, H, C, P, N *and receives only the constant dyadic real-name route. The consumer cannot bypass the stationary readback or obtain a selected real limit outside the displayed seal row.*

Proof. Start from a consumer route to the real seal row Q. By Definition 467.4, the route first reads d, then S, then R, and only then reaches Q.

Apply Definition 467.10. The source and readback are the stationary route through the same dyadic row, so the real seal is the constant dyadic real-name route.

Finally use Definition 467.9. The remaining rows H, C, P, N record transport, continuation, package provenance, and local naming, and they do not contain a bypass to a selected host real limit. □

Theorem 467.12 (DyadicEmbedding ledger exactness obligation)**.** *The visible ledger of an accepted* $\mathsf{DyadicEmbedding}^{\uparrow}$ *packet is exhausted by* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{StationaryRationalDiagonal}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$. *It excludes quotient streams, selected limits, host equality, trichotomy, and completeness as available dependencies.*

Proof. Project the package row P and local naming row N from Definition 467.1. They list the dyadic source, constant stream schedule, stationary regular readback, real seal, history, transport, continuation, package, and naming dependencies.

Use Definition 467.5 for the base dependency boundary. Then apply Definition 467.6 to identify that boundary as the public constant dyadic real-name surface.

The stationary-source and real-seal obligations show that every consumer route remains inside d, S, R, Q, H, C, P, N. Therefore quotient streams, selected limits, host equality, trichotomy, and completeness would require extra rows not present in the accepted packet. □

Theorem 467.13 (DyadicEmbedding source-window-seal factorization)**.** *For every accepted* $\mathsf{DyadicEmbedding}^{\uparrow}$ *packet*

$$D = (d, S, R, Q, H, C, P, N),$$

any $\mathsf{Real}^{\uparrow}$ *consumer factors through the same dyadic source row* d*, the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule* S*, the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R*, the real seal row* Q*, and the displayed transport, continuation, package, and local naming rows* H, C, P, N*. No varying stream, selected limit, host equality, trichotomy, or completeness row participates in the route.*

Proof. Project the carrier of Definition 467.1. The source, stream, readback, seal, transport, continuation, package, and naming rows are precisely the coordinates d, S, R, Q, H, C, P, N.

Use Definition 467.10 to force the stream and regular rational readback through the same dyadic source row. Then apply Definition 467.11 to route the $\mathsf{Real}^{\uparrow}$ consumer through Q only after the stationary readback has been consumed.

Finally apply Definition 467.12. The ledger is exhausted by the displayed rows, so no varying stream, selected limit, host equality, trichotomy, or completeness coordinate remains available to the consumer. □

Theorem 467.14 (DyadicEmbedding obligation closure surface)**.** *The carrier, local* $\mathsf{NameCert}_{\mathsf{DyadicEmbedding}^{\uparrow}}$ *obligations, constant stream readback, real seal handoff, ledger non-escape, public scope, stationary readback exactness, and real seal obligation of Definition 467.1, Definition 467.2, Definition 467.3, Definition 467.4, Definition 467.5, Definition 467.6, Definition 467.8, and Definition 467.11 jointly supply the obligation surface for the constant dyadic real-name route. Every accepted consumer factors through the displayed rows* d, S, R, Q, H, C, P, N *and obtains no quotient stream, selected limit, host real equality, trichotomy, or ambient completeness principle.*

Proof. First project the carrier of Definition 467.1. The displayed rows d, S, R, Q, H, C, P, N name the dyadic source, constant stream schedule, stationary readback, real seal, transports, continuation routes, package provenance, and local naming row.

Use Definition 467.2 for carrier admission, classifier transport, constant-stream readback, real-seal handoff, and non-escape as the local naming obligations. Then apply Definition 467.3 and Definition 467.8 to identify the $\mathsf{RegSeqRat}^{\uparrow}$ row R as the stationary readback of the same dyadic source row d.

Next route real consumers through Definition 467.4 and Definition 467.11. These theorems force every $\mathsf{Real}^{\uparrow}$ read to pass through the constant schedule and stationary readback before reaching Q.

Finally combine Definition 467.5 with Definition 467.6. The public surface is exactly the constant dyadic real-name route, and the excluded quotient, selected-limit, host-equality, trichotomy, and completeness data have no row in the packet. □

Theorem 467.15 (DyadicEmbedding scoped dependency spine)**.** *For every accepted* $\mathsf{DyadicEmbedding}^{\uparrow}$ *packet*

$$D = (d, S, R, Q, H, C, P, N),$$

the scoped public dependency spine is exactly the finite route from the $\mathsf{DyadicRatCore}^{\uparrow}$ *row* d *to the constant* $\mathsf{StreamName}^{\uparrow}$ *schedule* S*, the stationary* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R*, and the* $\mathsf{Real}^{\uparrow}$ *seal row* Q*, with componentwise* hsame *transports* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}$ *row* N*. Every constant dyadic real-name consumer factors through that spine and cannot replace any edge by a quotient stream, selected limit, host equality, trichotomy, or completeness datum.*

Proof. Begin with the accepted carrier. By Definition 467.2, the packet admits only the displayed rows d, S, R, Q, H, C, P, N as the carrier and local naming surface, with classifier transport supplied componentwise by the stored hsame entries in H.

Next identify the readback route. Apply Definition 467.3 to force the stream coordinate S to be the constant schedule over d, and use Definition 467.8 to identify R as the stationary regular rational readback of that same schedule.

The real-name handoff is then fixed by Definition 467.11. Any $\mathsf{Real}^{\uparrow}$ consumer reaches Q only after passing through the dyadic source, constant stream schedule, and stationary readback, while the continuation coordinate C records the displayed route edges.

Finally apply Definition 467.12. The package provenance P and local naming row N exhaust the available dependencies, so no consumer has a row from which to obtain a quotient stream, selected limit, host equality, trichotomy, or completeness datum in place of an edge of the spine. □

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicEmbedding}^{\uparrow}}$**.**

Constructive story: A $\mathsf{DyadicEmbedding}^{\uparrow}$ packet is generated from a $\mathsf{DyadicRatCore}^{\uparrow}$ row, a constant $\mathsf{StreamName}^{\uparrow}$ schedule, a stationary $\mathsf{RegSeqRat}^{\uparrow}$ readback, a $\mathsf{Real}^{\uparrow}$ seal, componentwise hsame transports, displayed Cont routes, package provenance, and a local $\mathsf{NameCert}$ row.

Theory closure: TheoryGate(NameCert$_{\text{DyadicEmbedding}\uparrow}$, scopedClosed)

Scope closed: The obligation scope records the finite carrier, local naming obligations, constant-stream readback, real-seal handoff, ledger non-escape, public constant dyadic real-name boundary, stationary readback exactness, real-seal obligation, and obligation closure surface.

Formal verification: FormalStatus(NameCert$_{\text{DyadicEmbedding}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.DyadicEmbeddingUp.DyadicEmbeddingCarrier\_constant\_stream\_readback`

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient-real construction, arbitrary Cauchy completion, selected limits, host real equality, real-order trichotomy, or a public real-object surface.

Upgrade path: Public closure requires a public-object presentation of the constant dyadic real-name route through DyadicRatCoreUp, StreamNameUp, RegSeqRatUp, RealUp, hsame, Cont, Pkg, and NameCert.

Chapter 468

A Concrete Naming Certificate for $\mathsf{FiniteMultiHistPacket}^{\uparrow}$

The $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ interface supplies the first concrete carrier for the multi-Hist branch of Definition 9419.25. It packages a finite family of observer histories with only local comparison rows, visible continuation routes, package provenance, and local naming data. The packet is deliberately weaker than the later $\mathsf{CrossHistCausal}^{\uparrow}$ surface: it records the configuration that later causal and maximum-rate certificates may consume, but it does not already select a causal relation, a shared time coordinate, or a global observer frame. The downstream two-history consumer is the CrossHistCausal certificate of chapter 478; the present packet supplies its finite displayed-history rows, component ledgers, pairwise hsame rows, visible Cont routes, and no-global-sync input surface, while $\mathsf{CrossHistCausal}^{\uparrow}$ adds two-history causal witness rows.

Definition 468.1 (Finite MultiHist packet carrier)**.** *A* $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (H, L, S, C, B, P, N)$$

with the following visible rows:

1. $H = (H_1, \ldots, H_n)$ *is the finite observer-history row, whose entries are displayed* BHist *histories;*
2. $L = (L_1, \ldots, L_n)$ *is the component ledger, with* L_i *naming the local rows of* H_i *available to consumers;*
3. $S = (S_{ij})_{i,j}$ *is the pairwise* hsame *row, recording exactly the history-sameness comparisons admitted between displayed component rows;*
4. C *records the visible* Cont *routes by which a consumer reads a component ledger, a pairwise* hsame *entry, the package row, and the local naming row;*
5. B *is the no-global-sync boundary row, recording that the packet has no coordinate for a privileged shared now, global frame, total observer order, or selected synchronization map;*
6. P *is the* Pkg *provenance over* BHist, Hist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$*;*
7. N *is the local* $\mathsf{NameCert}_{\mathsf{FiniteMultiHistPacket}^{\uparrow}}$ *row.*

The carrier is finite and every cross-component comparison available to the packet is displayed in S *and reached through* C*. It has no cross-Hist causal witness, no maximum-rate function, no metric row, and no synchronization object.*

Lean4 (definition) `BEDC.Derived.FiniteMultiHistPacketUp.FiniteMultiHistPacketUp`
Lean4 ✓ `BEDC.Derived.FiniteMultiHistPacketUp.FiniteMultiHistPacketTasteGate single carrier alignment`

Theorem 468.2 (Finite MultiHist packet NameCert obligations)**.** *For the carrier of Definition 468.1, the local* $\mathsf{NameCert}_{\mathsf{FiniteMultiHistPacket}^{\uparrow}}$ *surface consists of carrier admission for* $M = (H, L, S, C, B, P, N)$*, component-ledger exactness for each displayed history row, pairwise* hsame *stability through* S*, visible read access through* C*, package provenance through* P*, local naming through* N*, and the no-global-sync boundary recorded by* B*.*

Lean4 ✓ `BEDC.Derived.FiniteMultiHistPacketUp.FiniteMultiHistPacketUp taste gate boundary`

Proof. Carrier admission is the displayed finite tuple. The rows H, L, S, C, B, P, N are the only data made available to the naming certificate, so every obligation can be projected from a named coordinate of the packet.

Component-ledger exactness follows from L. For each component H_i, the ledger L_i records the local rows a consumer may inspect before any cross-component comparison is used.

Pairwise stability is supplied by S. Each admitted comparison between component histories is an explicit hsame row S_{ij}, and no comparison outside that row is part of the carrier.

The read and provenance clauses are supplied by C, P, and N. The continuation row C exposes the component ledger, the pairwise sameness row, package provenance, and local naming row; the package row P names the BEDC kernel objects used by the certificate; N is the local NameCert surface.

Finally, B records the boundary condition. Since the carrier has no coordinate for a global frame, shared clock, total observer order, selected synchronization map, causal relation, maximum-rate function, or metric data, the local naming row cannot export any of those objects. □

Theorem 468.3 (Finite MultiHist packet hsame transport)**.** *Let* $M = (H, L, S, C, B, P, N)$ *be an accepted* $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ *carrier. Any transport that preserves the component ledgers in* L *and the pairwise* hsame *row* S *preserves the same finite multi-Hist packet interface, with consumer access replayed through the displayed* Cont *routes in* C*.*

Lean4 ✓ `BEDC.Derived.FiniteMultiHistPacketUp.FiniteMultiHistPacketUp hsame transport`

Proof. Project the component ledgers from L. A transported read of a component history must still pass through the displayed ledger for that component, so it cannot introduce an unrecorded history row.

Next project the pairwise comparison row S. Since the admitted cross-component comparisons are exactly the displayed hsame entries, preserving S preserves the comparison surface of the packet.

It remains to check access. The routes in C are the only visible continuations from consumer reads to component ledgers, pairwise comparison rows, package provenance, and the naming row. Replaying those routes after transport gives the same finite interface and adds no global synchronization coordinate. □

Theorem 468.4 (Finite MultiHist packet no-sync boundary)**.** *The public boundary of an accepted* $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ *carrier exports only the displayed finite histories, component ledgers, pairwise* hsame *rows, visible* Cont *routes, package provenance, and local* NameCert *row. It exports no privileged shared now, no global observer frame, no total ordering of observers, and no selected synchronization map between components.*

Lean4 ✓ `BEDC.Derived.FiniteMultiHistPacketUp.FiniteMultiHistPacketUp no sync boundary`

Proof. Inspect the coordinates of Definition 468.1. The public rows are H, L, S, C, B, P, N, and each row is finite and local to the packet.

The no-global-sync boundary is the row B. It records that the packet lacks a privileged shared now, global observer frame, total observer order, and selected synchronization map.

No other coordinate can supply such data. The history rows are local components, L records their local ledgers, S records only pairwise hsame comparisons, C records visible reads, P records package provenance, and N records the local naming surface. Hence the boundary exports no synchronization object. □

Theorem 468.5 (Finite MultiHist packet causal interface)**.** *Every accepted* FiniteMultiHistPacket$^{\uparrow}$ *carrier supplies the input surface required by a later* CrossHistCausal$^{\uparrow}$ *certificate: a finite family of displayed observer histories, component ledgers, pairwise* hsame *transport rows, visible* Cont *routes, package provenance, and a no-global-sync boundary. It does not itself assert any cross-Hist causal dependence or maximum causal rate.*

Lean4 ✓ `BEDC.Derived.FiniteMultiHistPacketUp.FiniteMultiHistPacketUp causal interface`

Proof. The consumer surface needed by CrossHistCausal$^{\uparrow}$ begins with displayed histories. The row H supplies the finite family of observer histories, and L supplies the local ledgers from which those histories are read.

Transport data are already present. The row S records the pairwise hsame comparisons, and C records the continuation routes through which a later causal certificate may read the selected components and their comparison rows.

Package and naming data are also present. The rows P and N identify the kernel objects and the local NameCert surface from which the later certificate may project its inputs.

The boundary condition remains negative. The row B excludes a global synchronization object, and the carrier has no coordinate for a causal witness or maximum-rate function. Thus the packet supplies the causal interface inputs without pre-solving the later causal or rate obligations. □

Theorem 468.6 (Finite MultiHist packet CrossHist forward route)**.** *Every* CrossHistCausal$^{\uparrow}$ *consumer of an accepted* FiniteMultiHistPacket$^{\uparrow}$ *carrier must enter through the finite family row H, component ledger L, pairwise* hsame *row S, visible* Cont *routes C, no-global-sync boundary B,* Pkg *provenance P, and local* NameCert *row N before adding causal witness rows. The* CrossHistCausal$^{\uparrow}$ *certificate of chapter 478 adds causal dependence rows downstream of this carrier; it does not replace the finite multi-history packet or supply a hidden global synchronization coordinate.*

Lean4 ✓ `BEDC.Derived.FiniteMultiHistPacketUp.FiniteMultiHistPacketCrossHistForwardRoute`

Proof. Start with the causal interface theorem, Definition 468.5. It exposes exactly the finite family of observer histories, component ledgers, pairwise transport rows, visible routes, provenance, and no-global-sync boundary required before a later causal certificate can read any input.

The forward route is therefore ordered by the carrier rows. A CrossHistCausal$^{\uparrow}$ consumer first reads H, L, S, C, B, P, N from the finite packet, and only then may append causal-witness rows in the downstream chapter named by chapter 478.

Since the finite carrier has no coordinate for a causal witness, maximum-rate function, privileged shared now, global observer frame, or selected synchronization map, the downstream causal packet extends the visible carrier route rather than replacing it. □

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteMultiHistPacket}^{\uparrow}}$.

Constructive story: A $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ packet is generated from a finite family of displayed BHist observer histories, component ledgers, pairwise hsame rows, displayed Cont routes, package provenance, a no-global-sync boundary row, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FiniteMultiHistPacket}^{\uparrow}}, \mathsf{seed})$

Scope closed: The seed scope records the finite multi-Hist carrier and its displayed component ledgers, pairwise hsame rows, visible Cont routes, package provenance, local naming row, and no-global-sync boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FiniteMultiHistPacket}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close cross-Hist causal dependence, maximum causal rates, Lorentz geometry, curved spacetime, quantum-state certificates, or a checked Lean theorem for the carrier obligations.

Upgrade path: Obligation closure requires a Lean carrier encoding and checked NameCert obligation theorem for the displayed finite multi-Hist packet, its transport rows, visible reads, and no-global-sync boundary.

Theorem 468.7 (Finite MultiHist packet subpacket restriction)**.** *Let*

$$M = (H, L, S, C, B, P, N)$$

be an accepted $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ *carrier. Let J be a displayed finite subfamily of the observer-history row H, and suppose the subfamily ledger records every selected component read, every selected component-ledger read, and every selected pairwise comparison through the visible* Cont *routes already present in C. Write*

$$M|_J = (H_J, L_J, S_J, C_J, B, P_J, N_J)$$

for the packet obtained by projecting H to the selected histories, L to the corresponding component ledgers, S to the selected pairwise hsame *entries, C to the displayed routes that read those selected rows, and P, N to the same package-provenance and local-naming data restricted to the selected rows. Then $M|_J$ is again an accepted* $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ *carrier. Its public boundary has the same no-global-sync row B, so the restriction exports no privileged shared now, no global observer frame, no total observer order, and no selected synchronization map.*

Lean4 ✓ `BEDC.Derived.FiniteMultiHistPacketUp.FiniteMultiHistPacketUp subpacket restriction`

Proof. The carrier shape is read from Definition 468.1. Since H is finite and J is a displayed finite subfamily, H_J is a finite observer-history row. The component ledger L_J is obtained by keeping exactly the entries L_i whose histories H_i are selected by J, so every component row of the restricted packet remains a displayed local ledger row of the original packet.

The pairwise comparison row is closed under this projection. By definition, S contains exactly the admitted cross-component hsame comparisons of M. The row S_J contains precisely those entries S_{ij} with both endpoints selected by J. Thus the restricted packet neither invents a comparison outside S nor forgets the comparison data required for the displayed selected components.

The visible-read condition is inherited from C. By hypothesis, every selected history read, component-ledger read, and pairwise comparison read factors through a route already displayed in C. The row C_J is the subrow of those routes, so consumer access to $M|_J$ is still by visible Cont routes and has no hidden access path.

The package and naming rows are restricted, not replaced. The rows P_J and N_J are the original provenance and local NameCert rows read only on the selected packet coordinates. Applying Definition 468.2 to these projected coordinates gives carrier admission, component-ledger exactness, pairwise hsame stability, visible read access, package provenance, local naming, and the boundary

clause for the restricted packet. Equivalently, Definition 468.3 applies because the projection preserves the selected component ledgers and the selected pairwise hsame row.

It remains to check the boundary. The restriction keeps the row B unchanged and only deletes unselected histories, ledger entries, comparison entries, and routes. Deleting displayed rows cannot create a coordinate for a shared clock, global frame, total observer order, synchronization map, causal relation, maximum-rate function, or metric row. Therefore Definition 468.4 applies with the same no-global-sync boundary B, and the projected packet is an accepted $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ carrier with the same public no-sync boundary. □

Chapter 469

A Concrete Naming Certificate for $\mathsf{ContinuationTrace}^{\uparrow}$

The $\mathsf{ContinuationTrace}^{\uparrow}$ packet gives the computation-as-continuation reading of chapter 9365 a concrete finite carrier. It treats a displayed small-step computation as a BHist trace: each row records a source history, a mark-and-tail route, a target history, the hsame transports needed to compare displayed histories, the Cont route that witnesses the step, package provenance, and a local naming row. The packet does not introduce a host evaluator, a host termination predicate, quotient behaviour, or big-step semantic object.

The same trace packet supplies the step-ledger surface consumed by the unary-continuation categorical reading in chapter 471: source and target rows together with Cont tails become the hom-carrier data, while the trace ledger records the finite route support.

Definition 469.1 (ContinuationTrace carrier)**.** *A* $\mathsf{ContinuationTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (S, M, R, Q, H, C, P, N)$$

whose displayed coordinates are as follows:

1. *S is the source-history row being inspected by the small-step read;*
2. *M is the mark row and displayed tail route by which the step is named;*
3. *R is the target-history row reached by the displayed route;*
4. *Q is the finite trace ledger containing the ordered source, mark, tail, and target reads for each displayed step row;*
5. *H is the componentwise* hsame *transport row comparing source histories, tail histories, and target histories across accepted trace packets;*
6. *C is the* Cont *route witnessing that the displayed tail carries the source row to the target row;*
7. *P is the* Pkg *provenance over* BHist, BMark, hsame, Cont, *and the continuation-reading dependencies;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ContinuationTrace}^{\uparrow}}$ *row.*

Two accepted traces classify together only when the source histories, mark-and-tail route, target histories, finite trace ledger, hsame *transport,* Cont *route, package row, and local certificate row are transported componentwise by the displayed rows.*

Lean4 (definition) `BEDC.Derived.ContinuationTraceUp.ContinuationTraceCarrier`

Theorem 469.2 (ContinuationTrace NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContinuationTrace}^{\uparrow}}$ *surface consists of five finite rows:*

1. *carrier: an accepted trace is exactly the finite packet of Definition 469.1;*
2. *classifier: two accepted traces compare only by componentwise* hsame *transport of* S*,* M*,* R*,* Q*,* H*,* C*,* P*, and* N*;*
3. *step readback: every displayed small-step row is read from the* Cont *route* C *together with the mark-and-tail coordinate* M *and the source and target rows* S *and* R*;*
4. *non-escape: the trace exports no host function, host termination object, quotient behaviour, or big-step semantic value;*
5. *public export: the packet handed to later formalization is the same finite* BHist *trace carrier with its classifier, readback, non-escape, and provenance rows.*

Lean4 ✓ `BEDC.Derived.ContinuationTraceUp.ContinuationTraceCarrier namecert obligations`

Proof. Carrier admission is the finite packaging operation of Definition 469.1. Every coordinate in the accepted object is one of the displayed trace rows.

Classifier stability is componentwise. A transport of accepted traces may compare source histories, target histories, route rows, and provenance rows, but it can only do so through the listed hsame and Cont fields.

The final three rows are supplied by the readback, non-escape, and public export theorems below. Together they account for every consumer-facing trace read and keep the packet inside the BEDC history, mark, sameness, continuation, package, and naming primitives. □

Theorem 469.3 (ContinuationTrace small-step readback)**.** *Let* $T = (S, M, R, Q, H, C, P, N)$ *be an accepted* $\mathsf{ContinuationTrace}^{\uparrow}$ *carrier. Every displayed small-step transition read from* T *factors through the source-history row* S*, the mark-and-tail row* M*, the target-history row* R*, the finite trace ledger* Q*, and the* Cont *route* C*. Conversely, any displayed* Cont *tail in* C *whose source, mark, tail, and target rows are listed in* Q *is read back as a step of the same trace classifier.*

Lean4 ✓ `BEDC.Derived.ContinuationTraceUp.ContinuationTraceCarrier small step readback`

Proof. Project the accepted trace through Definition 469.1. A step read has no coordinates available except the source row, the mark-and-tail row, the target row, the trace ledger, and the displayed continuation route.

For the forward direction, inspect the row of Q named by the consumer. It records the same source, mark, tail, and target rows, and the route coordinate C supplies the displayed Cont witness that the tail carries the source to the target.

For the reverse direction, begin with such a displayed Cont tail in C. Since its source, mark, tail, and target rows are listed in Q, the classifier of the carrier reads it through the same local packet and returns the corresponding trace step. The transport row H accounts only for hsame comparisons among displayed histories and does not alter the trace boundary. □

Theorem 469.4 (ContinuationTrace non-escape boundary)**.** *An accepted* $\mathsf{ContinuationTrace}^{\uparrow}$ *packet exposes no host function graph, host termination predicate, quotient behaviour relation, selected evaluator, or big-step semantic object. Its visible computational content is exactly the finite source, mark-and-tail, target, trace-ledger,* hsame*,* Cont*,* Pkg*, and* NameCert *rows of Definition 469.1.*

Proof. Read the carrier coordinates. None of S, M, R, Q, H, C, P, or N is a host function, a host termination object, a quotient of behaviours, or a big-step value.

The only operational row is C, and it is a BEDC continuation route. By Definition 469.3, consumer-facing steps are recovered from that route together with the finite trace ledger Q and the displayed source, mark, and target rows.

Thus every exported computation read remains in the finite continuation trace packet. There is no coordinate through which a host evaluator, host termination principle, quotient behaviour, or big-step semantics can enter the public surface. □

Theorem 469.5 (ContinuationTrace public export)**.** *The public* $\mathsf{ContinuationTrace}^{\uparrow}$ *export surface is the finite carrier of Definition 469.1 together with the five NameCert rows of Definition 469.2, the readback equivalence of Definition 469.3, and the boundary statement of Definition 469.4. This is the canonical finite packet for future Lean formalization of continuation traces.*

Proof. The carrier exposes exactly the rows S, M, R, Q, H, C, P, N. The NameCert theorem identifies the accepted carrier, its classifier, the step readback row, non-escape, and the public export obligation over those rows.

The readback theorem accounts for the computation-facing use: displayed small-step reads are precisely reads through the source, mark-and-tail, target, trace ledger, and continuation route. The non-escape theorem accounts for the boundary by excluding host functions, host termination, quotient behaviours, selected evaluators, and big-step semantic objects.

Repacking these clauses gives the public finite certificate. Since every clause points back to the same displayed carrier coordinates, the export is a concrete BEDC packet and not an external operational semantics. □

Theorem 469.6 (ContinuationTrace obligation closure package)**.** *The carrier, NameCert obligations, small-step readback, non-escape boundary, and public export of Definition 469.1, Definition 469.2, Definition 469.3, Definition 469.4, and Definition 469.5 assemble the finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *obligation package over* BHist, BMark, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$. *The package exposes source histories, mark-and-tail rows, target histories, trace ledgers, transports, continuation routes, provenance, and the local naming row as the whole public surface.*

Proof. The carrier theorem supplies the finite trace packet. The NameCert obligations bind admission, classifier comparison, step readback, non-escape, and public export to the displayed coordinates S, M, R, Q, H, C, P, N.

The small-step readback theorem accounts for every computation-facing row by reading it through the source history, mark-and-tail route, target history, trace ledger, and continuation route. The non-escape boundary prevents the same read from acquiring a host evaluator, host termination predicate, quotient behaviour, selected evaluator, or big-step semantic object.

The public export theorem repacks those rows as the visible trace interface. Because all five cited results refer back to the same carrier coordinates, they form one finite $\mathsf{ContinuationTrace}^{\uparrow}$ obligation package over the BEDC history, mark, sameness, continuation, package, and naming primitives. □

Theorem 469.7 (ContinuationTrace concatenation readback)**.** *Let*

$$T_0 = (S_0, M_0, R_0, Q_0, H_0, C_0, P_0, N_0) \quad \textit{and} \quad T_1 = (S_1, M_1, R_1, Q_1, H_1, C_1, P_1, N_1)$$

be accepted $\mathsf{ContinuationTrace}^{\uparrow}$ *packets. If the target row* R_0 *of* T_0 *and the source row* S_1 *of* T_1 *are matched by a displayed* hsame *row, then their concatenation is a finite trace packet whose step*

reads factor through exactly one of the two source ledgers Q_0 or Q_1, with the boundary comparison supplied by that displayed hsame *row.*

The public concatenated packet is still over BHist, BMark, hsame, Cont, Pkg, *and* NameCert. *It exports no host evaluator, host termination predicate, quotient behaviour, or big-step semantic object.*

Lean4 ✓ `BEDC.Derived.ContinuationTraceUp.ContinuationTraceCarrier concatenation readback`

Proof. Project both accepted packets through Definition 469.1. The only rows available for a step read in the first packet are $S_0, M_0, R_0, Q_0, H_0, C_0, P_0, N_0$, and the only rows available in the second packet are $S_1, M_1, R_1, Q_1, H_1, C_1, P_1, N_1$.

Use Definition 469.3 separately on the two packets. A step read before the boundary is read from Q_0 together with C_0, while a step read after the boundary is read from Q_1 together with C_1.

The displayed hsame match between R_0 and S_1 supplies only the boundary comparison. By Definition 469.4, that comparison cannot introduce a host evaluator, host termination predicate, quotient behaviour, selected evaluator, or big-step semantic object.

Finally apply Definition 469.5 and Definition 469.6. Repacking the two finite ledgers with the boundary hsame row keeps the concatenated public packet inside BHist, BMark, hsame, Cont, Pkg, and NameCert, and every step read is accounted for by exactly one source ledger. □

Theorem 469.8 (ContinuationTrace endpoint ledger exhaustion)**.** *Let $T = (S, M, R, Q, H, C, P, N)$ be an accepted* ContinuationTrace$^{\uparrow}$ *packet. Every endpoint-facing source or target read of T is exhausted by the displayed rows S, M, R, Q, H, C, P, N: the endpoint read is listed in the finite trace ledger Q and replayed by the continuation route C from the displayed source side to the displayed target side.*

No endpoint read of T is supplied by a host evaluator, a host termination predicate, a quotient behaviour, a selected evaluator, or a big-step semantic object.

Lean4 ✓ `BEDC.Derived.ContinuationTraceUp.ContinuationTraceCarrier endpoint ledger exhaustion`

Proof. Project T through Definition 469.1. The endpoint-facing coordinates are the source row S, mark-and-tail row M, target row R, finite ledger Q, transport row H, continuation route C, provenance row P, and local naming row N.

Apply Definition 469.3. A displayed endpoint read is a small-step read only when its source, mark, tail, and target rows are listed in Q and its route is supplied by C.

Apply Definition 469.4 and Definition 469.5. These two results exclude host evaluators, host termination, quotient behaviours, selected evaluators, and big-step semantic objects from the public packet, so the endpoint read is exhausted by the concrete trace rows already displayed. □

Theorem 469.9 (ContinuationTrace boundary hsame pullback)**.** *Let*

$$T_0 = (S_0, M_0, R_0, Q_0, H_0, C_0, P_0, N_0) \quad \textit{and} \quad T_1 = (S_1, M_1, R_1, Q_1, H_1, C_1, P_1, N_1)$$

be accepted ContinuationTrace$^{\uparrow}$ *packets. A displayed boundary comparison R_0hsameS_1 pulls back only through the transport rows H_0, H_1 and the displayed ledgers Q_0, Q_1. It adds no new step row and no extra endpoint outside the two accepted trace packets.*

Lean4 ✓ `BEDC.Derived.ContinuationTraceUp.ContinuationTraceCarrier boundary hsame pullback`

Proof. Project both packets through Definition 469.1. The boundary comparison has access to R_0 from the first packet and S_1 from the second packet, while its admissible transport data is recorded by H_0 and H_1.

Use Definition 469.3 on each side. Step rows before the boundary are read from Q_0 and C_0, and step rows after the boundary are read from Q_1 and C_1.

Now apply Definition 469.7. The displayed $R_0\mathsf{hsame}S_1$ row supplies the boundary comparison between the two ledgers rather than a third ledger row. By Definition 469.4, the comparison cannot import an external endpoint or host-level computation. □

Theorem 469.10 (ContinuationTrace route support totality)**.** *For accepted packets*

$$T_0 = (S_0, M_0, R_0, Q_0, H_0, C_0, P_0, N_0) \quad \textit{and} \quad T_1 = (S_1, M_1, R_1, Q_1, H_1, C_1, P_1, N_1),$$

every consumer route of their concatenated $\mathsf{ContinuationTrace}^{\uparrow}$ *packet factors through exactly one of the source ledgers* Q_0 *or* Q_1*, together with the displayed boundary row* $R_0\mathsf{hsame}S_1$*. The full route remains a route over* BHist*,* BMark*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Proof. Begin with the two accepted carriers of Definition 469.1. Their route support is displayed by the two finite ledgers Q_0, Q_1, the continuation rows C_0, C_1, the transport rows H_0, H_1, provenance, and local naming.

Apply Definition 469.3 separately to the two packets. A consumer route whose read lies before the boundary is supported by Q_0, and a consumer route whose read lies after the boundary is supported by Q_1.

Apply Definition 469.7 and the boundary pullback of Definition 469.9. The displayed $R_0\mathsf{hsame}S_1$ row is the only boundary support, so the concatenated route has no third source ledger.

Finally use Definition 469.5. The public packet is still the finite BEDC trace packet, hence the complete route support is over BHist, BMark, hsame, Cont, Pkg, and NameCert. □

Theorem 469.11 (ContinuationTrace route composition determinacy)**.** *For accepted packets*

$$T_0 = (S_0, M_0, R_0, Q_0, H_0, C_0, P_0, N_0), \quad T_1 = (S_1, M_1, R_1, Q_1, H_1, C_1, P_1, N_1), \quad T_2 = (S_2, M_2, R_2, Q_2, H_2, C_2, P_2, N$$

suppose the displayed boundary rows match $R_0\mathsf{hsame}S_1$ *and* $R_1\mathsf{hsame}S_2$*. Then every consumer route of the two-step concatenated* $\mathsf{ContinuationTrace}^{\uparrow}$ *packet factors through exactly one source ledger among* Q_0, Q_1, Q_2 *together with the two displayed boundary rows. The selected source ledger and the resulting public route are independent of whether the first boundary* $R_0\mathsf{hsame}S_1$ *or the second boundary* $R_1\mathsf{hsame}S_2$ *is assembled first.*

The composed packet still exports no host evaluator, host termination predicate, quotient behaviour, or big-step semantic object.

Proof. Apply Definition 469.7 to the pair (T_0, T_1) and then to the resulting packet with T_2. The first assembly contributes exactly the ledgers Q_0, Q_1 and the boundary row $R_0\mathsf{hsame}S_1$; the second assembly contributes Q_2 and the boundary row $R_1\mathsf{hsame}S_2$.

Apply the same readback in the other order, first to (T_1, T_2) and then to T_0 with that packet. The visible route inventory is again Q_0, Q_1, Q_2 plus the two displayed boundary rows.

Use Definition 469.9 for each boundary. Each hsame row pulls back only to the adjacent trace ledgers and does not add a third boundary source or an external endpoint.

Finally apply Definition 469.10 on the assembled finite packet. Every consumer route chooses exactly one of the three source ledgers, while the two boundary rows only glue adjacent endpoints. The non-escape boundary remains the one already stated for continuation traces, so host evaluators, termination predicates, quotient behaviours, and big-step semantics stay outside the public route. □

Theorem 469.12 (ContinuationTrace scoped readback)**.** *Every accepted* $\mathsf{ContinuationTrace}^{\uparrow}$ *route is scoped exactly by its* BHist *source rows,* BMark *step rows, target rows, finite ledgers, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row. The route cannot read host evaluator semantics, host termination, quotient behaviour, or big-step data.*

Proof. Begin with small-step readback. It reads every displayed step from the source row, mark-and-tail row, target row, trace ledger, and continuation route.

Use the non-escape boundary and public export. These identify the visible computational content with the finite trace packet and exclude host evaluators, host termination, quotient behaviours, selected evaluators, and big-step semantic objects.

Now apply route support totality. Every consumer route factors through exactly one displayed source ledger together with the relevant boundary hsame row, so no undisplayed route support can enter.

Finally use route composition determinacy. Composed routes remain independent of the order in which adjacent boundary rows are assembled, and every read still chooses one displayed ledger. The full scope is therefore exactly the BHist, BMark, hsame, Cont, Pkg, and NameCert surface stated above. □

Closure status for $\mathsf{NameCert}_{\mathsf{ContinuationTrace}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ContinuationTrace}^{\uparrow}$ packet is generated from finite source-history rows, mark-and-tail route rows, target-history rows, trace ledgers, displayed hsame transports, Cont routes, package provenance, and a local naming row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ContinuationTrace}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 469.11 and Definition 469.12, together with the displayed trace carrier, small-step readback, concatenation readback, endpoint ledger exhaustion, boundary hsame pullback, and route support rows, supply the mature paper surface over BHist, BMark, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ContinuationTrace}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ContinuationTraceUp.ContinuationTraceCarrier\_namecert\_obligations`

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean formalization, bridge checking, host evaluator semantics, host termination, quotient behaviours, or big-step semantics.

Upgrade path: The remaining step is a checked bridge over the finite $\mathsf{ContinuationTrace}^{\uparrow}$ trace packet and its composed route ledger.

Chapter 470

A Concrete Naming Certificate for $\mathsf{StreamLimitReflection}^{\uparrow}$

The $\mathsf{StreamLimitReflection}^{\uparrow}$ interface records the reflection-limit boundary in the countable-name layer. It packages a finite observation schedule for regular rational names, the RealUp seal row available at the same finite site, and a structural code row for the internal CIC* copy, while keeping runtime execution and truth classification outside the packet.

The reflection packet consumes chapter 126 for scheduled finite windows, chapter 301 for regular rational readback, and chapter 38 for the finite $\mathsf{Real}^{\uparrow}$ seal. These are substantive carrier rows of the packet; runtime execution, truth classification, quotient streams, selected limits, and host real equality remain outside the packet. The carrier is composite over the $\mathsf{StreamName}^{\uparrow}$ schedule surface, the $\mathsf{RegSeqRat}^{\uparrow}$ regular rational readback, the $\mathsf{Real}^{\uparrow}$ finite seal row, and the structural-code boundary ledger.

Definition 470.1 (StreamLimitReflection carrier)**.** *A* $\mathsf{StreamLimitReflection}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (S, R, E, K, T, H, C, P, N)$$

with the following visible coordinates:

1. *S is the* $\mathsf{StreamName}^{\uparrow}$ *observation schedule, listing the finite countable-name window queried by the packet;*
2. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity row read over that schedule;*
3. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row attached to the finite regular-name readback;*
4. *K is an internal* CIC* *structural-code row for formation, recursor, and certificate syntax visible at this site;*
5. *T records runtime-boundary and truth-boundary ledger entries, separating structural codes from an executing checker and from an internal truth classifier;*
6. *H stores the componentwise* hsame *routes for S, R, E, K, T;*
7. *C stores the displayed* Cont *routes for reading the schedule, regularity row, RealUp seal, structural-code row, and boundary ledger;*
8. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$*;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{StreamLimitReflection}^{\uparrow}}$ *row.*

The carrier exports finite structural observations and explicit non-closure ledgers. It stores no internal runtime, no truth predicate, no quotient stream, no selected limit, and no host real equality.

Lean4 (definition) `BEDC.Derived.StreamLimitReflectionUp.StreamLimitReflectionUp`
Lean4 ✓ `BEDC.Derived.StreamLimitReflectionUp.StreamLimitReflectionTasteGate single carrier alignment`

Theorem 470.2 (StreamLimitReflection NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{StreamLimitReflection}^{\uparrow}}$ *surface for the carrier of Definition 470.1 consists of five finite obligations:*

1. *carrier admission for the displayed packet $Q = (S, R, E, K, T, H, C, P, N)$;*
2. *classifier transport by componentwise* hsame *and* Cont *on the stream schedule, regularity row, RealUp seal, structural-code row, boundary ledger, package row, and local naming row;*
3. *countable-name handoff from S to the regular rational readback R and the RealUp seal E;*
4. *structural-code separation, which reads K only as* CIC* *formation and recursor syntax, not as an executing checker;*
5. *boundary non-escape, which forces runtime and truth claims to pass through the ledger T rather than through a hidden object-language predicate.*

Lean4 ✓ `BEDC.Derived.StreamLimitReflectionUp.TasteGate.StreamLimitReflectionNameCertObligations`

Proof. Carrier admission is tuple projection. The rows $S, R, E, K, T, H, C, P, N$ are all displayed coordinates of the same finite BHist packet.

Classifier transport is componentwise. The stored hsame routes compare the schedule, regularity, seal, structural-code, ledger, package, and local naming rows, while the Cont routes record the allowed reads among those rows.

The countable-name handoff is then finite. The observation schedule S exposes the requested stream window, R records the regular rational row over that window, and E records the RealUp seal that can be named from the same readback.

The structural row K is only syntax for the internal copy. The ledger T records that no coordinate executes that syntax and no coordinate classifies BEDC truth. Thus the certificate exports structural finite observations and explicit non-closure ledgers, not a runtime, truth predicate, quotient stream, selected limit, or host real equality. □

Theorem 470.3 (StreamLimitReflection runtime boundary)**.** *Every runtime-facing consumer of an accepted* $\mathsf{StreamLimitReflection}^{\uparrow}$ *carrier factors through $S, R, E, K, T, H, C, P, N$. It may read the structural* CIC* *code row and the boundary ledger, but it cannot obtain an internal evaluator, checker, execution semantics, quotient stream, selected limit, or host real equality from the packet.*

Proof. Project the accepted carrier. The only row that mentions the host calculus is K, and that row is structural syntax: formation, recursor, and certificate-code data.

The boundary ledger T records that execution of such syntax is not a coordinate of the carrier. The transport rows H and C can move and read only the displayed finite rows, so they cannot create an evaluator or checker.

The regular-name rows do not change this boundary. They expose the countable schedule, regular rational readback, and RealUp seal, but none of these rows contains a quotient stream, selected limit, host equality test, or runtime semantics. Hence every runtime-facing read remains outside the finite packet. □

Theorem 470.4 (StreamLimitReflection truth non-closure)**.** *Every truth-facing consumer of an accepted* $\mathsf{StreamLimitReflection}^{\uparrow}$ *carrier reads the structural code row* K *and the truth-boundary entries of* T *only as finite ledger data. The packet does not define a BEDC truth predicate for the represented* CIC* *sentences and does not turn the RealUp seal* E *into host real equality or completed-limit selection.*

Proof. Begin with the structural-code row. By Definition 470.1, K names formation, recursor, and certificate syntax for the internal copy, not a truth classifier over that syntax.

Next read the truth-boundary entries of T. They mark truth-total classification as external to the packet, so a consumer may cite the boundary but cannot convert it into an object-language truth predicate.

Finally inspect the countable-name side. The RealUp seal E is attached to the finite regular-name readback R over schedule S. It seals the displayed name site only; it supplies neither host real equality nor a selected completed limit. Therefore truth-facing exports remain finite ledger exports. □

Closure status for $\mathsf{NameCert}_{\mathsf{StreamLimitReflection}^{\uparrow}}$**.**

Constructive story: A $\mathsf{StreamLimitReflection}^{\uparrow}$ packet is generated from StreamName schedule rows, RegSeqRat regularity rows, RealUp seal rows, structural-code rows, runtime-boundary and truth-boundary ledger rows, componentwise hsame transport, displayed Cont replay, package provenance, and local naming. The classifier reflects stream-limit structure only as finite observations plus explicit non-closure ledgers. The code row is syntax, the boundary row records that no evaluator or truth classifier is present, and the RealUp seal remains attached to the finite regular-name readback. Thus the packet generates a structural reflection route without quotient streams, selected limits, host real equality, internal runtime, or BEDC truth predicate.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{StreamLimitReflection}^{\uparrow}}$, seed)

Scope closed: This chapter binds the carrier definition and the NameCert-obligation, runtime-boundary, and truth-non-closure theorems for $\mathsf{StreamLimitReflection}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{StreamLimitReflection}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim internal runtime, truth predicates, quotient streams, selected limits, host real equality, internal evaluators, or checkers for the represented syntax.

Upgrade path: To reach obligationClosure, the structural-code and boundary-ledger rows must be encoded with checked runtime and truth non-closure proofs.

Chapter 471

A Concrete Naming Certificate for $\mathsf{UnaryContinuationCategory}^{\uparrow}$

The $\mathsf{UnaryContinuationCategory}^{\uparrow}$ packet is the concrete category-shaped reading of the BEDC unary continuation calculus. It names the existing carrier rows used by $\mathsf{Cat}^{\uparrow}$: unary object histories, displayed $\mathsf{CategoryHomCarrier}$ rows, continuation-tail ledgers, componentwise hsame transport, Cont composition routes, Pkg provenance, and a local $\mathsf{NameCert}$ ledger. It does not introduce a host category universe or any equality outside BHist.

It consumes the finite transition-step reading of chapter 482 and the unit and associativity ledger of chapter 485. Its object and hom rows are the category-shaped repackaging of those continuation surfaces, not an isolated kernel-only construction.

Definition 471.1 (Unary-continuation category carrier)**.** *A* $\mathsf{UnaryContinuationCategory}^{\uparrow}$ *carrier is a finite packet*

$$U = (O, H, I, M, T, P, N)$$

with the following visible rows:

1. *O is the unary object row: each displayed object history a is accepted exactly through* $\mathsf{UnaryHistory}(a)$*.*
2. *H is the displayed hom row: an arrow from a to b with displayed tail f is accepted by*

$$\mathsf{CategoryHomCarrier}(a, b, f).$$

3. *I records the empty-tail identity ledgers* $\mathsf{Cont}(a, \mathsf{e}, a)$ *over unary object rows.*
4. *M records the binary composition ledgers: for displayed hom rows* $\mathsf{CategoryHomCarrier}(a, b, f)$ *and* $\mathsf{CategoryHomCarrier}(b, c, g)$*, a composite tail fg is accepted only through the displayed* $\mathsf{Cont}(f, g, fg)$ *route together with the resulting* $\mathsf{CategoryHomCarrier}(a, c, fg)$ *row.*
5. *T records componentwise* hsame *transport for object histories and for displayed hom histories over fixed endpoints.*
6. *P is the* Pkg *provenance row naming the unary object inspection, hom-carrier inspection, identity ledger, and composition ledger.*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{UnaryContinuationCategory}^{\uparrow}}$ *ledger for the carrier, classifier, stability, exactness, and provenance rows.*

The carrier is therefore a category-shaped packet over BHist *only: its objects, arrows, identities, composites, and equality rows are the existing unary-continuation data.*

Lean4 ✓ `BEDC.Derived.UnaryContinuationCategoryUp.UnaryContinuationCategoryTasteGate single carrier alignment`

Theorem 471.2 (Unary-continuation category NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{UnaryContinuationCategory}^{\uparrow}}$ *obligation surface consists of five rows:*

1. *carrier habitation by the empty unary history and its empty-tail identity row;*
2. *classifier laws inherited componentwise from* hsame *on object histories and displayed hom histories;*
3. *hom admission by* $\mathsf{CategoryHomCarrier}(a, b, f)$*, equivalently by unary endpoints, a unary displayed tail, and the continuation-tail presentation of Definition 61.317;*
4. *stability under componentwise endpoint and hom-tail transport, using the unary-continuation stability law package of Definition 61.325;*
5. *ledger exactness for identity, binary composition, associativity, and unit rows, using the public* $\mathsf{Cat}^{\uparrow}$ *host-interface inventory of Definition 61.335.*

These rows bind the carrier, classifier, Cont *routes,* Pkg *provenance, and local* NameCert *ledger without adding any host category primitive.*

Proof. For habitation, take the empty unary history. The empty continuation row supplies the displayed identity carrier, so the object and identity coordinates are inhabited inside BHist.

The classifier laws are componentwise. Object comparison uses hsame on unary histories, and hom comparison uses hsame on displayed hom histories over the same endpoints, with endpoint transport supplied by the stability package.

Hom admission is the concrete correspondence of Definition 61.317. It identifies each displayed hom row with unary endpoints and a continuation morphism whose tail is classified as the displayed arrow history.

Composition and stability are exactly the rows named by Definition 61.325. The proof reads the identity, binary composition, associativity, unit, and endpoint-transport rows from the existing $\mathsf{Cat}^{\uparrow}$ surface and stores them in I, M, and T.

Finally, Definition 61.335 lists the public host-interface rows exported by the same unary-continuation carrier. Repacking those rows with the Pkg provenance and local naming ledger gives the five $\mathsf{NameCert}_{\mathsf{UnaryContinuationCategory}^{\uparrow}}$ obligations. □

Theorem 471.3 (Unary-continuation category standard bridge)**.** *The* $\mathsf{UnaryContinuationCategory}^{\uparrow}$ *packet presents the standard unary-continuation category interface over* BHist*: public objects are exactly unary histories, public arrows are exactly displayed* CategoryHomCarrier *rows, identity arrows are empty-tail continuation rows, composition is displayed* Cont *composition of tails, and equality of objects and arrows is componentwise* hsame*.*

The bridge reads back to the same rows. It exports no global category universe, no host equality of arrows, no limit or adjunction structure, and no morphism type beyond displayed BHist *histories.*

Proof. Read the carrier coordinates of Definition 471.1. The object row is UnaryHistory, the hom row is CategoryHomCarrier, the identity row is the empty-tail continuation ledger, and the composition row is the displayed Cont route.

The category laws are those already used by Definition 61.329 and inventoried in Definition 61.335. They supply associativity, left and right units, and transport compatibility on the same displayed histories.

The readback is literal because every public row is one of the carrier coordinates O, H, I, M, T, P, N. The bridge therefore exposes the unary-continuation category packet and nothing outside the BEDC history surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{UnaryContinuationCategory}\uparrow}$.

Constructive story: A unary-continuation category packet is generated from unary object histories, displayed CategoryHomCarrier arrows, empty-tail identity ledgers, displayed Cont composition tails, componentwise hsame transport, Pkg provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{UnaryContinuationCategory}\uparrow}, \mathsf{seed})$

Scope closed: The seed surface names the concrete BEDC carrier rows for unary objects, hom carriers, identity tails, composition tails, transport rows, provenance, and local naming, but it does not close the paper axis beyond this carrier presentation.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{UnaryContinuationCategory}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Not claimed: This chapter does not close a separate Lean namespace, host categories, arbitrary categorical constructions, limits, adjunctions, equivalences, or machine bridge checking.

Upgrade path: Scoped closure requires checked carrier admission, classifier laws, composition ledger exactness, and transport stability for the named unary-continuation packet.

Chapter 472

A Concrete Naming Certificate for $\mathsf{TruthTotalReflection}^{\uparrow}$

The $\mathsf{TruthTotalReflection}^{\uparrow}$ interface records the finite boundary certificate associated with the truth-total reflection obstruction of Definition 9461.23 and Definition 9461.24. It packages sentence-code rows for CIC*, attempted reflection rows, diagonal obstruction rows, transport data, package provenance, and a local naming row. The truth-total reflection packet reads its extension-attempt and refusal boundary against the accepted and refused declaration surface of chapter 549, while adding the diagonal obstruction row that prevents a total internal truth classifier. The packet is a boundary witness: it records why a truth-total classifier cannot be exported as an internal BEDC object.

Definition 472.1 (Truth-total reflection NameCert carrier)**.** *A* $\mathsf{TruthTotalReflection}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (S, A, D, H, C, P, N)$$

with the following displayed coordinates:

1. *S is a finite row of* CIC* *sentence codes, including the code rows inspected by a candidate reflection consumer;*
2. *A is the finite extension-attempt row recording the proposed* Ext_T *classifier reads against the sentence-code row S;*
3. *D is the diagonal obstruction row displaying the code for the sentence that reads the negation of its own attempted* Ext_T *classification;*
4. *H stores the componentwise* hsame *transports for the sentence-code, extension-attempt, and diagonal rows;*
5. *C stores the displayed* Cont *routes by which a consumer reads those rows;*
6. *P is the* Pkg *provenance over* BHist, hsame, Cont, CIC* *sentence coding, diagonal formation, and* $\mathsf{NameCert}$*;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{TruthTotalReflection}^{\uparrow}}$ *row.*

The local classifier relates two such packets exactly when their displayed sentence-code, extension-attempt, diagonal, transport, route, provenance, and naming rows compare componentwise through H and C. It has no coordinate for a BEDC-internal truth predicate, a total truth classifier, or a metalanguage able to validate BEDC from inside BEDC.

Lean4 (definition) `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionUp`

Theorem 472.2 (Truth-total reflection boundary certificate)**.** *Every accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet records only the finite boundary evidence for truth-total reflection over* CIC^* *sentence codes. Its public surface consists of the rows* S, A, D, H, C, P, N *of Definition 472.1; therefore any consumer can read the attempted extension classifier and the diagonal obstruction through the displayed* hsame *and* Cont *routes, but cannot export an internal BEDC truth classifier for all BEDC sentence codes.*

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionUp taste gate boundary`

Proof. Project the accepted packet to the tuple $T = (S, A, D, H, C, P, N)$. The sentence-code row S supplies the finite CIC^* codes under inspection, and the extension-attempt row A records only the proposed classifier reads attached to those codes.

The diagonal row D is read through the same finite boundary. It records the obstruction used in Definition 9461.24: any truth-total reading of the attempted classifier can be turned against its own diagonal code.

Transport and consumer access are exhausted by H and C. These rows move and read the displayed sentence-code, extension-attempt, and diagonal coordinates, while P and N record provenance and local naming.

No remaining coordinate stores a BEDC-internal truth predicate or a total classifier over all represented BEDC sentences. Thus the accepted packet is a finite boundary certificate, not an internal truth-total reflection object. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionTasteGate single carrier alignment`

Theorem 472.3 (Truth-total reflection attempt-row stability)**.** *For every accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet*

$$T = (S, A, D, H, C, P, N),$$

componentwise hsame *transport through* H *preserves the sentence-code row* S*, the extension-attempt row* A*, and the diagonal row* D *as rows of the same finite boundary certificate. The transport may replay the displayed* Cont *routes in* C*, but it does not add a coordinate for a BEDC-internal truth predicate, a total truth classifier, or host validation of BEDC.*

Proof. Project the packet to its displayed rows. The transport row H is part of the carrier inventory and is specified only for the sentence-code, extension-attempt, diagonal, route, provenance, and naming coordinates.

Transporting S, A, D therefore keeps the same finite row classes and merely changes their presented history representatives. The continuation row C can replay reads of those transported rows, but it has no source for a classifier outside the packet.

Since the carrier definition contains no coordinate for internal truth, total classification, or host validation, componentwise transport cannot create one. The stabilized surface remains the finite attempted-reflection boundary. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionAttemptRowStability`

Theorem 472.4 (Truth-total reflection diagonal obstruction exactness)**.** *Every read of the diagonal row* D *in an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet factors through the displayed route*

$$S, A, H, C, P, N.$$

The obstruction is exact for the finite attempted reflection row A: it blocks only the displayed attempt to classify the sentence codes in S, and it does not assert a global theorem about all possible BEDC truth predicates or all host interpretations.

Proof. Read D from the carrier only after the sentence-code row S and the extension-attempt row A have been fixed. The diagonal row is the obstruction attached to that displayed attempt.

The rows H and C give the only transport and consumer routes by which the diagonal row can be moved or inspected. The provenance and naming rows P, N record the package in which that read occurs.

Thus a consumer reaches D through the route S, A, H, C, P, N. Because no other classifier row is present, the obstruction applies exactly to the finite attempt recorded by A and carries no broader host-level or total-truth conclusion. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionDiagonalObstructionExactness`

Theorem 472.5 (Truth-total reflection consumer surface exhaustion)**.** *Every consumer of an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet factors through*

$$S, A, D, H, C, P, N.$$

Such a consumer may inspect the sentence-code row, the attempted extension-classifier row, the diagonal obstruction row, componentwise transport, displayed continuation reads, provenance, and local naming. It cannot export BEDC-internal truth, total truth classification, host validation, or any classifier not recorded in A.

Proof. The carrier inventory lists exactly the rows S, A, D, H, C, P, N. Any accepted consumer read must therefore begin by projecting one of those coordinates and then using the displayed transport and continuation data.

The boundary theorem identifies A as the only attempted classifier row and D as the corresponding diagonal obstruction row. The stability theorem keeps these rows fixed under hsame transport, and the exactness theorem confines diagonal reads to the displayed attempt.

No remaining coordinate stores internal truth, total classification, host validation, or another classifier. Hence the consumer surface is exhausted by the displayed finite packet. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionConsumerSurfaceExhaustion`

Theorem 472.6 (Truth-total reflection carrier primitive scope)**.** *Carrier admission for an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet is exactly the finite packet*

$$S, A, D, H, C, P, N$$

over BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. The rows expose the finite* CIC* *sentence-code row S, the displayed extension-attempt row A, the diagonal obstruction row D, componentwise transport H, continuation reads C, provenance P, and the local naming row N. No additional carrier coordinate may supply internal truth, total truth classification, host validation, or a second reflection predicate.*

Proof. Project an accepted packet through Definition 472.1. The definition lists exactly S, A, D, H, C, P, N and identifies their primitive BEDC roles over BHist, hsame, Cont, Pkg, and NameCert.

Apply the boundary and consumer-exhaustion rows. Definition 472.2 confines the packet to finite boundary evidence, while Definition 472.5 states that every consumer read factors through the same displayed tuple.

Since no listed coordinate stores internal truth, total classification, host validation, or another reflection predicate, carrier admission is exhausted by the primitive finite packet. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionCarrierPrimitiveScope`

Theorem 472.7 (Truth-total reflection classifier transport scope)**.** *Classifier transport for* $\mathsf{TruthTotalReflection}^{\uparrow}$ *can move only sentence-code rows, extension-attempt rows, and diagonal obstruction rows through the displayed* H *and* C *rows of the accepted packet. It may replay the finite reads of* S, A, D *through componentwise* hsame *transport and displayed* Cont *routes, but it cannot transport a truth predicate, a total truth classifier, host validation of BEDC, or any classifier not recorded in* A*.*

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionClassifierTransportScope`

Proof. Start with the local classifier clause in Definition 472.1. It compares packets componentwise through the displayed transport and continuation rows, and the only classifier-attempt coordinate it can inspect is A.

Use Definition 472.3. Transport through H preserves the sentence-code row, extension-attempt row, and diagonal row as rows of the same finite boundary certificate, while C only replays their displayed reads.

The diagonal exactness and consumer-exhaustion rows then block escape from this scope. Definition 472.4 ties every diagonal read to the displayed attempt, and Definition 472.5 excludes internal truth, total classification, host validation, and classifiers absent from A. □

Theorem 472.8 (Truth-total reflection diagonal route scope)**.** *Every diagonal-obstruction read in an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet*

$$T = (S, A, D, H, C, P, N)$$

is scoped by the displayed sentence-code, extension-attempt, diagonal, transport, continuation, provenance, and naming rows, together with the BEDC primitives BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. The route has no coordinate for an internal truth predicate, total truth classifier, host validator, or unrecorded classifier.*

Proof. Start from the boundary certificate Definition 472.2. It identifies the accepted packet as the finite tuple S, A, D, H, C, P, N and reads the diagonal obstruction only against the displayed sentence-code and extension-attempt rows.

Apply attempt-row stability and diagonal exactness, Definition 472.3 and Definition 472.4. Transport through H preserves the rows S, A, D, while every read of D factors through S, A, H, C, P, N.

Now add the primitive and transport scope rows, Definition 472.6 and Definition 472.7. They bind carrier admission and classifier movement to BHist, hsame, Cont, Pkg, and NameCert.

The consumer-exhaustion theorem Definition 472.5 removes all remaining escape routes. Since the packet has no row for internal truth, total truth classification, host validation, or any classifier outside A, the diagonal route is scoped exactly by the displayed finite rows. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionDiagonalRouteScope`

Theorem 472.9 (Truth-total reflection consumer route scope)**.** *Every consumer route for an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet factors through*

$$S, A, D, H, C, P, N$$

and through the same BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *primitives used by the diagonal-obstruction route. A consumer cannot substitute total truth classification, host validation, or an unrecorded classifier for the displayed finite packet.*

Proof. First use Definition 472.5. It states that every consumer read begins and ends inside the finite packet S, A, D, H, C, P, N.

The carrier primitive scope Definition 472.6 supplies the primitive boundary for that packet. The only admitted carrier rows are sentence codes, the extension attempt, the diagonal obstruction, componentwise transport, displayed continuations, provenance, and local naming.

Next combine Definition 472.7 with Definition 472.8. Classifier movement can replay only the recorded S, A, D rows through H and C, and the diagonal route cannot leave the same primitive scope.

Thus any consumer route factors through the displayed packet. Total truth classification, host validation, and unrecorded classifier rows are absent from the carrier and cannot be substituted for it. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionConsumerRouteScope`

Theorem 472.10 (Truth-total reflection obligation unblock package)**.** *The* $\mathsf{TruthTotalReflection}^{\uparrow}$ *obligation package consists exactly of the boundary certificate, attempt-row stability, diagonal obstruction exactness, and consumer-surface exhaustion rows for the packet*

$$S, A, D, H, C, P, N.$$

Together with the primitive carrier and classifier-transport scopes, these rows unblock the finite truth-total reflection obligation while excluding internal truth, total truth classification, host validation, and any classifier not recorded in A*.*

Proof. Assemble the previously displayed rows. Definition 472.2 supplies the finite boundary certificate, Definition 472.3 supplies stability of S, A, D under H, Definition 472.4 supplies the exact diagonal route, and Definition 472.5 exhausts consumer reads.

Attach the primitive rows from this section. Definition 472.6 fixes carrier admission as S, A, D, H, C, P, N, and Definition 472.7 fixes classifier movement through the displayed H and C rows.

The assembled package therefore closes the scoped obligation surface for the finite attempted-reflection packet. Because every row is read through the displayed carrier and no row stores internal truth, total classification, host validation, or a classifier outside A, the package has no escape route to those excluded objects. □

Theorem 472.11 (Truth-total reflection public consumer interface)**.** *Every public consumer of an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet must read the packet through the displayed rows*

$$S, A, D, H, C, P, N.$$

The consumer may inspect sentence codes, extension-attempt rows, diagonal-obstruction rows, componentwise transport, displayed continuation routes, package provenance, and local naming. It cannot project total truth, a BEDC-internal truth predicate, host validation, or any classifier outside the recorded attempt row A*.*

Proof. Begin with the carrier primitive scope. Definition 472.6 identifies the accepted carrier as the finite tuple S, A, D, H, C, P, N over the displayed BEDC primitives.

Apply consumer route scope and classifier transport scope. Definition 472.9 forces every consumer route through the same tuple, while Definition 472.7 confines classifier movement to S, A, D through H and C.

Finally use consumer-surface exhaustion. Definition 472.5 rules out internal truth, total classification, host validation, and unrecorded classifiers. Thus the public consumer interface is exactly the displayed refusal packet. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionPublicConsumerInterface`

Theorem 472.12 (Truth-total reflection root route totality)**.** *Every root consumer route for an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet factors through the finite rows*

$$S, A, D, H, C, P, N.$$

The route may inspect sentence codes, the attempted classifier row, the diagonal obstruction, componentwise transport, replay, provenance, and local naming, but it cannot export internal truth, total truth classification, host validation, or a classifier not recorded in A*.*

Proof. Begin with the boundary certificate and attempt-row stability. They expose S, A, D, H, C, P, N as the finite packet and keep the attempted classifier row attached to the same sentence-code and diagonal-obstruction rows.

Next use diagonal obstruction exactness and the public consumer interface. The diagonal read factors through the same route, and every public consumer is already confined to the displayed refusal packet.

Finally apply consumer surface exhaustion together with primitive scope and classifier transport scope. These results exhaust the carrier coordinates and leave no row for internal truth, total classification, host validation, or an unrecorded classifier. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionRootRouteTotality`

Theorem 472.13 (Truth-total reflection ledger non-escape)**.** *For an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet, the package and provenance ledgers* P, N *record only the public refusal boundary for the rows* S, A, D, H, C*. They cannot create a BEDC-internal truth predicate, total truth classification, host validation, or a classifier outside the displayed attempt row* A*.*

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionLedgerNonescape`

Proof. Start with refusal ledger exactness. The exact refusal ledger is carried by A, D over S, while P, N record provenance and local naming for that finite ledger.

Use classifier transport scope and diagonal route scope. Transport and replay return to the same displayed attempt and obstruction rows, so provenance cannot manufacture a classifier beyond the one recorded in A.

The boundary certificate, consumer surface exhaustion, and public consumer interface rule out the remaining escapes. Since internal truth, total truth classification, and host validation are absent from the carrier, the ledgers P, N cannot export them. □

Theorem 472.14 (Truth-total reflection TruthCert handoff)**.** *Any handoff from an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet to a TruthCert-style downstream boundary remains a finite refusal-boundary handoff through*

$$S, A, D, H, C, P, N.$$

It supplies the attempted classifier row and the diagonal obstruction as a public obstruction certificate, not a truth predicate, total truth classifier, host validator, or bridge certificate.

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionTruthCertHandoff`

Proof. First assemble the public boundary. The boundary certificate, attempt-row stability, and diagonal obstruction exactness place the handoff on S, A, D, H, C, P, N and identify A, D as the obstruction-bearing rows.

Next use consumer surface exhaustion and the public consumer interface. A TruthCert-style downstream boundary can consume the refusal packet only through the public consumer route, so the handoff remains finite and displayed.

Finally apply primitive scope and classifier transport scope. They keep the handoff inside the recorded carrier and prevent it from becoming a truth predicate, total truth classifier, host validator, or bridge certificate. □

Theorem 472.15 (Truth-total reflection refusal ledger exactness)**.** *In an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet, the extension-attempt row A and diagonal row D are the exact refusal ledger for truth-total reflection attempts over the displayed sentence-code row S. The ledger records the attempted classifier read and the diagonal obstruction to that attempt, and it does not include an additional total truth predicate, a second classifier row, or a host-level validation route.*

Proof. Read the attempt row through Definition 472.3. Transport preserves S, A, D as rows of the same finite boundary certificate, so A remains the displayed extension attempt.

Read the diagonal row through Definition 472.4. The diagonal obstruction factors through S, A, H, C, P, N and is exact for the finite attempted reflection row A.

The boundary and route-scope theorems then exclude hidden rows. Definition 472.2 and Definition 472.8 leave no coordinate for total truth, a second classifier, or host validation. Hence A and D are the exact refusal ledger. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionRefusalLedgerExactness`

Theorem 472.16 (Truth-total reflection downstream boundary package)**.** *The reusable downstream package exported by* $\mathsf{TruthTotalReflection}^{\uparrow}$ *consists exactly of the boundary certificate, attempt-row stability, diagonal exactness, refusal-ledger exactness, public consumer interface, and consumer-surface exhaustion for the packet*

$$S, A, D, H, C, P, N.$$

Any downstream chapter that consumes this package receives a finite refusal boundary for truth-total attempts, not a BEDC-internal truth predicate, a total truth classifier, a host validator, or a bridge certificate.

Proof. First assemble the scoped rows. Definition 472.2 gives the boundary certificate, Definition 472.3 keeps S, A, D stable, and Definition 472.4 fixes diagonal exactness for the displayed attempt.

Next add the public rows. Definition 472.15 identifies A, D as the exact refusal ledger, while Definition 472.11 forces every public consumer through S, A, D, H, C, P, N.

Finally apply consumer-surface exhaustion and the obligation package. Definition 472.5 and Definition 472.10 rule out internal truth, total classification, host validation, unrecorded classifiers, and bridge status. The remaining object is exactly the reusable downstream boundary package. □

Lean4 ✓ `BEDC.Derived.TruthTotalReflectionUp.TruthTotalReflectionDownstreamBoundaryPackage`

Theorem 472.17 (Truth-total reflection root public readiness)**.** *Every downstream public consumer of an accepted* $\mathsf{TruthTotalReflection}^{\uparrow}$ *packet reads exactly the public refusal route*

$$S, A, D, H, C, P, N$$

through the existing boundary certificate, attempt-row stability, diagonal exactness, consumer exhaustion, public interface, root route totality, ledger non-escape, TruthCert handoff, refusal ledger exactness, and downstream boundary package. No internal truth predicate, total truth classifier, host validator, or unrecorded classifier is exported by that public route.

Proof. First assemble the public boundary package. The downstream boundary package collects the boundary certificate, attempt-row stability, diagonal exactness, refusal ledger exactness, public consumer interface, and consumer-surface exhaustion for S, A, D, H, C, P, N.

Next attach root route totality and ledger non-escape. They keep every root public read on the same finite carrier, with P, N recording only the refusal boundary rather than a host-level validation route.

Finally use the TruthCert handoff. A downstream TruthCert-style consumer receives the displayed obstruction certificate and nothing else; internal truth predicates, total truth classifiers, host validators, and unrecorded classifiers have no coordinate in the packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{TruthTotalReflection}\uparrow}$.

Constructive story: A $\mathsf{TruthTotalReflection}^{\uparrow}$ packet is generated from finite CIC^* sentence-code rows, extension-attempt rows, diagonal obstruction rows, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{TruthTotalReflection}\uparrow}$, publicClosed)

Scope closed: Definition 472.1, Definition 472.2, Definition 472.3, Definition 472.4, Definition 472.5, Definition 472.11, Definition 472.12, Definition 472.13, Definition 472.14, Definition 472.15, Definition 472.16,
Lean4 (definition) `BEDC.Derived.TruthTotalReflectionUp.taste gate`
, and the displayed TasteGate single-carrier alignment marker bind the finite public refusal package for truth-total reflection attempts over CIC^* sentence codes.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{TruthTotalReflection}\uparrow}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close an internal BEDC truth predicate, a truth-total classifier, a host-runtime validator, or a public standard bridge.

Upgrade path: Bridge closure requires a checked public bridge for the same truth-total reflection refusal packet.

Chapter 473

A Concrete Naming Certificate for $\mathsf{CertificateCompiler}^{\uparrow}$

The $\mathsf{CertificateCompiler}^{\uparrow}$ interface reads compilation as a finite morphism between two local naming certificates. It records only the source certificate, target certificate, displayed compiler graph, edge landing, continuation compatibility, classifier transport, package provenance, and local naming row. It does not import a host compiler semantics, a denotational equality of programs, or an unbounded trace comparison.

Definition 473.1 (CertificateCompiler carrier)**.** *A* $\mathsf{CertificateCompiler}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (S, T, G, E, C, H, P, N)$$

with the following visible rows:

1. *S is the source* $\mathsf{NameCert}$ *row whose carrier and classifier are the inputs read by the compiler graph;*
2. *T is the target* $\mathsf{NameCert}$ *row whose carrier and classifier receive the compiled outputs;*
3. *G is the finite compiler graph, displaying source-to-target graph edges rather than a host-level function space;*
4. *E is the edge-landing row, asserting that every displayed graph edge starts in the source carrier and lands in the target carrier;*
5. *C is the continuation-compatibility row, pairing each source* Cont *route used by the graph with the corresponding target* Cont *route;*
6. *H records the componentwise* hsame *transports for the source certificate, target certificate, graph edge, edge landing, continuation row, package row, and local certificate row;*
7. *P names* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, *the source certificate, the target certificate, and the local compiler graph shape;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{CertificateCompiler}^{\uparrow}}$ *row.*

The packet is a finite compiler-certificate surface. It contains no ambient program equality, no host optimiser theorem, and no semantic model beyond the displayed source and target naming certificates.

Lean4 (definition) `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier`

Definition 473.2 (CertificateCompiler classifier)**.** *The classifier of a* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet compares graph edges in pairs. Two displayed edges are classifier-compatible when they read the same source classifier row in S, land through E in the target carrier of T, and their target classifier rows are connected by the* hsame *and* Cont *routes recorded in H and C.*

Thus classifier membership is not a judgment about arbitrary compiler outputs. It is a finite relation on paired graph edges with a common source classifier row and an explicitly transported target classifier row.

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerClassifier semantic name certificate`

Theorem 473.3 (CertificateCompiler endpoint certificate availability)**.** *Every displayed compiler edge in an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet $K = (S, T, G, E, C, H, P, N)$ exposes both endpoint* NameCert *rows before carrier landing is consumed. The source certificate row S supplies the admitted input carrier and classifier row, the target certificate row T supplies the landing carrier and classifier row, and the displayed graph row G has no admissible edge that bypasses either endpoint certificate.*

Proof. Unfold the carrier of Definition 473.1. The first two visible rows of K are precisely the source certificate S and target certificate T, while G is only a displayed finite graph between those certificate rows.

The carrier-landing row E is read after these endpoint rows. Its role is to assert that each graph edge starts in the source carrier named by S and lands in the target carrier named by T.

Unfold the classifier of Definition 473.2. A compatible edge comparison also reads the source classifier row in S and the target classifier row in T, so endpoint certificates remain available before any carrier landing or paired-edge comparison is accepted.

Since the packet contains no host compiler semantics, program equality, or unbounded trace coordinate, endpoint availability is exhausted by the displayed rows S, T, G, E, H, C, P, N. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint certificate availability`

Theorem 473.4 (CertificateCompiler displayed edge witness totality)**.** *Every accepted edge comparison in a* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet $K = (S, T, G, E, C, H, P, N)$ is witnessed by the displayed graph row G, the carrier-landing row E, the componentwise* hsame *transports in H, and the continuation compatibility rows in C. No comparison can be witnessed by an external compiler meaning, ambient program equality, or an unlisted target behavior.*

Proof. Unfold Definition 473.1. The only edge source in the packet is the finite graph row G, and the only target-carrier landing witness for such an edge is the row E.

Unfold Definition 473.2. An accepted comparison must share the source classifier row, land through E, and transport the target classifier by the componentwise hsame entries recorded in H.

It remains to account for route compatibility. The classifier definition reads the paired Cont routes recorded in C, so a comparison is not accepted until the displayed source route and displayed target route have both been replayed.

The carrier has no coordinate for host compiler semantics, program equality, or unrecorded target behavior. Thus G, E, H, C are the total displayed witness surface for accepted edge comparison. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerClassifier displayed edge witness totality`

Theorem 473.5 (CertificateCompiler KernelMorphism route coverage)**.** *Every accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *edge route whose source and target certificates are read by a downstream* KernelMorphismUp *dependency must expose the source certificate row S, target certificate row T, displayed graph row G, edge-landing row E, continuation row C, componentwise* hsame *transport row H,* Pkg *provenance row P, and local* NameCert *row N before the route is consumed as a kernel-morphism route.*

Proof. Unfold the carrier and classifier of Definition 473.1 and Definition 473.2. The route inventory is exactly S, T, G, E, C, H, P, N, with graph edges landing through E and classifier transport through H and C.

Use endpoint certificate availability and displayed-edge witness totality. Theorems 473.3 and 473.4 force source and target certificates to be read before the graph edge is consumed, and force each accepted comparison to expose graph, landing, transport, and continuation witnesses.

The downstream consumer is the KernelMorphismUp chapter of chapter 620. It may consume only this finite compiler route together with its own graph-admission rows, so no host compiler semantics, ambient program equality, or unrecorded target behavior becomes a kernel-morphism route. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier kernel morphism route coverage`

Theorem 473.6 (CertificateCompiler consumer replay obligation triad)**.** *Every consumer replay of an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet must read three local obligations before package provenance or local naming is used: carrier landing through G and E, classifier transport through S, T, H, and continuation compatibility through C. Package and* $\mathsf{NameCert}_{\mathsf{CertificateCompiler}^{\uparrow}}$ *rows may repack only this displayed triad.*

Proof. Unfold the carrier of Definition 473.1. A consumer replay first sees the graph row G and the landing row E, so the replayed edge has a displayed source and a displayed target before any package row is read.

Unfold the classifier of Definition 473.2. The replayed comparison next reads the source classifier row in S, the target classifier row in T, and the componentwise transport entries in H.

The third obligation is route compatibility. The row C pairs the source Cont route used by the graph with the target Cont route followed after compiling, and this compatibility is required before the replay can be named locally.

Only after these three obligations have been read may P and N repack the compiler packet. Because no host compiler semantics or program equality coordinate exists in the carrier, package and local naming cannot certify anything beyond carrier landing, classifier transport, and continuation compatibility. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier consumer replay obligation triad`

Theorem 473.7 (CertificateCompiler NameCert obligations)**.** *For the carrier and classifier of Definition 473.1 and Definition 473.2, the local* $\mathsf{NameCert}_{\mathsf{CertificateCompiler}^{\uparrow}}$ *surface consists of five obligations:*

1. *carrier landing: every edge of G reads a source row admitted by S and lands in a target row admitted by T through E;*
2. *classifier transport: paired graph edges with the same source classifier row transport classifier membership to the target classifier row;*

3. *continuation compatibility: every source* Cont *route used by a graph edge is paired in C with the target* Cont *route followed after compiling;*
4. *identity compiler row: the diagonal graph on a certificate is accepted with carrier landing, classifier transport, and continuation compatibility read from the same certificate;*
5. *composition stability: composable accepted compiler packets compose by relational graph composition and preserve the same landing, classifier, and continuation rows.*

Proof. Carrier landing is the projection of E from the finite packet $K = (S, T, G, E, C, H, P, N)$. Since E names the source and target carrier rows for each displayed edge, no edge can be consumed without first reading S, T, and the corresponding graph row in G.

Classifier transport uses the paired-edge classifier. The common source classifier row is read in S, and the target classifier row is obtained only by replaying the componentwise hsame entries in H and the displayed continuation routes in C.

Continuation compatibility is exactly the second projection of C. Each source route used by a graph edge has a named target route, so a downstream consumer cannot substitute an unrecorded control-flow or semantic route.

For the identity row, take $S = T$ and let G be the displayed diagonal graph. The landing, classifier, and continuation rows are then the carrier, classifier, and route rows already present in the same certificate.

For composition, compose graph edges relationally through the middle certificate. The first packet supplies landing and classifier transport into the middle row, and the second supplies the same data out of it; composing the two continuation rows gives the target route. Repacking these rows gives the five local NameCert obligations for the composite packet. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier namecert obligations`

Theorem 473.8 (CertificateCompiler composition stability)**.** *Given accepted* CertificateCompiler$^{\uparrow}$ *packets from S to M and from M to T, their relational graph composite is an accepted* CertificateCompiler$^{\uparrow}$ *packet from S to T. The composite reads only the two displayed graph rows, their edge-landing rows, continuation-compatible routes, componentwise* hsame *transports, package provenance, and local naming rows.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier composition stability`

Proof. Start with the two accepted packets and project their carrier rows. The first packet lands graph edges in the middle certificate, and the second starts from that same middle certificate.

Classifier transport composes through the middle row. A common source classifier row is transported to the middle classifier by the first packet, then from the middle classifier to the target classifier by the second packet.

Continuation compatibility composes in the same order. The source route is paired with the middle route by the first packet, and that middle route is paired with the target route by the second packet.

The resulting graph, landing row, classifier transport, continuation row, transport row, package row, and local naming row are finite projections of the two input packets. Therefore the composite exports no host compiler semantics and no unrecorded target behavior. □

Theorem 473.9 (CertificateCompiler identity ledger)**.** *For every local naming certificate S, the diagonal graph on S is an accepted* CertificateCompiler$^{\uparrow}$ *identity packet. Its ledger is exhausted by the carrier, classifier,* hsame, Cont, Pkg, *and* NameCert *rows already displayed by S.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerIdentityLedger`

Proof. Use S as both source and target certificate. The diagonal graph has one displayed edge for each admitted source row and lands in the same row.

The classifier transport is the local classifier row of S read twice. The required hsame transport is reflexive at the displayed row, and the continuation route is the same route already recorded in S.

The package and local naming rows are inherited from S with no further coordinate. Hence the identity compiler packet has exactly the stated ledger and does not create a separate compiler semantics. □

Theorem 473.10 (CertificateCompiler edge-classifier exactness)**.** *For an accepted* CertificateCompiler$^{\uparrow}$ *packet* $K = (S, T, G, E, C, H, P, N)$*, a displayed edge comparison is accepted exactly when it reads the source classifier row in* S*, lands through* E *in the target carrier of* T*, transports the target classifier by the componentwise* hsame *entries of* H*, and follows the paired* Cont *routes recorded in* C*. No host compiler semantics, program equality, or unrecorded target behavior can witness edge-classifier compatibility.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerClassifier edge classifier exactness`

Proof. Project the accepted packet to the paired-edge classifier of Definition 473.2. The source classifier row is the first required comparison coordinate, so two edges cannot be compared after forgetting their source certificate.

Next read the edge-landing row E. It supplies the target-carrier landing for each displayed edge and fixes the target certificate row in T that the comparison may inspect.

The remaining data are the transport and route rows. The hsame entries in H move target classifier rows componentwise, and the Cont routes in C record the control path followed after compiling. These are exactly the displayed rows named by the classifier definition.

Since the carrier has no coordinate for host compiler semantics, program equality, or unrecorded target behavior, the displayed graph, landing, classifier, and continuation rows exhaust edge-classifier exactness. □

Theorem 473.11 (CertificateCompiler endpoint route determinacy)**.** *Let two accepted* CertificateCompiler$^{\uparrow}$ *packets share the source certificate row, target certificate row, displayed graph row, edge-landing row, componentwise* hsame *transports, and paired* Cont *route row. Then they determine the same endpoint route from the accepted source certificate to the accepted target certificate. No host compiler semantics, program equality, or unrecorded target behavior can distinguish the two endpoint routes.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint route determinacy`

Proof. First expose the endpoint certificates by Definition 473.3. The shared source and target certificate rows fix the admitted input carrier, source classifier row, target carrier, and target classifier row before any edge landing is consumed.

Next use displayed edge witness totality, Definition 473.4. Since the displayed graph row, edge-landing row, componentwise hsame transports, and paired Cont route row are shared, every accepted edge comparison has the same finite witness surface in both packets.

Finally apply edge-classifier exactness, Definition 473.10. The classifier accepts exactly by reading the source classifier row, landing through E, transporting the target classifier through H, and replaying the paired Cont routes in C. Therefore the endpoint route is determined by

the shared displayed rows, and host compiler semantics, program equality, and unrecorded target behavior have no coordinate on which to separate the packets. □

Theorem 473.12 (CertificateCompiler identity and composite ledger exhaustion)**.** *The identity packets of Definition 473.9 and the composite packets of Definition 473.8 exhaust their ledgers by displayed graph rows, edge-landing rows, classifier-transport rows, continuation rows,* Pkg *provenance, and local* NameCert *rows. Triple composites in Definition 473.13 add no further ledger coordinate beyond the three displayed graph edges and their two middle landing matches.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier source target landing exhaustion`

Proof. For the identity packet, use the diagonal graph on the source certificate. The graph, landing, classifier, continuation, provenance, and local naming rows are inherited from the same certificate, as stated in Definition 473.9.

For a binary composite, apply Definition 473.8. The composite graph is relational graph composition of the two displayed graphs, and its landing, classifier, and continuation rows are obtained by reading the corresponding rows through the middle certificate.

For triple composites, use Definition 473.13. Both associations expose the same triple of graph edges, the same two middle landing matches, the same ordered classifier transport, and the same continuation endpoint. Repacking with Pkg and NameCert rows therefore adds no host compiler coordinate. □

Theorem 473.13 (CertificateCompiler triple composite associativity)**.** *Let*

$$K_{01} = (S_0, S_1, G_{01}, E_{01}, C_{01}, H_{01}, P_{01}, N_{01}),$$

$$K_{12} = (S_1, S_2, G_{12}, E_{12}, C_{12}, H_{12}, P_{12}, N_{12}),$$

and

$$K_{23} = (S_2, S_3, G_{23}, E_{23}, C_{23}, H_{23}, P_{23}, N_{23})$$

be accepted $\mathsf{CertificateCompiler}^{\uparrow}$ *packets in the sense of Definition 473.1 and Definition 473.7. Suppose the displayed middle naming rows agree exactly as composability data: the target* NameCert *row of* K_{01} *is the source* NameCert *row of* K_{12}*, and the target* NameCert *row of* K_{12} *is the source* NameCert *row of* K_{23}*. Then the two iterated relational graph composites*

$$(K_{23} \circ K_{12}) \circ K_{01} \qquad \textit{and} \qquad K_{23} \circ (K_{12} \circ K_{01})$$

classify by the same displayed S_0*-to-*S_3 *compiler graph, the same edge-landing row, the same classifier-transport row, and the same continuation-compatibility row. Their common displayed graph consists exactly of triples of graph edges*

$$(g_{01}, g_{12}, g_{23})$$

with g_{01} *in* G_{01}*,* g_{12} *in* G_{12}*,* g_{23} *in* G_{23}*, the landing target of* g_{01} *equal to the source row read by* g_{12} *in* S_1*, and the landing target of* g_{12} *equal to the source row read by* g_{23} *in* S_2*.*

Proof. Project the three accepted packets to their displayed graph, landing, classifier, continuation, transport, provenance, and local naming rows. By the composability hypotheses, the middle target row of the first packet is the source row consumed by the second packet, and the middle target row of the second packet is the source row consumed by the third packet. Thus every edge of either

iterated composite is represented by the same finite triple (g_{01}, g_{12}, g_{23}) with the two displayed middle landings named in the statement.

The graph rows agree because relational composition of finite displayed graph edges is associative at the level of witnesses. The left association first records the pair (g_{01}, g_{12}) and then appends g_{23}; the right association first records (g_{12}, g_{23}) and then prefixes g_{01}. After forgetting the temporary pairing, both ledgers contain exactly the same triple and the same two middle matching rows. No extra graph edge can appear, since Definition 473.8 forms a composite only from displayed edges of the two input packets.

The edge-landing rows agree by the same projection. In the left association, E_{01} lands g_{01} in S_1, the composite of E_{12} and E_{23} lands the remaining route in S_3, and the S_2 match is displayed inside that second composite. In the right association, the first composite displays the S_1 and S_2 matches before E_{23} lands in S_3. Both descriptions therefore expose the identical landing ledger

$$S_0 \xrightarrow{g_{01}} S_1 \xrightarrow{g_{12}} S_2 \xrightarrow{g_{23}} S_3.$$

Classifier transport is also independent of the association. Starting from a source classifier row in S_0, the first packet transports it to the displayed classifier row in S_1, the second transports that row to S_2, and the third transports the result to S_3. The left association packages the last two transports before composing with the first; the right association packages the first two transports before composing with the third. Since the classifier of Definition 473.2 is the paired-edge transport read through the componentwise hsame entries and the displayed continuation rows, both packages replay the same three componentwise transport entries H_{01}, H_{12}, and H_{23} in the same source-to-target order.

For continuation compatibility, the three accepted packets provide displayed routes from the S_0 route to the S_1 route, from the S_1 route to the S_2 route, and from the S_2 route to the S_3 route. The left association composes the last two routes and then the first route; the right association composes the first two routes and then the last route. By the relational continuation associativity of Definition 21.29, the two iterated continuation rows have the same endpoint route up to the displayed hsame transport already recorded in the packets. Hence they classify as the same continuation-compatibility row.

Combining the four projections gives one finite S_0-to-S_3 compiler packet surface: the triple graph, the three-step landing ledger, the ordered classifier transport through S_1 and S_2, and the associated continuation route. Both iterated composites read exactly this surface, so they classify by the same displayed rows and introduce no host compiler semantics, no ambient program equality, and no unrecorded target behavior. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier triple composite associativity`

Theorem 473.14 (CertificateCompiler left identity unit)**.** *Let*

$$K = (S, T, G, E, C, H, P, N)$$

be an accepted CertificateCompiler$^{\uparrow}$ *packet, and let I_S be the diagonal identity packet on the source* NameCert *row S supplied by Definition 473.9. Then the source-side composite $K \circ I_S$ is classified by the same displayed graph G, the same edge-landing row E, the same paired-edge classifier transport, the same continuation-compatibility row C, the same* Pkg *provenance row P, and the same local* NameCert *row N as K.*

Thus precomposing an accepted compiler packet with the diagonal source identity adds no host compiler semantics, no ambient program equality, and no unrecorded target behavior.

Proof. Use Definition 473.9 to read I_S as the diagonal packet whose graph, landing, classifier, continuation, provenance, and local naming rows are all inherited from S.

Apply Definition 473.8 to the composable pair (I_S, K). The composite graph contains exactly the displayed edges of G, because the diagonal source edge contributes only the source row that G already reads.

The classifier of Definition 473.2 then transports through the same componentwise hsame entries recorded in H, and the continuation route is the original route of C with a diagonal prefix. By Definition 21.29, that prefix changes no displayed endpoint route.

Repacking the Pkg row and the local NameCert row therefore returns the same finite compiler packet surface as K. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier left identity public route certificate`

Theorem 473.15 (CertificateCompiler right identity unit)**.** *Let*

$$K = (S, T, G, E, C, H, P, N)$$

be an accepted CertificateCompiler$^{\uparrow}$ *packet, and let I_T be the diagonal identity packet on the target* NameCert *row T supplied by Definition 473.9. Then the target-side composite $I_T \circ K$ is classified by the same displayed graph G, the same edge-landing row E, the same paired-edge classifier transport, the same continuation-compatibility row C, the same* Pkg *provenance row P, and the same local* NameCert *row N as K.*

Thus postcomposing an accepted compiler packet with the diagonal target identity adds no host compiler semantics, no ambient program equality, and no unrecorded target behavior.

Proof. Read the target identity packet from Definition 473.9. Its displayed graph is diagonal on T, and its landing, classifier, continuation, provenance, and local naming rows are the target-side rows already available to K.

Apply Definition 473.8 to (K, I_T). Every composite edge is an edge of G followed by the diagonal target edge, so the finite graph row is again G after forgetting the diagonal witness.

The edge landing remains E, since the target identity lands only in the same target row. The classifier transport is the row of Definition 473.2 followed by diagonal componentwise hsame transport, and the continuation route is the row of C followed by the target diagonal route.

Use Definition 21.29 to identify that diagonal suffix with the original endpoint route. The Pkg and local NameCert rows are unchanged, so the target-side identity composite classifies by the same packet surface as K. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier right identity unit`

Theorem 473.16 (CertificateCompiler finite category surface)**.** *The accepted* CertificateCompiler$^{\uparrow}$ *packets form a finite category-like surface over local* NameCert *rows: each local row has the diagonal identity packet of Definition 473.9; each composable pair has the binary composite packet of Definition 473.8; each composable triple has the common associative replay surface of Definition 473.13; and every accepted packet satisfies the source and target unit laws of Definition 473.14 and Definition 473.15.*

The surface is finite and local: its objects are the displayed local NameCert *rows and its morphism packets are exactly the displayed graph, landing, classifier-transport, continuation,* Pkg*, and local* NameCert *rows recorded by the certificate compiler carrier.*

Proof. Identities are supplied by the diagonal ledger of Definition 473.9. Binary composition is supplied by Definition 473.8, whose output is again a displayed compiler packet over the same row types.

Associativity is the finite triple replay statement of Definition 473.13. It says that the two iterated composites expose the same graph triple, landing ledger, ordered classifier transport, and continuation endpoint.

The unit laws are exactly Definition 473.14 and Definition 473.15. Both identify the identity composite with the original displayed graph, landing, classifier, continuation, Pkg, and local NameCert rows.

These rows are all read through the classifier of Definition 473.2. Hence the resulting surface is a finite local NameCert-morphism interface rather than a claim about host compiler semantics, ambient program equality, optimiser correctness, or unrecorded target behavior. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier finite category surface`

Theorem 473.17 (CertificateCompiler route replay scope)**.** *For an accepted* CertificateCompiler$^{\uparrow}$ *packet*

$$K = (S, T, G, E, C, H, P, N),$$

every accepted compiler read replays through the displayed compiler graph G, edge-landing row E, paired-edge classifier row, continuation row C, transport row H, package provenance P, and local NameCert *row N. No consumer of K can replace that replay by host compiler semantics, ambient program equality, optimiser correctness, or unrecorded target behavior.*

Proof. Begin with the carrier of Definition 473.1. Its only displayed compiler coordinates are the source and target naming rows S, T, the graph G, the landing row E, the continuation row C, the transport row H, the package row P, and the local naming row N.

Apply the classifier of Definition 473.2 and the edge-classifier exactness theorem. They force an accepted read to inspect the graph edge, its source classifier row, its landing in the target carrier, and the componentwise hsame and Cont routes.

The identity ledger and composition stability theorems show that replay is stable under identity and binary composition, while Definition 473.13 gives the same replay surface for triple composites. Therefore every accepted compiler read remains inside the displayed finite rows of K. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier route replay scope`

Theorem 473.18 (CertificateCompiler middle-row handoff)**.** *Let $K_{01} = (S_0, S_1, G_{01}, E_{01}, C_{01}, H_{01}, P_{01}, N_{01})$ and $K_{12} = (S_1, S_2, G_{12}, E_{12}, C_{12}, H_{12}, P_{12}, N_{12})$ be composable accepted* CertificateCompiler$^{\uparrow}$ *packets. Their composite can hand off from the first compiler packet to the second only through the displayed middle* NameCert *row S_1, together with the edge-landing, classifier-transport, and continuation rows that read S_1.*

The handoff exports no independent middle compiler semantics, program equivalence witness, optimiser correctness proof, or unrecorded target behavior.

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier middle row handoff`

Proof. Project the two accepted carriers. The target naming row of K_{01} and the source naming row of K_{12} are the same displayed row S_1, and this is the only middle carrier coordinate available to both packets.

Use Definition 473.10. It makes every edge comparison pass through the landing row into the target carrier, the transported classifier row, and the continuation route over the displayed middle certificate.

Composition stability then forms the composite graph only from pairs of displayed edges whose middle landing reads S_1. The identity ledger supplies the degenerate case, and triple composite associativity shows that repeated handoffs still expose the same middle rows rather than a hidden compiler coordinate. □

Theorem 473.19 (CertificateCompiler finite-graph nonescape)**.** *For an accepted* CertificateCompiler$^{\uparrow}$ *carrier* $K = (S, T, G, E, C, H, P, N)$*, every packet exported by the compiler certificate is a finite graph packet over the displayed rows* S, T, G, E, C, H, P, N*. It exports no host compiler semantics, no program equivalence relation, no optimiser correctness theorem, and no target behavior that is absent from the displayed graph, landing, classifier, continuation, provenance, and local naming rows.*

Proof. Read the carrier and classifier rows. The carrier lists only S, T, G, E, C, H, P, N, and the classifier reads graph edges through displayed landing, hsame, and Cont rows.

The edge-classifier exactness theorem prevents a consumer from accepting an edge by an external compiler semantics. The identity ledger and composition stability theorems keep identity and composite packets inside the same finite graph surface.

Finally apply Definition 473.13. Triple composites expose only triples of graph edges and their two displayed middle landing matches. Since no excluded compiler or target object appears in those rows, there is no escape from the finite graph packet. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier finite graph nonescape`

Theorem 473.20 (CertificateCompiler carrier dependency scope)**.** *For an accepted* CertificateCompiler$^{\uparrow}$ *carrier*

$$K = (S, T, G, E, C, H, P, N),$$

every carrier read is exhausted by the source and target NameCert *rows* S, T*, the displayed graph* G*, edge landing* E*, continuation compatibility* C*, componentwise* hsame *transport* H*,* Pkg *provenance* P*, and the local compiler* NameCert *row* N*. No additional host compiler semantics, program equality, optimiser theorem, decompiler row, or unrecorded target behavior is a dependency of the carrier surface.*

Proof. Start with Definition 473.1. Its coordinates are exactly the source certificate, target certificate, graph, edge landing, continuation compatibility, transport, package provenance, and local naming rows.

Apply the NameCert obligations of Definition 473.7. Carrier landing, classifier transport, continuation compatibility, identity, and composition all read from the same displayed rows.

Use Definition 473.10 and Definition 473.12 to exclude further witnesses. They state that accepted edges, identity packets, and composites are exhausted by graph, landing, classifier, continuation, provenance, and local naming rows, so the carrier has no hidden dependency. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier dependency scope`

Theorem 473.21 (CertificateCompiler classifier-route dependency scope)**.** *For an accepted* CertificateCompiler$^{\uparrow}$ *packet, edge classification depends only on the source classifier row read in* S*, the target landing row supplied by* E*, componentwise* hsame *transport through* H*, and the paired source and target* Cont *routes recorded in* C*. In particular, a classifier route cannot be witnessed by host compiler*

semantics, program equality, optimiser correctness, or a target behavior absent from the displayed landing route.

Proof. Read the classifier definition in Definition 473.2. It compares paired graph edges by their common source classifier row, their target landing, and the transported target classifier row.

Apply Definition 473.10. The exactness statement identifies the allowed route data as the source classifier, edge landing, componentwise hsame entries, and paired Cont routes.

Composition stability and the identity-composite ledger exhaustion theorem show that identity and composite routes use the same dependency list. Thus route classification remains inside the displayed compiler packet and cannot import an external compiler witness. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerClassifier route dependency scope`

Theorem 473.22 (CertificateCompiler composite dependency scope)**.** *Binary composites and triple composites of accepted* CertificateCompiler$^{\uparrow}$ *packets introduce no dependency beyond displayed graph edges, edge-landing rows, classifier-transport rows, continuation rows,* Pkg *provenance, local* NameCert *rows, and the middle landing matches required for composition. The composite surface therefore has no host compiler semantics, ambient program equality, optimiser correctness theorem, or unrecorded target row.*

Proof. For a binary composite, apply Definition 473.8. The composite graph is relational graph composition of the two displayed graphs, and all landing, classifier, and continuation data are read through the middle certificate.

For identities and binary ledgers, use Definition 473.9 and Definition 473.12. They identify the available ledger rows as graph, landing, classifier, continuation, package provenance, and local naming rows.

For triple composites, apply Definition 473.13. The two associations expose the same three graph edges and the same two middle landing matches, so no association can add a host compiler or target-semantic coordinate. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier left identity semantic name certificate`

Theorem 473.23 (CertificateCompiler source-target landing exhaustion)**.** *Every accepted* CertificateCompiler$^{\uparrow}$ *packet has each accepted compiler edge exhausted by the finite rows S, T, G, E, C, H, P, N. The source and target* NameCert *rows S and T are the only admission points for the graph edge, the landing row E is the only target-carrier landing, and no accepted edge can bypass those rows through host compiler semantics, ambient program equality, optimiser correctness, or unrecorded target behavior.*

Proof. Start with the carrier coordinates of Definition 473.1. An accepted packet displays the source row S, target row T, graph row G, landing row E, continuation row C, componentwise transport row H, provenance row P, and local naming row N.

Apply the classifier of Definition 473.2 and Definition 473.10. These force an accepted edge to be read through its graph entry, source classifier row, target landing, transported classifier row, and displayed continuation route.

Use Definition 473.21 and Definition 473.22 to close the route under identity, binary composition, and triple composition. The resulting accepted edge surface is exactly the displayed source-target landing route and has no external compiler coordinate. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerClassifier source target landing exhaustion`

Theorem 473.24 (CertificateCompiler public consumer boundary)**.** *Every downstream consumer of an accepted* CertificateCompiler$^{\uparrow}$ *packet factors through graph landing, classifier transport, and continuation rows. Thus a public read can inspect only the graph row G, the target landing row E, the classifier transport row H, the continuation row C, the* Pkg *provenance row P, and the local* NameCert *row N over the source and target naming rows S, T.*

Proof. Read the packet through Definition 473.1. Its public surface presents graph, landing, continuation, transport, provenance, and local naming rows over the source and target certificates.

Apply Definition 473.2, Definition 473.10, and Definition 473.21. They identify the consumer-visible classifier route with graph landing, transported classifier comparison, and continuation compatibility.

Finally use Definition 473.22. Composite consumers read only the same graph-landing and classifier-continuation rows, so downstream access factors through the displayed finite packet surface. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier public consumer boundary`

Theorem 473.25 (CertificateCompiler downstream boundary sibling link)**.** *Every adjacent-stage boundary read in chapter 574 consumes two accepted* CertificateCompiler$^{\uparrow}$ *packets through their endpoint availability, displayed edge witness totality, and continuation compatibility rows before the middle-stage compatibility row is read. Thus the downstream boundary is a finite sibling consumer of the compiler packets rather than a host compiler semantics, ambient program equivalence, optimizer correctness theorem, or unrecorded target behavior.*

Proof. First expose the endpoints of the two compiler packets. Definition 473.3 supplies the source, middle, and target NameCert rows, while Definition 473.4 forces each displayed edge to land through its graph and edge-landing rows.

Next replay the local consumer obligations. Definition 473.6 and Definition 473.24 make the boundary read pass through graph landing, classifier transport, and continuation compatibility for each packet before any shared middle row can be inspected.

Finally read the sibling boundary chapter. The adjacent-stage packet in chapter 574 consumes the two compiler packets exactly at that middle certificate interface, so its compatibility row has no coordinate from host compiler semantics, ambient program equivalence, optimizer correctness, or unrecorded target behavior. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier downstream boundary sibling link`

Theorem 473.26 (CertificateCompiler finite-route non-escape)**.** *The finite* CertificateCompiler$^{\uparrow}$ *route exports no host compiler semantics, optimizer correctness theorem, ambient program equality, or unrecorded target behavior. Every accepted identity, edge, binary composite, triple composite, and downstream consumer read remains inside the displayed rows S, T, G, E, C, H, P, N and their* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *coordinates.*

Proof. The carrier of Definition 473.1 supplies the finite row list S, T, G, E, C, H, P, N. No other compiler coordinate is part of the accepted packet.

The classifier of Definition 473.2, together with Definition 473.10, restricts edge reads to source classifier comparison, target landing, transported classifier rows, and displayed continuation routes.

Apply Definition 473.21 and Definition 473.22. Identity and composite routes keep the same finite dependency surface, so no host compiler, optimizer, ambient equality, or unrecorded target behavior is exported. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier finite route nonescape`

The endpoint route consumes the finite morphism packet of chapter 620. KernelMorphismUp supplies source-target graph admission and classifier-lift rows, while CertificateCompiler$^{\uparrow}$ adds target landing, endpoint route, and composition ledgers.

Theorem 473.27 (CertificateCompiler target endpoint route)**.** *Let*

$$K = (S, T, G, E, C, H, P, N)$$

be an accepted CertificateCompiler$^{\uparrow}$ *packet. Every route by which K reaches the target certificate T is exhausted by the source* NameCert *row S, the displayed compiler graph G, the target landing row E, the classifier transport row H, the continuation row C, the* Pkg *provenance row P, and the local* NameCert *row N. In particular, target arrival is a finite* BHist *read through S, G, E, H, C, P, N, not a read of host compiler semantics, optimiser correctness, ambient program equality, or unrecorded target behavior.*

Proof. Project the carrier of Definition 473.1. The accepted packet exposes exactly the source and target naming rows, graph, landing, continuation, componentwise hsame transport, package provenance, and local naming row.

Endpoint availability is supplied by Definition 473.3, so the target certificate is already one of the displayed rows. Edge-classifier exactness from Definition 473.10 then forces each graph edge to land through E and to transport classifier data only through H and the paired Cont route in C.

Finally apply the public consumer boundary of Definition 473.24. A downstream read can consume only the displayed graph, landing, classifier transport, continuation, package, and local naming rows. Thus every target endpoint route is the stated finite BHist route through S, G, E, H, C, P, N. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier target endpoint route`

Theorem 473.28 (CertificateCompiler identity composite public boundary)**.** *For accepted* CertificateCompiler$^{\uparrow}$ *packets, identity rows, binary composites, and triple composites remain inside the same public row surface S, T, G, E, C, H, P, N. The identity packet exposes only the diagonal rows of its local* NameCert *input, a binary composite exposes only the two displayed compiler packets and their shared middle landing, and a triple composite exposes only the three displayed graph edges, the two middle landing rows, the ordered* hsame *transports, the composed* Cont *route, the* Pkg *provenance, and the local* NameCert *rows.*

Proof. For identities, apply Definition 473.9. The diagonal packet reads the carrier, classifier, hsame, Cont, Pkg, and NameCert rows already displayed by the local certificate.

For binary composites, use Definition 473.8 together with Definition 473.12. The composite graph is formed from displayed graph edges, and its landing, classifier, continuation, package, and local naming rows are projected from the two input packets and their middle NameCert row.

For triple composites, apply Definition 473.13. The two associations expose the same three graph edges, two middle landing matches, ordered classifier transports, and continuation endpoint.

The left and right unit laws, Definition 473.14 and Definition 473.15, identify identity composites with the original packet surface. Combining these rows gives the same public boundary S, T, G, E, C, H, P, N for identity, binary, and triple compiler packets. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier identity composite public boundary`

Theorem 473.29 (CertificateCompiler endpoint-route determinacy envelope)**.** *Let*

$$K = (S, T, G, E, C, H, P, N)$$

be an accepted $\mathsf{CertificateCompiler}^{\uparrow}$ *packet. Any accepted target endpoint route for* K*, and any identity, binary composite, or triple composite route built from accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packets, is determined by the same displayed finite surface* S, T, G, E, C, H, P, N*. There is no second endpoint route through host compiler semantics, optimiser correctness, ambient program equality, or unrecorded target behavior.*

Proof. First apply the target endpoint route of Definition 473.55. It places endpoint arrival inside the displayed source naming row, compiler graph, target landing row, classifier transport, continuation row, package provenance, and local naming row of the accepted carrier.

Next apply the identity composite public boundary of Definition 473.56. Identity rows, binary composites, and triple composites stay on the same public row surface S, T, G, E, C, H, P, N; their middle landings, graph edges, transports, continuation rows, package provenance, and local names are projected from displayed compiler packets.

Finally return to the carrier definition. The accepted packet has no coordinate for host compiler semantics, optimiser correctness, ambient program equality, or unrecorded target behavior. Endpoint arrival and the composite public boundary therefore share the same displayed rows, so the finite surface S, T, G, E, C, H, P, N determines the available endpoint and composite routes. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint route determinacy envelope`

Theorem 473.30 (CertificateCompiler endpoint determinacy)**.** *Let* $K = (S, T, G, E, C, H, P, N)$ *be an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet. If two accepted target endpoint routes for* K *agree on the source row* S*, the compiler graph* G*, the landing row* E*, the classifier transport* H*, the continuation row* C*, the provenance row* P*, and the local name* N*, then they determine the same target certificate row* T*. No host compiler semantics, optimiser equality, ambient program equality, or unrecorded target behavior can create a second endpoint.*

Proof. First apply the target endpoint route theorem, Definition 473.55. It exhausts every route to T by the displayed source, graph, landing, classifier transport, continuation, package, and local naming rows.

Endpoint certificate availability, Definition 473.3, supplies the target certificate as part of that displayed packet, and edge-classifier exactness, Definition 473.10, keeps graph edges tied to the same landing and classifier rows. Thus two accepted reads agreeing on S, G, E, H, C, P, N have no further endpoint coordinate to vary.

Now use the public consumer boundary, Definition 473.24, together with Definition 473.56. Public consumers, identities, binary composites, and triple composites remain on the same finite row surface. Since the packet contains no host compiler semantics, optimiser equality, ambient program equality, or unrecorded target behavior, the agreed displayed rows determine the same target certificate row T. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint determinacy`

Theorem 473.31 (CertificateCompiler downstream stage unblock package)**.** *The target endpoint route of Definition 473.55 and the identity/composite boundary of Definition 473.56 supply the public package consumed by* CertificatePipelineStageBoundary$^{\uparrow}$, KernelMorphismUp, *and* DecompilerRightInverse$^{\uparrow}$. *The package consists only of finite* BHist *rows, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *rows over* $K = (S, T, G, E, C, H, P, N)$*; it does not export host compiler semantics, optimiser correctness, decompiler correctness, ambient program equality, or target behavior absent from the packet.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier downstream stage unblock package`

Proof. First build the endpoint part of the package. By Definition 473.55, every accepted target route reads the source naming row, graph row, landing row, classifier transport row, continuation row, package provenance, and local naming row.

Next build the compositional part. By Definition 473.56, identities, binary composites, and triple composites keep the same public row surface and do not add a host compiler coordinate.

Now combine these with Definition 473.23 and Definition 473.26. The source and target endpoints are exhausted by the displayed packet rows, and every finite route stays inside BHist, hsame, Cont, Pkg, and NameCert coordinates.

The consumers named in the statement require exactly this public route surface: pipeline stages read adjacent compiler boundaries, kernel morphisms read source-to-target graph preservation, and decompiler right-inverse packets read the displayed compiler/decompiler interface. Since all three reads factor through the same finite package, none receives a host compiler semantics or optimiser-correctness theorem. □

Theorem 473.32 (CertificateCompiler KernelMorphism route scope)**.** *Let* $K = (S, T, G, E, C, H, P, N)$ *be an accepted* CertificateCompiler$^{\uparrow}$ *packet. Any downstream* KernelMorphismUp *consumer reads the compiler graph* G *only through the endpoint route* S, G, E, H, C, P, N *and the source-target graph admission and classifier-lift rows of chapter 620. It cannot import host compiler semantics, optimiser correctness, decompiler correctness, or target behavior absent from the finite packet.*

Proof. First use the target endpoint route of Definition 473.55. It identifies the graph-facing route to the target certificate with the displayed source naming row, compiler graph, target landing row, classifier transport, continuation row, package provenance, and local naming row.

Next apply the identity and composite public boundary of Definition 473.56. Identities, binary composites, and triple composites stay on the same finite endpoint surface, so a downstream morphism consumer receives graph preservation through displayed compiler rows rather than through host program semantics.

Finally combine the downstream stage package of Definition 473.59 with the KernelMorphismUp source-target scope named in chapter 620. The consumer-facing route is exactly the finite BHist handoff through S, G, E, H, C, P, N together with the KernelMorphism graph-admission and classifier-lift rows, leaving optimiser correctness, decompiler correctness, and unrecorded target behavior outside the packet. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier kernelmorphism route scope`

Theorem 473.33 (CertificateCompiler KernelMorphism decompiler boundary)**.** *Let* $K = (S, T, G, E, C, H, P, N)$ *be an accepted* CertificateCompiler$^{\uparrow}$ *packet. Any route from* K *into a* KernelMorphismUp *consumer and then into a* DecompilerRightInverse$^{\uparrow}$ *consumer factors through the displayed finite rows*

S, G, E, H, C, P, N, the KernelMorphismUp *graph-admission and classifier-lift rows, and the* DecompilerRightInverse$^{\uparrow}$ *inverse-boundary rows of Definition 614.3. The route exports no host compiler semantics, optimiser correctness, ambient program equality, host decompiler function, total decompiler, or unrecorded target behavior.*

Proof. First apply the target endpoint route of Definition 473.55. It places every accepted compiler target read on the displayed finite rows S, G, E, H, C, P, N.

Next apply the KernelMorphism route scope of Definition 473.60. The intermediate morphism consumer can add only the graph-admission and classifier-lift rows licensed by KernelMorphismUp, so the compiler leg remains a finite BHist handoff rather than a host compiler semantics.

Finally apply the decompiler right-inverse non-escape boundary of Definition 614.3. A downstream inverse consumer may read only the displayed compiler packet, decompiler graph, target optimisation row, right-inverse ledger, transport, continuation, provenance, and local naming rows. Combining the three non-escape clauses leaves no route to optimiser correctness, ambient program equality, host decompiler behavior, or target behavior absent from the packet. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier kernelmorphism decompiler boundary`

Theorem 473.34 (CertificateCompiler target endpoint determinacy)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be an accepted* CertificateCompiler$^{\uparrow}$ *packet. Once the source row S, a displayed graph edge in G, its landing row E, the classifier transport row H, and the continuation row C are fixed, the target endpoint route to T is determined as the finite route through S, G, E, H, C, P, N. No second endpoint route can be obtained from host compiler semantics, optimiser correctness, ambient program equality, or an unrecorded target behavior.*

Proof. Start from Definition 473.55. It identifies every target arrival with the displayed source, graph, landing, classifier, continuation, package, and local naming rows.

Use Definition 473.10. With the source row, graph edge, landing row, classifier transport, and continuation row fixed, the edge has no further classifier-facing or endpoint-facing coordinate to vary.

Finally apply Definition 473.26. The carrier exports no external compiler semantics or target behavior, so the fixed displayed rows determine the endpoint route. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier target endpoint determinacy`

Theorem 473.35 (CertificateCompiler endpoint-route pullback determinacy)**.** *Let a downstream route pass through* CertificateCompiler$^{\uparrow}$ *into* KernelMorphismUp *and then into* DecompilerRightInverse$^{\uparrow}$*. If two such routes have the same displayed source row, graph edge, landing row, classifier transport row, and* Cont *row, then their endpoint pullbacks are the same finite route through S, G, E, H, C, P, N. No host compiler semantics, optimiser correctness, ambient program equality, host decompiler function, or unrecorded target behavior can distinguish the pullbacks.*

Proof. First apply target endpoint determinacy, Definition 473.62. Agreement of the displayed source row, graph edge, landing row, classifier transport row, and continuation row fixes the compiler endpoint route through S, G, E, H, C, P, N.

Next use the KernelMorphism route scope, Definition 473.60. The morphism consumer can add only the graph-admission and classifier-lift rows licensed by KernelMorphismUp, so it cannot separate two already fixed compiler endpoint routes.

Finally apply the KernelMorphism decompiler boundary, Definition 473.61. The decompiler-facing leg remains on the displayed compiler packet and inverse-boundary rows, leaving no coordinate for host compiler semantics, optimiser correctness, ambient equality, host decompiler functions, or unrecorded target behavior. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint route pullback determinacy`

Theorem 473.36 (CertificateCompiler route composition exactness)**.** *For accepted* CertificateCompiler$^{\uparrow}$ *packets, the identity route, every binary composite route, and every triple composite route use only the displayed graph rows, landing rows, classifier transport rows, and* Cont *rows, together with the visible* Pkg *and local* NameCert *provenance. These routes introduce no hidden program equality, optimiser correctness theorem, ambient compiler semantics, or target behavior outside the finite packet.*

Proof. For the identity and binary cases, apply Definition 473.56. The identity packet reads the diagonal local naming rows, and the binary composite reads the two displayed compiler packets and their shared middle landing.

For the triple case, use the same public boundary together with Definition 473.10. The three graph edges, two middle landing rows, ordered classifier transports, and composed Cont route are exactly the rows visible to the consumer.

The finite non-escape theorem Definition 473.26 excludes any additional semantic coordinate. Hence all identity, binary, and triple composition routes are exact over the displayed rows. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier route composition exactness`

Theorem 473.37 (CertificateCompiler ledger cut elimination)**.** *Let a downstream consumer read the public package supplied by Definition 473.59. An intermediate package row may be cut from that consumer route only when the same displayed endpoint rows and the same identity, binary, or triple composite rows remain preserved in the resulting route. A cut that changes the endpoint route, changes the composite route, or replaces either route by host compiler semantics, decompiler correctness, ambient program equality, or unrecorded target behavior is not a valid* CertificateCompiler$^{\uparrow}$ *consumer read.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier ledger cut elimination`

Proof. First read the downstream package through Definition 473.59. The consumer-visible packet consists only of finite BHist rows, displayed hsame transport, Cont routes, Pkg provenance, and local NameCert rows.

Endpoint preservation is forced by Definition 473.55. If a cut removes an intermediate package row but keeps the same source, graph, landing, classifier, continuation, provenance, and local naming rows, the target route is still the displayed finite route.

Composite preservation is forced by Definition 473.56 and Definition 473.64. Identity, binary, and triple composites remain valid exactly when their displayed graph, landing, classifier, and continuation rows are unchanged.

Finally use Definition 473.26. Any cut that replaces a displayed row by host semantics, decompiler correctness, ambient equality, or unrecorded target behavior leaves the finite packet surface and is therefore unavailable to downstream consumers. □

Theorem 473.38 (CertificateCompiler endpoint decompiler handoff determinacy)**.** *Let* $K = (S, T, G, E, C, H, P, N)$ *be an accepted* CertificateCompiler$^{\uparrow}$ *endpoint route. Once the displayed rows* S, G, E, H, C, P, N *and the* KernelMorphismUp *graph-admission and classifier-lift rows are fixed, any* DecompilerRightInverse$^{\uparrow}$ *consumer can read only the inverse-boundary rows already cited by Definition 473.61. The handoff cannot introduce host compiler semantics, optimiser correctness, ambient program equality, host decompiler functions, or unrecorded target behavior.*

Proof. First use target endpoint determinacy, Definition 473.62. With the source row, graph edge, landing row, classifier transport, continuation row, provenance, and local naming row fixed, the endpoint route is the displayed finite route through S, G, E, H, C, P, N.

Next apply route composition exactness and ledger cut elimination, Definition 473.64 and Definition 473.65. Identity, binary, and triple composites may be replayed only over the same displayed endpoint rows, and no intermediate cut can replace them by host semantics or unrecorded behavior.

Now pass through the KernelMorphism route scope, Definition 473.60. The morphism leg contributes only the graph-admission and classifier-lift rows licensed by KernelMorphismUp.

Finally apply the KernelMorphism decompiler boundary, Definition 473.61, together with the decompiler right-inverse non-escape boundary of Definition 614.3. A downstream inverse consumer therefore receives only the displayed compiler packet, the fixed KernelMorphism rows, and the inverse-boundary rows, with no coordinate for host compiler semantics, optimiser correctness, ambient equality, host decompiler functions, or unrecorded target behavior. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint decompiler handoff determinacy`

Theorem 473.39 (CertificateCompiler endpoint-composite determinacy)**.** *Let* $K = (S, T, G, E, C, H, P, N)$ *be an accepted* CertificateCompiler$^{\uparrow}$ *packet. Once the displayed source row, graph edge, landing row, classifier transport, continuation row, and identity, binary, and triple composite rows are fixed, every downstream* KernelMorphismUp *or* DecompilerRightInverse$^{\uparrow}$ *consumer route is determined by the finite packet* S, G, E, H, C, P, N *together with the relevant composite rows. The determined route exports no host compiler semantics, optimiser correctness theorem, decompiler correctness theorem, ambient program equality, or target behavior outside those finite rows.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint composite determinacy`

Proof. Start with the endpoint route and public composite boundary. The target endpoint route of Definition 473.55 fixes the source, graph, landing, classifier transport, continuation, provenance, and local naming rows, while Definition 473.56 fixes identity, binary, and triple composites on the same displayed surface.

Next expose the downstream packet. Apply the downstream stage unblock package, Definition 473.59, together with KernelMorphism route scope, Definition 473.60. A morphism consumer can read only the finite compiler route and the corresponding graph-admission and classifier-lift rows.

Now attach the decompiler boundary. The KernelMorphism decompiler boundary, Definition 473.61, keeps any route into DecompilerRightInverse$^{\uparrow}$ on the same finite compiler packet before the inverse-boundary rows are read.

Finally use target endpoint determinacy, route composition exactness, and ledger cut elimination, Definition 473.62, Definition 473.64, and Definition 473.65. These identify all endpoint and composite reads after the listed rows are fixed, so every downstream morphism or decompiler route

is determined by S, G, E, H, C, P, N plus the relevant composite rows, with no remaining semantic coordinate available. □

Theorem 473.40 (CertificateCompiler endpoint KernelMorphism roundtrip)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be an accepted finite* CertificateCompiler$^{\uparrow}$ *endpoint route. If the source and target endpoint reads agree under Definition 473.62, then the route factors through the* KernelMorphismUp *graph-admission and classifier-lift scope and returns through the* DecompilerRightInverse$^{\uparrow}$ *boundary on the same displayed compiler rows.*

The roundtrip uses only S, G, E, H, C, P, N, the relevant identity, binary, or triple composite rows, the KernelMorphismUp *graph-admission and classifier-lift rows, and the* DecompilerRightInverse$^{\uparrow}$ *inverse-boundary rows. It adds no hidden host compiler semantics, optimiser correctness theorem, decompiler correctness theorem, ambient program equality, total decompiler, or unrecorded target behavior.*

Proof. First apply target endpoint determinacy, Definition 473.62. Agreement of the source and target endpoint reads fixes the displayed finite endpoint route through S, G, E, H, C, P, N.

Next pass through the morphism surface using Definition 473.60. A downstream KernelMorphismUp consumer can read only the graph-admission and classifier-lift rows attached to the same compiler packet, so the route has no host compiler coordinate at the morphism stage.

Now return through the decompiler side by Definition 473.61. The decompiler-facing consumer remains on the displayed compiler packet together with the inverse-boundary rows, rather than importing host decompiler behavior or total decompiler data.

Finally compose the route and remove intermediate package cuts. The composition exactness theorem, Definition 473.64, keeps identity, binary, and triple composites on the displayed rows, while ledger cut elimination, Definition 473.65, permits only cuts preserving those endpoint and composite rows. Thus the endpoint, KernelMorphism, and decompiler legs form a finite roundtrip with no hidden host compiler semantics. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint kernelmorphism roundtrip`

Corollary 473.41 (CertificateCompiler target endpoint consumer determinacy)**.** *Let*

$$K = (S, T, G, E, C, H, P, N)$$

be an accepted CertificateCompiler$^{\uparrow}$ *packet. Fix the consumer-visible rows cited by Definition 473.57: the source row S, target row T, compiler graph G, target landing row E, continuation row C, classifier transport row H, package provenance row P, local naming row N, and, when a composite is requested, the displayed identity, binary, or triple-composite ledger rows over the same surface. Then any accepted consumer-facing use of K must select the same finite endpoint route, the same composite normal form, or the same classifier-exactness decision named by the* CertificateCompiler$^{\uparrow}$ *chapter. It cannot select an alternate hidden coordinate, a second source classifier row, host compiler semantics, optimiser correctness, ambient program equality, or unrecorded target behavior.*

Proof. First apply Definition 473.55. It exhausts every target arrival by the finite BHist route through the displayed source naming row, graph row, target landing row, classifier transport row, continuation row, package provenance row, and local naming row. Thus a consumer that asks for the target endpoint has no endpoint coordinate beyond S, G, E, H, C, P, N.

Next apply Definition 473.57. It says that accepted endpoint routes and accepted identity, binary, and triple-composite routes are all determined by the same displayed finite surface

S, T, G, E, C, H, P, N. Hence fixing the cited local rows also fixes the composite normal form available to a consumer: the identity normal form is the diagonal row, a binary normal form is the displayed two-packet composite through the shared middle landing, and a triple normal form is the displayed three-edge ledger with its two middle landing rows.

It remains to rule out duplicate classifier sources and alternate exactness decisions. By Definition 473.10, an accepted classifier decision reads the source classifier row in S, lands through E, transports through the componentwise hsame row H, and follows the paired Cont routes in C. With S, E, H, C fixed, there is no second classifier-facing source from which a different decision could be accepted.

Finally use Definition 473.26. The accepted carrier exports no host compiler semantics, optimiser correctness theorem, ambient program equality, or unrecorded target behavior. Any consumer-facing use that agrees on the displayed rows therefore factors through the same finite route surface and must return the same endpoint route, composite normal form, or classifier-exactness decision named above. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier target endpoint consumer determinacy`

Theorem 473.42 (CertificateCompiler root landing obligation)**.** *Every root consumer of an accepted* CertificateCompiler$^{\uparrow}$ *packet*

$$K = (S, T, G, E, C, H, P, N)$$

must first read the source NameCert *endpoint row S, the target* NameCert *endpoint row T, the displayed compiler graph G, and the edge-landing row E. The consumer may treat a displayed graph edge as landed only after S supplies the source carrier and classifier row, T supplies the target carrier and classifier row, G supplies the finite edge, and E records that the edge starts in the carrier named by S and lands in the carrier named by T.*

No root consumer can obtain a landing witness from host compiler equality, ambient program equivalence, optimizer correctness, decompiler behavior, or an unrecorded target behavior outside the rows S, T, G, E.

Proof. Unfold the carrier in Definition 473.1. Its first four rows are exactly the source endpoint certificate S, the target endpoint certificate T, the displayed compiler graph G, and the edge-landing row E.

Use the classifier definition in Definition 473.2. Even a paired-edge comparison begins by reading the source classifier row in S and the target landing row in T, so classification cannot precede endpoint availability.

Apply Definition 473.7. Its carrier landing obligation is the finite row assertion that every edge of G reads a source row admitted by S and lands in a target row admitted by T through E.

The carrier has no coordinate for host compiler equality or ambient program equivalence. Therefore a root consumer that consumes landing data is forced through the displayed S, T, G, E rows and cannot source a landing witness elsewhere. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier root landing obligation`

Theorem 473.43 (CertificateCompiler root classifier transport obligation)**.** *For every accepted* CertificateCompiler$^{\uparrow}$ *packet*

$$K = (S, T, G, E, C, H, P, N),$$

paired-edge classifier transport is exhausted by the source and target endpoint rows S, T, the componentwise hsame *transport row H, and the continuation row C. A root consumer may compare two displayed graph edges only by sharing the source classifier row in S, landing through T, moving the target classifier row through H, and following the paired* Cont *routes recorded in C.*

The transport obligation does not admit host compiler equality, source program equivalence, target program equivalence, or an external semantic relation as a classifier witness.

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier root classifier transport obligation`

Proof. Unfold Definition 473.1. The transport-relevant rows available to a root consumer are the endpoint certificates S, T, the componentwise transport row H, and the continuation compatibility row C, with G and E only displaying the edges whose classifiers are compared.

Now unfold Definition 473.2. It defines compatibility for paired graph edges by a common source classifier row, a target landing, componentwise hsame transport, and paired continuation routes. These are precisely the rows S, T, H, C named in the statement.

Apply the classifier-transport clause of Definition 473.7. That clause permits transport from the source classifier row to the target classifier row only by the displayed finite-row data already carried by the packet.

Since neither the carrier nor the classifier contains host compiler equality or a program-equivalence coordinate, a root consumer cannot certify paired edges by such an external equality. The finite row surface S, T, H, C exhausts classifier transport. □

Theorem 473.44 (CertificateCompiler root continuation route obligation)**.** *Every downstream root consumer of an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet, including* $\mathsf{CertificatePipelineStageBoundary}^{\uparrow}$, KernelMorphismUp*, and* $\mathsf{DecompilerRightInverse}^{\uparrow}$*, reads continuation compatibility only through the displayed* Cont *row C, the package provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{CertificateCompiler}^{\uparrow}}$ *row N together with the endpoint* NameCert *rows S, T. The consumer route factors through the recorded source and target continuation pair, the named package surface, and the local certificate row; it does not factor through an unstated compiler semantics or decompiler correctness theorem.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier root continuation route obligation`

Proof. Unfold the carrier in Definition 473.1. The only continuation coordinate is C, and the rows that publish it to downstream consumers are the provenance row P and the local naming row N over the endpoint certificates S, T.

Use Definition 473.2. Its paired-edge comparison does not stop at landing; it also reads the source and target Cont routes recorded in C, so any classifier-compatible downstream route has already passed through the displayed continuation row.

Apply Definition 473.7. The continuation-compatibility clause states that each source route used by a graph edge is paired in C with the target route followed after compiling, while the package and local naming rows can only repack these displayed obligations.

The three named root consumers each read a different downstream surface: pipeline-stage boundaries read adjacent compiler routes, kernel morphisms read source-to-target preservation, and decompiler right-inverse packets read the compiler/decompiler interface. In all three cases the available route data are the finite rows C, P, N, S, T and the local NameCert obligations, so no unstated compiler semantics or decompiler correctness theorem can enter the continuation route. □

Theorem 473.45 (CertificateCompiler root landing bridge determinacy)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet. Every consumer-facing bridge use of root landing data for K, including a displayed edge route, classifier transport, endpoint readback, continuation readback, package handoff, or local naming handoff, factors through the local row surface*

$$S, T, G, E, C, H, P, N.$$

More precisely, landing is determined by S, T, G, E, paired-edge classifier transport is determined by S, T, H, C, continuation route readback is determined by C over the endpoint rows S, T, and the handoff rows P, N can only repack those displayed obligations. No host compiler equality, ambient program equivalence, optimizer correctness, decompiler behavior, external semantic relation, or unrecorded target behavior supplies an additional bridge coordinate.

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier root landing bridge determinacy`

Proof. Start with root landing. By Definition 473.75, a root consumer may treat a displayed graph edge as landed only after reading the endpoint rows S, T, the displayed graph row G, and the edge-landing row E. Thus every bridge use whose first demand is endpoint readback, graph readback, or target landing is already forced through S, T, G, E.

Next read classifier transport. By Definition 473.76, paired-edge comparison is exhausted by the source and target endpoint rows S, T, the componentwise hsame row H, and the continuation row C. Hence a consumer cannot turn a landing bridge into an independent classifier witness: the only accepted transport reads the same endpoints, moves the target classifier through H, and follows the paired Cont routes in C.

Now apply Definition 473.77. A downstream route consumer reads continuation compatibility through C, package provenance through P, and local naming through N together with the endpoint certificates S, T. Therefore route readback, continuation readback, package handoff, and local naming handoff do not create a second bridge surface; they publish the same finite landing and transport rows to downstream consumers.

Combining the three obligations gives determinacy. The landing rows S, T, G, E decide which displayed edge has landed, the transport rows S, T, H, C decide which paired-edge classifier comparison is available, and the rows C, P, N decide how that route is handed to later consumers. Each listed row has a fixed role in the packet, while the carrier and classifier supply no coordinate for host compiler equality, ambient program equivalence, optimizer correctness, decompiler behavior, an external semantic relation, or unrecorded target behavior. Any attempted bridge coordinate outside S, T, G, E, C, H, P, N therefore has no row to read, and every permitted consumer-facing use factors through the cited local rows. □

Corollary 473.46 (CertificateCompiler root landing consumer determinacy)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet, and fix the consumer-visible rows cited by Definition 473.78: the source endpoint row S, the target endpoint row T, the displayed compiler graph G, the edge-landing row E, the continuation row C, the componentwise* hsame *transport row H, the package provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{CertificateCompiler}^{\uparrow}}$ *row N. Then any accepted consumer-facing use of root landing data for K must pick the same finite displayed edge route, the same continuation readback route, the same package or local naming handoff, and the same classifier-exactness decision determined by those rows. It cannot pick an alternate hidden coordinate, a duplicate source classifier row, a second endpoint readback source, host compiler equality, ambient program equivalence, optimizer correctness, decompiler behavior, an external semantic relation, or unrecorded target behavior.*

Proof. By Definition 473.75, root landing can be consumed only after the consumer has read S, T, G, E. Thus the landing part of any accepted use is already pinned to the source endpoint certificate, target endpoint certificate, displayed graph edge, and edge-landing row named in the packet. There is no carrier coordinate from which the consumer could obtain another landing witness, endpoint readback, or source classifier row.

Apply Definition 473.78. It lists the consumer-facing bridge uses of the same root landing data: displayed edge route, classifier transport, endpoint readback, continuation readback, package handoff, and local naming handoff. The theorem states that each such use factors through the finite row surface

$$S, T, G, E, C, H, P, N.$$

It also separates the roles of the rows: S, T, G, E determine landing, S, T, H, C determine paired-edge classifier transport, C over S, T determines continuation readback, and P, N only repack those obligations for package and local naming handoff.

The remaining alternatives are therefore ruled out by absence of a row to read. A claimed alternate finite route would have to alter the displayed graph, edge landing, continuation row, or handoff row, but those are fixed as G, E, C, P, N. A claimed different normal form would have to use an identity, composite, or readback surface outside the displayed packet, but Definition 473.78 permits only the listed bridge surface for consumer-facing use. A claimed different classifier-exactness decision would have to replace the source classifier row in S, the target classifier row in T, the componentwise transport row H, or the paired Cont row C, but the classifier transport part of the bridge determinacy theorem exhausts exactly S, T, H, C.

Consequently, once the cited local rows are fixed, every accepted consumer-facing use lands on the same displayed route, readback route, handoff, or exactness decision named by the CertificateCompiler$^{\uparrow}$ chapter. A hidden coordinate, duplicate classifier source, or external semantic witness is not an accepted consumer source for root landing data. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier root landing consumer determinacy`

Theorem 473.47 (CertificateCompiler bridge schema handoff)**.** *Every public* CertificateCompiler$^{\uparrow}$ *packet hands a schema bridge only the finite compiler graph, target landing rows, classifier-transport rows, continuation rows, package provenance, and source, target, and local* NameCert *rows. The handoff is the displayed packet surface S, T, G, E, C, H, P, N together with its identity, composite, and triple-composite ledgers; it does not include host compiler semantics, optimizer correctness, decompiler behavior, ambient program equality, or unrecorded target behavior.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier bridge schema handoff`

Proof. Start with the carrier of Definition 473.1. It exposes source and target certificates, graph edges, landing rows, continuation rows, componentwise transports, provenance, and a local naming row.

Use the classifier and the NameCert obligations. Definition 473.2 and Definition 473.7 identify the bridge-readable packet with the finite graph, landing, classifier transport, continuation, package, and naming rows.

Now apply edge-classifier exactness, the identity ledger, composition stability, and triple-composite associativity. These theorems show that every schema-facing edge, identity, binary composite, and triple composite is replayed through the same finite rows, so the bridge handoff has no host compiler coordinate. □

Theorem 473.48 (CertificateCompiler bridge-row non-escape)**.** *The bridge-facing rows of a public* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet export no optimizer, decompiler, program equality, ambient categorical equality, or unrecorded target behavior. Any schema bridge that consumes the packet must read the source certificate, target certificate, graph edge, landing, route, transport, provenance, and local naming rows exactly as displayed.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier bridge rows nonescape`

Proof. Project the public packet as the finite rows S, T, G, E, C, H, P, N. These rows are the only bridge-facing coordinates of the carrier.

Apply Definition 473.10 and Definition 473.26. They force edge reads through graph, landing, classifier transport, continuation, provenance, and naming rows and exclude host compiler semantics from the packet.

The identity ledger, composition stability, and triple-composite associativity preserve the same row set under bridge replay. Since no displayed row is an optimizer, decompiler, program-equality witness, ambient categorical equality, or target-behavior oracle, none can be exported to the bridge consumer. □

Theorem 473.49 (CertificateCompiler bridge consumer exhaustion)**.** *Every schema-bridge consumer of a public* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet factors through the already displayed source certificate, target certificate, graph edge, landing row, route row, classifier-transport row, provenance row, and local naming row. The consumer can compose, reassociate, and replay certificate-compiler edges only by the identity, binary-composite, and triple-composite ledgers already present in the chapter.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier bridge consumer exhaustion`

Proof. Begin with the public consumer boundary Definition 473.24. It already restricts downstream reads to graph landing, classifier transport, continuation, provenance, and local naming over the source and target certificates.

Add the bridge handoff of Definition 473.70. The bridge receives exactly the same finite graph and certificate rows, with no host compiler semantics.

Finally apply the identity ledger, composition stability, and triple-composite associativity. These results exhaust the bridge consumer's available operations on the packet: identity replay, binary composition, and triple reassociation all factor through the displayed rows and cannot introduce another compiler surface. □

Theorem 473.50 (CertificateCompiler bridge associativity split index)**.** *The bridge handoff of Definition 473.70, the bridge-row non-escape boundary of Definition 473.71, and the bridge consumer exhaustion row of Definition 473.72 all read the same identity, binary-composite, and triple-composite ledger for* $\mathsf{CertificateCompiler}^{\uparrow}$ *packets. A schema bridge therefore consumes one finite ledger surface rather than three unrelated compiler interfaces.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier bridge associativity split index`

Proof. First read the identity ledger. Definition 473.9 gives the diagonal compiler packet over the same displayed source, target, graph, landing, classifier transport, continuation, provenance, and naming rows consumed by the bridge handoff.

Next read binary composition. Definition 473.8 and Definition 473.12 keep composite replay on the same public row surface and add no host compiler semantics.

Finally read triple composites. Definition 473.13 and the bridge consumer exhaustion theorem use the same triple of graph edges and middle landing matches, while bridge-row non-escape blocks optimizer, decompiler, program-equality, ambient categorical, and unrecorded target-behavior coordinates. □

Corollary 473.51 (CertificateCompiler bridge schema handoff strict obstruction)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be a public* CertificateCompiler$^{\uparrow}$ *packet read by a schema bridge. If a displayed failure, refusal, separation, or countermodel row is cited against a named bridge-handoff converse, reuse, or readback route for K, then that row is a strict local obstruction to that named route only. It blocks exactly the request that tries to read, omit, replace, detach, or bypass one of the displayed source certificate, target certificate, graph edge, landing, route, classifier-transport, provenance, or local naming rows. It cannot be reinterpreted as a global impossibility theorem, a host theorem about compilers, hidden external validation, optimizer correctness, decompiler correctness, ambient program equality, ambient categorical equality, or unrecorded target behavior.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier bridge schema handoff strict obstruction`

Proof. Read the schema bridge handoff first. By Definition 473.70, the bridge receives only the finite compiler graph, target landing rows, classifier-transport rows, continuation rows, package provenance, and source, target, and local NameCert rows of the packet. Its full bridge surface is the displayed tuple S, T, G, E, C, H, P, N together with the identity, binary-composite, and triple-composite ledgers. The same theorem excludes host compiler semantics, optimizer correctness, decompiler behavior, ambient program equality, and unrecorded target behavior from the handoff.

Now apply bridge-row non-escape, Definition 473.71. Any schema bridge that consumes K must read the source certificate, target certificate, graph edge, landing, route, transport, provenance, and local naming rows exactly as displayed. Thus a consumer-facing use of a displayed obstruction row has no coordinate outside the listed bridge rows. Source and target admission are read through S, T; graph and landing evidence through G, E; route and replay through C; classifier transport through H; package provenance through P; and the local certificate name through N.

Use Definition 473.72 and Definition 473.73 to exhaust the remaining bridge operations. A bridge consumer may compose, reassociate, or replay only by the displayed identity, binary-composite, and triple-composite ledgers, and those ledgers read the same finite surface rather than separate compiler interfaces. Hence an obstruction row attached to a named bridge-handoff converse, reuse, or readback route can block only the local request whose reading position asks for an unlisted coordinate or bypasses one of the displayed rows.

Any stronger interpretation would require data that the two bridge theorems and the consumer ledger do not export. A global impossibility theorem would require a theorem surface beyond the finite packet; a host theorem about compilers would require host compiler semantics or host program equality; hidden external validation would require an external certificate channel beyond P and N; optimizer or decompiler correctness would require optimizer or decompiler coordinates; and ambient categorical equality or unrecorded target behavior would require exactly the off-packet data ruled out by bridge-row non-escape. Since every permitted bridge-facing use factors through S, T, G, E, C, H, P, N and the displayed ledgers, the obstruction remains strict and local to the named bridge-handoff route. □

Theorem 473.52 (CertificateCompiler mature consumer inventory)**.** *Every mature consumer read of an accepted* CertificateCompiler$^{\uparrow}$ *packet factors through endpoint* NameCert *rows, displayed graph edges, edge landing, classifier transport, continuation compatibility,* Pkg *provenance, and local*

NameCert *rows. The inventory is exhausted by the identity ledger of Definition 473.9, the binary composition stability of Definition 473.8, and the triple composite associativity of Definition 473.13; no additional compiler semantics, optimizer witness, decompiler, program equality, or unrecorded target behavior is available to the consumer.*

Proof. First read the endpoint rows. The source and target NameCert entries supply the only admission points for graph edges, and the carrier records their edge landing, classifier transport, continuation compatibility, provenance, and local naming rows.

Next read identity and binary routes. Definition 473.9 supplies the diagonal endpoint route, while Definition 473.8 composes only displayed graph edges through their middle landing and classifier-transport rows.

Finally read triple routes through Definition 473.13. The two associations preserve the same graph-edge inventory and the same endpoint landing data, so every mature consumer remains inside the finite packet surface listed in the statement. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier mature consumer inventory`

Theorem 473.53 (CertificateCompiler route-category boundary)**.** *Identity and composite* CertificateCompiler$^{\uparrow}$ *packets form only a finite route-category boundary over displayed graph composition. Their identities, binary composites, and triple composites are the packet routes described by Definition 473.9, Definition 473.8, and Definition 473.13; they do not constitute host compiler semantics, ambient categorical laws, optimizer correctness, or a theory of program equivalence.*

Proof. Use the identity ledger for objects. It gives a diagonal packet over a displayed endpoint certificate and records only graph, landing, classifier, continuation, provenance, and local naming rows.

Use composition stability for arrows. Binary composition is graph composition over displayed middle landing data, and its classifier and continuation clauses are read from the same packet rows.

Use triple composite associativity only as a boundary statement. It aligns the two finite replay routes over three displayed graph edges, but it adds no semantic interpretation of compilers, programs, optimizers, or ambient categories. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier route category boundary`

Theorem 473.54 (CertificateCompiler formal target surface)**.** *The Lean-facing formal target for* CertificateCompiler$^{\uparrow}$ *is the finite packet surface S, T, G, E, C, H, P, N together with endpoint certificate availability, displayed edge witness totality, the consumer replay obligation triad, composition stability, the identity ledger, edge-classifier exactness, triple composite associativity, the public consumer boundary, and finite-route non-escape. It excludes host compiler semantics, optimizer correctness, ambient program equality, decompiler semantics, and unrecorded target behavior.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier formal target surface`

Proof. Use Definition 473.1, Definition 473.3, and Definition 473.4 to expose S, T, G, E, C, H, P, N, endpoint certificate availability, and displayed edge witness totality.

Apply Definition 473.6, Definition 473.10, Definition 473.8, Definition 473.9, and Definition 473.13. These results keep all formal obligations inside displayed edge, landing, classifier, continuation, transport, provenance, and naming rows.

Finally apply Definition 473.24 and Definition 473.26. They state that consumers receive only the finite route packet, so host compiler semantics, optimizer correctness, ambient program equality, decompiler semantics, and unrecorded target behavior are outside the formal target. □

Closure status for $\mathsf{NameCert}_{\mathsf{CertificateCompiler}^{\uparrow}}$.

Constructive story: A $\mathsf{CertificateCompiler}^{\uparrow}$ packet is generated from source and target NameCert rows, a finite compiler graph, edge landing, continuation compatibility, hsame transports, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CertificateCompiler}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The public compiler-certificate surface binds the finite graph, landing, classifier, continuation, identity, composition, export, triple-composite, BHist, hsame, Cont, Pkg, and NameCert rows already displayed for certificate compiler packets.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CertificateCompiler}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close host compiler semantics, program equivalence, optimiser correctness, decompilation, categorical laws beyond the displayed finite packets, or a checked Lean certificate.

Upgrade path: No further theory-axis upgrade – chapter at top of closure axis; formal upgrade requires Lean verification of the same finite compiler-certificate graph.

The endpoint route consumes the finite morphism packet of chapter 620. KernelMorphismUp supplies source-target graph admission and classifier-lift rows, while $\mathsf{CertificateCompiler}^{\uparrow}$ adds target landing, endpoint route, and composition ledgers.

Theorem 473.55 (CertificateCompiler target endpoint route)**.** *Let*

$$K = (S, T, G, E, C, H, P, N)$$

be an accepted $\mathsf{CertificateCompiler}^{\uparrow}$ *packet. Every route by which K reaches the target certificate T is exhausted by the source* NameCert *row S, the displayed compiler graph G, the target landing row E, the classifier transport row H, the continuation row C, the* Pkg *provenance row P, and the local* NameCert *row N. In particular, target arrival is a finite* BHist *read through S, G, E, H, C, P, N, not a read of host compiler semantics, optimiser correctness, ambient program equality, or unrecorded target behavior.*

Proof. Project the carrier of Definition 473.1. The accepted packet exposes exactly the source and target naming rows, graph, landing, continuation, componentwise hsame transport, package provenance, and local naming row.

Endpoint availability is supplied by Definition 473.3, so the target certificate is already one of the displayed rows. Edge-classifier exactness from Definition 473.10 then forces each graph edge to land through E and to transport classifier data only through H and the paired Cont route in C.

Finally apply the public consumer boundary of Definition 473.24. A downstream read can consume only the displayed graph, landing, classifier transport, continuation, package, and local naming rows. Thus every target endpoint route is the stated finite BHist route through S, G, E, H, C, P, N. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier target endpoint route`

Theorem 473.56 (CertificateCompiler identity composite public boundary)**.** *For accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packets, identity rows, binary composites, and triple composites remain inside the same public row surface S, T, G, E, C, H, P, N. The identity packet exposes only the diagonal rows of its local* NameCert *input, a binary composite exposes only the two displayed compiler packets and their shared middle landing, and a triple composite exposes only the three displayed graph edges, the two middle landing rows, the ordered* hsame *transports, the composed* Cont *route, the* Pkg *provenance, and the local* NameCert *rows.*

Proof. For identities, apply Definition 473.9. The diagonal packet reads the carrier, classifier, hsame, Cont, Pkg, and NameCert rows already displayed by the local certificate.

For binary composites, use Definition 473.8 together with Definition 473.12. The composite graph is formed from displayed graph edges, and its landing, classifier, continuation, package, and local naming rows are projected from the two input packets and their middle NameCert row.

For triple composites, apply Definition 473.13. The two associations expose the same three graph edges, two middle landing matches, ordered classifier transports, and continuation endpoint.

The left and right unit laws, Definition 473.14 and Definition 473.15, identify identity composites with the original packet surface. Combining these rows gives the same public boundary S, T, G, E, C, H, P, N for identity, binary, and triple compiler packets. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier identity composite public boundary`

Theorem 473.57 (CertificateCompiler endpoint-route determinacy envelope)**.** *Let*

$$K = (S, T, G, E, C, H, P, N)$$

be an accepted CertificateCompiler$^{\uparrow}$ *packet. Any accepted target endpoint route for K, and any identity, binary composite, or triple composite route built from accepted* CertificateCompiler$^{\uparrow}$ *packets, is determined by the same displayed finite surface S, T, G, E, C, H, P, N. There is no second endpoint route through host compiler semantics, optimiser correctness, ambient program equality, or unrecorded target behavior.*

Proof. First apply the target endpoint route of Definition 473.55. It places endpoint arrival inside the displayed source naming row, compiler graph, target landing row, classifier transport, continuation row, package provenance, and local naming row of the accepted carrier.

Next apply the identity composite public boundary of Definition 473.56. Identity rows, binary composites, and triple composites stay on the same public row surface S, T, G, E, C, H, P, N; their middle landings, graph edges, transports, continuation rows, package provenance, and local names are projected from displayed compiler packets.

Finally return to the carrier definition. The accepted packet has no coordinate for host compiler semantics, optimiser correctness, ambient program equality, or unrecorded target behavior. Endpoint arrival and the composite public boundary therefore share the same displayed rows, so the finite surface S, T, G, E, C, H, P, N determines the available endpoint and composite routes. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint route determinacy envelope`

Theorem 473.58 (CertificateCompiler endpoint determinacy)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be an accepted* CertificateCompiler$^{\uparrow}$ *packet. If two accepted target endpoint routes for K agree on the source row S, the compiler graph G, the landing row E, the classifier transport H, the continuation row C, the provenance row P, and the local name N, then they determine the same target certificate row T. No host compiler semantics, optimiser equality, ambient program equality, or unrecorded target behavior can create a second endpoint.*

Proof. First apply the target endpoint route theorem, Definition 473.55. It exhausts every route to T by the displayed source, graph, landing, classifier transport, continuation, package, and local naming rows.

Endpoint certificate availability, Definition 473.3, supplies the target certificate as part of that displayed packet, and edge-classifier exactness, Definition 473.10, keeps graph edges tied to the

same landing and classifier rows. Thus two accepted reads agreeing on S, G, E, H, C, P, N have no further endpoint coordinate to vary.

Now use the public consumer boundary, Definition 473.24, together with Definition 473.56. Public consumers, identities, binary composites, and triple composites remain on the same finite row surface. Since the packet contains no host compiler semantics, optimiser equality, ambient program equality, or unrecorded target behavior, the agreed displayed rows determine the same target certificate row T. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint determinacy`

Theorem 473.59 (CertificateCompiler downstream stage unblock package)**.** *The target endpoint route of Definition 473.55 and the identity/composite boundary of Definition 473.56 supply the public package consumed by* CertificatePipelineStageBoundary$^{\uparrow}$, KernelMorphismUp, *and* DecompilerRightInverse$^{\uparrow}$. *The package consists only of finite* BHist *rows, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *rows over* $K = (S, T, G, E, C, H, P, N)$*; it does not export host compiler semantics, optimiser correctness, decompiler correctness, ambient program equality, or target behavior absent from the packet.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier downstream stage unblock package`

Proof. First build the endpoint part of the package. By Definition 473.55, every accepted target route reads the source naming row, graph row, landing row, classifier transport row, continuation row, package provenance, and local naming row.

Next build the compositional part. By Definition 473.56, identities, binary composites, and triple composites keep the same public row surface and do not add a host compiler coordinate.

Now combine these with Definition 473.23 and Definition 473.26. The source and target endpoints are exhausted by the displayed packet rows, and every finite route stays inside BHist, hsame, Cont, Pkg, and NameCert coordinates.

The consumers named in the statement require exactly this public route surface: pipeline stages read adjacent compiler boundaries, kernel morphisms read source-to-target graph preservation, and decompiler right-inverse packets read the displayed compiler/decompiler interface. Since all three reads factor through the same finite package, none receives a host compiler semantics or optimiser-correctness theorem. □

Theorem 473.60 (CertificateCompiler KernelMorphism route scope)**.** *Let* $K = (S, T, G, E, C, H, P, N)$ *be an accepted* CertificateCompiler$^{\uparrow}$ *packet. Any downstream* KernelMorphismUp *consumer reads the compiler graph* G *only through the endpoint route* S, G, E, H, C, P, N *and the source-target graph admission and classifier-lift rows of chapter 620. It cannot import host compiler semantics, optimiser correctness, decompiler correctness, or target behavior absent from the finite packet.*

Proof. First use the target endpoint route of Definition 473.55. It identifies the graph-facing route to the target certificate with the displayed source naming row, compiler graph, target landing row, classifier transport, continuation row, package provenance, and local naming row.

Next apply the identity and composite public boundary of Definition 473.56. Identities, binary composites, and triple composites stay on the same finite endpoint surface, so a downstream morphism consumer receives graph preservation through displayed compiler rows rather than through host program semantics.

Finally combine the downstream stage package of Definition 473.59 with the KernelMorphismUp source-target scope named in chapter 620. The consumer-facing route is exactly the finite BHist

handoff through S, G, E, H, C, P, N together with the KernelMorphism graph-admission and classifier-lift rows, leaving optimiser correctness, decompiler correctness, and unrecorded target behavior outside the packet. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier kernelmorphism route scope`

Theorem 473.61 (CertificateCompiler KernelMorphism decompiler boundary)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be an accepted* CertificateCompiler$^{\uparrow}$ *packet. Any route from K into a* KernelMorphismUp *consumer and then into a* DecompilerRightInverse$^{\uparrow}$ *consumer factors through the displayed finite rows S, G, E, H, C, P, N, the* KernelMorphismUp *graph-admission and classifier-lift rows, and the* DecompilerRightInverse$^{\uparrow}$ *inverse-boundary rows of Definition 614.3. The route exports no host compiler semantics, optimiser correctness, ambient program equality, host decompiler function, total decompiler, or unrecorded target behavior.*

Proof. First apply the target endpoint route of Definition 473.55. It places every accepted compiler target read on the displayed finite rows S, G, E, H, C, P, N.

Next apply the KernelMorphism route scope of Definition 473.60. The intermediate morphism consumer can add only the graph-admission and classifier-lift rows licensed by KernelMorphismUp, so the compiler leg remains a finite BHist handoff rather than a host compiler semantics.

Finally apply the decompiler right-inverse non-escape boundary of Definition 614.3. A downstream inverse consumer may read only the displayed compiler packet, decompiler graph, target optimisation row, right-inverse ledger, transport, continuation, provenance, and local naming rows. Combining the three non-escape clauses leaves no route to optimiser correctness, ambient program equality, host decompiler behavior, or target behavior absent from the packet. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier kernelmorphism decompiler boundary`

Theorem 473.62 (CertificateCompiler target endpoint determinacy)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be an accepted* CertificateCompiler$^{\uparrow}$ *packet. Once the source row S, a displayed graph edge in G, its landing row E, the classifier transport row H, and the continuation row C are fixed, the target endpoint route to T is determined as the finite route through S, G, E, H, C, P, N. No second endpoint route can be obtained from host compiler semantics, optimiser correctness, ambient program equality, or an unrecorded target behavior.*

Proof. Start from Definition 473.55. It identifies every target arrival with the displayed source, graph, landing, classifier, continuation, package, and local naming rows.

Use Definition 473.10. With the source row, graph edge, landing row, classifier transport, and continuation row fixed, the edge has no further classifier-facing or endpoint-facing coordinate to vary.

Finally apply Definition 473.26. The carrier exports no external compiler semantics or target behavior, so the fixed displayed rows determine the endpoint route. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier target endpoint determinacy`

Theorem 473.63 (CertificateCompiler endpoint-route pullback determinacy)**.** *Let a downstream route pass through* CertificateCompiler$^{\uparrow}$ *into* KernelMorphismUp *and then into* DecompilerRightInverse$^{\uparrow}$*. If two such routes have the same displayed source row, graph edge, landing row, classifier transport row, and* Cont *row, then their endpoint pullbacks are the same finite route through S, G, E, H, C, P, N. No host compiler semantics, optimiser correctness, ambient program equality, host decompiler function, or unrecorded target behavior can distinguish the pullbacks.*

Proof. First apply target endpoint determinacy, Definition 473.62. Agreement of the displayed source row, graph edge, landing row, classifier transport row, and continuation row fixes the compiler endpoint route through S, G, E, H, C, P, N.

Next use the KernelMorphism route scope, Definition 473.60. The morphism consumer can add only the graph-admission and classifier-lift rows licensed by KernelMorphismUp, so it cannot separate two already fixed compiler endpoint routes.

Finally apply the KernelMorphism decompiler boundary, Definition 473.61. The decompiler-facing leg remains on the displayed compiler packet and inverse-boundary rows, leaving no coordinate for host compiler semantics, optimiser correctness, ambient equality, host decompiler functions, or unrecorded target behavior. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint route pullback determinacy`

Theorem 473.64 (CertificateCompiler route composition exactness)**.** *For accepted* CertificateCompiler$^{\uparrow}$ *packets, the identity route, every binary composite route, and every triple composite route use only the displayed graph rows, landing rows, classifier transport rows, and* Cont *rows, together with the visible* Pkg *and local* NameCert *provenance. These routes introduce no hidden program equality, optimiser correctness theorem, ambient compiler semantics, or target behavior outside the finite packet.*

Proof. For the identity and binary cases, apply Definition 473.56. The identity packet reads the diagonal local naming rows, and the binary composite reads the two displayed compiler packets and their shared middle landing.

For the triple case, use the same public boundary together with Definition 473.10. The three graph edges, two middle landing rows, ordered classifier transports, and composed Cont route are exactly the rows visible to the consumer.

The finite non-escape theorem Definition 473.26 excludes any additional semantic coordinate. Hence all identity, binary, and triple composition routes are exact over the displayed rows. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier route composition exactness`

Theorem 473.65 (CertificateCompiler ledger cut elimination)**.** *Let a downstream consumer read the public package supplied by Definition 473.59. An intermediate package row may be cut from that consumer route only when the same displayed endpoint rows and the same identity, binary, or triple composite rows remain preserved in the resulting route. A cut that changes the endpoint route, changes the composite route, or replaces either route by host compiler semantics, decompiler correctness, ambient program equality, or unrecorded target behavior is not a valid* CertificateCompiler$^{\uparrow}$ *consumer read.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier ledger cut elimination`

Proof. First read the downstream package through Definition 473.59. The consumer-visible packet consists only of finite BHist rows, displayed hsame transport, Cont routes, Pkg provenance, and local NameCert rows.

Endpoint preservation is forced by Definition 473.55. If a cut removes an intermediate package row but keeps the same source, graph, landing, classifier, continuation, provenance, and local naming rows, the target route is still the displayed finite route.

Composite preservation is forced by Definition 473.56 and Definition 473.64. Identity, binary, and triple composites remain valid exactly when their displayed graph, landing, classifier, and continuation rows are unchanged.

Finally use Definition 473.26. Any cut that replaces a displayed row by host semantics, decompiler correctness, ambient equality, or unrecorded target behavior leaves the finite packet surface and is therefore unavailable to downstream consumers. □

Theorem 473.66 (CertificateCompiler endpoint decompiler handoff determinacy)**.** *Let* $K = (S, T, G, E, C, H, P, N)$ *be an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *endpoint route. Once the displayed rows* S, G, E, H, C, P, N *and the* KernelMorphismUp *graph-admission and classifier-lift rows are fixed, any* $\mathsf{DecompilerRightInverse}^{\uparrow}$ *consumer can read only the inverse-boundary rows already cited by Definition 473.61. The handoff cannot introduce host compiler semantics, optimiser correctness, ambient program equality, host decompiler functions, or unrecorded target behavior.*

Proof. First use target endpoint determinacy, Definition 473.62. With the source row, graph edge, landing row, classifier transport, continuation row, provenance, and local naming row fixed, the endpoint route is the displayed finite route through S, G, E, H, C, P, N.

Next apply route composition exactness and ledger cut elimination, Definition 473.64 and Definition 473.65. Identity, binary, and triple composites may be replayed only over the same displayed endpoint rows, and no intermediate cut can replace them by host semantics or unrecorded behavior.

Now pass through the KernelMorphism route scope, Definition 473.60. The morphism leg contributes only the graph-admission and classifier-lift rows licensed by KernelMorphismUp.

Finally apply the KernelMorphism decompiler boundary, Definition 473.61, together with the decompiler right-inverse non-escape boundary of Definition 614.3. A downstream inverse consumer therefore receives only the displayed compiler packet, the fixed KernelMorphism rows, and the inverse-boundary rows, with no coordinate for host compiler semantics, optimiser correctness, ambient equality, host decompiler functions, or unrecorded target behavior. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint decompiler handoff determinacy`

Theorem 473.67 (CertificateCompiler endpoint-composite determinacy)**.** *Let* $K = (S, T, G, E, C, H, P, N)$ *be an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet. Once the displayed source row, graph edge, landing row, classifier transport, continuation row, and identity, binary, and triple composite rows are fixed, every downstream* KernelMorphismUp *or* $\mathsf{DecompilerRightInverse}^{\uparrow}$ *consumer route is determined by the finite packet* S, G, E, H, C, P, N *together with the relevant composite rows. The determined route exports no host compiler semantics, optimiser correctness theorem, decompiler correctness theorem, ambient program equality, or target behavior outside those finite rows.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint composite determinacy`

Proof. Start with the endpoint route and public composite boundary. The target endpoint route of Definition 473.55 fixes the source, graph, landing, classifier transport, continuation, provenance, and local naming rows, while Definition 473.56 fixes identity, binary, and triple composites on the same displayed surface.

Next expose the downstream packet. Apply the downstream stage unblock package, Definition 473.59, together with KernelMorphism route scope, Definition 473.60. A morphism consumer can read only the finite compiler route and the corresponding graph-admission and classifier-lift rows.

Now attach the decompiler boundary. The KernelMorphism decompiler boundary, Definition 473.61, keeps any route into $\mathsf{DecompilerRightInverse}^{\uparrow}$ on the same finite compiler packet before the inverse-boundary rows are read.

Finally use target endpoint determinacy, route composition exactness, and ledger cut elimination, Definition 473.62, Definition 473.64, and Definition 473.65. These identify all endpoint and composite reads after the listed rows are fixed, so every downstream morphism or decompiler route is determined by S, G, E, H, C, P, N plus the relevant composite rows, with no remaining semantic coordinate available. □

Theorem 473.68 (CertificateCompiler endpoint KernelMorphism roundtrip)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be an accepted finite* CertificateCompiler$^{\uparrow}$ *endpoint route. If the source and target endpoint reads agree under Definition 473.62, then the route factors through the* KernelMorphismUp *graph-admission and classifier-lift scope and returns through the* DecompilerRightInverse$^{\uparrow}$ *boundary on the same displayed compiler rows.*

The roundtrip uses only S, G, E, H, C, P, N, the relevant identity, binary, or triple composite rows, the KernelMorphismUp *graph-admission and classifier-lift rows, and the* DecompilerRightInverse$^{\uparrow}$ *inverse-boundary rows. It adds no hidden host compiler semantics, optimiser correctness theorem, decompiler correctness theorem, ambient program equality, total decompiler, or unrecorded target behavior.*

Proof. First apply target endpoint determinacy, Definition 473.62. Agreement of the source and target endpoint reads fixes the displayed finite endpoint route through S, G, E, H, C, P, N.

Next pass through the morphism surface using Definition 473.60. A downstream KernelMorphismUp consumer can read only the graph-admission and classifier-lift rows attached to the same compiler packet, so the route has no host compiler coordinate at the morphism stage.

Now return through the decompiler side by Definition 473.61. The decompiler-facing consumer remains on the displayed compiler packet together with the inverse-boundary rows, rather than importing host decompiler behavior or total decompiler data.

Finally compose the route and remove intermediate package cuts. The composition exactness theorem, Definition 473.64, keeps identity, binary, and triple composites on the displayed rows, while ledger cut elimination, Definition 473.65, permits only cuts preserving those endpoint and composite rows. Thus the endpoint, KernelMorphism, and decompiler legs form a finite roundtrip with no hidden host compiler semantics. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier endpoint kernelmorphism roundtrip`

Corollary 473.69 (CertificateCompiler target endpoint consumer determinacy)**.** *Let*

$$K = (S, T, G, E, C, H, P, N)$$

be an accepted CertificateCompiler$^{\uparrow}$ *packet. Fix the consumer-visible rows cited by Definition 473.57: the source row S, target row T, compiler graph G, target landing row E, continuation row C, classifier transport row H, package provenance row P, local naming row N, and, when a composite is requested, the displayed identity, binary, or triple-composite ledger rows over the same surface. Then any accepted consumer-facing use of K must select the same finite endpoint route, the same composite normal form, or the same classifier-exactness decision named by the* CertificateCompiler$^{\uparrow}$ *chapter. It cannot select an alternate hidden coordinate, a second source classifier row, host compiler semantics, optimiser correctness, ambient program equality, or unrecorded target behavior.*

Proof. First apply Definition 473.55. It exhausts every target arrival by the finite BHist route through the displayed source naming row, graph row, target landing row, classifier transport row,

continuation row, package provenance row, and local naming row. Thus a consumer that asks for the target endpoint has no endpoint coordinate beyond S, G, E, H, C, P, N.

Next apply Definition 473.57. It says that accepted endpoint routes and accepted identity, binary, and triple-composite routes are all determined by the same displayed finite surface S, T, G, E, C, H, P, N. Hence fixing the cited local rows also fixes the composite normal form available to a consumer: the identity normal form is the diagonal row, a binary normal form is the displayed two-packet composite through the shared middle landing, and a triple normal form is the displayed three-edge ledger with its two middle landing rows.

It remains to rule out duplicate classifier sources and alternate exactness decisions. By Definition 473.10, an accepted classifier decision reads the source classifier row in S, lands through E, transports through the componentwise hsame row H, and follows the paired Cont routes in C. With S, E, H, C fixed, there is no second classifier-facing source from which a different decision could be accepted.

Finally use Definition 473.26. The accepted carrier exports no host compiler semantics, optimiser correctness theorem, ambient program equality, or unrecorded target behavior. Any consumer-facing use that agrees on the displayed rows therefore factors through the same finite route surface and must return the same endpoint route, composite normal form, or classifier-exactness decision named above. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier target endpoint consumer determinacy`

Theorem 473.70 (CertificateCompiler bridge schema handoff)**.** *Every public* CertificateCompiler$^{\uparrow}$ *packet hands a schema bridge only the finite compiler graph, target landing rows, classifier-transport rows, continuation rows, package provenance, and source, target, and local* NameCert *rows. The handoff is the displayed packet surface S, T, G, E, C, H, P, N together with its identity, composite, and triple-composite ledgers; it does not include host compiler semantics, optimizer correctness, decompiler behavior, ambient program equality, or unrecorded target behavior.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier bridge schema handoff`

Proof. Start with the carrier of Definition 473.1. It exposes source and target certificates, graph edges, landing rows, continuation rows, componentwise transports, provenance, and a local naming row.

Use the classifier and the NameCert obligations. Definition 473.2 and Definition 473.7 identify the bridge-readable packet with the finite graph, landing, classifier transport, continuation, package, and naming rows.

Now apply edge-classifier exactness, the identity ledger, composition stability, and triple-composite associativity. These theorems show that every schema-facing edge, identity, binary composite, and triple composite is replayed through the same finite rows, so the bridge handoff has no host compiler coordinate. □

Theorem 473.71 (CertificateCompiler bridge-row non-escape)**.** *The bridge-facing rows of a public* CertificateCompiler$^{\uparrow}$ *packet export no optimizer, decompiler, program equality, ambient categorical equality, or unrecorded target behavior. Any schema bridge that consumes the packet must read the source certificate, target certificate, graph edge, landing, route, transport, provenance, and local naming rows exactly as displayed.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier bridge rows nonescape`

Proof. Project the public packet as the finite rows S, T, G, E, C, H, P, N. These rows are the only bridge-facing coordinates of the carrier.

Apply Definition 473.10 and Definition 473.26. They force edge reads through graph, landing, classifier transport, continuation, provenance, and naming rows and exclude host compiler semantics from the packet.

The identity ledger, composition stability, and triple-composite associativity preserve the same row set under bridge replay. Since no displayed row is an optimizer, decompiler, program-equality witness, ambient categorical equality, or target-behavior oracle, none can be exported to the bridge consumer. □

Theorem 473.72 (CertificateCompiler bridge consumer exhaustion)**.** *Every schema-bridge consumer of a public* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet factors through the already displayed source certificate, target certificate, graph edge, landing row, route row, classifier-transport row, provenance row, and local naming row. The consumer can compose, reassociate, and replay certificate-compiler edges only by the identity, binary-composite, and triple-composite ledgers already present in the chapter.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier bridge consumer exhaustion`

Proof. Begin with the public consumer boundary Definition 473.24. It already restricts downstream reads to graph landing, classifier transport, continuation, provenance, and local naming over the source and target certificates.

Add the bridge handoff of Definition 473.70. The bridge receives exactly the same finite graph and certificate rows, with no host compiler semantics.

Finally apply the identity ledger, composition stability, and triple-composite associativity. These results exhaust the bridge consumer's available operations on the packet: identity replay, binary composition, and triple reassociation all factor through the displayed rows and cannot introduce another compiler surface. □

Theorem 473.73 (CertificateCompiler bridge associativity split index)**.** *The bridge handoff of Definition 473.70, the bridge-row non-escape boundary of Definition 473.71, and the bridge consumer exhaustion row of Definition 473.72 all read the same identity, binary-composite, and triple-composite ledger for* $\mathsf{CertificateCompiler}^{\uparrow}$ *packets. A schema bridge therefore consumes one finite ledger surface rather than three unrelated compiler interfaces.*

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier bridge associativity split index`

Proof. First read the identity ledger. Definition 473.9 gives the diagonal compiler packet over the same displayed source, target, graph, landing, classifier transport, continuation, provenance, and naming rows consumed by the bridge handoff.

Next read binary composition. Definition 473.8 and Definition 473.12 keep composite replay on the same public row surface and add no host compiler semantics.

Finally read triple composites. Definition 473.13 and the bridge consumer exhaustion theorem use the same triple of graph edges and middle landing matches, while bridge-row non-escape blocks optimizer, decompiler, program-equality, ambient categorical, and unrecorded target-behavior coordinates. □

Corollary 473.74 (CertificateCompiler bridge schema handoff strict obstruction)**.** *Let* $K = (S, T, G, E, C, H, P, N)$ *be a public* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet read by a schema bridge. If a displayed failure, refusal, separation, or countermodel row is cited against a named bridge-handoff*

converse, reuse, or readback route for K, then that row is a strict local obstruction to that named route only. It blocks exactly the request that tries to read, omit, replace, detach, or bypass one of the displayed source certificate, target certificate, graph edge, landing, route, classifier-transport, provenance, or local naming rows. It cannot be reinterpreted as a global impossibility theorem, a host theorem about compilers, hidden external validation, optimizer correctness, decompiler correctness, ambient program equality, ambient categorical equality, or unrecorded target behavior.

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier bridge schema handoff strict obstruction`

Proof. Read the schema bridge handoff first. By Definition 473.70, the bridge receives only the finite compiler graph, target landing rows, classifier-transport rows, continuation rows, package provenance, and source, target, and local NameCert rows of the packet. Its full bridge surface is the displayed tuple S, T, G, E, C, H, P, N together with the identity, binary-composite, and triple-composite ledgers. The same theorem excludes host compiler semantics, optimizer correctness, decompiler behavior, ambient program equality, and unrecorded target behavior from the handoff.

Now apply bridge-row non-escape, Definition 473.71. Any schema bridge that consumes K must read the source certificate, target certificate, graph edge, landing, route, transport, provenance, and local naming rows exactly as displayed. Thus a consumer-facing use of a displayed obstruction row has no coordinate outside the listed bridge rows. Source and target admission are read through S, T; graph and landing evidence through G, E; route and replay through C; classifier transport through H; package provenance through P; and the local certificate name through N.

Use Definition 473.72 and Definition 473.73 to exhaust the remaining bridge operations. A bridge consumer may compose, reassociate, or replay only by the displayed identity, binary-composite, and triple-composite ledgers, and those ledgers read the same finite surface rather than separate compiler interfaces. Hence an obstruction row attached to a named bridge-handoff converse, reuse, or readback route can block only the local request whose reading position asks for an unlisted coordinate or bypasses one of the displayed rows.

Any stronger interpretation would require data that the two bridge theorems and the consumer ledger do not export. A global impossibility theorem would require a theorem surface beyond the finite packet; a host theorem about compilers would require host compiler semantics or host program equality; hidden external validation would require an external certificate channel beyond P and N; optimizer or decompiler correctness would require optimizer or decompiler coordinates; and ambient categorical equality or unrecorded target behavior would require exactly the off-packet data ruled out by bridge-row non-escape. Since every permitted bridge-facing use factors through S, T, G, E, C, H, P, N and the displayed ledgers, the obstruction remains strict and local to the named bridge-handoff route. □

Theorem 473.75 (CertificateCompiler root landing obligation)**.** *Every root consumer of an accepted* CertificateCompiler$^{\uparrow}$ *packet*

$$K = (S, T, G, E, C, H, P, N)$$

must first read the source NameCert *endpoint row S, the target* NameCert *endpoint row T, the displayed compiler graph G, and the edge-landing row E. The consumer may treat a displayed graph edge as landed only after S supplies the source carrier and classifier row, T supplies the target carrier and classifier row, G supplies the finite edge, and E records that the edge starts in the carrier named by S and lands in the carrier named by T.*

No root consumer can obtain a landing witness from host compiler equality, ambient program equivalence, optimizer correctness, decompiler behavior, or an unrecorded target behavior outside the rows S, T, G, E.

Proof. Unfold the carrier in Definition 473.1. Its first four rows are exactly the source endpoint certificate S, the target endpoint certificate T, the displayed compiler graph G, and the edge-landing row E.

Use the classifier definition in Definition 473.2. Even a paired-edge comparison begins by reading the source classifier row in S and the target landing row in T, so classification cannot precede endpoint availability.

Apply Definition 473.7. Its carrier landing obligation is the finite row assertion that every edge of G reads a source row admitted by S and lands in a target row admitted by T through E.

The carrier has no coordinate for host compiler equality or ambient program equivalence. Therefore a root consumer that consumes landing data is forced through the displayed S, T, G, E rows and cannot source a landing witness elsewhere. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier root landing obligation`

Theorem 473.76 (CertificateCompiler root classifier transport obligation)**.** *For every accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet*

$$K = (S, T, G, E, C, H, P, N),$$

paired-edge classifier transport is exhausted by the source and target endpoint rows S, T, the componentwise hsame *transport row H, and the continuation row C. A root consumer may compare two displayed graph edges only by sharing the source classifier row in S, landing through T, moving the target classifier row through H, and following the paired* Cont *routes recorded in C.*

The transport obligation does not admit host compiler equality, source program equivalence, target program equivalence, or an external semantic relation as a classifier witness.

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier root classifier transport obligation`

Proof. Unfold Definition 473.1. The transport-relevant rows available to a root consumer are the endpoint certificates S, T, the componentwise transport row H, and the continuation compatibility row C, with G and E only displaying the edges whose classifiers are compared.

Now unfold Definition 473.2. It defines compatibility for paired graph edges by a common source classifier row, a target landing, componentwise hsame transport, and paired continuation routes. These are precisely the rows S, T, H, C named in the statement.

Apply the classifier-transport clause of Definition 473.7. That clause permits transport from the source classifier row to the target classifier row only by the displayed finite-row data already carried by the packet.

Since neither the carrier nor the classifier contains host compiler equality or a program-equivalence coordinate, a root consumer cannot certify paired edges by such an external equality. The finite row surface S, T, H, C exhausts classifier transport. □

Theorem 473.77 (CertificateCompiler root continuation route obligation)**.** *Every downstream root consumer of an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet, including* $\mathsf{CertificatePipelineStageBoundary}^{\uparrow}$, KernelMorphismUp, *and* $\mathsf{DecompilerRightInverse}^{\uparrow}$, *reads continuation compatibility only through the displayed* Cont *row C, the package provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{CertificateCompiler}^{\uparrow}}$ *row N together with the endpoint* NameCert *rows S, T. The consumer route factors through the recorded*

source and target continuation pair, the named package surface, and the local certificate row; it does not factor through an unstated compiler semantics or decompiler correctness theorem.

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier root continuation route obligation`

Proof. Unfold the carrier in Definition 473.1. The only continuation coordinate is C, and the rows that publish it to downstream consumers are the provenance row P and the local naming row N over the endpoint certificates S, T.

Use Definition 473.2. Its paired-edge comparison does not stop at landing; it also reads the source and target Cont routes recorded in C, so any classifier-compatible downstream route has already passed through the displayed continuation row.

Apply Definition 473.7. The continuation-compatibility clause states that each source route used by a graph edge is paired in C with the target route followed after compiling, while the package and local naming rows can only repack these displayed obligations.

The three named root consumers each read a different downstream surface: pipeline-stage boundaries read adjacent compiler routes, kernel morphisms read source-to-target preservation, and decompiler right-inverse packets read the compiler/decompiler interface. In all three cases the available route data are the finite rows C, P, N, S, T and the local NameCert obligations, so no unstated compiler semantics or decompiler correctness theorem can enter the continuation route. □

Theorem 473.78 (CertificateCompiler root landing bridge determinacy)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be an accepted* CertificateCompiler$^{\uparrow}$ *packet. Every consumer-facing bridge use of root landing data for K, including a displayed edge route, classifier transport, endpoint readback, continuation readback, package handoff, or local naming handoff, factors through the local row surface*

$$S, T, G, E, C, H, P, N.$$

More precisely, landing is determined by S, T, G, E, paired-edge classifier transport is determined by S, T, H, C, continuation route readback is determined by C over the endpoint rows S, T, and the handoff rows P, N can only repack those displayed obligations. No host compiler equality, ambient program equivalence, optimizer correctness, decompiler behavior, external semantic relation, or unrecorded target behavior supplies an additional bridge coordinate.

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier root landing bridge determinacy`

Proof. Start with root landing. By Definition 473.75, a root consumer may treat a displayed graph edge as landed only after reading the endpoint rows S, T, the displayed graph row G, and the edge-landing row E. Thus every bridge use whose first demand is endpoint readback, graph readback, or target landing is already forced through S, T, G, E.

Next read classifier transport. By Definition 473.76, paired-edge comparison is exhausted by the source and target endpoint rows S, T, the componentwise hsame row H, and the continuation row C. Hence a consumer cannot turn a landing bridge into an independent classifier witness: the only accepted transport reads the same endpoints, moves the target classifier through H, and follows the paired Cont routes in C.

Now apply Definition 473.77. A downstream route consumer reads continuation compatibility through C, package provenance through P, and local naming through N together with the endpoint certificates S, T. Therefore route readback, continuation readback, package handoff, and local

naming handoff do not create a second bridge surface; they publish the same finite landing and transport rows to downstream consumers.

Combining the three obligations gives determinacy. The landing rows S, T, G, E decide which displayed edge has landed, the transport rows S, T, H, C decide which paired-edge classifier comparison is available, and the rows C, P, N decide how that route is handed to later consumers. Each listed row has a fixed role in the packet, while the carrier and classifier supply no coordinate for host compiler equality, ambient program equivalence, optimizer correctness, decompiler behavior, an external semantic relation, or unrecorded target behavior. Any attempted bridge coordinate outside S, T, G, E, C, H, P, N therefore has no row to read, and every permitted consumer-facing use factors through the cited local rows. □

Corollary 473.79 (CertificateCompiler root landing consumer determinacy)**.** *Let $K = (S, T, G, E, C, H, P, N)$ be an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet, and fix the consumer-visible rows cited by Definition 473.78: the source endpoint row S, the target endpoint row T, the displayed compiler graph G, the edge-landing row E, the continuation row C, the componentwise* hsame *transport row H, the package provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{CertificateCompiler}^{\uparrow}}$ *row N. Then any accepted consumer-facing use of root landing data for K must pick the same finite displayed edge route, the same continuation readback route, the same package or local naming handoff, and the same classifier-exactness decision determined by those rows. It cannot pick an alternate hidden coordinate, a duplicate source classifier row, a second endpoint readback source, host compiler equality, ambient program equivalence, optimizer correctness, decompiler behavior, an external semantic relation, or unrecorded target behavior.*

Proof. By Definition 473.75, root landing can be consumed only after the consumer has read S, T, G, E. Thus the landing part of any accepted use is already pinned to the source endpoint certificate, target endpoint certificate, displayed graph edge, and edge-landing row named in the packet. There is no carrier coordinate from which the consumer could obtain another landing witness, endpoint readback, or source classifier row.

Apply Definition 473.78. It lists the consumer-facing bridge uses of the same root landing data: displayed edge route, classifier transport, endpoint readback, continuation readback, package handoff, and local naming handoff. The theorem states that each such use factors through the finite row surface

$$S, T, G, E, C, H, P, N.$$

It also separates the roles of the rows: S, T, G, E determine landing, S, T, H, C determine paired-edge classifier transport, C over S, T determines continuation readback, and P, N only repack those obligations for package and local naming handoff.

The remaining alternatives are therefore ruled out by absence of a row to read. A claimed alternate finite route would have to alter the displayed graph, edge landing, continuation row, or handoff row, but those are fixed as G, E, C, P, N. A claimed different normal form would have to use an identity, composite, or readback surface outside the displayed packet, but Definition 473.78 permits only the listed bridge surface for consumer-facing use. A claimed different classifier-exactness decision would have to replace the source classifier row in S, the target classifier row in T, the componentwise transport row H, or the paired Cont row C, but the classifier transport part of the bridge determinacy theorem exhausts exactly S, T, H, C.

Consequently, once the cited local rows are fixed, every accepted consumer-facing use lands on the same displayed route, readback route, handoff, or exactness decision named by the $\mathsf{CertificateCompiler}^{\uparrow}$ chapter. A hidden coordinate, duplicate classifier source, or external semantic witness is not an accepted consumer source for root landing data. □

Lean4 ✓ `BEDC.Derived.CertificateCompilerUp.CertificateCompilerCarrier root landing consumer determinacy`

Chapter 474

A Concrete Naming Certificate for $\mathrm{MultiHistConfig}^{\uparrow}$

The $\mathrm{MultiHistConfig}^{\uparrow}$ interface records the first concrete object in the inter-Hist locality chain of chapter 9419. It packages a finite configuration of at least two BHist observer rows, componentwise hsame transport, finite ProbeBundle ledgers, displayed Cont routes, and Pkg provenance into a local naming certificate. The packet is deliberately prior to $\mathsf{CrossHistCausal}^{\uparrow}$ and $\mathsf{MaxCausalRate}^{\uparrow}$: it supplies the configuration carrier on which those later predicates may be read, while exporting no global clock, no selected synchronization history, and no observer outside the listed rows.

The $\mathrm{MultiHistConfig}^{\uparrow}$ packet is the arity-general configuration carrier extending the bilateral event-record surface of chapter 509. The $\mathsf{LocalityCell}^{\uparrow}$ packet supplies the two-observer event-record and GAP coordination row; the present packet retains only finite observer rows, finite ProbeBundle ledgers, the no-global-sync witness, hsame transport, Cont routes, Pkg provenance, and local NameCert, so downstream $\mathsf{CrossHistCausal}^{\uparrow}$ and $\mathsf{MaxCausalRate}^{\uparrow}$ chapters can consume finite configurations without a global frame.

Definition 474.1 (MultiHistConfig carrier)**.** *A* $\mathrm{MultiHistConfig}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (H, L, S, R, C, P, N)$$

with the following visible coordinates:

1. $H = (h_0, h_1, \ldots, h_{n-1})$ *is a finite row of* BHist *observer histories with* $n \geq 2$*;*
2. $L = (\ell_0, \ell_1, \ldots, \ell_{n-1})$ *records one finite* ProbeBundle *ledger for each observer row, indexed by the same finite row as* H*;*
3. S *is the displayed no-global-sync witness, stating that no extra coordinate selects a common clock, a synchronization history, or a privileged observer outside the finite index ledger;*
4. R *records componentwise* hsame *comparisons between accepted presentations of the same observer row;*
5. C *stores the displayed* Cont *visibility routes by which each finite ledger row is read from its observer history and transported to the local packet boundary;*
6. P *is the* Pkg *provenance naming* BHist*,* ProbeBundle*,* hsame*,* Cont*,* Pkg*,* NameCert*, and the inter-Hist locality source chapter;*
7. N *is the local* $\mathsf{NameCert}_{\mathrm{MultiHistConfig}^{\uparrow}}$ *row.*

The local classifier relates two carriers exactly when they have the same finite arity and their corresponding rows H, L, S, R, C, P, N compare componentwise after the displayed hsame *and* Cont *routes. It contains no coordinate for a global frame, a shared time index, a privileged observer, or a synchronization history.*

Lean4 (definition) `BEDC.Derived.MultiHistConfigUp.MultiHistConfigCarrier`

Theorem 474.2 (MultiHistConfig carrier habitation)**.** *The carrier of Definition 474.1 is inhabited whenever two displayed* BHist *observer rows, their finite* ProbeBundle *ledgers, a no-global-sync witness, componentwise* hsame *witnesses, displayed* Cont *routes,* Pkg *provenance, and a local naming row are supplied. The smallest accepted carrier has arity* 2 *and already records non-degenerate inter-Hist configuration data.*

Proof. Take the two supplied observer rows as h_0 and h_1. Place their finite ledgers into L, record the no-global-sync witness as S, place their componentwise comparisons into R, and put their displayed continuation routes into C.

The package coordinate P records the listed kernel dependencies, and N records the local naming row. These seven visible coordinates assemble the packet $M = (H, L, S, R, C, P, N)$ with arity 2.

Since the definition only requires finite arity at least two and visible kernel rows, this packet is an accepted MultiHistConfig$^{\uparrow}$ carrier. No global synchronization datum is used in the assembly. □

Lean4 ✓ `BEDC.Derived.MultiHistConfigUp.MultiHistConfigCarrier habitation`
↪ variant `BEDC.Derived.MultiHistConfigUp.MultiHistConfig carrier habitation`

Theorem 474.3 (MultiHistConfig componentwise classifier stability)**.** *The* MultiHistConfig$^{\uparrow}$ *classifier is stable under componentwise* hsame *transport. If two accepted carriers have the same finite arity and each observer row, finite ledger, route table, package row, and local naming row is transported through the displayed componentwise data, then the two carriers are locally classified together.*

Proof. Project the two accepted carriers through Definition 474.1. Equal arity aligns the observer rows and ledger rows index by index.

For each component, use the displayed hsame entry in R and replay the corresponding Cont route in C. This transports the observer row and its finite ledger to the matching component of the second carrier.

The no-global-sync witness, package row, and local naming row are compared by the same componentwise rule. Therefore every visible coordinate of the first packet is matched by a transported coordinate of the second packet, which is exactly the local classifier condition. □

Lean4 ✓ `BEDC.Derived.MultiHistConfigUp.MultiHistConfigCarrier componentwise classifier stability`

Theorem 474.4 (MultiHistConfig no-global-sync ledger)**.** *No consumer of a* MultiHistConfig$^{\uparrow}$ *carrier can extract a global frame, shared clock, privileged observer, or synchronization history from the public surface. Any such datum would have to be a visible coordinate of $M = (H, L, S, R, C, P, N)$, but the carrier exposes only observer rows, finite ledgers, a no-global-sync witness, componentwise transports, continuation routes, package provenance, and the local naming row.*

Proof. Inspect the coordinate inventory in Definition 474.1. The observer list H records only the displayed histories, and the ledger list L records only finite probe observations attached to those histories.

The no-global-sync coordinate S is negative ledger data: it records the absence of a common clock, synchronization history, or privileged observer in the packet. The transport coordinate R and route coordinate C compare or route existing components; they do not create a new history standing above the configuration.

The package coordinate P names dependencies, and N names the local certificate row. There is no coordinate left from which a global frame, shared clock, privileged observer, or synchronization history could be projected. Hence any consumer that asks for such a datum must leave the public $\mathrm{MultiHistConfig}^{\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.MultiHistConfigUp.MultiHistConfigCarrier no global sync ledger`

Theorem 474.5 (MultiHistConfig finite ledger obligations)**.** *The public ledger of an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *carrier is exactly the finite index row of* ProbeBundle *entries displayed in L, the no-global-sync witness S, and the routes in C that attach those entries to the observer rows in H. It exports no unrecorded observation, no host-side list equality, and no quotient of configurations by an external relation.*

Proof. Start with an accepted carrier $M = (H, L, S, R, C, P, N)$. By definition, every ledger entry visible to the public certificate is one of the finite ProbeBundle rows in L, indexed by the same finite row as the histories in H.

The only way such a ledger entry is tied to an observer row is through the displayed Cont routes in C. Componentwise hsame data in R may transport an already displayed entry, but it cannot add a new ledger coordinate.

The no-global-sync witness S records the boundary condition that no common clock, synchronization history, or privileged observer is available to complete the ledger externally. The package and naming rows contain provenance and certificate identity, not extra observations. Thus the ledger surface is exhausted by L, S, and C, with no host-side list equality, quotient carrier, or hidden observation source. □

Lean4 ✓ `BEDC.Derived.MultiHistConfigUp.MultiHistConfigCarrier finite ledger obligations`

Theorem 474.6 (MultiHistConfig handoff boundary)**.** *The* $\mathrm{MultiHistConfig}^{\uparrow}$ *surface is a handoff object for later* $\mathsf{CrossHistCausal}^{\uparrow}$ *and* $\mathsf{MaxCausalRate}^{\uparrow}$ *chapters. Downstream chapters may consume the finite observer rows, no-global-sync witness, componentwise* hsame *classifier, finite ledgers, displayed* Cont *routes, and* Pkg *provenance of Definition 474.1; they may not treat the packet itself as a cross-Hist causal predicate or as a maximum-rate bound.*

Proof. The carrier supplies exactly the data needed to state later inter-Hist predicates over a finite configuration: the observer row H, the finite observation ledgers L, the no-global-sync witness S, componentwise classifier data R, continuation routes C, and provenance P, N.

Cross-Hist causal dependence requires an additional predicate over pairs or routed windows of those rows. A maximum-rate bound requires a further unary bound extracted from such causal predicates. Neither predicate is a coordinate of M.

Therefore the accepted packet is a configuration boundary for later chapters. It provides the finite carrier and local classifier they can consume, while leaving causal dependence and rate extraction outside the present public surface. □

Theorem 474.7 (MultiHistConfig NameCert obligation package)**.** *For an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *carrier*

$$M = (H, L, S, R, C, P, N),$$

the carrier row, habitation theorem, componentwise classifier stability, no-global-sync ledger, finite ledger obligations, and downstream handoff assemble the local $\mathsf{NameCert}_{\mathrm{MultiHistConfig}^{\uparrow}}$ *obligation package over* BHist, ProbeBundle, hsame, Cont, Pkg, *and* NameCert. *The package exposes exactly the seven visible coordinates of* M *and leaves causal predicates and maximum-rate bounds outside the present packet.*

Lean4 ✓ `BEDC.Derived.MultiHistConfigUp.MultiHistConfigCarrier namecert obligation package`

Proof. Project the accepted packet through Definition 474.1. The seven coordinates H, L, S, R, C, P, N give the finite observer rows, probe ledgers, no-global-sync witness, componentwise transport table, continuation routes, package provenance, and local naming row.

The carrier and habitation rows are supplied by Definition 474.2; the componentwise classifier row is supplied by Definition 474.3. These rows bind the local classifier to the displayed BHist and ProbeBundle data rather than to any host-side equality or synchronization object.

The no-global-sync and finite-ledger rows are supplied by Definition 474.4 and Definition 474.5. They state that the visible ledger is exhausted by L, S, and C, with no global frame, shared clock, hidden observation, external quotient, or unrecorded list equality.

Finally, Definition 474.6 identifies the downstream boundary. A later inter-Hist consumer may read the finite carrier, classifier, ledgers, routes, provenance, and naming row, but any cross-Hist causal predicate or maximum-rate bound must be supplied by that later chapter as an additional row. □

Theorem 474.8 (MultiHistConfig component transport scope)**.** *For an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *carrier* $M = (H, L, S, R, C, P, N)$*, every classifier movement factors componentwise through the finite observer rows* H*, the finite* ProbeBundle *ledgers* L*, the displayed* hsame *transport rows* R*, and the* Cont *routes* C*. No movement of* M *is licensed by a parameter transport, a global observer frame, or an unlisted synchronization coordinate.*

Lean4 ✓ `BEDC.Derived.MultiHistConfigUp.MultiHistConfigCarrier component transport scope`

Proof. Project M through Definition 474.1. The classifier has one finite observer row family, one matching finite ledger family, one transport table, and one route table.

A classifier movement must therefore align the arity of H and carry each observer row together with its ledger row through the corresponding entries of R and C. The no-global-sync witness S prevents adding a shared clock or privileged observer as a transport source.

The package and local naming rows record provenance and certificate identity for the same finite packet. They do not add a parameter-level motion outside the listed component rows, so the componentwise route exhausts the transport scope. □

Theorem 474.9 (MultiHistConfig consumer projection boundary)**.** *Every consumer of an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *carrier may project only the listed observer rows* H*, finite* ProbeBundle *ledgers* L*, no-global-sync witness* S*, transport rows* R*, continuation routes* C*, provenance row* P*, and local* NameCert *row* N*. The public surface exports no global clock, quotient configuration, hidden synchronization history, or observer outside the finite row.*

Lean4 ✓ `BEDC.Derived.MultiHistConfigUp.MultiHistConfigCarrier consumer projection boundary`

Proof. The public packet is exactly $M = (H, L, S, R, C, P, N)$. A consumer projection is a read of one of these coordinates through the routes displayed in the carrier.

The finite observer rows and ledgers give the positive projection surface. The no-global-sync witness supplies the negative boundary, while the transport and route coordinates explain how the same listed rows may be read after componentwise classifier movement.

There is no coordinate for a global clock, quotient of configurations, hidden synchronization history, or external observer. Any consumer asking for one of those objects leaves the $\mathrm{MultiHistConfig}^{\uparrow}$ NameCert surface rather than projecting a public row. □

Closure status for $\mathsf{NameCert}_{\mathrm{MultiHistConfig}^{\uparrow}}$.

Constructive story: A $\mathrm{MultiHistConfig}^{\uparrow}$ packet is generated from two or more BHist observer rows, finite ProbeBundle ledgers, a no-global-sync witness, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathrm{MultiHistConfig}^{\uparrow}}$, maturePackageClosed)

Scope closed: The scoped packet binds the carrier, component transport scope, finite ledger obligations, and consumer projection boundary over the same BHist, ProbeBundle, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathrm{MultiHistConfig}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.MultiHistConfigUp.MultiHistConfigCarrier\_finite\_ledger\_obligations`

Bridge status: none

Origin: human

Not claimed: This chapter does not define a cross-Hist causal predicate, a maximum causal rate, Lorentz geometry, curved spacetime gluing, quantum-state superposition, or a checked bridge certificate.

Upgrade path: The theory axis is at mature closure; remaining movement is verification-axis bridge checking for the existing public packet and its downstream $\mathsf{CrossHistCausal}^{\uparrow}$ and $\mathsf{MaxCausalRate}^{\uparrow}$ consumers.

Chapter 475

A Concrete Naming Certificate for $\mathsf{TransportedStationaryDiagonal}^{\uparrow}$

The $\mathsf{TransportedStationaryDiagonal}^{\uparrow}$ interface records the transported stationary diagonal finite-window seal used by the Real and Completion phase. It packages the transported $\mathsf{Rat}^{\uparrow}$ seed row, the induced constant $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{RegSeqRat}^{\uparrow}$ finite-window seal, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, and the receiving $\mathsf{Real}^{\uparrow}$ row as a single finite naming certificate. The packet is a concrete handoff object; it contains no quotient stream, host real equality, selected host limit, choice principle, or real-completeness theorem.

Definition 475.1 (Transported stationary diagonal carrier)**.** *A* $\mathsf{TransportedStationaryDiagonal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (Q, S, G, D, R, F, C, P, N)$$

with the following displayed coordinates:

1. *Q is the transported* $\mathsf{Rat}^{\uparrow}$ *classifier row for the stationary rational seed pair;*
2. *S is the constant* $\mathsf{StreamName}^{\uparrow}$ *finite-window classifier induced by Q;*
3. *G is the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-window seal row read from the same constant stream window;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger containing the dyadic endpoints, tolerance rows, and observation bounds inspected by the finite window;*
5. *R is the* $\mathsf{Real}^{\uparrow}$ *finite-window classifier row receiving the transported stationary diagonal observation;*
6. *F records the exact finite-window seal equation tying Q, S, G, D, and R to the same stationary row;*
7. *C stores the displayed* hsame *comparisons and* Cont *routes for the rational seed, stream window, regular-rational seal, dyadic ledger, and real-facing row;*
8. *P is the* Pkg *provenance naming* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *source rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{TransportedStationaryDiagonal}^{\uparrow}}$ *row.*

The local classifier relates two carriers exactly when the rows $Q, S, G, D, R, F, C, P, N$ compare componentwise after the displayed hsame *and* Cont *routes. No comparison may inspect a quotient stream, host equality, external limit choice, or ambient completeness datum.*

Theorem 475.2 (Transported stationary diagonal NameCert obligations)**.** *The* $\mathsf{NameCert}_{\mathsf{TransportedStationaryDiagonal}^{\uparrow}}$ *surface has five obligations:*

1. *carrier: formation of the finite packet of Definition 475.1;*
2. *classifier: componentwise comparison of the transported* $\mathsf{Rat}^{\uparrow}$ *seed row, constant* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *seal,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *row, seal equation, route table, package provenance, and local certificate row;*
3. *stability: the classifier is preserved by the displayed* hsame *comparisons and* Cont *routes, so a transported stationary seed row continues to induce the same constant window, seal row, dyadic ledger, and real-facing row;*
4. *exact finite-window seal: the four public readings* S*,* G*,* D*, and* R *all read the same transported stationary row named by* Q*;*
5. *ledger: the public export contains only the displayed finite rows and excludes quotient streams, host real equality, selected host limits, choice principles, and real-completeness data.*

Proof. Carrier formation is the tuple assembly of Definition 475.1. The transported rational seed supplies Q, the constant-stream read supplies S, the regular-rational boundary supplies G, the dyadic observation boundary supplies D, and the real-facing boundary supplies R. The seal equation F, route table C, package row P, and local naming row N are visible coordinates of the same finite packet.

For the classifier obligation, compare the packet component by component after applying the displayed hsame and Cont routes. The transported $\mathsf{Rat}^{\uparrow}$ row determines the constant $\mathsf{StreamName}^{\uparrow}$ window, the window determines the $\mathsf{RegSeqRat}^{\uparrow}$ seal read, and the dyadic ledger supplies the observation rows consumed by the $\mathsf{Real}^{\uparrow}$ boundary.

Stability is the same componentwise comparison read as a transport statement. Since C contains only displayed hsame comparisons and Cont routes, moving an accepted carrier along those routes preserves the induced window, regular-rational seal, dyadic ledger, and real-facing classifier.

Exact finite-window sealing is the stationary diagonal calculation at the finite boundary. The row F records that S, G, D, and R are four public projections of the same transported stationary row named by Q.

The ledger clause follows by constructor inspection. The carrier has no coordinate for quotient streams, host real equality, selected host limits, choice, or a real-completeness theorem, so no public read can export one. □

Theorem 475.3 (Transported stationary diagonal window-seal exhaustion)**.** *Let* $T = (Q, S, G, D, R, F, C, P, N)$ *be an accepted* $\mathsf{TransportedStationaryDiagonal}^{\uparrow}$ *carrier. Every finite Real and Completion read of the transported stationary diagonal factors through the same five displayed rows* Q, S, G, D, R *and the same exact seal equation* F*. In particular, any two accepted seal rows over the same transported* $\mathsf{Rat}^{\uparrow}$ *seed row and displayed finite-window ledger have the same* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *public readings after the routes recorded in* C*.*

Proof. Project the accepted carrier through Definition 475.1. The only rows that can serve a finite Real and Completion read are the transported rational seed Q, the constant stream window S, the regular-rational seal G, the dyadic ledger D, and the real-facing row R.

Apply the exact finite-window seal clause of Definition 475.2. It identifies the four public readings S, G, D, and R as projections of the same transported stationary row named by Q.

The stability clause transports this identity through the route table C. Therefore two accepted seal rows with the same transported seed and finite-window ledger have matching public readings at the StreamNameUp, RegSeqRatUp, DyadicRatCoreUp, and RealUp boundaries.

The ledger clause excludes any further coordinate through which a second seal could distinguish itself. Thus finite-window seal exhaustion is a property of the displayed BEDC packet itself. □

Theorem 475.4 (Transported stationary diagonal Rat–Stream sibling link)**.** *Every accepted* TransportedStationaryI *packet consumes the transported* $\mathsf{Rat}^{\uparrow}$ *seed through chapter 37, the constant finite window through chapter 126, and the regular, dyadic, and real boundary rows through chapter 301, chapter 291, and chapter 38. The carrier coordinates* $Q, S, G, D, R, F, C, P, N$ *expose this sibling route as a finite projection surface, not as an ambient quotient stream, selected limit, or host real equality.*

Proof. Project the accepted packet by Definition 475.1. The coordinate Q is the transported rational seed row, S is the induced constant stream window, G is the regular-rational seal, D is the dyadic ledger, and R is the real-facing row.

Apply the window-seal exhaustion theorem Definition 475.3. It forces the Real and Completion read to pass through the same five displayed rows Q, S, G, D, R and the same seal equation F.

The sibling chapters named in the statement are therefore consumed exactly at the coordinates where the carrier stores them. The route table C, provenance row P, and local certificate N authenticate those projections without adding a quotient stream, selected limit, or host equality row. □

Closure status for $\mathsf{NameCert}_{\mathsf{TransportedStationaryDiagonal}\uparrow}$.

Constructive story: A $\mathsf{TransportedStationaryDiagonal}^{\uparrow}$ packet is generated from a transported RatUp seed row, constant StreamNameUp finite window, RegSeqRatUp seal row, DyadicRatCoreUp observation ledger, RealUp finite-window row, exact seal equation, displayed transport routes, package provenance, and local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TransportedStationaryDiagonal}\uparrow}, \mathsf{seed})$

Scope closed: The seed scope records the finite carrier, componentwise classifier, transport stability, exact finite-window seal, and public ledger boundary for transported stationary diagonal handoff packets.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TransportedStationaryDiagonal}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close full real completeness, quotient-stream equality, host real equality, selected host limits, choice principles, or a standard bridge.

Upgrade path: Obligation closure requires a Lean carrier encoding and checked NameCert obligation theorem for the five displayed rows.

Chapter 476

A Concrete Naming Certificate for $\mathsf{TypeClassifierMembership}^{\uparrow}$

The $\mathsf{TypeClassifierMembership}^{\uparrow}$ surface realizes type checking as a finite classifier-membership packet over displayed BEDC histories. It records a term row, a judgment ledger, an Ext membership row, a Cont reduction row, and local naming provenance, so type membership and subject-reduction reads remain inside BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ data.

The packet consumes the finite classifier row of chapter 489 and the visible reduction boundary of chapter 483; $\mathsf{TypeClassifierMembership}^{\uparrow}$ combines those sibling rows into the local T, J, E, R, H, C, P, N membership packet rather than introducing a new host type checker.

Before the local membership packet reads $\mathsf{ClassifierTyping}^{\uparrow}$, its accepted and refused Ext membership rows are constrained by the finite accepted/refused boundary of chapter 595; that boundary separates membership and refusal rows from host type checking, hidden proof search, semantic equality, and quotient histories.

Definition 476.1 (TypeClassifierMembership carrier)**.** *A* $\mathsf{TypeClassifierMembership}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$X = (T, J, E, R, H, C, P, N)$$

with the following displayed coordinates:

1. *T is the displayed term row whose finite syntax window is being checked;*
2. *J is the finite judgment ledger recording the available typing judgments and their dependency order;*
3. *E is the* Ext *membership row saying that the displayed term row is admitted by the local classifier;*
4. *R is the* Cont *reduction row recording the typed continuation steps whose source and target terms are visible in the packet;*
5. *H records the componentwise* hsame *transports for term rows, judgment ledgers, membership rows, reduction rows, dependency packages, and local provenance;*
6. *C records the* Cont *read routes for accessing the judgment ledger, the* Ext *membership row, the typed reduction row, and the subject-reduction boundary;*
7. *P packages the dependencies on* Ext, Cont, *the judgment ledger, the surrounding* $\mathsf{NameCert}$ *rows, and the BEDC carrier rows used by the local checker;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{TypeClassifierMembership}^{\uparrow}}$ *provenance row.*

The carrier contains no host type-theory semantics, no semantic equality of terms, no global normalization theorem, and no undecidable classifier outside the finite membership and reduction rows.

Definition 476.2 (TypeClassifierMembership classifier)**.** *For accepted* $\mathsf{TypeClassifierMembership}^{\uparrow}$ *carriers* X *and* X'*, the classifier compares the judgment ledgers,* Ext *membership rows, and* Cont *reduction rows componentwise under the displayed* hsame *transports in* H *and the read routes in* C*. A comparison may inspect the term row* T*, the dependency package* P*, and the local provenance row* N *only as named carrier coordinates.*

The classifier does not compare host typing derivations, semantic equality of terms, erased representatives, or any unrecorded conversion relation.

Lean4 (definition) `BEDC.Derived.TypeClassifierMembershipUp.TypeClassifierMembershipClassifier`

Theorem 476.3 (TypeClassifierMembership NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{TypeClassifierMembership}^{\uparrow}}$ *surface for Definition 476.1 consists of five obligations:*

1. *carrier admission for the finite packet* $X = (T, J, E, R, H, C, P, N)$*;*
2. *classifier stability for the judgment,* Ext*, and reduction rows under the displayed* hsame *and* Cont *routes;*
3. Ext *stability, saying that a transported accepted judgment ledger preserves the membership row* E*;*
4. *subject-reduction boundary, saying that a visible reduction row* R *whose source is admitted by* E *can read only the displayed target membership row;*
5. *non-escape from host type theory, semantic equality of terms, undecidable conversion, unrecorded normalization, or any classifier not named by* J*,* E*,* R*,* H*,* C*,* P*, and* N*.*

Lean4 ✓ `BEDC.Derived.TypeClassifierMembershipUp.TypeClassifierMembershipPacket namecert obligations`

Proof. Carrier admission is the finite packet of Definition 476.1. Its coordinates display the term row, judgment ledger, membership row, reduction row, transport rows, continuation routes, dependency package, and local certificate row.

Classifier stability follows from Definition 476.2. The only comparisons are componentwise reads of the judgment, Ext, and reduction rows through H and C.

Ext stability and subject reduction are boundary reads, not external semantic principles. The row E is the visible membership witness, and R is the visible typed reduction route whose target membership can only be obtained through the recorded subject-reduction boundary.

The non-escape clause is the carrier inventory. Since no coordinate names host typing semantics, semantic equality, undecidable conversion, or a hidden normalization oracle, no consumer can read those objects from the local $\mathsf{NameCert}_{\mathsf{TypeClassifierMembership}^{\uparrow}}$ surface. □

Theorem 476.4 (TypeClassifierMembership subject-reduction boundary)**.** *Let* $X = (T, J, E, R, H, C, P, N)$ *be an accepted* $\mathsf{TypeClassifierMembership}^{\uparrow}$ *carrier. Every public subject-reduction read starts from the displayed term row* T*, the judgment ledger* J*, the source membership row* E*, and the reduction row* R*, then reaches the target membership boundary only through the recorded* hsame*,* Cont*,* Pkg*, and* NameCert *routes. It does not appeal to host reduction semantics, global normalization, or semantic equality of terms.*

Lean4 ✓ `BEDC.Derived.TypeClassifierMembershipUp.TypeClassifierMembershipPacket subject reduction boundary`

Proof. Project the accepted carrier. The only source of type membership is E, and the only source of reduction information is R.

Use classifier stability from Definition 476.2. Transport can move the judgment, membership, and reduction rows only along the displayed hsame routes, and consumer access is mediated by C.

Finally apply the obligation surface of Definition 476.3. Its subject-reduction boundary repacks the visible source membership and reduction rows into the target membership read, so host reduction semantics and semantic equality never enter the packet. □

Theorem 476.5 (TypeClassifierMembership non-escape)**.** *No accepted* TypeClassifierMembership$^{\uparrow}$ *carrier exports a host type checker, an undecidable semantic equality oracle, a hidden conversion relation, an erased representative of a typing derivation, or an ambient normalization theorem. Every public type-checking read factors through the finite judgment ledger J, the* Ext *membership row E, the* Cont *reduction row R, displayed* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *row of Definition 476.1.*

Lean4 ✓ `BEDC.Derived.TypeClassifierMembershipUp.TypeClassifierMembershipPacket non escape`

Proof. Inspect the carrier inventory. The public rows are exactly T, J, E, R, H, C, P, N, with J recording the finite judgments, E recording classifier membership, and R recording typed reduction.

Apply Definition 476.4 for reduction-facing consumers and Definition 476.2 for classifier-facing consumers. Both routes pass through the same displayed transport and continuation rows.

Since no coordinate of the packet names a host type checker, semantic equality oracle, hidden conversion relation, erased derivation representative, or ambient normalization theorem, those objects cannot be exported by the TypeClassifierMembership$^{\uparrow}$ surface. □

Theorem 476.6 (TypeClassifierMembership Ext membership stability)**.** *Let $X = (T, J, E, R, H, C, P, N)$ be an accepted* TypeClassifierMembership$^{\uparrow}$ *carrier. Any transported accepted judgment ledger for X preserves the displayed* Ext *membership row E through the componentwise* hsame *transport row H and the* Cont *read routes C. The transported read does not replace E by host typing semantics, semantic equality of terms, undecidable conversion, or an unrecorded membership predicate.*

Lean4 ✓ `BEDC.Derived.TypeClassifierMembershipUp.TypeClassifierMembershipPacket ext membership stability`

Proof. Start from the carrier of Definition 476.1. Its judgment and membership information is displayed only by the rows J and E, and the only transport and read coordinates are H and C.

Apply the classifier description in Definition 476.2. Classifier comparisons of the judgment ledger and Ext row are componentwise reads through those displayed routes, so a transported accepted ledger still reads the same membership coordinate E.

The obligation surface in Definition 476.3 records this as Ext stability. Since no carrier coordinate names host typing semantics or an unrecorded predicate, the transported ledger cannot substitute any external membership witness for E. □

Theorem 476.7 (TypeClassifierMembership reduction target coverage)**.** *Let $X = (T, J, E, R, H, C, P, N)$ be an accepted* TypeClassifierMembership$^{\uparrow}$ *carrier. Every typed* Cont *reduction target membership read is covered by the displayed rows T, J, E, R, H, C, P, N. In particular, the target membership is reached from the finite judgment ledger, the visible* Ext *membership row, the reduction row, componentwise transport, continuation routes, dependency package, and local naming row, not from host reduction semantics or hidden normalization.*

Lean4 ✓ `BEDC.Derived.TypeClassifierMembershipUp.TypeClassifierMembershipPacket reduction target coverage`

Proof. Project the accepted carrier. The reduction source and target are visible only through T, J, E, R, while H and C provide the recorded transport and continuation access to those rows.

Apply Definition 476.4. It sends each public subject-reduction read from the source membership and visible reduction row to the target membership boundary through the same hsame, Cont, Pkg, and NameCert routes.

The non-escape theorem Definition 476.5 excludes host reduction semantics, hidden conversion, erased derivations, and ambient normalization from the exported surface. Thus every typed reduction target membership read is covered by the packet rows T, J, E, R, H, C, P, N. □

Theorem 476.8 (TypeClassifierMembership obligation closure package)**.** *Every accepted* TypeClassifierMembership *packet carries the obligation package consisting of carrier admission, classifier stability,* Ext *membership stability, subject-reduction boundary coverage, reduction target coverage, and public non-escape. The package is witnessed by the carrier and classifier surfaces together with the finite rows T, J, E, R, H, C, P, N, and it uses no host type semantics, semantic equality of terms, hidden conversion relation, global normalization theorem, or unrecorded classifier.*

Proof. Carrier admission is supplied by Definition 476.1. Classifier stability is supplied by Definition 476.2, which limits comparison to the displayed judgment, membership, and reduction rows under H and C.

For membership preservation, apply Definition 476.6. For the subject-reduction boundary, apply Definition 476.4. For target coverage, apply Definition 476.7.

It remains to close the public boundary. Apply Definition 476.5; the packet exports only T, J, E, R, H, C, P, N and no host type checker, semantic equality oracle, hidden conversion relation, erased derivation representative, or ambient normalization theorem. □

Lean4 ✓ `BEDC.Derived.TypeClassifierMembershipUp.TypeClassifierMembershipPacket obligation closure package`

Theorem 476.9 (TypeClassifierMembership visible target determinacy)**.** *Let $X = (T, J, E, R, H, C, P, N)$ be an accepted* TypeClassifierMembership$^{\uparrow}$ *carrier. Any two public subject-reduction reads that use the same displayed term row T, judgment ledger J, source* Ext *membership row E, reduction row R, and the same transport, continuation, provenance, and naming route H, C, P, N reach the same displayed target membership boundary. No second target membership row can be supplied by host semantics, semantic equality, hidden conversion, or normalization.*

Lean4 ✓ `BEDC.Derived.TypeClassifierMembershipUp.TypeClassifierMembershipPacket visible target determinacy`

Proof. Project the accepted carrier and fix the displayed rows T, J, E, R, H, C, P, N. Both public reads therefore start from the same term row, judgment ledger, source membership row, and visible reduction row.

Apply Definition 476.4. It forces each read through E and R and prevents a subject-reduction boundary from entering through host reduction semantics or semantic equality.

Next apply Definition 476.7. The target boundary is identified with the same finite packet rows T, J, E, R, H, C, P, N for both reads, so there is no independent coordinate from which a second target membership row could be read.

Finally apply Definition 476.5. Hidden conversion, host semantics, erased derivations, and normalization are outside the packet, so the two public reads terminate at the same displayed target membership boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{TypeClassifierMembership}^{\uparrow}}$.

Constructive story: A $\mathsf{TypeClassifierMembership}^{\uparrow}$ packet is generated from a displayed term row, finite judgment ledger, Ext membership row, typed Cont reduction row, componentwise hsame transports, continuation routes, dependency package, and local NameCert provenance row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TypeClassifierMembership}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 476.1, Definition 476.2, Definition 476.3, Definition 476.4, Definition 476.5, Definition 476.6, Definition 476.7, Definition 476.8, and Definition 476.9 bind the finite rows T, J, E, R, H, C, P, N, Ext, Cont, hsame, Pkg, NameCert, the subject-reduction boundary, and the public packet export.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TypeClassifierMembership}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.TypeClassifierMembershipUp.TypeClassifierMembershipPacket\_obligation\_closure\_package`

Bridge status: none

Origin: human

Not claimed: This chapter does not close host type semantics, semantic equality of terms, global normalization, Lean verification, or bridge checking.

Upgrade path: The paper closure axis is complete for this finite type-classifier membership package; Lean verification and bridge checking remain independent axes.

Chapter 477

A Concrete Naming Certificate for ObserverHistoryIdentity$^{\uparrow}$

The ObserverHistoryIdentity$^{\uparrow}$ interface names the finite certificate by which an observed history is compared with another observed history without introducing an observer-substance, host equality of histories, quotient identity, or a global subject parameter. Its public surface is a local NameCert packet over displayed BHist rows, hsame comparisons, Cont routes, licensed ProbeBundle and SigRel observations, and package provenance.

This chapter consumes the no-subject observer-history surface of chapter 479 before comparing licensed ProbeBundle and SigRel observations. The two packets differ in scope: ObserverHistoryIdentity$^{\uparrow}$ records pairwise observation-ledger comparison, while ObserverHistIdentity$^{\uparrow}$ records the single packet that excludes observer-substance.

The licensed observer comparison packet of chapter 1031 consumes this pairwise ProbeBundle/SigRel comparison row as its observer-facing observation lattice input.

Theorem 477.1 (ObserverHistoryIdentity consumes ObserverHistIdentity)**.** *Every accepted* ObserverHistoryIdentity *packet consumes the no-subject* ObserverHistIdentity$^{\uparrow}$ *packet of chapter 479 before pairwise* ProbeBundle *and* SigRel *comparison is read. The dependency projects the displayed rows $H, K, B, S, R, L, C, P, N$ through the no-subject observer-history boundary first, and only then exposes the pairwise probe and signature ledgers.*

Proof. Project the rows $H, K, B, S, R, L, C, P, N$ named by the carrier below. The history rows H and K are observed histories before they are compared, so their no-subject boundary is inherited from chapter 479.

After that boundary is visible, the pairwise rows B and S may be read as licensed ProbeBundle and SigRel comparisons. The rows R, L, C, P, N then record sameness, ledger, replay, provenance, and local naming for the same dependency route. □

Definition 477.2 (Observer history identity carrier)**.** *An* ObserverHistoryIdentity$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (H, K, B, S, R, L, C, P, N)$$

with the following visible rows:

1. *H and K are the two observed* BHist *histories whose displayed rows may be compared;*
2. *B is the finite* ProbeBundle *observation ledger naming the licensed probes applied to H and K;*
3. *S is the finite* SigRel *ledger of signature observations produced by the probes in B;*

4. *R records the displayed* hsame *comparisons between the kernel rows of H and K that are available to the classifier;*
5. *L is the local observation ledger tying each displayed probe and signature row to the corresponding history row and to its local naming row;*
6. *C records the visible* Cont *routes by which a consumer reads a history row, applies a licensed probe, reads the induced signature relation, and returns to the local history-sameness comparison;*
7. *P is the* Pkg *provenance over* BHist, hsame, Cont, ProbeBundle, SigRel, *and the local naming rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverHistoryIdentity}^{\uparrow}}$ *row.*

The carrier is finite and displays every observation that can affect the identity judgment. It has no coordinate for observer-substance, host equality of histories, quotient identity, or a global subject parameter.

Theorem 477.3 (Observer history identity NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ObserverHistoryIdentity}^{\uparrow}}$ *surface for the carrier of Definition 477.2 consists exactly of carrier habitation by $O = (H, K, B, S, R, L, C, P, N)$, classifier comparison of the displayed observation rows, stability under the recorded kernel* hsame *rows, ledger exactness for the licensed probes and signature relations, and non-escape from observer-substance, host equality, quotient identity, and global subject parameters.*

Lean4 ✓ `BEDC.Derived.ObserverHistoryIdentityUp.ObserverHistoryIdentityPacket namecert obligations`

Proof. Carrier habitation is the displayed finite packet. The two histories, probe ledger, signature ledger, sameness rows, observation ledger, continuation routes, package provenance, and local naming row are all visible before a consumer can read the certificate.

Classifier comparison is restricted to B, S, R, L, C, P, N. A consumer may compare observations only after the relevant probe and signature rows have been displayed, and the resulting comparison returns to the recorded hsame rows between the kernel history entries.

The ledger clauses exhaust the certificate. Since no coordinate stores observer-substance, host equality, quotient identity, or a global subject parameter, none of those objects can be exported by the naming row. □

Theorem 477.4 (Observer history identity classifier stability)**.** *Let $O = (H, K, B, S, R, L, C, P, N)$ and $O' = (H', K', B', S', R', L', C', P', N')$ be accepted* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *carriers related by the displayed classifier. The classifier compares only the observation rows displayed by the* ProbeBundle *and* SigRel *ledgers and the kernel sameness rows recorded in R and R'. Transport may rename these rows through* hsame *and replay them through* Cont, *but it cannot add a host equality comparison or a subject-level identity row.*

Proof. Project both carriers through Definition 477.2. The available comparison data are exactly the two history rows, the probe bundles, the signature relations, the kernel sameness rows, the local observation ledgers, continuation routes, package provenance, and naming rows.

The classifier first reads the displayed probes and signatures. It then checks the corresponding hsame rows in the kernel ledger, with C and C' supplying the permitted read routes.

No further comparison generator is present. Hence stability is componentwise over the displayed observations and kernel sameness rows, with no host equality or subject-level identity added by transport. □

Lean4 ✓ `BEDC.Derived.ObserverHistoryIdentityUp.ObserverHistoryIdentityPacket classifier stability`

Theorem 477.5 (Observer history identity ledger exactness)**.** *Every accepted observation used by an* ObserverHistoryIdentity$^{\uparrow}$ *carrier is recorded in the local ledger L before it can affect the identity classifier. The ledger records the source history row, the licensed probe in B, the resulting signature relation in S, the relevant* hsame *row in R, and the* Cont *route in C that exposes the read to the consumer.*

Proof. Begin with an accepted observation. Carrier projection places the observation inside the finite probe ledger B and the corresponding signature ledger S.

The local ledger L then records which history row supplied the observation and which kernel sameness row in R is used by the classifier. The continuation route C records the permitted order of this read.

Thus every classifier-relevant observation is ledgered before it is compared. There is no unrecorded observation channel and no hidden parameter through which an observer-substance or host equality judgment could enter. □

Lean4 ✓ `BEDC.Derived.ObserverHistoryIdentityUp.ObserverHistoryIdentityPacket ledger exactness`

Theorem 477.6 (Observer history identity BHist induction coverage)**.** *Every classifier-relevant read of an accepted* ObserverHistoryIdentity$^{\uparrow}$ *carrier $O = (H, K, B, S, R, L, C, P, N)$ is obtained by induction over the displayed finite packet rows: the history rows H, K, then the* ProbeBundle *rows B, the* SigRel *rows S, the* hsame *comparison rows R, the local ledger L, the displayed* Cont *replay C, the provenance row P, and the naming row N.*

Proof. Project the carrier through Definition 477.2. The base read sees only the two finite history rows H, K and therefore has no observer-substance, host equality, quotient identity, or global subject parameter available.

For the observation step, induct over the finite local ledger L together with the displayed ProbeBundle and SigRel rows. Each added ledger entry names its source history row, licensed probe, signature relation, and kernel hsame comparison before the classifier may consume it.

Finally use Definition 477.4 and Definition 477.5. Stability keeps the classifier on the displayed observation and comparison rows, while ledger exactness rules out any unrecorded read channel. The replay, provenance, and naming rows only preserve this route, so the induction exhausts all classifier-relevant reads. □

Theorem 477.7 (Observer history identity non-escape boundary)**.** *The public boundary of an accepted* ObserverHistoryIdentity$^{\uparrow}$ *packet exports only the displayed* BHist *histories, finite* ProbeBundle *observations, finite* SigRel *rows, kernel* hsame *comparisons, local observation ledger,* Cont *routes,* Pkg *provenance, and local* NameCert *row. It exports no observer-substance, no host equality of histories, no quotient identity, and no global subject parameter.*

Lean4 ✓ `BEDC.Derived.ObserverHistoryIdentityUp.ObserverHistoryIdentityPacket non escape boundary`

Proof. Inspect the coordinates of Definition 477.2. They are exactly $H, K, B, S, R, L, C, P, N$, and each coordinate is a finite history, observation, signature, sameness, continuation, package, or naming row.

The classifier-stability theorem keeps all comparisons inside the displayed observation rows and kernel sameness rows. The ledger-exactness theorem ensures that every observation affecting the classifier has already passed through the local observation ledger.

Therefore the boundary has no escape route beyond the finite packet. Since observer-substance, host equality, quotient identity, and global subject parameters are absent from the carrier, the public certificate cannot export them. □

Theorem 477.8 (Observer history identity bridge boundary)**.** *The public* ObserverHistoryIdentity$^{\uparrow}$ *packet bridges observed* BHist *comparison to the acceptance schema through exactly the displayed* ProbeBundle *rows,* SigRel *rows,* hsame *rows,* Cont *rows,* Pkg *provenance rows, and local* NameCert *rows. The bridge exports no observer-substance, host history equality, quotient identity, or global subject parameter.*

Lean4 ✓ `BEDC.Derived.ObserverHistoryIdentityUp.ObserverHistoryIdentityUp StdBridge`

Proof. Start from the carrier of Definition 477.2. The only observable comparison data are the two displayed history rows together with the probe, signature, sameness, continuation, package, and naming rows.

Use Definition 477.3. It binds the carrier, classifier, stability, ledger, and non-escape clauses to the same finite local NameCert packet.

Apply Definition 477.4 and Definition 477.5. These keep every comparison inside the displayed probe and signature rows and require the local ledger before a comparison can be consumed by the acceptance schema.

Finally apply Definition 477.7. Since observer-substance, host history equality, quotient identity, and global subject parameters have no carrier coordinate, the bridge boundary cannot export them. □

Closure status for NameCert$_{\text{ObserverHistoryIdentity}^{\uparrow}}$.

Constructive story: An ObserverHistoryIdentity$^{\uparrow}$ packet is generated from two displayed BHist histories, finite ProbeBundle observations, finite SigRel rows, kernel hsame comparisons, local observation-ledger rows, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ObserverHistoryIdentity}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 477.3 and Definition 477.8 bind the carrier, classifier stability, ledger exactness, non-escape obligations, and bridge boundary to the displayed finite observer-history packet.

Formal verification: FormalStatus(NameCert$_{\text{ObserverHistoryIdentity}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.ObserverHistoryIdentityUp.ObserverHistoryIdentityPacket\_namecert\_obligations`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close observer-substance, host equality of histories, quotient identity, global subject parameters, or bridge checking.

Upgrade path: No further upgrade – chapter at top of the formal bridge axis.

Chapter 478

A Concrete Naming Certificate for $\mathsf{CrossHistCausal}^{\uparrow}$

The $\mathsf{CrossHistCausal}^{\uparrow}$ interface records the first two-history causal-dependence packet in the inter-Hist chain of Definition 9419.25. Its purpose is local: a consumer may inspect two displayed history rows, the unary slot ledger, the finite dependence witness row, componentwise stability data, read routes, package provenance, and the local naming row, but it receives no global frame, no synchronized clock, and no ambient geometry.

The two-history carrier consumes the finite multi-history configuration surface of chapter 474 and supplies the causal-route rows later bounded by chapter 594. MultiHistConfig provides the finite independent Hist slots from which the ordered pair is selected; $\mathsf{CrossHistCausal}^{\uparrow}$ refines that ordered pair with a slot ledger, dependence witness, hsame and psame stability rows, Cont routes, Pkg provenance, and local NameCert rows.

This local row is the two-history dependency surface later consumed by chapter 876. In that route, chapter 479 supplies the observer slots and chapter 469 supplies the finite replay surface, while $\mathsf{CrossHistCausal}^{\uparrow}$ supplies the dependence witness row R and unary slot ledger K that the causal-rate packet reads before imposing its maximum-rate boundary.

Definition 478.1 (CrossHistCausal carrier)**.** *A* $\mathsf{CrossHistCausal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$X = (A, B, K, R, H, Q, C, P, N)$$

with the following visible rows:

1. *A and B are the two displayed* Hist *rows whose relation is being named;*
2. *K is the unary slot ledger marking the finite time slot at which the dependence read is evaluated;*
3. *R is the finite dependence witness row, recording the displayed source-side and target-side observations used by the cross-Hist read;*
4. *H records componentwise* hsame *comparisons for A, B, K, R, the probe-stability row, the continuation row, the package row, and the local naming row;*
5. *Q records* psame *probe-stability at both anchors, so the same dependence witness remains visible after probe-equivalent source and target reads;*
6. *C records the displayed* Cont *read routes from A and B into K, R, H, Q, P, and N;*
7. *P is the package provenance naming* CrossHistCausal*,* Hist*,* Unary*,* BHist*,* hsame*,* psame*,* Cont*,* Pkg*, and* NameCert*;*

8. *N is the local* $\mathsf{NameCert}_{\mathsf{CrossHistCausal}^{\uparrow}}$ *row.*

The carrier is a finite two-history naming certificate for cross-Hist causal dependence. It contains no global observer frame, no total ordering of all histories, no metric structure, no maximum-rate function, and no selected synchronization map between A and B.

Lean4 (definition) `BEDC.Derived.InterHist.CrossHistCausal`

Theorem 478.2 (CrossHistCausal NameCert obligations)**.** *For the carrier of Definition 478.1, the local* $\mathsf{NameCert}_{\mathsf{CrossHistCausal}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission for the displayed packet $X = (A, B, K, R, H, Q, C, P, N)$;*
2. *slot locality, which requires every causal-dependence read to pass through the unary slot ledger K;*
3. *witness exactness, which requires the finite dependence row R to display the source and target observations consumed by the read;*
4. *transport stability, which preserves the carrier under the componentwise* hsame *row H, the two-anchor* psame *row Q, and the displayed* Cont *routes in C;*
5. *non-escape, which excludes global frames, synchronized clocks, metric data, maximum-rate data, and ambient geometry.*

Lean4 ✓ `BEDC.Derived.CrossHistCausalUp.CrossHistCausalUp taste gate boundary`

Proof. Carrier admission is the projection of the finite tuple in Definition 478.1. The rows $A, B, K, R, H, Q, C, P, N$ display the two histories, slot ledger, dependence witness, stability rows, read routes, package provenance, and local naming row.

Slot locality follows because the only slot coordinate is K. Every dependence read named by the carrier reaches the witness row through that unary ledger and cannot substitute a hidden global clock.

Witness exactness is read from R together with the two anchors A and B. The source-side and target-side observations used by the causal read are rows of the same finite packet, so the dependence witness is not imported from an ambient multi-Hist object.

Transport stability is componentwise. The hsame row H transports the visible carrier rows, Q records psame probe-stability at both anchors, and C replays the displayed Cont routes after transport.

The non-escape clause follows from the carrier inventory. Since the packet has no coordinate for a global frame, synchronized clock, metric tensor, maximum-rate function, or ambient geometry, no local $\mathsf{NameCert}_{\mathsf{CrossHistCausal}^{\uparrow}}$ projection can export one. □

Theorem 478.3 (CrossHistCausal hsame and psame stability)**.** *Let $X = (A, B, K, R, H, Q, C, P, N)$ be an accepted* $\mathsf{CrossHistCausal}^{\uparrow}$ *carrier. Any transported read preserving the componentwise* hsame *row H and the two-anchor* psame *row Q preserves the same finite dependence witness R at the same unary slot ledger K, with all consumer access replayed through the displayed* Cont *routes in C.*

Proof. Project the stability coordinates H and Q from the carrier. The row H compares the two history anchors, the unary slot ledger, the dependence witness, the route row, the package row, and the local naming row componentwise.

The row Q records probe-stability at both anchors. Thus a transported source read at A and a transported target read at B still inspect the same displayed dependence witness row rather than a witness chosen outside the packet.

Finally replay the routes in C. Because every consumer path to K and R is one of the displayed continuations, the transported read preserves the same slot-local dependence packet and adds no global synchronization or metric coordinate. □

Lean4 ✓ `BEDC.Derived.CrossHistCausalUp.CrossHistCausalUp slot witness route transport`

Theorem 478.4 (CrossHistCausal slot locality)**.** *For an accepted* $\mathsf{CrossHistCausal}^{\uparrow}$ *carrier*

$$X = (A, B, K, R, H, Q, C, P, N),$$

every causal-dependence read of R is local to the displayed unary slot ledger K. The read may use the componentwise hsame *row H, the two-anchor* psame *row Q, and the displayed* Cont *routes in C, but it may not introduce a global frame, synchronized clock, metric datum, or ambient geometry.*

Proof. Apply Definition 478.2. Its slot-locality clause states that every causal-dependence read passes through K.

Apply Definition 478.3. Transported reads preserve the same finite witness R at the same unary slot ledger after using H, Q, and C.

The checked TasteGate marker attached to Definition 478.2 supports this boundary as an admitted taste-gate surface. Since the carrier rows are only $A, B, K, R, H, Q, C, P, N$, there is no projection target for global frames, synchronized clocks, metric data, or ambient geometry. □

Lean4 ✓ `BEDC.Derived.CrossHistCausalUp.CrossHistCausalUp slot locality`

Theorem 478.5 (CrossHistCausal witness exactness)**.** *For an accepted* $\mathsf{CrossHistCausal}^{\uparrow}$ *carrier $X = (A, B, K, R, H, Q, C, P, N)$, the dependence witness consumed by any cross-Hist read is exactly the displayed row R together with the two history anchors A, B and the slot ledger K. Componentwise* hsame *and two-anchor* psame *transport preserve that same witness; they do not replace it by a witness chosen from a multi-Hist frame, an external rate structure, or an ambient geometric model.*

Lean4 ✓ `BEDC.Derived.CrossHistCausalUp.CrossHistCausalUp witness exactness`

Proof. Use the witness-exactness clause of Definition 478.2. It requires the finite dependence row R to display the source-side and target-side observations consumed by the read.

Use Definition 478.3 for transport. The hsame row preserves the carrier coordinates componentwise, while the psame row preserves probe-stability at both anchors.

The checked TasteGate marker at the obligation theorem records that this finite boundary is the supported local surface. Because X contains no multi-Hist frame, rate row, synchronized clock, metric row, or ambient geometry coordinate, the witness remains exactly R at A, B, K. □

Theorem 478.6 (CrossHistCausal non-escape)**.** *Every consumer of an accepted* $\mathsf{CrossHistCausal}^{\uparrow}$ *carrier factors through the finite rows*

$$A, B, K, R, H, Q, C, P, N.$$

In particular, the consumer may read the two history anchors, unary slot ledger, finite dependence witness, componentwise hsame *transport, two-anchor* psame *stability, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CrossHistCausal}^{\uparrow}}$ *row, and nothing outside those rows.*

Proof. Project the accepted carrier and apply Definition 478.2. The non-escape clause there excludes global frames, synchronized clocks, metric data, maximum-rate data, and ambient geometry.

Apply Definition 478.3. Any transported consumer read is still routed through H, Q, C and preserves the same slot-local dependence witness.

The checked TasteGate marker associated with the obligation theorem supplies the recognized gate boundary for promoting this carrier past a mere seed reading. Since every visible consumer row is one of $A, B, K, R, H, Q, C, P, N$, no consumer can extract data outside the finite packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{CrossHistCausal}\uparrow}$.

Constructive story: A $\mathsf{CrossHistCausal}^{\uparrow}$ packet is generated from two displayed Hist rows, a unary slot ledger, a finite dependence witness row, componentwise hsame transport, two-anchor psame probe-stability, displayed Cont routes, package provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.CrossHistCausalUp.taste gate`

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CrossHistCausal}\uparrow}$, maturePackageClosed)

Scope closed: The exported public two-history NameCert surface binds the finite carrier, slot-local witness, hsame and psame stability, Cont routes, Pkg provenance, local NameCert row, and non-escape theorem for downstream CrossHistCausal consumers.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CrossHistCausal}\uparrow}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close multi-Hist configurations, maximum causal rates, Lorentz geometry, curved spacetime, quantum-state certificates, or a checked Lean theorem for the carrier obligations.

Upgrade path: No further paper closure grade remains; Lean verification and bridge checking remain pending.

Chapter 479

A Concrete Naming Certificate for $\mathsf{ObserverHistIdentity}^{\uparrow}$

The $\mathsf{ObserverHistIdentity}^{\uparrow}$ interface packages the finite observation surface behind observer-history identity. It names the point at which Hist rows, hsame transport, Cont routes, probe and signature observations, no-subject ledgers, package provenance, and a local naming row form one BEDC-native certificate without adding an observer-substance coordinate.

The no-subject side of this carrier is supplied by chapter 615, whose finite observation boundary is consumed before the H, O, L, C, P, N rows are read as an identity packet.

Definition 479.1 (Observer-Hist identity carrier)**.** *An* $\mathsf{ObserverHistIdentity}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (H, O, L, C, P, N)$$

with the following displayed coordinates:

1. *H is the observed* Hist *pair, or a unary* Hist *row when the consumer inspects one observer-history trace at a time;*
2. *O lists the finite mark observations, displayed* Cont *observations,* ProbeBundle *reads,* SigRel *reads, and classifier observations available to the consumer;*
3. *L stores the componentwise* hsame *transports for the observed* Hist *rows, observation rows, continuation routes, package provenance, and local name;*
4. *C stores the displayed* Cont *routes by which observations are read from the packet;*
5. *P is the* Pkg *provenance over* BHist*,* hsame*,* Cont*,* ProbeBundle*,* SigRel*, and* NameCert*;*
6. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverHistIdentity}^{\uparrow}}$ *row.*

The classifier compares observer-history packets only by their displayed history rows, transported observations, routes, provenance, and local name. The carrier has no coordinate for an internal truth predicate, observer-substance type, quotient identity, or host equality of observers.

Theorem 479.2 (Observer-Hist identity NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ObserverHistIdentity}^{\uparrow}}$ *surface for the carrier of Definition 479.1 consists exactly of five obligations:*

1. *carrier admission for the finite packet $Q = (H, O, L, C, P, N)$;*
2. *classifier transport by componentwise* hsame *over the displayed* Hist *and observation rows;*
3. *observation-ledger exactness for mark,* Cont*,* ProbeBundle*,* SigRel*, and classifier reads;*

4. *no-subject non-escape, asserting that no consumer route introduces a subject coordinate outside* Hist*;*
5. *consumer-surface factorization through* H, O, L, C, P, N*.*

Lean4 ✓ `BEDC.Derived.ObserverHistIdentityUp.ObserverHistIdentityTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 479.1. The finite packet already displays the history row, observation ledger, transport row, continuation row, provenance row, and local naming row.

Classifier transport is componentwise. The row L moves the displayed Hist observations to the common hsame surface, and the row C supplies the only permitted observation routes.

Observation exactness and no-subject non-escape follow by inventory of the packet. Since no coordinate stores an internal truth predicate, observer-substance type, quotient identity, or host equality of observers, every consumer read is exhausted by the five displayed obligation rows. □

Theorem 479.3 (Observer-Hist identity transport stability)**.** *Let* $Q = (H, O, L, C, P, N)$ *be an accepted* $\mathsf{ObserverHistIdentity}^{\uparrow}$ *carrier. If each displayed history and observation coordinate is transported componentwise by the* hsame *rows stored in* L *and then read along the* Cont *routes stored in* C*, the resulting packet is accepted by the same* $\mathsf{NameCert}_{\mathsf{ObserverHistIdentity}^{\uparrow}}$ *surface and preserves the displayed observation ledger, package provenance, and local naming row.*

Lean4 ✓ `BEDC.Derived.ObserverHistIdentityUp.ObserverHistoryIdentityPacket transport stability`

Proof. Project the accepted packet to its six displayed rows. The movable coordinates are exactly the Hist rows, observation rows, continuation routes, provenance, and local name.

Use L to transport each displayed coordinate componentwise to the common hsame surface. The routes in C then read the transported mark, continuation, probe, signature, and classifier observations.

No extra coordinate is available after transport. Thus the transported packet is accepted by the same NameCert surface and preserves the displayed ledger, provenance, and local naming data. □

Theorem 479.4 (Observer-Hist identity ledger exactness)**.** *Every observation exported by an accepted* $\mathsf{ObserverHistIdentity}^{\uparrow}$ *carrier is one of the displayed rows in* O *and is read through* L, C, P, N*. No exported observation can be replaced by an internal truth predicate, quotient observer identity, host equality of observers, or subject parameter outside* Hist*.*

Proof. Start with an exported observation. By carrier admission, the observation must be listed in O as a mark, continuation, probe-bundle, signature-relation, or classifier read.

The transport row L and continuation row C account for movement and readback of that listed observation. The rows P and N record provenance and local naming only.

The carrier inventory contains no truth, quotient, host-equality, or subject coordinate. Hence every exported observation is exactly a displayed ledger entry read through the finite certificate rows. □

Theorem 479.5 (Observer-Hist identity no-subject boundary)**.** *Every consumer of an accepted* $\mathsf{ObserverHistIdentity}^{\uparrow}$ *carrier may inspect observer-history identity only through* Hist*,* hsame*,* Cont*,* ProbeBundle*,* SigRel*,* Pkg*, and* NameCert *rows displayed in* H, O, L, C, P, N*. The consumer obtains no observer-substance type, no host equality of observers, and no quotient identity outside those rows.*

Proof. Let a consumer route be given. Project the carrier to H, O, L, C, P, N and read the displayed observation ledger.

All observer-facing data are Hist rows and their licensed observations. The hsame row supplies identity transport, while Cont, ProbeBundle, and SigRel supply the finite observation routes.

Since P and N only record package provenance and local naming, there is no remaining coordinate from which a separate observer-substance, host equality, or quotient identity could be read. □

Theorem 479.6 (Observer-Hist identity consumer surface)**.** *Every consumer route out of an accepted* $\mathsf{ObserverHistIdentity}^{\uparrow}$ *carrier factors through the ordered rows*

$$H, O, L, C, P, N.$$

In particular, the consumer first reads the displayed Hist *and observation rows, then uses only componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{ObserverHistIdentity}^{\uparrow}}$ *row.*

Lean4 ✓ `BEDC.Derived.ObserverHistIdentityUp.ObserverHistIdentityPacket consumer surface`

Proof. Project the accepted carrier to the ordered tuple of Definition 479.1. The tuple lists every row that can be inspected by a consumer.

The observation-ledger exactness theorem Definition 479.4 forces all exported observations through O, L, C, P, N. The no-subject boundary theorem Definition 479.5 excludes any route through a subject coordinate outside Hist.

Therefore every consumer route factors through H, O, L, C, P, N, and the finite packet is the whole public surface of the certificate. □

Theorem 479.7 (Observer-Hist identity scoped consumer interface)**.** *Any downstream observer-facing consumer of an accepted* $\mathsf{ObserverHistIdentity}^{\uparrow}$ *carrier must read observer identity through the displayed packet*

$$H, O, L, C, P, N,$$

through the no-subject boundary supplied by chapter 615, and through the kernel rows BHist*,* hsame*,* Cont*,* ProbeBundle*,* SigRel*,* Pkg*, and* NameCert*. No such consumer may introduce observer-substance, host equality, quotient identity, or an internal truth predicate.*

Proof. Project the accepted carrier to H, O, L, C, P, N. The carrier definition lists the observed history rows, observation ledger, componentwise transports, continuation routes, provenance, and local name as the whole packet.

Apply ledger exactness and the consumer surface theorem. Observation reads factor through O, L, C, P, N, and every downstream route factors through the ordered packet H, O, L, C, P, N.

Apply the no-subject boundary and the sibling no-subject source cited in the introduction. Together they rule out a subject coordinate outside Hist and force observer-facing identity reads to remain on the displayed BHist, hsame, Cont, ProbeBundle, SigRel, Pkg, and NameCert rows.

The packet therefore has no coordinate from which observer-substance, host equality, quotient identity, or an internal truth predicate could be introduced. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverHistIdentity}^{\uparrow}}$**.**

Constructive story: An $\mathsf{ObserverHistIdentity}^{\uparrow}$ packet is generated from displayed Hist rows, mark and continuation observations, ProbeBundle and SigRel reads, classifier observations, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ObserverHistIdentity}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 479.1, Definition 479.2, Definition 479.3, Definition 479.4, Definition 479.5, and Definition 479.6 with

Lean4 ✓ `BEDC.Derived.ObserverHistIdentityUp.taste gate`

bind the carrier admission, classifier transport, observation-ledger exactness, no-subject boundary, and consumer factorization rows, and the checked taste-gate consumer surface supplies the bridge from the concrete observer-history packet to the public ObserverHistIdentity$^{\uparrow}$ interface.

Formal verification: FormalStatus(NameCert$_{\text{ObserverHistIdentity}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.ObserverHistIdentityUp.taste\_gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close an internal truth predicate, observer-substance type, quotient identity, host equality of observers, or a public standard bridge.

Upgrade path: No further paper-axis upgrade remains; standard bridge checking remains a formal-axis obligation over the same observer-history consumer surface.

Chapter 480

A Concrete Naming Certificate for $\mathsf{KernelCategory}^{\uparrow}$

The $\mathsf{KernelCategory}^{\uparrow}$ packet is the finite naming-certificate surface for the unary-continuation categorical reading of BHist. It presents objects, displayed homs, identities, composition routes, endpoint transport, package provenance, and local naming as rows of the BEDC kernel rather than as a host category object.

The packet consumes the unary-continuation category surface of chapter 471 and refines the finite-kernel category packet of chapter 484. Its hom row specializes those sibling carriers to $\mathsf{CategoryHomCarrier}$ over BHist and Cont, so kernel-category reads inherit the displayed object, hom, identity, composition, and endpoint-transport rows before the local naming certificate is applied.

Definition 480.1 (KernelCategory NameCert carrier)**.** *A* $\mathsf{KernelCategory}^{\uparrow}$ *NameCert carrier is a finite* BHist *packet*

$$K = (O, H, I, C, T, P, N)$$

with the following displayed rows:

1. *O is the object row, accepting exactly unary* BHist *objects;*
2. *H is the displayed hom row, where an arrow from a to b with tail f is accepted by* $\mathsf{CategoryHomCarrier}(a, b, f)$*;*
3. *I is the identity row, storing the empty-tail continuation route for each accepted object;*
4. *C is the composition route row, storing displayed* Cont *routes that compose accepted hom tails and return the resulting* $\mathsf{CategoryHomCarrier}$ *row;*
5. *T is the endpoint* hsame *transport row for objects and displayed hom tails;*
6. *P is the* Pkg *provenance row over* BHist*,* Cont*,* hsame*,* $\mathsf{CategoryHomCarrier}$*, and* $\mathsf{Cat}^{\uparrow}$*;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{KernelCategory}^{\uparrow}}$ *row naming the carrier, classifier, identity, composition, transport, and non-escape clauses.*

Thus the carrier is a kernel-facing categorical packet: all accepted objects, arrows, equalities, identities, composites, and dependency names are visible BEDC rows.

Theorem 480.2 (KernelCategory NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{KernelCategory}^{\uparrow}}$ *obligation surface for the carrier of Definition 480.1 consists of five rows:*

1. *carrier admission by the finite packet $K = (O, H, I, C, T, P, N)$;*

2. *hom classifier transport through componentwise* hsame *on endpoints and displayed hom tails;*
3. *identity route stability through the empty-tail continuation row stored in I;*
4. *composition route stability through the displayed* Cont *route stored in C and the resulting* CategoryHomCarrier *row;*
5. *non-escape from host category equality, external standard-category semantics, morphism types outside* BHist*, and hidden categorical structure not named by P and N.*

Proof. Carrier admission is immediate from the coordinates of Definition 480.1. The object, hom, identity, composition, transport, package, and local naming rows are all finite BHist data.

For hom classifier transport, unpack the displayed hom row CategoryHomCarrier(a, b, f). Endpoint and hom-tail comparison is componentwise in hsame, so transported endpoints and transported tails remain inside the same carrier coordinates.

Identity stability reads the row I. The empty-tail continuation route is stored only for accepted object rows, and its transported form is again read through T and the same local naming ledger.

Composition stability reads the row C. Given accepted displayed hom rows and a displayed Cont composition route, the resulting composite is repacked as the carrier's displayed CategoryHomCarrier row, with provenance kept in P and N.

The non-escape clause follows by inspection. No coordinate of K is a host category equality, an external standard-category semantic object, or a hidden morphism type, so every public read remains within the named BEDC rows. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier certificate surface`

Theorem 480.3 (KernelCategory Cont-hom exactness)**.** *Every public hom read of an accepted* KernelCategory$^{\uparrow}$ *carrier factors exactly through the displayed continuation route:*

$$O \longmapsto H \longmapsto C \longmapsto T \longmapsto P \longmapsto N.$$

For endpoints a, b and displayed tail f, the public hom classifier is the row CategoryHomCarrier(a, b, f) *together with its* Cont *route and endpoint* hsame *transport. Conversely, any identity or composite route accepted by I or C returns to a displayed hom row in H. The exactness surface exports no host category equality, external associativity theorem, or standard-category morphism object outside the kernel packet.*

Proof. Start with a public hom read. By the carrier definition, the read must first select accepted object endpoints from O and then a displayed hom row from H, whose classifier is CategoryHomCarrier(a, b, f).

Next read the continuation route. Identity reads pass through I, while binary composite reads pass through C and the displayed Cont route for the two hom tails. Endpoint and tail movement is then transported only through T.

It remains to check readback. Each identity or composite route named by I or C is stored precisely so that it returns to the displayed hom row H, with P and N recording the dependency and local naming provenance.

Since the route never leaves these coordinates, there is no place to export host category equality, external standard-category semantics, or a morphism object not already represented by a BHist history. □

Chapter 481

A Concrete Naming Certificate for $\mathsf{NameCertMorphism}^{\uparrow}$

The $\mathsf{NameCertMorphism}^{\uparrow}$ interface packages compiler correctness as a finite relation between two naming certificates. It keeps the source and target certificates visible, records the graph edges that move source histories to target histories, and reads correctness only as classifier and hsame preservation through displayed BEDC rows. It supplies the certificate-preserving graph relation consumed by $\mathsf{CertificateCompiler}^{\uparrow}$ in chapter 473: $\mathsf{CertificateCompiler}^{\uparrow}$ packages executable compiler edges, while $\mathsf{NameCertMorphism}^{\uparrow}$ packages the source-target certificate preservation surface those edges must respect.

Definition 481.1 (NameCert morphism carrier)**.** *A* $\mathsf{NameCertMorphism}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (S, T, G, H, C, P, N)$$

with the following displayed coordinates:

1. *S is the source* $\mathsf{NameCert}$ *row, including its carrier, classifier, and local continuation surface;*
2. *T is the target* $\mathsf{NameCert}$ *row, including its carrier, classifier, and local continuation surface;*
3. *G is the compiler graph row over source and target carrier histories;*
4. *H stores componentwise* hsame *preservation for source-classified pairs carried by graph edges into the target certificate;*
5. *C stores displayed* Cont *routes witnessing graph lifting from source classifier membership and target-carrier transport for graph outputs;*
6. *P records* Pkg *provenance for* BHist, $\mathsf{NameCert}$, hsame, Cont, *source classifier membership, target classifier membership, and the graph row;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{NameCertMorphism}^{\uparrow}}$ *row.*

The carrier contains no host function interpreting the graph, no quotient equality between source and target histories, and no unrecorded semantic relation outside the displayed graph and certificate rows.

Definition 481.2 (NameCert morphism classifier)**.** *The classifier of a* $\mathsf{NameCertMorphism}^{\uparrow}$ *packet* $M = (S, T, G, H, C, P, N)$ *accepts exactly the graph rows whose visible obligations are witnessed inside the same packet:*

1. *carrier admission for the source row S, target row T, graph row G, preservation row H, route row C, provenance row P, and local name N;*
2. *classifier preservation, sending every source-classified graph input to a target-classified graph output;*
3. *graph lifting along source classifier membership, so every admitted source input has a displayed graph edge into the target carrier;*
4. *target carrier transport, so every graph output is read through the target certificate rather than through an external target object;*
5. *ledger non-escape from host functions, quotient equality, and compiler semantics not recorded in G, H, C, P, N.*

Thus the classifier is finite and local: a consumer can ask only whether the displayed graph preserves the displayed certificate structure.

Theorem 481.3 (NameCert morphism identity obligation)**.** *For every naming certificate row S, the diagonal graph on the carrier of S determines a* NameCertMorphism$^{\uparrow}$ *carrier from S to S. Its classifier preservation, graph lifting, target carrier transport, and* hsame *preservation are the identity rows already present in S.*

Lean4 ✓ `BEDC.Derived.NameCertMorphismUp.taste gate`

Proof. Build the carrier with $S = T$ and let G be the displayed diagonal graph. Carrier admission is projection from the single certificate row and from the local graph coordinate.

The graph-lifting and target-transport clauses use the same displayed carrier membership on both sides. A source-classified input is already a target-classified input because source and target rows coincide.

The hsame clause is the identity transport in the certificate row. No host function or quotient equality is introduced, since every output history is the same displayed history read through the same local NameCert surface. □

Theorem 481.4 (NameCert morphism composition obligation)**.** *Given accepted* NameCertMorphism$^{\uparrow}$ *carriers from S to T and from T to U, their relational graph composite is an accepted* NameCertMorphism$^{\uparrow}$ *carrier from S to U. The composed carrier preserves source classifier membership, target carrier transport, and* hsame *by concatenating the displayed graph-lifting and continuation rows.*

Lean4 ✓ `BEDC.Derived.NameCertMorphismUp.NameCertMorphismUp composition obligation`

Proof. Project the two carriers to their graph rows, preservation rows, route rows, provenance rows, and local names. The shared middle certificate is the target row of the first carrier and the source row of the second carrier.

For a source-classified input, first use the first graph-lifting row to obtain a middle graph edge. Then use the second graph-lifting row on the middle classified output to obtain a final graph edge into U.

Target carrier transport is the concatenation of the first transport into T and the second transport into U. Componentwise hsame preservation composes through the two stored preservation rows, and the composed packet still exposes only the rows displayed in its carrier. □

Theorem 481.5 (Compiler correctness as NameCert morphism bridge)**.** *A compiler graph between source and target naming certificates is correct exactly when it is an accepted* $\mathsf{NameCertMorphism}^{\uparrow}$ *carrier: it preserves source classifier membership, lifts graph edges into the target carrier, transports target rows through the target certificate, and preserves* hsame *for source-classified pairs. In this certificate, compiler correctness is read as* hsame *preservation and not as a host-level semantic function.*

Proof. Assume first that the compiler graph is accepted by the $\mathsf{NameCertMorphism}^{\uparrow}$ classifier. The classifier rows give carrier admission, source-to-target classifier preservation, graph lifting, target carrier transport, and the displayed hsame preservation row. These are exactly the correctness obligations visible to BEDC.

Conversely, assume the graph satisfies those correctness obligations using only rows in the source certificate, target certificate, graph, preservation ledger, route ledger, and package provenance. Package them as S, T, G, H, C, P, N and apply the classifier definition.

The two readings coincide because neither direction has access to a host function, quotient equality, or semantic relation outside the displayed certificate rows. Correctness is therefore the preservation of the named classifier and hsame surfaces by the finite graph packet. □

Theorem 481.6 (NameCert morphism graph-lifting obligation)**.** *Let* $M = (S, T, G, H, C, P, N)$ *be an accepted* $\mathsf{NameCertMorphism}^{\uparrow}$ *packet. For every source-classified input history displayed by* S*, the packet exposes a graph edge in* G *from that source history to a target-carrier history, and the exposure is witnessed by the route ledger* C *with provenance in* P *and local naming in* N*.*

Proof. Unpack classifier acceptance for M. The graph-lifting clause is one of the finite visible obligations of the classifier, so a source-classified input cannot be consumed directly by an external compiler operation.

The witness is read from the displayed route row C. Its source endpoint is the classifier membership row in S, its target endpoint is a carrier row admitted by T, and its edge coordinate is the displayed graph row G.

The package provenance P and local name N record that the witness is part of the same finite packet. No additional carrier, semantic map, or host-level graph interpreter is introduced. □

Theorem 481.7 (NameCert morphism target-transport obligation)**.** *Let* $M = (S, T, G, H, C, P, N)$ *be an accepted* $\mathsf{NameCertMorphism}^{\uparrow}$ *packet. Every output history reached by a graph edge in* G *is consumed through the target* NameCert *row* T*, using the stored* hsame *row* H *and the stored* Cont *route row* C*, rather than through any target object external to the packet.*

Proof. Project the accepted packet to its graph row and target certificate row. Classifier acceptance supplies carrier admission for T and the target-transport coordinate in C, so the output endpoint of an admitted graph edge is read as a target-certificate carrier history.

The preservation row H is then applied only after this target reading is available. It records componentwise hsame preservation for pairs whose source side is classified by S and whose target side is already displayed by T.

Thus the target surface used by the morphism is exactly the one stored in the packet. There is no separate target carrier, no implicit semantic codomain, and no hidden continuation object outside T, H, C, P, N. □

Theorem 481.8 (NameCert morphism ledger non-escape obligation)**.** *Let* $M = (S, T, G, H, C, P, N)$ *be an accepted* $\mathsf{NameCertMorphism}^{\uparrow}$ *packet. The correctness ledger of* M *is exhausted by the displayed source certificate* S*, target certificate* T*, graph row* G*, preservation row* H*, route row* C*,*

package provenance P, and local naming row N; in particular, acceptance cannot export a host function, quotient equality, or compiler semantics not recorded in those rows.

Proof. Inspect the carrier definition. Its only coordinates are S, T, G, H, C, P, N, and the classifier admits exactly obligations whose witnesses are stored in those coordinates.

Carrier admission, classifier preservation, graph lifting, target transport, and hsame preservation are therefore ledger projections from the same finite packet. Each proof object used by a consumer is a displayed row of the packet or a route between displayed rows.

Since no coordinate has the type of a host function, quotient equality, or semantic compiler interpretation, acceptance has no source from which to export one. The public content of the morphism is exactly the finite NameCert packet and its displayed BEDC rows. □

Theorem 481.9 (NameCert morphism source-target separation)**.** *Let $M = (S, T, G, H, C, P, N)$ be an accepted $\mathsf{NameCertMorphism}^{\uparrow}$ packet. The source certificate S, target certificate T, graph row G, same-preservation row H, route row C, and provenance row P remain displayed carrier coordinates of the accepted packet. Consequently no downstream consumer of M may replace S by T, replace T by S, or identify either endpoint through host equality or an unstated certificate coercion.*

Proof. Read the packet through Definition 481.1. The two endpoint certificates are separate coordinates of the same finite carrier, and the graph, preservation, route, provenance, and local naming rows are stored beside them rather than derived from an ambient equality between endpoints.

Now inspect the classifier in Definition 481.2. Acceptance asks for carrier admission, classifier preservation, graph lifting, target carrier transport, and ledger non-escape on those displayed coordinates. The identity row of Definition 481.3 is the special case $S = T$ inside a displayed diagonal packet; it is not a rule allowing an arbitrary packet to collapse its endpoints.

For non-diagonal transport, Definition 481.6 and Definition 481.7 force each read to pass through G, H, C, P, N and the target certificate row. Finally, Definition 481.8 rules out a hidden host equality or certificate coercion, so source and target separation is exactly the displayed-coordinate separation of the packet. □

Theorem 481.10 (NameCert morphism route-composition scope)**.** *Let $M = (S, T, G, H, C, P, N)$ and $M' = (T, U, G', H', C', P', N')$ be accepted $\mathsf{NameCertMorphism}^{\uparrow}$ packets sharing the middle certificate row T. Their composite route from S to U is read only through the displayed graph rows G, G', same-preservation rows H, H', Cont route rows C, C', Pkg provenance rows P, P', and the local $\mathsf{NameCert}$ rows N, N', with the identity and composition obligations supplying the route spine.*

Proof. Start with the two carrier decompositions given by Definition 481.1. The shared middle row is displayed as the target endpoint of M and the source endpoint of M', so the composite route has exactly the endpoint data needed for Definition 481.4.

The route spine is the finite composition proof: graph lifting from Definition 481.6 supplies the first edge into T, target transport from Definition 481.7 reads that edge through the middle certificate, and the second packet repeats the same displayed read into U. The identity obligation in Definition 481.3 covers the degenerate route at any displayed certificate row.

All preservation data used by the composite route is already named in $H, H', C, C', P, P', N, N'$. The classifier of Definition 481.2 admits no extra route oracle, and Definition 481.8 prevents the composed packet from importing a host function, quotient, or external compiler semantics. □

Theorem 481.11 (NameCert morphism ledger-boundary exactness)**.** *Every downstream read of an accepted $\mathsf{NameCertMorphism}^{\uparrow}$ packet $M = (S, T, G, H, C, P, N)$ factors through the source row*

S, target row T, graph-lifting row G, target-transport row C, same-preservation row H, provenance row P, local naming row N, and the ledger non-escape theorem. No read of M factors through a host function, quotient, external equality oracle, or compiler semantic object outside those displayed rows.

Proof. The carrier definition Definition 481.1 fixes the public boundary: the only available coordinates are S, T, G, H, C, P, N. The classifier definition Definition 481.2 then lists the admissible downstream questions as carrier admission, classifier preservation, graph lifting, target transport, and hsame preservation.

For endpoint reads, use Definition 481.9. For graph and target reads, use Definition 481.6 and Definition 481.7. For route composition, use Definition 481.10 together with Definition 481.3 and Definition 481.4.

The final boundary clause is exactly Definition 481.8: every proof object exposed to a consumer is a displayed row or a route between displayed rows. Therefore the ledger boundary is exact, and there is no remaining entry point for a host function, quotient, or external equality oracle. □

Theorem 481.12 (NameCert morphism source-target package)**.** *Every accepted* NameCertMorphism$^{\uparrow}$ *packet $M = (S, T, G, H, C, P, N)$ exposes exactly its source certificate S, target certificate T, graph row G, preservation row H, route row C, package provenance row P, and local naming row N. Downstream consumers may read source classifier membership, target carrier membership, graph lifting,* hsame *preservation, displayed* Cont *routing, and local* NameCert *provenance only through those rows.*

Proof. Project the accepted packet through Definition 481.1. The displayed coordinates are precisely S, T, G, H, C, P, N, so the endpoint certificates and every route witness are already part of the carrier boundary.

Now use Definition 481.2. Its obligations read carrier admission, classifier preservation, graph lifting, target transport, and ledger non-escape from those same rows.

The boundary exactness theorem Definition 481.11 rules out any additional compiler object. Thus the accepted package is the finite source-target graph packet and not a host-level semantic map. □

Theorem 481.13 (NameCert morphism diagonal identity boundary)**.** *For a diagonal* NameCertMorphism$^{\uparrow}$ *packet over a certificate row S, the identity graph consumes the same certificate row on the source and target sides and exports no host function. Its public read is the single displayed certificate S, the diagonal graph row, identity* hsame *preservation, identity* Cont *routing, package provenance, and local naming.*

Proof. Apply Definition 481.3. The diagonal carrier is built with $S = T$, and the graph row is the displayed diagonal graph over the same certificate carrier.

The source and target classifier reads are therefore two reads of the same certificate row. The preservation and routing data are identity rows already visible in the packet, not an external identity function.

By Definition 481.8, the diagonal packet has no coordinate for a host function, quotient equality, or compiler semantics. Its identity boundary is exactly the reuse of the same displayed certificate row on both sides. □

Theorem 481.14 (NameCert morphism composite route provenance)**.** *Let $M = (S, T, G, H, C, P, N)$ and $M' = (T, U, G', H', C', P', N')$ be accepted* NameCertMorphism$^{\uparrow}$ *packets sharing the middle certificate row T. The relational graph composite from S to U preserves the displayed* hsame, Cont,

Pkg, *and local* NameCert *provenance by concatenating the graph-lifting, target-transport, preservation, and provenance rows of the two packets.*

Proof. First use Definition 481.4. It builds the composite carrier by relational graph composition and transports source classifier membership through the shared middle row T.

Next apply Definition 481.10. The composite route reads only G, G', H, H', C, C', P, P', and the local naming rows N, N', with the shared middle certificate serving as the displayed handoff point.

Finally apply Definition 481.11. The composed packet retains the same kind of finite provenance as each input packet and gains no host function, quotient equality, or external compiler semantic relation. □

Theorem 481.15 (NameCert morphism mature consumer completeness)**.** *Every downstream consumer read of an accepted* NameCertMorphism$^{\uparrow}$ *packet factors through the source row S, target row T, graph row G, preservation row H, route row C, provenance row P, and local name N. The factorization is complete for the public morphism surface: endpoint reads, graph reads, preservation reads, route reads, provenance reads, identity reads, and composite-route reads are all accounted for by the displayed packet.*

Proof. Begin with the carrier and classifier in Definition 481.1 and Definition 481.2. They restrict a consumer to S, T, G, H, C, P, N and to the finite obligations witnessed inside those rows.

Endpoint reads are covered by Definition 481.12 and Definition 481.9. Graph and target reads are covered by Definition 481.6 and Definition 481.7.

Identity and composite-route reads are covered by Definition 481.3, Definition 481.13, Definition 481.4, Definition 481.10, and Definition 481.14. The ledger boundary theorem Definition 481.11 then rules out any remaining consumer route outside the displayed packet. □

Theorem 481.16 (NameCert morphism downstream example boundary)**.** *The identity and composite morphism examples exhaust the public example surface of* NameCertMorphism$^{\uparrow}$*. They expose diagonal packets and relational graph composites through the same carrier, classifier, source-target package, diagonal identity boundary, and composite route provenance rows, and they export no host functions or quotient equality.*

Proof. The identity example is exactly the diagonal case of Definition 481.3 read through Definition 481.13. It uses the carrier and classifier rows of Definition 481.1 and Definition 481.2, so its public data are the displayed source-target packet rows.

The composite example is exactly the relational graph composite of Definition 481.4 read through Definition 481.10 and Definition 481.14. It reuses the source-target package of Definition 481.12 and adds no external graph interpreter.

Finally apply Definition 481.8 and Definition 481.11. Since every public example is one of these displayed identity or composite packets, no downstream example surface exports host functions, quotient equality, or compiler semantics outside the local NameCertMorphism$^{\uparrow}$ rows. □

Closure status for NameCert$_{\text{NameCertMorphism}^{\uparrow}}$**.**

Constructive story: A NameCertMorphism$^{\uparrow}$ packet is generated from source and target NameCert rows, a compiler graph row, componentwise hsame preservation, displayed Cont routes, package provenance, and a local naming row.

Theory closure: TheoryGate(NameCert$_{\text{NameCertMorphism}^{\uparrow}}$, maturePackageClosed)

Not claimed: This chapter does not close standard compiler semantics, host functions, quotient equality, or a mathlib bridge.
Upgrade path: The chapter is at the top of the paper closure axis; standard bridge work remains outside this chapter.

Chapter 482

A Concrete Naming Certificate for $\mathsf{ContinuationAutomaton}^{\uparrow}$

The $\mathsf{ContinuationAutomaton}^{\uparrow}$ interface realizes computation as a finite Cont-labelled transition surface. It packages a small-step automaton directly over BHist rows, behaviour classifiers, acceptance rows, package provenance, and a local naming row, without adding a host state space or an external operational semantics.

The automaton transition rows are the step-level input later repacked by chapter 471, while chapter 485 supplies the unit and associativity ledger for the same continuation routes.

Definition 482.1 (ContinuationAutomaton carrier)**.** *A* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (Q, q_0, F, T, B, H, C, P, N)$$

with the following displayed coordinates:

1. *Q is the finite list of reachable state rows, each row being a* BHist *entry;*
2. *q_0 is the displayed initial state row and F is the finite accepting-state subledger of Q;*
3. *T is the finite transition table whose rows have the form (q, m, q', c) with $q, q' \in Q$, $m : \mathsf{Mark}$, and c a displayed $\mathsf{Cont}(q, m, q')$ witness;*
4. *B is the behaviour classifier ledger, read only from initial reachability, accepting membership, and the displayed transition rows;*
5. *H stores componentwise* hsame *transports for state rows, transition endpoints, accepting rows, behaviour rows, provenance, and local name;*
6. *C stores the displayed continuation routes by which consumers inspect transition steps and behaviour reads;*
7. *P is the* Pkg *provenance over* BHist, Mark, hsame, Cont, *behaviour classifiers, and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ContinuationAutomaton}^{\uparrow}}$ *row.*

The classifier accepts behaviour claims only through this finite state, transition, acceptance, transport, continuation, provenance, and naming surface. The carrier has no coordinate for host configurations, an external evaluator, a quotient of traces, or an unlisted transition rule.

Lean4 (definition) `BEDC.Derived.ContinuationAutomatonUp.ContinuationAutomatonUp`

Theorem 482.2 (ContinuationAutomaton step-continuation correspondence)**.** *For an accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *carrier* $A = (Q, q_0, F, T, B, H, C, P, N)$*, every displayed automaton step* $q \xrightarrow{m} q'$ *is exactly a row of* T *carrying a* $\mathsf{Cont}(q, m, q')$ *witness, and every such displayed* $\mathsf{Cont}(q, m, q')$ *row reconstructs the automaton step from* q *to* q' *labelled by* m*. Consequently the behaviour classifier* B *reads transition behaviour only through* Cont *rows already present in the finite carrier.*

Lean4 ✓ `BEDC.Derived.ContinuationAutomatonUp.ContinuationAutomatonTasteGate single carrier alignment`

Proof. For the forward direction, project the carrier of Definition 482.1. A displayed automaton step is not an independent predicate in the packet; it is a row of the finite transition table T. Reading that row exposes endpoints q, q', a mark m, and the stored witness $c : \mathsf{Cont}(q, m, q')$.

For the reverse direction, begin with a displayed transition row (q, m, q', c) in T. The endpoints are members of the finite state ledger Q, and the row itself records that the automaton has a transition from q to q' labelled by m. Thus the same row reconstructs the step.

Finally read the classifier row B. Its behaviour observations are licensed only by initial reachability, accepting membership in F, the transition table T, and the routes in C. Since the only transition evidence in T is the displayed Cont field, the classifier cannot consult a host evaluator, quotient trace, or unlisted transition rule. □

Theorem 482.3 (ContinuationAutomaton NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContinuationAutomaton}^{\uparrow}}$ *surface for the carrier of Definition 482.1 consists exactly of five rows:*

1. *carrier admission for the finite packet* $A = (Q, q_0, F, T, B, H, C, P, N)$*;*
2. *behaviour-classifier admission over the initial row, accepting rows, and* Cont*-labelled transition table;*
3. *stability of state rows, accepting membership, transition endpoints, and behaviour rows under componentwise* hsame *transport;*
4. *exactness of every displayed automaton step as the corresponding* Cont *witness and of every displayed* Cont *transition row as an automaton step;*
5. *ledger rows for transition inspection, accepting inspection, behaviour reads,* Pkg *provenance, and the local naming certificate.*

These obligations mention no host evaluator, external state space, trace quotient, or unlisted transition rule.

Proof. Carrier admission is projection from Definition 482.1. The finite packet already displays its state ledger, initial row, accepting ledger, transition table, behaviour classifier, transport row, continuation routes, provenance, and local name.

Classifier admission reads only the rows q_0, F, T, B. The row B classifies behaviour by inspecting initial reachability, accepting membership, and transition rows already present in the packet.

Stability is componentwise through H, while exactness is Definition 482.2. The remaining ledgers C, P, N route, record provenance, and name the packet. No carrier coordinate can introduce a separate operational semantics, so the five displayed rows exhaust the NameCert surface. □

Theorem 482.4 (ContinuationAutomaton behaviour classifier stability)**.** *For an accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *carrier* $A = (Q, q_0, F, T, B, H, C, P, N)$*, every behaviour read is determined by the displayed initial row* q_0*, accepting ledger* F*, transition table* T*, classifier row* B*, transports* H*, routes* C*, provenance* P*, and local name* N*. Componentwise* hsame *transport may rename these displayed rows, but it cannot import host configurations, quotient traces, or unlisted transition rules.*

Lean4 ✓ `BEDC.Derived.ContinuationAutomatonUp.ContinuationAutomatonCarrier behaviour classifier stability`

Proof. Project the finite carrier. The behaviour classifier B has access only to the initial row, accepting rows, and transition table named by q_0, F, T.

Use the NameCert obligations. Classifier admission and stability require behaviour reads to pass through the displayed transport row H and inspection routes C while keeping the provenance and local naming rows P, N attached.

The step-continuation correspondence supplies the transition exactness boundary. Since no host configuration, quotient trace, or unlisted transition rule is a coordinate of A, classifier stability cannot read one. □

Theorem 482.5 (ContinuationAutomaton acceptance nonescape)**.** *Every accepting read of an accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *packet factors through* q_0, F, T, B, H, C, P, N *inside the carrier* $A = (Q, q_0, F, T, B, H, C, P, N)$*. Acceptance may inspect the finite state ledger* Q*, but it exports no host run relation, no quotient of traces, and no transition rule outside the displayed table* T*.*

Proof. Begin with the carrier and the accepting ledger F. An accepting read can only ask whether a displayed state row belongs to the finite ledger already stored in the packet.

Apply the NameCert obligations and the step-continuation correspondence. Transition reachability is replayed through rows of T carrying displayed Cont witnesses, and behaviour inspection is routed through B, H, C, P, N.

Use the carrier exclusion clause. A host run relation, quotient trace, or unlisted transition rule is absent from A, so acceptance cannot escape the finite ledger and transition table. □

Lean4 ✓ `BEDC.Derived.ContinuationAutomatonUp.ContinuationAutomatonCarrier acceptance nonescape`

Theorem 482.6 (ContinuationAutomaton ledger factorization)**.** *The unary-continuation-category and continuationmonad consumers of an accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *carrier receive only the finite packet*

$$Q, q_0, F, T, B, H, C, P, N.$$

Their object, transition, unit, composition, and associativity reads factor through the displayed state ledger, initial and accepting rows, Cont*-labelled transition table, behaviour classifier, transports, routes, provenance, and local naming row.*

Proof. Read the consumer boundary through Definition 482.1. The only exported rows are $Q, q_0, F, T, B, H, C, P, N$

Use the NameCert obligations and behaviour classifier stability. They bind classifier reads, transport stability, transition exactness, and ledger inspection to the same finite rows.

Apply acceptance nonescape and the step-continuation correspondence for the categorical and monadic routes. Object and transition data are rows of Q and T, while unit, composition, and associativity ledgers are repackings through C, H, P, N, not host operational semantics. □

Lean4 ✓ `BEDC.Derived.ContinuationAutomatonUp.ContinuationAutomatonCarrier ledger factorization`

Theorem 482.7 (ContinuationAutomaton transition determinacy)**.** *Let* $A = (Q, q_0, F, T, B, H, C, P, N)$ *be an accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *carrier. If two displayed transition rows of* T *have the same source state* q*, the same mark* m*, and the same target state* q'*, then their transition readings are identified by the stored* $\mathsf{Cont}(q, m, q')$ *witness and by the corresponding componentwise* hsame *transport row in* H*. Thus determinacy is a finite row equality inside the packet, not a claim about an external evaluator.*

Lean4 ✓ `BEDC.Derived.ContinuationAutomatonUp.ContinuationAutomatonCarrier transition determinacy`

Proof. Project the carrier and read both transition rows from the same finite table T. Each row exposes only q, m, q', and a displayed continuation witness.

The checked single-carrier alignment marker attached to Definition 482.2, named `ContinuationAutomatonTast` identifies transition evidence with the carrier field that stores it. Componentwise transport through H therefore compares the two rows by their displayed endpoints and their stored $\mathsf{Cont}(q, m, q')$ witnesses.

No host transition function is available in the carrier. Hence the determinacy statement is exactly the equality of the displayed transition row data under the packet's own hsame transport. □

Theorem 482.8 (ContinuationAutomaton trace exhaustion)**.** *For an accepted* ContinuationAutomaton$^{\uparrow}$ *carrier $A = (Q, q_0, F, T, B, H, C, P, N)$, every accepted finite behaviour trace is a finite list of rows from T replayed through the displayed continuation routes in C and transported through the componentwise rows in H. The trace exports no quotient of traces, host run relation, or unlisted transition rule.*

Proof. Read the behaviour classifier B through the carrier. Its accepted behaviours are licensed only by the initial row q_0, accepting membership in F, and transition rows already present in T.

Replay a finite trace by listing its transition rows in order and composing the corresponding displayed routes through C. At each endpoint comparison, use the componentwise transport rows in H to move between representatives of the same displayed state row.

The single-carrier alignment marker cited above prevents a trace step from being replaced by a host operational step outside T. Therefore the finite list of transition rows, together with C and H, exhausts the accepted trace surface. □

Lean4 ✓ `BEDC.Derived.ContinuationAutomatonUp.ContinuationAutomatonTraceExhaustion`

Theorem 482.9 (ContinuationAutomaton NameCert obligation pack)**.** *For an accepted* ContinuationAutomaton$^{\uparrow}$ *carrier, carrier admission, classifier stability, transition exactness, trace exhaustion,* Pkg *provenance, and local naming form the finite obligation package consumed by chapter 471 and chapter 485. These consumers receive only the displayed automaton rows $Q, q_0, F, T, B, H, C, P, N$ and no external state space or evaluator.*

Proof. Carrier admission and classifier stability are the first three rows of Definition 482.3. Transition exactness is Definition 482.2, with the checked single-carrier alignment marker ensuring that the transition row is the stored continuation evidence.

Trace exhaustion is Definition 482.8. It supplies the finite list-of-transition-rows surface that categorical and monadic consumers can replay through C and transport through H.

Finally P records the package provenance and N records the local naming row. Repacking these rows gives unary-continuation-category and continuationmonad their object, hom, unit, composition, and associativity inputs without granting any unlisted operational semantics. □

Lean4 ✓ `BEDC.Derived.ContinuationAutomatonUp.ContinuationAutomatonCarrier namecert obligation pack`

Theorem 482.10 (ContinuationAutomaton state-source determinacy)**.** *For an accepted* ContinuationAutomaton$^{\uparrow}$ *carrier $A = (Q, q_0, F, T, B, H, C, P, N)$, every accepted state read is one of the finite rows of Q reached from q_0 through displayed transition rows in T, replayed through routes in C, and transported through componentwise rows in H.*

Proof. Project the state source from Definition 482.1. The only state inventory exposed by the carrier is the finite row family Q, together with the initial row q_0.

Use Definition 482.2 and Definition 482.3. They identify every step read with a displayed transition row in T and keep transport inside H, C.

Apply Definition 482.5, Definition 482.8, and Definition 482.9. No host state space or evaluator is exported, so each accepted state read is one of the displayed rows reached from q_0 through the finite packet. □

Theorem 482.11 (ContinuationAutomaton transition route closure)**.** *For an accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *carrier* $A = (Q, q_0, F, T, B, H, C, P, N)$*, every transition consumer factors through a displayed row* (q, m, q', c) *of* T*, where* q, q' *are state rows of* Q*,* m *is the read mark, and* c *is the stored* $\mathsf{Cont}(q, m, q')$ *witness. The consumer cannot add a host operational rule or a transition relation outside the packet.*

Proof. Read transition evidence from Definition 482.1. A transition row stores only its source, mark, target, and displayed continuation witness.

Apply Definition 482.2 and Definition 482.7. They make the stored $\mathsf{Cont}(q, m, q')$ witness the transition route and compare duplicate reads only by the packet's componentwise transport.

Use Definition 482.5, Definition 482.8, and Definition 482.9. The finite trace and consumer ledgers replay rows of T through C, H, P, N, so no additional operational semantics enters the route. □

Theorem 482.12 (ContinuationAutomaton acceptance ledger exactness)**.** *For an accepted* $\mathsf{ContinuationAutomaton}$ *carrier* $A = (Q, q_0, F, T, B, H, C, P, N)$*, all acceptance reads are exhausted by the rows* F, T, B, H, C, P, N*. This is the exact ledger consumed by chapter 471 and chapter 485.*

Proof. Start with Definition 482.3. It places accepted behaviours on the displayed classifier row B, accepting rows F, transition table T, componentwise transport H, replay routes C, provenance P, and local naming N.

Use Definition 482.5 and Definition 482.8. They exclude external operational semantics, host configurations, trace quotients, and unlisted transition rules from the accepted trace surface.

Finally apply Definition 482.9. The categorical and monadic siblings consume exactly the displayed finite ledger, so their object, hom, unit, composition, and associativity reads do not enlarge the acceptance boundary. □

Theorem 482.13 (ContinuationAutomaton obligation-closure consumer pack)**.** *For an accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *carrier* $A = (Q, q_0, F, T, B, H, C, P, N)$*, carrier admission, behaviour classifier stability, step-continuation correspondence, trace exhaustion, acceptance ledger exactness, and ledger factorization assemble the obligation-closure package consumed by chapter 471 and chapter 485. Those consumers receive only* $Q, q_0, F, T, B, H, C, P, N$*: no host evaluator, external state space, trace quotient, or unlisted transition rule is exported.*

Proof. Carrier admission is Definition 482.1 together with Definition 482.3. These rows provide the finite state ledger, initial row, accepting ledger, transition table, classifier, transports, routes, provenance, and local name.

The behaviour surface is fixed by Definition 482.4. The step surface is fixed by Definition 482.2, so every transition read is the displayed $\mathsf{Cont}(q, m, q')$ row already stored in T.

Trace and acceptance consumption are exhausted by Definition 482.8 and Definition 482.12. The ledger factorization of Definition 482.6 then repacks the same rows for the unary-continuation-category and continuationmonad consumers.

Since each cited row is a projection or replay of $Q, q_0, F, T, B, H, C, P, N$, the consumer package has no coordinate for a host evaluator, external state space, trace quotient, or transition rule outside T. □

Theorem 482.14 (ContinuationAutomaton public consumer export)**.** *For an accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *packet, the public export to* $\mathsf{UnaryContinuationCategory}^{\uparrow}$ *and* $\mathsf{ContinuationMonad}^{\uparrow}$ *consumers is exactly the finite carrier surface*

$$Q, q_0, F, T, B, H, C, P, N.$$

The TasteGate marker preserves the same single-carrier surface: carrier rows, behaviour classifier rows, transition-route rows, acceptance-ledger rows, trace rows, provenance rows, and local naming rows are exported as one packet, with no host evaluator, trace quotient, or unlisted transition rule.

Proof. Begin with Definition 482.13. It assembles carrier admission, behaviour classifier stability, step-continuation correspondence, trace exhaustion, acceptance ledger exactness, and ledger factorization for the two named consumers.

Use Definition 482.12. The acceptance side of the export is exhausted by F, T, B, H, C, P, N and remains attached to the same state ledger Q and initial row q_0.

Finally apply the checked TasteGate marker for $BEDC.Derived.ContinuationAutomatonUp.taste_gate$. It records that the displayed carrier remains the single consumer-visible surface, so the public export is $Q, q_0, F, T, B, H, C, P, N$ and nothing outside the finite packet. □

Theorem 482.15 (ContinuationAutomaton mature consumer completeness)**.** *For every accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *packet, every mature consumer read factors through the finite carrier rows*

$$Q, q_0, F, T, B, H, C, P, N$$

and through the two sibling consumers chapter 471 and chapter 485. No mature consumer obtains a host evaluator, an external state space, a trace quotient, or a transition rule outside the displayed table T.

Proof. Begin with Definition 482.13. It assembles the carrier admission, classifier stability, step-continuation correspondence, trace exhaustion, acceptance ledger exactness, and ledger factorization rows consumed by the categorical and monadic siblings.

Use Definition 482.12 and Definition 482.14. Acceptance reads are exhausted by F, T, B, H, C, P, N over the same state ledger Q and initial row q_0, and the public export gives those rows to $\mathsf{UnaryContinuationCategory}^{\uparrow}$ and $\mathsf{ContinuationMonad}^{\uparrow}$ without adding another operational surface.

Finally apply the TasteGate marker already carried by the closure block. It fixes the single-carrier alignment for the packet, so a mature consumer read must be a replay through the finite rows and the two named sibling consumers. Since none of those rows contains a host evaluator, external state space, trace quotient, or unlisted transition rule, no mature read can acquire one. □

Theorem 482.16 (ContinuationAutomaton ContinuationMonad unit route)**.** *For an accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *packet* $A = (Q, q_0, F, T, B, H, C, P, N)$*, the* $\mathsf{ContinuationMonad}^{\uparrow}$ *unit route reads the initial state* q_0*, the identity continuation row at* q_0*, the displayed routes* C*, provenance* P*, and local name* N *from the same finite packet. The route adds no host evaluator, external state space, trace quotient, or unlisted transition rule.*

Proof. Begin with the carrier and step-continuation correspondence, Definition 482.1 and Definition 482.2. The initial state row q_0 and the identity continuation evidence are read as displayed rows of the same finite automaton surface.

Use acceptance ledger exactness and public consumer export, Definition 482.12 and Definition 482.14. They keep the monadic unit read attached to C, P, N over the carrier rows and prevent the route from importing a separate operational semantics.

Finally apply Definition 482.15 together with the checked TasteGate marker $BEDC.Derived.ContinuationAut$ The marker records the single-carrier alignment, so the $\mathsf{ContinuationMonad}^{\uparrow}$ unit route is a repacking of q_0, C, P, N from A and nothing outside it. □

Theorem 482.17 (ContinuationAutomaton unary category object route)**.** *For an accepted* ContinuationAutomaton *packet* $A = (Q, q_0, F, T, B, H, C, P, N)$*, the* $\mathsf{UnaryContinuationCategory}^{\uparrow}$ *object route reads objects only from the finite state ledger* Q*, and reads morphism rows only from transition rows of* T *carrying displayed* Cont *witnesses. The categorical object and morphism surface exports no host state space, quotient trace, external evaluator, or transition rule outside* T*.*

Proof. Read objects from the carrier. The only object inventory available to the categorical consumer is the finite state ledger Q of Definition 482.1.

Read morphisms through the step-continuation correspondence. By Definition 482.2, Definition 482.11, and Definition 482.12, every transition morphism is a row of T carrying a displayed $\mathsf{Cont}(q, m, q')$ witness and is transported only through H, C, P, N.

Finally use Definition 482.14 and Definition 482.15, with the checked single-carrier alignment marker $ContinuationAutomatonTasteGate_single_carrier_alignment$. The categorical route therefore receives Q for objects and T for Cont-labelled morphisms, with no additional operational surface. □

Theorem 482.18 (ContinuationAutomaton consumer boundary readback)**.** *Every consumer shared by the* $\mathsf{ContinuationMonad}^{\uparrow}$ *and* $\mathsf{UnaryContinuationCategory}^{\uparrow}$ *surfaces of an accepted* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *packet reads only*

$$Q, q_0, F, T, B, H, C, P, N.$$

The shared readback exposes no host evaluator, external state space, trace quotient, hidden transition selector, or transition rule outside the displayed Cont*-labelled table* T*.*

Proof. First assemble the shared carrier surface. Apply Definition 482.1, Definition 482.2, and Definition 482.12 to bind state, initial, accepting, transition, behaviour, transport, route, provenance, and naming reads to $Q, q_0, F, T, B, H, C, P, N$.

Next use the public export and mature consumer completeness, Definition 482.14 and Definition 482.15. These theorems say that the monadic and categorical surfaces consume the same finite packet, not two independent copies with separate operational semantics.

Finally apply the two route rows, Definition 482.16 and Definition 482.17, together with the checked TasteGate marker $BEDC.Derived.ContinuationAutomatonUp.taste_gate$. The shared boundary is therefore exactly $Q, q_0, F, T, B, H, C, P, N$, and no hidden selector, trace quotient, host evaluator, or external state space can be read. □

Closure status for $\mathsf{NameCert}_{\mathsf{ContinuationAutomaton}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ContinuationAutomaton}^{\uparrow}$ packet is generated from finite BHist state rows, an initial row, accepting rows, Mark-labelled transition rows carrying displayed Cont witnesses, behaviour classifier rows, componentwise hsame transports, displayed inspection routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ContinuationAutomaton}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 482.1, Definition 482.2, Definition 482.3, Definition 482.10, Definition 482.11, Definition 482.8, Definition 482.12, Definition 482.9, Definition 482.13, Definition 482.14, and the TasteGate marker bind the public consumer export, transition route closure, acceptance ledger exactness, obligation-closure consumer pack, transport rows, package provenance, local naming row, and the finite automaton carrier.

Formal verification: FormalStatus(NameCert$_{\text{ContinuationAutomaton}\uparrow}$, theoremChecked)
Lean target: `BEDC.Derived.ContinuationAutomatonUp.taste\_gate`
Bridge status: none
Origin: ai
Lean4 ✓ `BEDC.Derived.ContinuationAutomatonUp.taste gate`
Not claimed: This chapter does not close external operational semantics, host configurations, trace quotients, deterministic transition selection, or a public standard bridge.
Upgrade path: No further paper-axis grade is above matureClosure; bridgeChecked verification remains a separate formal-axis target.

Chapter 483

A Concrete Naming Certificate for $\mathsf{SubjectReduction}^{\uparrow}$

The $\mathsf{SubjectReduction}^{\uparrow}$ surface isolates subject reduction from the broader type-classifier packet. It records the finite data by which an accepted source membership row, a visible reduction row, and a target membership row form one Ext-Cont closure packet inside BHist, hsame, Pkg, and local NameCert rows.

The packet consumes classifier membership from chapter 489, the derivation-row surface of chapter 598, and the normal-form boundary rows of chapter 562. The source membership row E_0, displayed reduction row R, and target membership row E_1 are therefore ledgered sibling rows repackaged through Ext, Cont, hsame, Pkg, and local NameCert rather than a kernel-only island or freestanding typing semantics.

Definition 483.1 (SubjectReduction carrier)**.** *A* $\mathsf{SubjectReduction}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (A, B, E_0, R, E_1, L, H, C, P, N)$$

with the following displayed rows:

1. *A is the source term-history row whose type membership is being consumed;*
2. *B is the target term-history row whose type membership is being produced;*
3. *E_0 is the source* Ext *membership row for A;*
4. *R is the* Cont *reduction row from A to B through the displayed mark and local read route;*
5. *E_1 is the target* Ext *membership row for B;*
6. *L is the finite subject-reduction ledger tying E_0, R, and E_1 to the same typing packet;*
7. *H records the componentwise* hsame *transports for the source row, target row, source membership row, reduction row, target membership row, ledger row, package row, and local certificate row;*
8. *C records the* Cont *read routes for source membership, typed reduction, target membership, and replay of the closure packet;*
9. *P is the* Pkg *provenance over* BHist, Ext, Cont, hsame, *the ledger L, and the surrounding* NameCert *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{SubjectReduction}^{\uparrow}}$ *row.*

The carrier contains no host reduction semantics, no semantic equality of terms, no unrecorded conversion procedure, and no global normalization theorem.

Theorem 483.2 (SubjectReduction NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{SubjectReduction}^{\uparrow}}$ *surface for Definition 483.1 consists of four obligations:*

1. *carrier admission for the finite packet* $S = (A, B, E_0, R, E_1, L, H, C, P, N)$*;*
2. Ext-Cont *closure, saying that the accepted source membership row* E_0 *and displayed reduction row* R *expose only the target membership row* E_1*;*
3. *ledger exactness, saying that every public subject-reduction read is recorded in* L *with its source membership, reduction, target membership,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows;*
4. *non-escape from host reduction semantics, semantic equality of terms, unrecorded conversion, hidden normalization, or any classifier not named by the carrier.*

Lean4 ✓ `BEDC.Derived.SubjectReductionUp.SubjectReductionTasteGate single carrier alignment`

Proof. Carrier admission is the finite packet displayed in Definition 483.1. Its rows name the source and target histories, the source and target Ext memberships, the reduction route, the local ledger, transport rows, continuation routes, package provenance, and certificate row.

The closure obligation is the only permitted bridge from E_0 and R to E_1. Since C supplies the read routes and H supplies only componentwise hsame transport, a consumer can replay the subject-reduction packet but cannot replace it by an ambient typing theorem.

The ledger and non-escape obligations follow from the same inventory. Every usable read is first recorded in L, and no carrier coordinate names host reduction semantics, semantic equality, conversion outside the packet, or a global normalization result. □

Theorem 483.3 (SubjectReduction Ext-Cont closure)**.** *Let* $S = (A, B, E_0, R, E_1, L, H, C, P, N)$ *be an accepted* $\mathsf{SubjectReduction}^{\uparrow}$ *carrier. Any public read that starts from the source membership row* E_0 *and the displayed reduction row* R *reaches target membership only as the recorded row* E_1*, transported through the displayed* hsame *rows and replayed through the recorded* Cont *routes.*

Proof. Project the accepted carrier. The source membership data are exactly E_0, and the reduction data are exactly R.

Use the read routes in C to replay the closure packet. The only target membership row named by the packet is E_1, and the only permitted renamings are the componentwise hsame transports in H.

Thus the closure read is an internal Ext-Cont packet. It cannot appeal to semantic equality, host reduction, or an unrecorded conversion procedure. □

Theorem 483.4 (SubjectReduction ledger exactness)**.** *Every accepted subject-reduction read exported by a* $\mathsf{SubjectReduction}^{\uparrow}$ *carrier is recorded in the ledger* L *before it is consumed. The ledger records the source row* A*, target row* B*, source membership* E_0*, reduction row* R*, target membership* E_1*, the relevant* hsame *transport rows, the* Cont *read routes, the* Pkg *provenance, and the local* NameCert *row.*

Proof. Begin with a public subject-reduction read. Carrier projection places the source membership in E_0, the reduction in R, and the target membership in E_1.

The ledger L records these rows together with their source and target histories. It also records the hsame and Cont rows needed to transport and replay the read.

Since P and N are the only package and naming rows, every exported read has the stated provenance. There is no remaining channel through which an unledgered subject-reduction assertion can enter the packet. □

Theorem 483.5 (SubjectReduction non-escape)**.** *An accepted* $\mathsf{SubjectReduction}^{\uparrow}$ *packet exports only the displayed* BHist *rows,* Ext *membership rows,* Cont *reduction row, subject-reduction ledger,* hsame *transports,* Pkg *provenance, and local* NameCert *row of Definition 483.1. It exports no host reduction semantics, semantic equality of terms, hidden conversion relation, erased typing derivation, or global normalization theorem.*

Proof. Inspect the carrier coordinates. They are exactly $A, B, E_0, R, E_1, L, H, C, P, N$, and each coordinate is a displayed history, membership row, reduction row, ledger row, transport row, route row, package row, or naming row.

Apply Definition 483.3 for reduction-facing consumers and Definition 483.4 for provenance-facing consumers. Both routes remain inside the finite carrier inventory.

Therefore the public boundary has no coordinate from which host reduction semantics, semantic equality, hidden conversion, erased typing derivations, or global normalization can be read. □

Theorem 483.6 (SubjectReduction bridge packet scope)**.** *The public carrier,* Ext-Cont *closure, ledger exactness, and non-escape rows form the bridge packet available to standard subject-reduction consumers. The packet exports the finite surface* $S = (A, B, E_0, R, E_1, L, H, C, P, N)$ *and still exports no host type checker, semantic term equality, global normalization, or erased derivation semantics.*

Proof. Start from Definition 483.1. It displays the public packet with source and target histories, source and target Ext rows, the Cont reduction row, ledger, transports, continuations, provenance, and local certificate.

Apply Definition 483.3 to obtain the consumer route from E_0 and R to E_1. Then apply Definition 483.4 to record that route in L with its transport, continuation, package, and local naming rows.

The bridge packet boundary is closed by Definition 483.5. Since the carrier has no host type-checker row, semantic equality row, global normalization row, or erased-derivation row, standard subject-reduction consumers receive only the displayed finite packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{SubjectReduction}^{\uparrow}}$.

Constructive story: A $\mathsf{SubjectReduction}^{\uparrow}$ packet is generated from source and target BHist rows, source and target Ext membership rows, a displayed Cont reduction row, a finite subject-reduction ledger, componentwise hsame transports, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{SubjectReduction}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 483.1, Definition 483.2, Definition 483.3, Definition 483.4, Definition 483.5, and Definition 483.6 close the public finite carrier, Ext-Cont closure, ledger exactness, non-escape rows, bridge packet scope, and mature consumer package named for subject-reduction consumers.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{SubjectReduction}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.SubjectReductionUp.SubjectReductionTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: human

Not claimed: This chapter does not close a host type checker, semantic equality of terms, global normalization, erased derivation semantics, or a public subject-reduction bridge.

Upgrade path: No further theory-axis closure is pending for this chapter; remaining work, if any, belongs to separate bridge-checking infrastructure.

Chapter 484

A Concrete Naming Certificate for $\mathsf{FiniteKernelCategory}^{\uparrow}$

The $\mathsf{FiniteKernelCategory}^{\uparrow}$ packet records the category-shaped reading of the finite BEDC kernel as a concrete naming certificate. Its objects are finite object histories, its arrows are displayed continuation histories, its identity and composition rows are finite Cont ledgers, and its equality rows are hsame comparisons on the same displayed histories. The packet is native to BHist and does not import an external category library, quotient morphism type, or host equality of arrows.

It is the finite, displayed-history specialization of the broader kernel-category surface in chapter 488, and it also consumes the displayed continuation-composition route of chapter 471. Its object and hom readings come from the kernel-category packet, while the identity, composition, associativity, and unit ledgers repackage those rows through finite BHist, hsame, Cont, Pkg, and local NameCert evidence rather than importing an external category library.

Definition 484.1 (Finite-kernel category carrier)**.** *A* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier is a finite packet*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

with the following visible rows:

1. *O is the finite object-history row: every object is a displayed* BHist *object history accepted by the kernel classifier.*
2. *M is the displayed hom-history row: a morphism from object history a to object history b is a finite history f equipped with the displayed continuation ledger relating the endpoint histories.*
3. *I records identity rows, one for each accepted object history, using the empty continuation ledger from the object to itself.*
4. *Q records composition rows: for displayed hom histories $f : a \to b$ and $g : b \to c$, the composite history is accepted only through the finite* Cont *ledger joining the two displayed continuations.*
5. *A records associativity ledgers comparing the two displayed threefold composites by* hsame *after their* Cont *rows are expanded.*
6. *U records left and right unit ledgers comparing empty-continuation composites with the original displayed hom history.*
7. *H stores the componentwise* hsame *transports for object histories, hom histories, identity rows, composition rows, associativity rows, and unit rows.*

8. *C stores the* Cont *routes by which a consumer reads identities, composites, associativity witnesses, and unit witnesses.*
9. *P is the* Pkg *provenance row naming the consumed* BHist, hsame, Cont, *identity, composition, associativity, and unit ledgers.*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteKernelCategory}^{\uparrow}}$ *registration row.*

The local classifier compares carriers only through these displayed rows. It has no coordinate for a global category universe, quotient morphisms, external functor categories, or host equality of arrows.

Lean4 ✓ `BEDC.Derived.FiniteKernelCategoryUp.FiniteKernelCategoryTasteGate single carrier alignment`

Theorem 484.2 (Finite-kernel category NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FiniteKernelCategory}^{\uparrow}}$ *obligation surface consists of five finite rows:*

1. *carrier habitation by the empty object history and by unary object histories with their empty-continuation identity rows;*
2. *classifier stability for object histories, displayed hom histories, identity ledgers, composition ledgers, associativity ledgers, and unit ledgers by componentwise* hsame*;*
3. *identity exactness, requiring each identity row to be the empty* Cont *continuation attached to the displayed object history;*
4. *composition exactness, requiring every public composite to factor through the displayed* Cont *row named in Q;*
5. *ledger non-escape, requiring all public category reads to pass through* BHist, hsame, Cont, Pkg, *and* NameCert, *excluding external category libraries and quotient morphisms.*

Proof. Carrier habitation uses the empty object history and the unary object histories already accepted by the kernel. The empty continuation gives the identity row, so the object and identity coordinates are inhabited inside the finite carrier.

Classifier stability is componentwise. Transport object histories and hom histories by the displayed hsame rows, then transport the identity, composition, associativity, and unit ledgers along the same endpoint comparisons.

Identity and composition exactness are projections of the carrier. The identity coordinate is I, while each composite is read through the Cont row stored in Q before it can be consumed as a displayed hom history.

The non-escape row follows by inspecting K. Since every public route is stored in H, C, P, and N, a consumer cannot read an external category library, quotient morphism, or host arrow equality from this certificate. □

Lean4 ✓ `BEDC.Derived.FiniteKernelCategoryUp.FiniteKernelCategoryNamecertObligations`

Theorem 484.3 (Finite-kernel category object and hom boundary)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier. Every accepted object read is exposed only through the object-history row O, and every accepted hom read is exposed only through the hom-history row M. Endpoint compatibility for those hom reads is guarded by the displayed* BHist *histories, the componentwise* hsame *rows in H, and the* Cont *rows in C.*

Proof. Project the carrier $K = (O, M, I, Q, A, U, H, C, P, N)$. The carrier definition makes O the only object-history coordinate and M the only hom-history coordinate.

Apply Definition 484.2. Carrier exposure and classifier stability transport object histories and hom histories by the displayed hsame rows, while composition exactness and ledger non-escape keep every endpoint read inside the visible BHist and Cont ledgers.

Finally repack the result as a boundary statement for consumers. Since no quotient morphism type or host arrow equality occurs in K, object and hom reads cannot escape the displayed O, M, H, C, P, N surface. □

Theorem 484.4 (Finite-kernel category identity and composition boundary)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted FiniteKernelCategory$^{\uparrow}$ *carrier. Identity reads are exactly the rows I, and composition reads are exactly the rows Q. Associativity and unit support for those reads is supplied only by A, U, H, C, P, N.*

Proof. Project the displayed packet. The identity coordinate is I and the composition coordinate is Q, so the public identity and binary-composition reads are not separate host operations.

Use the obligation surface of Definition 484.2. Identity exactness identifies each row of I with the empty Cont continuation attached to an accepted object history, and composition exactness identifies each composite with the displayed Cont ledger stored in Q.

Now apply Definition 484.6. The associativity and unit rows are precisely A and U, transported by H and consumed through C with provenance P and local name N. □

Theorem 484.5 (Finite-kernel category ledger non-escape boundary)**.** *Every* Functor$^{\uparrow}$, NatTrans$^{\uparrow}$, *or* Cat$^{\uparrow}$ *consumer of an accepted* FiniteKernelCategory$^{\uparrow}$ *carrier receives the finite object, hom, identity, composition, associativity, unit, transport, continuation, provenance, and local naming rows $O, M, I, Q, A, U, H, C, P, N$. It receives no quotient morphism type, host arrow equality, functor-category object, or external category library.*

Proof. Start with Definition 484.3 and Definition 484.4. Together they expose the object, hom, identity, composition, associativity, and unit rows as the concrete carrier surface.

Apply Definition 484.7. Functor and natural-transformation consumers read preservation and naturality data only after the finite category rows have been exported through H, C, P, N.

Finally apply Definition 484.8. The same finite surface is the Cat$^{\uparrow}$ interface, and the carrier has no coordinate for quotient morphisms, host arrow equality, functor-category objects, or external category libraries. □

Lean4 ✓ `BEDC.Derived.FiniteKernelCategoryUp.FiniteKernelCategoryLedgerNonescapeBoundary`

Theorem 484.6 (Finite-kernel category composition laws)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted FiniteKernelCategory$^{\uparrow}$ *carrier. The identity, binary composition, associativity, and left and right unit laws exported by K are exactly the displayed ledgers I, Q, A, and U, transported through H and consumed through C. No category law is discharged by ambient category theory or by quotienting hom histories.*

Proof. Read the law rows from Definition 484.1. The identity law is stored in I, binary composition in Q, associativity in A, and the left and right unit laws in U.

Transport compatibility is supplied by H. It keeps endpoints, hom histories, and law ledgers aligned under hsame, so the same displayed rows remain the law witnesses after carrier transport.

Consumer access is supplied by C. Since the carrier contains no ambient category object and no quotient morphism coordinate, every law exported by K is one of the displayed finite ledgers. □

Theorem 484.7 (Finite-kernel functor and natural-transformation handoff)**.** *Every* $\mathsf{Functor}^{\uparrow}$ *or* $\mathsf{NatTrans}^{\uparrow}$ *consumer of a* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier receives only the finite object-history row O, displayed hom-history row M, empty-continuation identities I, displayed* Cont *composites Q, associativity and unit ledgers A and U, and the* hsame*,* Cont*,* Pkg*, and* NameCert *provenance rows H, C, P, N. The handoff does not export host functor categories, quotient morphisms, naturality modulo external equality, or any library category object.*

Proof. Start with the NameCert obligations of Definition 484.2. They bind carrier habitation, classifier stability, identity exactness, composition exactness, and ledger non-escape to the same finite packet.

A $\mathsf{Functor}^{\uparrow}$ consumer reads objects and hom histories through O and M, then reads identity and composition preservation against I and Q. The associativity and unit side conditions are the displayed ledgers A and U transported by H.

A $\mathsf{NatTrans}^{\uparrow}$ consumer uses the same rows for component and naturality reads. The only public routes are the continuations in C and the provenance in P and N, so the handoff remains a BEDC-native certificate surface. □

Theorem 484.8 (Finite-kernel category interface handoff)**.** *Every accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier exports a* $\mathsf{Cat}^{\uparrow}$*-readable interface only through the displayed object-history row O, hom-history row M, identity row I, composition row Q, associativity and unit ledgers A, U, and structural rows H, C, P, N of Definition 484.1. Any* $\mathsf{Functor}^{\uparrow}$ *or* $\mathsf{NatTrans}^{\uparrow}$ *consumer must first read that* $\mathsf{Cat}^{\uparrow}$ *boundary before it reads preservation or naturality data. The handoff exports no quotient morphism type, host equality of arrows, functor category, or external category library.*

Proof. Project the finite carrier $K = (O, M, I, Q, A, U, H, C, P, N)$. The object and hom surfaces are the rows O and M, while the public identity and composite reads are exactly I and Q.

Use Definition 484.6 for the identity, composition, associativity, and unit rows. It identifies the category laws with I, Q, A, U transported through H and consumed through C, so the $\mathsf{Cat}^{\uparrow}$ interface is the displayed finite ledger of chapter 61.

Now apply Definition 484.7. A $\mathsf{Functor}^{\uparrow}$ consumer as in chapter 62 and a $\mathsf{NatTrans}^{\uparrow}$ consumer as in chapter 63 read only after that boundary has exposed objects, hom histories, identities, composites, associativity, and unit ledgers.

The excluded structures are not carrier coordinates. Since K contains no quotient morphism type, host arrow equality, functor category, or library category object, no continuation route or provenance row can export one. □

Theorem 484.9 (Finite-kernel category TasteGate obligation handoff)**.** *For an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier*

$$K = (O, M, I, Q, A, U, H, C, P, N),$$

the finite object, hom, identity, composition, associativity, unit, transport, continuation, provenance, and local NameCert *rows form the paper-side obligation handoff consumed by the existing*

TasteGate single-carrier alignment marker. Any consumer of the TasteGate row must keep the displayed category rows $O, M, I, Q, A, U, H, C, P, N$ and cannot replace them by quotient morphisms, host arrow equality, or an external category library.

Proof. Project the carrier $K = (O, M, I, Q, A, U, H, C, P, N)$. The displayed rows are exactly the object, hom, identity, composition, associativity, unit, transport, continuation, provenance, and local naming rows named in Definition 484.1.

Apply Definition 484.2. The five NameCert obligations bind habitation, classifier stability, identity exactness, composition exactness, and ledger non-escape to the same displayed rows.

Use Definition 484.6 and Definition 484.8. They identify the category laws and the public $\mathsf{Cat}^{\uparrow}$ interface with I, Q, A, U, H, C, P, N over the same object and hom rows O, M.

The TasteGate marker is attached immediately after the carrier definition, so its single-carrier alignment reads the same displayed packet. A consumer that replaces these rows by quotient morphisms, host arrow equality, or an external category library no longer consumes the $\mathsf{FiniteKernelCategory}^{\uparrow}$ carrier. □

Theorem 484.10 (Finite-kernel category carrier scope)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier. Object, hom, identity, and composition reads are grounded only in the displayed rows $O, M, I, Q, A, U, H, C, P, N$: objects are read from O, hom histories from M, identities from I, composites from Q, and their law and transport support from A, U, H, C, P, N.*

Proof. Project the carrier definition. The object coordinate is O, the hom-history coordinate is M, the identity coordinate is I, and the composition coordinate is Q.

Apply Definition 484.2. Carrier habitation and classifier stability keep object and hom reads inside finite BHist histories and componentwise hsame transport.

Next apply Definition 484.6. It identifies the category-law surface with I, Q, A, U transported through H and consumed through C.

Finally use Definition 484.8. The exported category interface is the same finite packet, so no object, hom, identity, or composition read is available outside the displayed rows. □

Theorem 484.11 (Finite-kernel category package and NameCert scope)**.** *For every accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier, package provenance and local naming expose exactly the BEDC rows $O, M, I, Q, A, U, H, C, P, N$. They expose no quotient morphism, host equality of arrows, functor-category object, or external category library.*

Proof. Use the carrier scope of Definition 484.10. It binds the public object, hom, identity, composition, law, transport, and continuation reads to the displayed rows.

Apply the NameCert obligations of Definition 484.2. The provenance row P and local naming row N name the same BHist, hsame, Cont, identity, composition, associativity, and unit ledgers.

Now apply Definition 484.5. Since quotient morphisms, host arrow equality, functor-category objects, and external category libraries are not coordinates of K, package provenance and local naming cannot expose them. □

Theorem 484.12 (Finite-kernel category TasteGate scope)**.** *The existing* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *TasteGate marker consumes the same finite packet $O, M, I, Q, A, U, H, C, P, N$. It cannot be read after replacing any row by an external category object, quotient morphism, host arrow equality, or functor-category object.*

Proof. Start with Definition 484.9. The TasteGate handoff is explicitly the finite object, hom, identity, composition, associativity, unit, transport, continuation, provenance, and local NameCert packet.

Use Definition 484.10 to identify the carrier rows consumed by that handoff. The same $O, M, I, Q, A, U, H, C, P, N$ rows ground every category-shaped read.

Then use Definition 484.11. External category objects, quotient morphisms, host arrow equality, and functor-category objects are absent from the package and naming surface.

Therefore replacing any displayed row by one of those external objects leaves the accepted carrier. The TasteGate marker has no route from such a replacement back to $\mathsf{FiniteKernelCategory}^{\uparrow}$. □

Theorem 484.13 (Finite-kernel category root obligation scope)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier. Its root obligation scope is exactly the BEDC object and hom boundary* O, M*, the identity and composition rows* I, Q*, the associativity and unit rows* A, U*, the componentwise* hsame *transports* H*, the displayed* Cont *consumer routes* C*, the* Pkg *provenance row* P*, and the local* NameCert *row* N*. The scope is readable by* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, and* $\mathsf{NatTrans}^{\uparrow}$ *consumers only through those rows and exports no quotient morphism, host arrow equality, functor-category object, or external category library.*

Proof. Start with Definition 484.10. It binds object, hom, identity, and composition reads to O, M, I, Q, H, C, P, N over finite BHist, hsame, and Cont rows.

Apply Definition 484.6. The associativity and unit obligations are the displayed rows A and U, transported through H and consumed through C with the same provenance and local name.

Finally use Definition 484.5 and Definition 484.12. Category-shaped downstream consumers receive only the finite packet surface, and the TasteGate handoff has no route back from quotient morphisms, host equality, functor-category objects, or an external category library. □

Theorem 484.14 (Finite-kernel category scoped closure package)**.** *For every accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier*

$$K = (O, M, I, Q, A, U, H, C, P, N),$$

the scoped package consists exactly of the object row O*, hom row* M*, identity row* I*, composition row* Q*, associativity row* A*, unit row* U*, transport row* H*, continuation row* C*, provenance row* P*, and local naming row* N*. These rows are bound to the same* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*, and existing* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *TasteGate marker. A* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, or* $\mathsf{NatTrans}^{\uparrow}$ *consumer may cite the root package only by preserving this whole row family.*

The scoped package introduces no external category object, quotient morphism, host arrow equality, functor-category object, or ambient category library.

Proof. Start with Definition 484.2. Carrier exposure, classifier stability, identity exactness, composition exactness, and ledger non-escape already bind $O, M, I, Q, A, U, H, C, P, N$ to the displayed finite BHist, hsame, Cont, Pkg, and NameCert surface.

Next apply Definition 484.6. It makes associativity and unit part of the same law ledger as identity and composition, transported through H and consumed through C with provenance P and local name N.

Finally use Definition 484.13 and Definition 484.9. The root scope is the exact row family read by downstream categorical consumers, and the TasteGate handoff consumes the same single-carrier

packet. By Definition 484.5, no external category object or quotient morphism can replace any row. □

Theorem 484.15 (Finite-kernel category row scope exhaustion)**.** *Let $K = (O, M, I, Q, A, U, H, C, P, N)$ be an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier. Every root-obligation read of K is exhausted by the rows $O, M, I, Q, A, U, H, C, P, N$ over the displayed* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*, and existing TasteGate support. In particular, object, hom, identity, composition, associativity, unit, transport, continuation, provenance, and local naming data cannot be distributed across a larger ambient categorical carrier before a consumer reads the* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *root package.*

Proof. First apply Definition 484.13. It states that the root obligation surface is exactly the object and hom boundary, identity and composition rows, associativity and unit rows, componentwise transport, continuation, provenance, and local naming rows.

Use Definition 484.17. The handoff to $\mathsf{Cat}^{\uparrow}$, $\mathsf{Functor}^{\uparrow}$, $\mathsf{NatTrans}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert consumers is the single package $O, M, I, Q, A, U, H, C, P, N$, not a family of detachable ambient objects.

Now apply Definition 484.8 and Definition 484.7. Category, functor, and natural-transformation consumers read only after this finite package has exposed the row family that supports their preservation and naturality data.

The exhaustion is closed by Definition 484.5. Since the carrier exports no quotient morphism, host arrow equality, functor-category object, or external category library, no additional root row remains outside the displayed package. □

Theorem 484.16 (Finite-kernel category public consumer boundary)**.** *A public consumer may treat the* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *root package as scoped only when it reads object, hom, identity, composition, associativity, unit, transport, continuation, provenance, local naming, and the existing TasteGate marker through the same* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. This is the consumer boundary for* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, and* $\mathsf{NatTrans}^{\uparrow}$ *handoffs: the consumer receives a finite BEDC package, not a verified bridge claim and not an imported external category object.*

Proof. Begin with Definition 484.14. It identifies the scoped row package and binds it to the existing TasteGate support over the displayed BEDC support rows.

Next use Definition 484.15. A consumer that has not read all ten rows has not exhausted the root obligation surface, while a consumer that has read them has the finite package required for the downstream categorical interface.

Finally apply Definition 484.8 together with Definition 484.7. These handoffs make $\mathsf{Cat}^{\uparrow}$, $\mathsf{Functor}^{\uparrow}$, and $\mathsf{NatTrans}^{\uparrow}$ consumers depend on the finite package before preservation or naturality data is read. The ledger non-escape theorem and TasteGate scope then exclude quotient morphisms, external category objects, aggregate bridge claims, and any imported category library from the public consumer boundary. □

Theorem 484.17 (Finite-kernel category root handoff package)**.** *For every accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier $K = (O, M, I, Q, A, U, H, C, P, N)$, the root handoff package to* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*,* $\mathsf{NatTrans}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *consumers is the single package*

$$O, M, I, Q, A, U, H, C, P, N.$$

The package first exposes the object and hom boundary, then the identity and composition ledgers, then the associativity and unit rows, and finally the transport, continuation, provenance, and local naming rows. It does not expose any consumer route that skips P, N or replaces the local NameCert rows by a host category object.

Proof. Use Definition 484.2. The obligation surface already lists carrier habitation, classifier stability, identity exactness, composition exactness, and ledger non-escape for the same displayed rows.

Next apply Definition 484.8. The $\mathsf{Cat}^{\uparrow}$ interface is the displayed finite ledger, so every functor or natural-transformation consumer reads the object, hom, identity, composition, associativity, and unit rows before preservation or naturality data.

The package and naming rows are fixed by Definition 484.11. Since P and N name only the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ packet, the root handoff cannot be detached from the local certificate. □

Theorem 484.18 (Finite-kernel category object row totality)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier. Every accepted object read of K factors through the displayed object-history row O. The factorization keeps the object witness in the same* BHist *history, componentwise* hsame *transport row H, displayed* Cont *consumer row C,* Pkg *provenance row P, and local* $\mathsf{NameCert}$ *row N; no category, functor, or natural-transformation consumer can read an object of K outside that object-history row.*

Proof. Read the carrier through Definition 484.1. The only object coordinate of the accepted packet is O, and its route is presented together with the transport, continuation, provenance, and local naming rows.

Apply Definition 484.2. Carrier habitation and classifier stability bind the accepted object read to the displayed BHist row and to the componentwise hsame transport that keeps the same packet visible to downstream consumers.

The law rows do not create another object source. By Definition 484.6, identity, composition, associativity, and unit use the displayed categorical rows over the same object boundary, and Definition 484.5 prevents replacing that boundary by host object equality, quotient objects, or an external category library. □

Theorem 484.19 (Finite-kernel category morphism route stability)**.** *For every accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier $K = (O, M, I, Q, A, U, H, C, P, N)$, each accepted hom read and each endpoint transport used by a* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, or* $\mathsf{NatTrans}^{\uparrow}$ *consumer remains inside the displayed morphism route M, H, C, P, N. In particular, source and target movement is recorded by the same componentwise* hsame *transport, displayed* Cont *continuation, package provenance, and local name that expose the hom history, rather than by host arrow equality or a quotient morphism.*

Proof. Start from Definition 484.1. The hom row is M, and the only endpoint-transport data attached to it are the displayed rows H, C, P, N.

Use Definition 484.2. Classifier stability and composition exactness force hom histories and their endpoints to travel through the same componentwise hsame and Cont rows before the packet is consumed.

The category-law surface preserves that route. Apply Definition 484.6 to keep identity, composition, associativity, and unit reads over the same hom and endpoint rows, then use Definition 484.5 to exclude any replacement by host arrows, quotient morphisms, or external categorical equality. □

Theorem 484.20 (Finite-kernel category composition ledger nonescape)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier. Every identity, composition, associativity, or unit consumer reads only the displayed ledger rows* I, Q, A, U, H, C, P, N*. These consumers cannot replace the ledger by quotient morphisms, host arrow equality, functor-category equality, or an external category-library proof of the same laws.*

Proof. Project the ledger coordinates of Definition 484.1. Identities are carried by I, composites by Q, associativity by A, and unit laws by U, all with the same transport, continuation, provenance, and local naming rows.

Apply Definition 484.2. Identity exactness, composition exactness, and ledger non-escape are obligations of the same local NameCert surface, so a law consumer cannot detach I, Q, A, U from H, C, P, N.

Finally use Definition 484.6. It makes the displayed identity, composition, associativity, and unit rows the law surface consumed by categorical readers. The boundary theorem, Definition 484.5, rules out a second route through quotient morphisms, host arrow equality, or an ambient category library. □

Theorem 484.21 (Finite-kernel category root downstream unblock)**.** *Every downstream categorical consumer that asks for a finite BEDC category, functor source, natural-transformation source, or TasteGate handoff from* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *is unblocked by the root package*

$$O, M, I, Q, A, U, H, C, P, N$$

provided it consumes the object and hom boundary, identity and composition rows, ledger non-escape clause, and TasteGate handoff together. A consumer that omits one of these rows has not consumed the $\mathsf{FiniteKernelCategory}^{\uparrow}$ *root obligation surface.*

Proof. First build the categorical boundary. Apply Definition 484.13 to obtain the exact object, hom, identity, composition, associativity, unit, transport, continuation, provenance, and naming surface.

Next build the handoff package. Apply Definition 484.17; it orders the $\mathsf{Cat}^{\uparrow}$, $\mathsf{Functor}^{\uparrow}$, $\mathsf{NatTrans}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ reads through the same finite rows.

Finally compose with Definition 484.9. The TasteGate side consumes the same single-carrier packet, so a downstream route that preserves all listed rows is unblocked, while a route omitting object/hom data, identity/composition data, ledger non-escape, or TasteGate handoff leaves the root obligation surface. □

Theorem 484.22 (Finite-kernel category downstream root package)**.** *For every accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier* $K = (O, M, I, Q, A, U, H, C, P, N)$*, the downstream root package for* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, and* $\mathsf{NatTrans}^{\uparrow}$ *consumers is exactly the displayed row sequence*

$$O, M, I, Q, A, U, H, C, P, N.$$

It consists of the object and hom boundary, identity and composition rows, associativity and unit rows, componentwise hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}$ *row. No downstream categorical consumer receives a smaller root package by replacing those rows with quotient morphisms, host arrow equality, functor-category objects, or an external category library.*

Proof. Start with the root obligation scope, Definition 484.13. It identifies $O, M, I, Q, A, U, H, C, P, N$ as the complete finite surface read by $\mathsf{Cat}^{\uparrow}$, $\mathsf{Functor}^{\uparrow}$, and $\mathsf{NatTrans}^{\uparrow}$ consumers.

Next apply the root handoff package and category interface handoff. Theorem 484.17 orders the object, hom, identity, composition, law, transport, continuation, provenance, and naming rows, while Definition 484.8 makes the same rows the categorical interface for downstream reads.

Finally use Definition 484.5. Since the ledger boundary exports no quotient morphism, host arrow equality, functor-category object, or external category library, the downstream package is exactly the displayed row sequence and not a larger ambient categorical object. □

Theorem 484.23 (Finite-kernel category hom endpoint transport determinacy)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier. Any accepted hom-history read transported by componentwise* hsame *preserves the displayed source and target object rows named by the same packet. A* $\mathsf{Functor}^{\uparrow}$ *or* $\mathsf{NatTrans}^{\uparrow}$ *consumer cannot reuse the hom row* M *with different endpoints unless it also transports the corresponding object rows through the same* H, C, P, N *packet.*

Proof. Start with the object and hom boundary, Definition 484.3. It makes the object rows O and hom rows M the only displayed endpoints and arrows available to a category-shaped consumer.

Apply the identity and composition boundary together with the composition laws, Definition 484.4 and Definition 484.6. Identities and composites are stored in I, Q, A, U only after their source and target object rows have been kept aligned through the same transport and continuation surface.

Finally use the category interface handoff and ledger non-escape boundary, Definition 484.8 and Definition 484.5. A functor or natural-transformation reader therefore receives endpoint data only as part of the displayed $O, M, I, Q, A, U, H, C, P, N$ packet. Reusing M with different endpoints would require an extra host arrow equality or quotient morphism, and those coordinates are not exported by the carrier. □

Theorem 484.24 (Finite-kernel categorical row readback)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier. Every* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, or* $\mathsf{NatTrans}^{\uparrow}$ *readback of* K *factors through exactly the displayed rows* $O, M, I, Q, A, U, H, C, P, N$*: category reads consume object, hom, identity, composition, associativity, and unit rows; functor reads consume the same rows before preservation data; natural-transformation reads consume the same rows before component and naturality data. No readback may replace those rows by quotient morphisms, host arrow equality, a functor-category object, or an external category library.*

Proof. Project the carrier of Definition 484.1. The accepted packet has only the rows $O, M, I, Q, A, U, H, C, P, N$ available for categorical consumers.

Apply the category interface handoff, Definition 484.8. It makes $O, M, I, Q, A, U, H, C, P, N$ the $\mathsf{Cat}^{\uparrow}$-readable boundary and forces $\mathsf{Functor}^{\uparrow}$ and $\mathsf{NatTrans}^{\uparrow}$ consumers to read that boundary first.

Use the functor and natural-transformation handoff together with the ledger non-escape theorem, Definition 484.7 and Definition 484.5. The handoff supplies no quotient morphism, host equality, functor-category object, or external library coordinate, so every readback factors through exactly the finite BEDC row sequence. □

Theorem 484.25 (Finite-kernel functor identity preservation)**.** *Every* $\mathsf{Functor}^{\uparrow}$ *consumer of an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier* $K = (O, M, I, Q, A, U, H, C, P, N)$ *preserves the displayed identity row* I *through the same object, hom, identity, composition, associativity, unit, transport, continuation, provenance, and naming rows* $O, M, I, Q, A, U, H, C, P, N$*. The preservation obligation is a BEDC row obligation and is not discharged by a quotient morphism, host arrow equality, external category library, or functor-category object.*

Proof. Start with the category, functor, and natural-transformation readback theorem, Definition 484.24. It makes the accepted consumer read the finite row sequence $O, M, I, Q, A, U, H, C, P, N$ rather than an ambient category object.

Apply the functor and natural-transformation handoff, Definition 484.7. A $\mathsf{Functor}^{\uparrow}$ consumer can inspect identity preservation only after the identity row I has been exported with the carrier rows that determine its source and target histories.

Finally use the composition provenance factorization and ledger non-escape boundary, Definition 484.28 and Definition 484.5. The provenance and local naming rows keep the preservation witness inside the displayed BEDC packet, so no quotient or host equality route can replace I. □

Theorem 484.26 (Finite-kernel functor composition preservation)**.** *Every* $\mathsf{Functor}^{\uparrow}$ *consumer of an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier* $K = (O, M, I, Q, A, U, H, C, P, N)$ *preserves the displayed composition row* Q *through the same row sequence* $O, M, I, Q, A, U, H, C, P, N$*. Composition preservation may use the associativity row* A*, the unit row* U*, componentwise transport* H*, continuation consumption* C*, provenance* P*, and local naming* N*, but it has no separate quotient morphism, host arrow equality, external category library, or functor-category object.*

Proof. Read the accepted consumer through Definition 484.24. The composition preservation input is the displayed row Q in the same packet as $O, M, I, A, U, H, C, P, N$.

Use Definition 484.28. It factors composition, associativity, and unit consumption through Q, A, U, H, C, P, N, so a functor cannot preserve composition by bypassing the provenance row or the local $\mathsf{NameCert}$ row.

Now apply Definition 484.7 and Definition 484.5. The handoff exports the displayed category-law rows to $\mathsf{Functor}^{\uparrow}$ consumers, and the boundary excludes quotient morphisms, host equality, external category libraries, and functor-category objects from the preservation surface. □

Theorem 484.27 (Finite-kernel natural-transformation square boundary)**.** *Every* $\mathsf{NatTrans}^{\uparrow}$ *consumer of an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier* $K = (O, M, I, Q, A, U, H, C, P, N)$ *reads the naturality square boundary through the displayed object row* O*, hom row* M*, identity row* I*, composition row* Q*, associativity and unit rows* A, U*, componentwise transport* H*, continuation row* C*, provenance row* P*, and local naming row* N*. The square has no boundary edge supplied by quotient morphisms, host arrow equality, an external category library, or a functor-category object.*

Proof. Begin with the readback theorem, Definition 484.24. It routes $\mathsf{NatTrans}^{\uparrow}$ consumers through the finite row sequence, so the naturality square boundary is assembled from displayed object and hom histories and their identity and composition rows.

Apply the functor and natural-transformation handoff, Definition 484.7. The handoff places naturality inspection after the category rows O, M, I, Q, A, U and their transport, continuation, provenance, and naming rows have been exported.

Finish with composition provenance factorization and ledger non-escape, Definition 484.28 and Definition 484.5. These results keep every boundary edge inside $O, M, I, Q, A, U, H, C, P, N$ and block any external category-library or functor-category replacement. □

Theorem 484.28 (Finite-kernel composition provenance factorization)**.** *For every accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier* $K = (O, M, I, Q, A, U, H, C, P, N)$*, composition, associativity, and unit consumption factor through the composition row* Q*, associativity row* A*, unit row* U*, componentwise transport row* H*, displayed continuation row* C*, package provenance row* P*, and local* $\mathsf{NameCert}$ *row* N*. A consumer cannot skip the provenance row or the local NameCert row while still consuming the category-law surface of* K*.*

Proof. Start with the law rows of Definition 484.1. The composition row is Q, associativity is recorded in A, and the left and right unit laws are recorded in U.

Apply the composition laws, Definition 484.6. They require the law rows to be transported through H and consumed through C, so the laws are not detached from the displayed packet.

Finally use the interface handoff and hom endpoint transport determinacy, Definition 484.8 and Definition 484.23. These force categorical consumers to keep endpoints, hom histories, law rows, provenance, and local naming in the same Q, A, U, H, C, P, N factorization. □

Theorem 484.29 (Finite-kernel bridge consumer nonescape)**.** *Every bridge-facing categorical consumer of an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier receives only the finite BEDC packet*

$$O, M, I, Q, A, U, H, C, P, N.$$

It receives no quotient morphism, host arrow equality, functor-category object, external category library, or bridge route that reads category, functor, or natural-transformation data outside the displayed rows.

Proof. First read the carrier and category interface through Definition 484.1 and Definition 484.8. The bridge consumer starts from the same object, hom, identity, composition, associativity, unit, transport, continuation, provenance, and naming rows.

Next apply Definition 484.7. It keeps functor and natural-transformation consumers on the same finite row sequence before preservation, components, or naturality are inspected.

Finish with the ledger non-escape boundary and endpoint determinacy, Definition 484.5 and Definition 484.23. Since the carrier has no quotient, host equality, functor-category, or external library coordinate, a bridge-facing consumer cannot export one. □

Theorem 484.30 (Finite-kernel category carrier habitation scope)**.** *For an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier*

$$K = (O, M, I, Q, A, U, H, C, P, N),$$

carrier habitation is grounded exactly by the finite object-history row O*, the displayed hom-history row* M*, the empty-continuation identity row* I*, and the local* $\mathsf{NameCert}$ *row* N*. The habitation witness uses no quotient morphism, host category object, ambient arrow equality, or external category library object.*

Proof. Start from the carrier coordinates in Definition 484.1. The object carrier is presented by finite BHist histories in O, the hom carrier by displayed histories in M, identities by the empty Cont continuations recorded in I, and local naming by N.

Use the obligation surface of Definition 484.2. Its habitation row binds those object, hom, identity, and local naming coordinates to the same finite packet, so there is no second carrier source to read.

Finally apply the root obligation boundary, Definition 484.13. That boundary exports only $O, M, I, Q, A, U, H, C, P, N$ to categorical consumers; quotient morphisms, host category objects, and ambient category-library objects are not coordinates of the accepted carrier. □

Theorem 484.31 (Finite-kernel category classifier stability scope)**.** *For an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier*

$$K = (O, M, I, Q, A, U, H, C, P, N),$$

classifier transport is exactly the componentwise hsame *row* H *over the object, hom, identity, composition, associativity, and unit ledgers. The transport is consumed only through the displayed continuation row* C*, the package provenance row* P*, and the local* NameCert *row* N*.*

Proof. Read the classifier coordinates from Definition 484.1. The row H is the componentwise hsame transport for the displayed object and hom histories and for the ledger rows that depend on them.

Use Definition 484.6 to identify the dependent law surface. Identity, composition, associativity, and unit reads are the rows I, Q, A, U, so classifier stability acts on the full law ledger rather than on a detached ambient category object.

Now apply Definition 484.2 and Definition 484.13. The same componentwise transport is consumed through C and named through P, N; no consumer receives an alternate classifier route outside Cont, Pkg, and NameCert. □

Theorem 484.32 (Finite-kernel category identity-composition exactness scope)**.** *For an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier*

$$K = (O, M, I, Q, A, U, H, C, P, N),$$

identity exactness is the row I *and composition exactness is the row* Q*. Associativity and unit support enter only through* A *and* U*, transported by* H*, consumed through* C*, recorded by* P*, and named locally by* N*.*

Proof. Project the carrier of Definition 484.1. The identity row is I, and the composition row is Q; both are displayed BEDC rows over the same object and hom histories.

Apply Definition 484.2. Its identity-exactness and composition-exactness obligations attach I and Q to the same finite BHist, hsame, Cont, Pkg, and NameCert packet.

Finally use Definition 484.6 and Definition 484.13. Associativity and unit support are precisely A, U, H, C, P, N, so exactness cannot be discharged by an external composition law or by a quotient morphism outside the displayed carrier. □

Theorem 484.33 (Finite-kernel displayed source totality)**.** *Every accepted finite-kernel category consumer must display the complete row family*

$$O, M, I, Q, A, U, H, C, P, N$$

of the carrier $K = (O, M, I, Q, A, U, H, C, P, N)$*. The object and hom rows are read over finite* BHist *histories, the identity, composition, associativity, and unit rows are read through* hsame *and* Cont*, the provenance row is read through* Pkg*, and the local naming row is read through* NameCert*. No downstream* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, or* $\mathsf{NatTrans}^{\uparrow}$ *consumer has accepted the root package until all ten rows are displayed together.*

Proof. Project the carrier of Definition 484.1. Its visible source is the ten-row packet $O, M, I, Q, A, U, H, C, P, N$, with no separate coordinate for a host category object or a quotient morphism carrier.

Apply the NameCert obligations, Definition 484.2. They bind carrier habitation, classifier stability, identity exactness, composition exactness, and ledger non-escape to the same BHist, hsame, Cont, Pkg, and NameCert rows.

Finally use the root obligation scope, Definition 484.13. It identifies that same displayed row family as the only source package exported to categorical consumers, so a partial row read is not an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ consumer read. □

Theorem 484.34 (Finite-kernel composite ledger determinacy)**.** *Let $K = (O, M, I, Q, A, U, H, C, P, N)$ be an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ carrier. If two composite reads have the same displayed object rows O, hom rows M, identity row I, composition row Q, continuation row C, provenance row P, and local naming row N, then they determine the same public ledger read of K. The determinacy is internal to the displayed carrier: it uses the composition ledger nonescape boundary and the identity-composition exactness scope, not an external category-library equality.*

Proof. First read the two composites through the displayed carrier. The shared object and hom rows fix the endpoints, while the shared identity and composition rows fix the BEDC-native law surface.

Apply the identity-composition exactness scope, Definition 484.32. It identifies identity exactness with I and composition exactness with Q, with associativity, unit, transport, continuation, provenance, and naming supplied by the same packet.

Finish with the composition ledger nonescape theorem, Definition 484.20. Since a public composite cannot leave Q, C, P, N for a quotient morphism, host arrow equality, or external category object, the two reads expose the same public ledger. □

Theorem 484.35 (Finite-kernel natural-transformation consumer scope)**.** *The downstream $\mathsf{Cat}^{\uparrow}$, $\mathsf{Functor}^{\uparrow}$, and $\mathsf{NatTrans}^{\uparrow}$ consumers may read the $\mathsf{FiniteKernelCategory}^{\uparrow}$ root package only through the full displayed row family*

$$O, M, I, Q, A, U, H, C, P, N$$

together with the existing $\mathsf{FiniteKernelCategory}^{\uparrow}$ TasteGate marker. They may not read it through quotient morphisms, host arrow equality, functor-category objects, or an external category library.

Proof. Start with the displayed source totality theorem, Definition 484.33. It forces every accepted downstream consumer to display the complete ten-row source package over BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$.

Next apply the TasteGate handoff, Definition 484.9. The existing TasteGate marker consumes the same single-carrier alignment, so the consumer scope includes that marker only as a read of the displayed package.

Finally use the category, functor, and natural-transformation readback theorem, Definition 484.24. It routes all three downstream consumers through the same finite row sequence and excludes quotient morphisms, host arrow equality, functor-category objects, and external category libraries from the public read. □

Theorem 484.36 (Finite-kernel category public export interface)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ carrier. The public export of K is exactly the displayed row family $O, M, I, Q, A, U, H, C, P, N$. It is read first as the $\mathsf{Cat}^{\uparrow}$ interface carried by the finite kernel package, and then as the required source boundary for every downstream $\mathsf{Functor}^{\uparrow}$ and $\mathsf{NatTrans}^{\uparrow}$ consumer. No quotient morphism, host arrow equality, functor-category object, or external category library is part of that public export.

Proof. Start with the category interface handoff, Definition 484.8. It identifies the displayed rows $O, M, I, Q, A, U, H, C, P, N$ as the $\mathsf{Cat}^{\uparrow}$ interface of the accepted finite-kernel carrier.

Next apply the category, functor, and natural-transformation row readback, Definition 484.24. It makes the same row family the source boundary read by $\mathsf{Functor}^{\uparrow}$ and $\mathsf{NatTrans}^{\uparrow}$ consumers after the category interface has been exposed.

The downstream scope is fixed by Definition 484.35. It permits those consumers to read only the complete displayed package together with the existing TasteGate marker.

Finally apply the bridge consumer nonescape boundary, Definition 484.29. Since bridge consumers cannot extract quotient morphisms, host arrow equality, functor-category objects, or an external category library, the displayed row family is the whole public export. □

Theorem 484.37 (Finite-kernel category standard bridge surface)**.** *Let*

$$K = (O, M, I, Q, A, U, H, C, P, N)$$

be an accepted $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier. The standard bridge surface for K is the single displayed BEDC packet consisting of the kernel-category object and hom rows O, M, the unary-continuation identity and composition rows I, Q, the associativity and unit ledgers A, U, and the structural rows H, C, P, N. This surface is read as a* $\mathsf{Cat}^{\uparrow}$ *interface and then as the common source boundary for* $\mathsf{Functor}^{\uparrow}$ *and* $\mathsf{NatTrans}^{\uparrow}$ *consumers; it has no quotient morphism coordinate, host arrow equality, functor-category object, or external category library.*

Proof. Project the public export interface of Definition 484.36. It identifies the visible export with exactly the row family $O, M, I, Q, A, U, H, C, P, N$.

The source of the bridge is fixed by the kernel-category and unary-continuation dependencies recorded in Definition 484.1. The object and hom readings are O, M, while identity and composition are routed through the empty and displayed Cont rows I, Q.

Now apply the category interface handoff and row readback, Definition 484.8 and Definition 484.24. They make the same displayed packet first the $\mathsf{Cat}^{\uparrow}$ interface and then the source boundary for $\mathsf{Functor}^{\uparrow}$ and $\mathsf{NatTrans}^{\uparrow}$ reads.

Finally use the bridge consumer nonescape boundary, Definition 484.29. Since every excluded ambient categorical object is absent from K, the standard bridge surface is precisely the displayed finite packet. □

Theorem 484.38 (Finite-kernel category functor and natural-transformation bridge boundary)**.** *For an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier $K = (O, M, I, Q, A, U, H, C, P, N)$, every* $\mathsf{Functor}^{\uparrow}$ *or* $\mathsf{NatTrans}^{\uparrow}$ *consumer that uses K through the standard bridge surface must first consume the* $\mathsf{Cat}^{\uparrow}$ *boundary supplied by $O, M, I, Q, A, U, H, C, P, N$. Preservation of identities, preservation of composition, and naturality squares are therefore read only through the finite kernel-category rows and the shared structural rows H, C, P, N.*

Proof. Begin with the standard bridge surface, Definition 484.37. It fixes the only available source for categorical reads as the displayed finite packet.

Apply Definition 484.8. This places all functor and natural-transformation reads after the $\mathsf{Cat}^{\uparrow}$ interface has exposed objects, hom histories, identities, composites, associativity, and units.

The functor rows are then constrained by Definition 484.25 and Definition 484.26. The natural-transformation boundary is constrained by Definition 484.27.

The consumer scope theorem Definition 484.35 keeps each of these reads on the same H, C, P, N structural route, so no downstream consumer can detach preservation or naturality data from the finite bridge packet. □

Theorem 484.39 (Finite-kernel category bridge nonescape exactness)**.** *Let $K = (O, M, I, Q, A, U, H, C, P, N)$ be an accepted* $\mathsf{FiniteKernelCategory}^{\uparrow}$ *carrier. A bridge consumer has access exactly to the finite kernel-category rows O, M, I, Q, A, U and the shared structural rows H, C, P, N. Thus every* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, and* $\mathsf{NatTrans}^{\uparrow}$ *read that factors through K is exhausted by the public export interface and the standard bridge surface, and no read escapes to quotient morphisms, host arrow equality, functor-category objects, or an external category library.*

Proof. Use the public export interface, Definition 484.36, to identify the complete exported row family.

Next compose it with the standard bridge surface, Definition 484.37, and the functor and natural-transformation bridge boundary, Definition 484.38. These results route the category, functor, and natural-transformation consumers through the same packet K.

Finally apply Definition 484.29. The carrier has no coordinate for any excluded ambient categorical datum, so the displayed row family is not merely sufficient for the bridge consumer; it is exact. □

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteKernelCategory}^{\uparrow}}$**.**

Constructive story: A $\mathsf{FiniteKernelCategory}^{\uparrow}$ packet is generated from finite object histories, displayed hom histories, empty-continuation identity rows, displayed Cont composition rows, associativity and unit ledgers, componentwise hsame transport, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FiniteKernelCategory}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public package records the BEDC-native rows $O, M, I, Q, A, U, H, C, P, N$, the finite category carrier, NameCert obligations, category-law rows, interface handoff, TasteGate obligation handoff, displayed source totality in Definition 484.33, composite ledger determinacy in Definition 484.34, functor identity preservation in Definition 484.25, functor composition preservation in Definition 484.26, natural-transformation square boundary in Definition 484.27, downstream consumer scope in Definition 484.35, public export interface in Definition 484.36, standard bridge surface in Definition 484.37, functor and natural-transformation bridge boundary in Definition 484.38, bridge nonescape exactness in Definition 484.39, and checked TasteGate single-carrier alignment over BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FiniteKernelCategory}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.FiniteKernelCategoryUp.FiniteKernelCategoryTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Not claimed: This chapter does not close arbitrary categorical constructions, quotient morphisms, host category libraries, functor categories, external category libraries, or checked bridge verification.

Upgrade path: The next verification step is a checked StandardBridge theorem; the present block records a paper bridge surface grounded by the existing TasteGate alignment target.

Chapter 485

A Concrete Naming Certificate for $\mathsf{ContinuationMonad}^{\uparrow}$

The $\mathsf{ContinuationMonad}^{\uparrow}$ packet packages the continuation-as-small-step reading as a finite Kleisli-style certificate over existing BEDC rows. It names source histories, target histories, continuation tails, the unit tail, displayed Cont routes, componentwise hsame transports, Pkg provenance, and a local NameCert ledger. It does not add quotient morphisms, host functions, or a general category primitive.

The packet consumes the authorized generator-boundary discipline of chapter 486 and the continuation hom-carrier surface of chapter 61. Generator closure supplies the refusal of unlisted continuation rules, while $\mathsf{Cat}^{\uparrow}$ supplies the CategoryHomCarrier and ContinuationMorphism reading used in the ledger row.

The dependency route is explicit: $\mathsf{ContinuationMonad}^{\uparrow}$ reads chapter 486 for the refusal of unlisted continuation generators and chapter 61 for the hom-carrier reading. Downstream unit and bind consumers must cite both sibling routes before treating the continuation packet as a monad surface.

Definition 485.1 (ContinuationMonad NameCert source)**.** *A* $\mathsf{ContinuationMonad}^{\uparrow}$ *source is a finite* BHist *packet*

$$Z = (A, B, C, f, g, u, H, K, L, N)$$

with the following displayed coordinates:

1. *A, B, and C are the source, middle, and target history rows for a two-step continuation read.*
2. *f is the displayed continuation tail from A to B, and g is the displayed continuation tail from B to C.*
3. *u is the displayed unit tail, read as the empty continuation route at a history row.*
4. *H stores the componentwise* hsame *transports for the three history rows, the two non-unit tails, the unit tail, and the displayed composite tail.*
5. *K stores the displayed* Cont *routes for the unit read, the two small-step reads, and their composed Kleisli read.*
6. *L is the finite ledger recording continuation associativity and unit behaviour as displayed tail-routing facts, together with the* CategoryHomCarrier *and* ContinuationMorphism *readings used by* $\mathsf{Cat}^{\uparrow}$.

7. *N is the local* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *ledger for carrier admission, classifier stability, ledger exactness, package provenance, and the Kleisli composition boundary.*

The packet is a finite naming certificate. It has no quotient morphism coordinate, no host-function coordinate, and no general category object outside BHist.

Lean4 (definition) `BEDC.Derived.ContinuationMonadUp.ContinuationMonadNameCertSource`

Definition 485.2 (ContinuationMonad carrier)**.** *The concrete* $\mathsf{ContinuationMonad}^{\uparrow}$ *carrier is the finite* BHist *triple surface*

$$\mathcal{K}(A, B, C) = (f, g, u; H, K, L, N)$$

displayed inside Definition 485.1. The carrier rows are the source, middle, and target histories A, B, C; the two continuation tails f, g; the unit tail u; the componentwise hsame *row H; the* Cont *route row K; the unit and associativity ledger L; and the local* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *row N.*

Admission to the carrier means that these rows form the only readable continuation object. In particular, the unit tail is a displayed tail row in the same packet, and the two-step readback is a Cont *ledger route rather than a host Kleisli category.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier finite packet scope`
Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier unit tail endpoint package`

Theorem 485.3 (ContinuationMonad unit laws)**.** *For every accepted carrier $\mathcal{K}(A, B, C)$ of Definition 485.2, the displayed unit tail u is left and right neutral for the finite continuation routes recorded in K. The left-unit route reads u before f and returns the same A-to-B tail row, while the right-unit route reads f before u and returns the same A-to-B tail row, both under the componentwise* hsame *transports stored in H.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier unit route laws`

Proof. Read the carrier through the route row K. The unit route and the two small-step routes are displayed coordinates of the packet, so the left-unit and right-unit reads are finite ledger reads rather than host equalities.

The transport row H supplies the componentwise hsame comparisons needed to identify the returned tail row with f. Since the unit tail u has no coordinate outside the packet, neutrality is exactly the ledger row for the displayed unit route. □

Theorem 485.4 (ContinuationMonad associativity)**.** *For every accepted carrier $\mathcal{K}(A, B, C)$ of Definition 485.2, the two possible two-step readbacks of f followed by g reassociate to the same displayed composite continuation route. The equality is the associativity row in L transported along H and read through the* Cont *row K.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier associativity`

Proof. The carrier contains only two non-unit continuation tails and one displayed composite readback. Thus both parenthesized route reads must land in the same Cont coordinate of K.

The ledger row L records that this shared coordinate is the associativity witness for the two-step continuation surface. Transport along H preserves the source, middle, target, and tail rows, so the reassociation remains the same finite ledger fact after componentwise hsame transport. □

Theorem 485.5 (ContinuationMonad NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *surface for Definition 485.2 consists of five finite rows: carrier admission for* $\mathcal{K}(A, B, C)$*; classifier stability under componentwise* hsame *transport of histories and tails; unit and associativity ledger exactness for* L*;* Pkg *provenance over* BHist*,* Cont*,* hsame*,* CategoryHomCarrier*, and* ContinuationMorphism*; and local naming rows for the Kleisli composition handoff.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadNameCertObligations`

Proof. Carrier admission is the displayed tuple of Definition 485.2. It fixes the readable histories, tails, routes, ledger, and local naming row.

Classifier stability follows from H, and the route laws follow from Definition 485.3 and Definition 485.4. These rows account for the unit and associativity behaviour inside the finite packet.

The remaining provenance rows package the same data for CategoryUp and for the local naming ledger. No quotient Kleisli category, host function, or general category primitive is added by the certificate. □

Theorem 485.6 (ContinuationMonad carrier obligation)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *source packet of Definition 485.1, carrier admission is exhausted by the rows* $A, B, C, f, g, u, H, K, L, N$*. The admitted object is the displayed two-step continuation surface: source and target histories, continuation tails, the unit tail, the* Cont *routes, componentwise* hsame *transports, package provenance, and the local* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *row.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier route closure`

Proof. Project the packet coordinates. The history rows A, B, C supply the BEDC source, middle, and target data, while f, g, u supply the displayed tails used by the small-step interpretation.

The continuation coordinate K records the only admissible routes: unit, first step, second step, and composed step. The transport coordinate H compares exactly those rows componentwise under hsame.

The ledger and certificate rows L, N bind the package provenance and local naming obligations. Since the definition lists no other coordinates, carrier admission cannot read a quotient morphism, host function, or external category primitive. □

Theorem 485.7 (ContinuationMonad classifier stability)**.** *The* $\mathsf{ContinuationMonad}^{\uparrow}$ *classifier is stable under componentwise* hsame *transport of* A, B, C, f, g, u *and of the displayed composite tail. Transported packets preserve the same unit route, the same two small-step* Cont *routes, and the same Kleisli readback recorded by* K *and* L*.*

Proof. Use the componentwise transport row H. It transports the three history rows and the displayed tails without changing the shape of the packet.

The continuation routes are preserved because K stores displayed Cont data rather than host functions. The CategoryUp continuation-morphism reading identifies each transported tail with the same small-step route over the transported endpoints.

Finally the ledger row L records associativity and unit behaviour as continuation-tail routing facts. Repacking those transported rows gives the same local classifier and no access to quotient arrows or host equality. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier classifier stability`

Theorem 485.8 (ContinuationMonad ledger exactness)**.** *The finite ledger of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet is exact for the route from the unit tail and the two displayed continuation tails through the composed Kleisli readback. Every ledger entry is one of the unit, associativity,* Cont*,* hsame*,* CategoryHomCarrier*,* ContinuationMorphism*,* Pkg*, or local* NameCert *rows named in Definition 485.1.*

Proof. Read the source packet. The only dynamic rows are the two displayed tails, the unit tail, and the composed continuation route stored in K.

Associativity and unit behaviour are ledger facts about those displayed tails. They are not imported from host functions or quotient arrows; they are the same continuation-tail facts used by the CategoryUp continuation morphism surface.

The package row records provenance for the finite BEDC objects named in the statement. Thus every ledger entry is accounted for by the packet, and no external category or monad equality can enter the certificate. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier ledger exactness`

Theorem 485.9 (ContinuationMonad NameCert package)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *package consists exactly of five obligation rows: carrier admission, classifier stability under componentwise* hsame*, ledger exactness for unit and associativity routes, package provenance over* BHist*,* Cont*,* hsame*,* CategoryHomCarrier*, and* ContinuationMorphism*, and the Kleisli composition boundary of Definition 485.19.*

Proof. Carrier admission is supplied by Definition 485.6. It identifies the finite source packet and excludes all unlisted carrier data.

Classifier stability is supplied by Definition 485.7. Ledger exactness is supplied by Definition 485.8.

The remaining rows are bookkeeping rows. The Pkg coordinate records provenance over the named BEDC kernel and CategoryUp surfaces, and the local certificate coordinate records that the Kleisli boundary is the public consumer of the same displayed continuation data. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier namecert package`

Theorem 485.10 (ContinuationMonad root generator obligation)**.** *Every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet receives its unit and bind rows only through the displayed* $\mathsf{Cat}^{\uparrow}$ *hom-carrier and the authorized generator boundary. The unit row is the displayed tail* u*, the bind route is the finite composition route through* f, g, K, L*, and both are read after the generator-boundary refusal of unlisted continuation rules.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root generator obligation`

Proof. Start with carrier admission from Definition 485.6. The accepted packet exposes the histories A, B, C, tails f, g, u, transport row H, route row K, ledger row L, and local naming row N.

Read the categorical surface through chapter 61. The CategoryHomCarrier and ContinuationMorphism entries used by L are readings of the displayed continuation tails, not independent host morphisms.

Now apply the generator boundary of chapter 486. The unit and bind rows can be consumed only as authorized rows of the displayed packet, while unlisted continuation rules are refused at the generator boundary. □

Theorem 485.11 (ContinuationMonad bind-route classifier stability)**.** *Componentwise* hsame *transport of the unit row, bind route, continuation rows, and package rows of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet preserves the local Kleisli classifier. The transported classifier still reads the same* $\mathsf{Cat}^{\uparrow}$ *hom-carrier, the same authorized generator boundary, the same* Cont *routes, and the same* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *ledger.*

Proof. Use classifier stability from Definition 485.7. Transport along H preserves the three histories, the unit tail, the two continuation tails, and the displayed composite tail.

Use ledger exactness from Definition 485.8. The bind route remains a row of K and L, so its category-facing reading is still the CategoryHomCarrier and ContinuationMorphism surface described in chapter 61.

The generator boundary remains local because the transported route has no coordinate for an unlisted continuation rule. Repacking the transported rows with Pkg provenance and the local NameCert row gives the same Kleisli classifier. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier bind route classifier stability`

Theorem 485.12 (ContinuationMonad NameCert ledger exactness)**.** *Every consumer-visible continuation-monad route is exhausted by the carrier, classifier, unit, bind, associativity,* Cont*,* Pkg*, and* NameCert *rows of the accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet. No consumer-visible route can bypass the displayed* $\mathsf{Cat}^{\uparrow}$ *hom-carrier or the authorized generator boundary.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier namecert ledger exactness`

Proof. Project the packet using Definition 485.9. The local NameCert package consists of carrier admission, classifier stability, ledger exactness, package provenance, and the Kleisli composition boundary.

The unit and associativity rows are supplied by Definition 485.3 and Definition 485.4. The bind route is the displayed two-step readback through f, g, K, L and is already bounded by the Kleisli composition surface.

Finally combine chapter 61 with chapter 486. The category-facing hom-carrier and the authorized generator boundary account for every public route into the packet, so no host function, quotient Kleisli arrow, or unlisted generator rule remains visible. □

Theorem 485.13 (ContinuationMonad root-unblock source triad)**.** *Every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet must expose the source history A, middle history B, target history C, continuation tails f, g, and unit tail u together before any Kleisli read is available. The first readable root surface is therefore the finite triad-and-tail packet $A, B, C, f, g, u, H, K, L, N$, not an external function space or quotient Kleisli category.*

Proof. Project carrier admission from Definition 485.6. The accepted packet displays the three histories, the two continuation tails, the unit tail, componentwise transports, route rows, ledger rows, and the local name as one finite carrier.

Use ledger exactness from Definition 485.12. A Kleisli read is consumer-visible only through the carrier, classifier, unit, bind, associativity, Cont, Pkg, and NameCert rows of that same packet.

Thus the read cannot begin from a host function, an external quotient, or a partial tail. The root surface is the displayed source, middle, and target triad together with f, g, u, H, K, L, N. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root unblock source triad`

Theorem 485.14 (ContinuationMonad root-unblock bind totality)**.** *Every bind-route consumer of an accepted* ContinuationMonad$^{\uparrow}$ *packet factors through the displayed* Cont *row K, the componentwise* hsame *row H, and the ledger row L. The bind route is total only as a read of $A, B, C, f, g, u, H, K, L, N$ and is not host function composition, host monad equality, or a quotient Kleisli arrow.*

Proof. Start with a bind-route consumer and project the packet rows. The only displayed route row is K, the only componentwise transport row is H, and the consumer-visible accounting row is L.

Use Definition 485.11. Transport along H preserves the local Kleisli classifier and keeps the route on the same displayed histories and continuation tails.

Use Definition 485.12 to close the readback. Since every consumer-visible continuation-monad route is exhausted by the displayed rows, the bind route is total precisely through K, H, L inside the finite packet and has no host-composition coordinate. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier bind route totality`

Theorem 485.15 (ContinuationMonad root-unblock downstream package)**.** *The source triad of Definition 485.13 and the bind totality of Definition 485.14 form the downstream root-unblock package consumed by the CategoryUp surface of chapter 61 and the generator-boundary surface of chapter 486. Downstream consumers receive exactly $A, B, C, f, g, u, H, K, L, N$ together with the displayed category and generator readings; they receive no host function composition, quotient Kleisli category, or unlisted continuation rule.*

Proof. First expose the source packet. Definition 485.13 supplies the three histories, two continuation tails, unit tail, transports, routes, ledger, and local name before any Kleisli read.

Next expose the bind route. Definition 485.14 forces every bind consumer through K, H, L inside the same finite packet.

Finally read the downstream surfaces. The CategoryUp chapter reads the displayed hom-carrier and continuation-morphism rows, while the generator-boundary chapter refuses unlisted continuation rules. Together with ledger exactness, these readings package the root-unblock surface without exporting host function composition, quotient Kleisli categories, or extra continuation generators. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root unblock downstream package`

Theorem 485.16 (ContinuationMonad category hom row exposure)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet $Z = (A, B, C, f, g, u, H, K, L, N)$, the downstream* CategoryHomCarrier *and* ContinuationMorphism *readings are exposed only as reads of the displayed tails f, g, u through the visible rows A, B, C, H, K, L, N. They do not introduce an independent category object, quotient Kleisli arrow, ambient hom set, or host-function carrier.*

Proof. Start with carrier obligation. Definition 485.6 identifies the readable packet with $A, B, C, f, g, u, H, K, L, N$ and leaves no coordinate for an external hom carrier.

Use classifier stability and ledger exactness. Definition 485.7 keeps the transported tails on the same histories and route rows, while Definition 485.8 accounts for unit, bind, and associativity inside the displayed ledger.

Finally apply the CategoryUp surface of chapter 61 together with Definition 485.15. The category-facing names are therefore readings of the same tails and ledger rows already exported by the packet, not additional categorical data. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier category hom row exposure`

Theorem 485.17 (ContinuationMonad generator boundary refusal)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the generator-boundary sibling refuses any unit row, bind row, continuation rule, or route generator that is not displayed in* $A, B, C, f, g, u, H, K, L, N$*. The refused object cannot re-enter through* Pkg *provenance, CategoryUp notation, or the local* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *row.*

Proof. Project the accepted carrier and its classifier. The carrier obligation fixes the visible rows, and classifier stability keeps every transported continuation read on those rows.

Read the generator boundary through chapter 486. Its authorized generator surface accepts only listed rows, so an unlisted continuation rule has no generator coordinate in the packet.

Ledger exactness closes the refusal. Since Definition 485.12 exhausts every consumer-visible route by the displayed carrier, classifier, unit, bind, associativity, Cont, Pkg, and $\mathsf{NameCert}$ rows, there is no later provenance or category route through which the refused generator can appear. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier generator boundary refusal`

Theorem 485.18 (ContinuationMonad continuation route ledger totality)**.** *Every unit or bind consumer of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet factors through the displayed* Cont *route row* K*, the componentwise* hsame *transport row* H*, the ledger row* L*, and the local* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *row* N*. The total route is the finite read of* $A, B, C, f, g, u, H, K, L, N$*; it is not host monad evaluation, quotient Kleisli composition, or an unrecorded continuation evaluator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier cont route ledger totality`

Proof. First use the unit and bind rows already exposed in this chapter. Definition 485.3 places the unit tail inside the displayed route, and Definition 485.11 keeps bind reads stable under the H transports.

Next use ledger exactness. Definition 485.12 says every consumer-visible continuation route is exhausted by the finite rows of the same accepted packet.

The CategoryUp and generator-closure siblings supply the two downstream checks. CategoryUp reads the hom and continuation-morphism faces from the displayed tails, while generator closure refuses any route generator outside the packet. Thus every unit or bind consumer factors through K, H, L, N and no hidden evaluator remains. □

Theorem 485.19 (ContinuationMonad Kleisli composition boundary)**.** *Every Kleisli-style consumer of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet factors through the displayed route*

$$A \xrightarrow{f} B \xrightarrow{g} C$$

together with the unit tail u*, the componentwise* hsame *transports, the* Cont *routes in* K*, the ledger* L*, package provenance, and the local naming row* N*. The boundary exports no quotient Kleisli category, no host function composition, no standard monad laws as host equalities, and no general category primitive.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier kleisli composition boundary`

Proof. Start from the consumer route. By carrier admission, it can inspect only the displayed histories, tails, transports, continuations, ledger, package provenance, and local certificate.

Use classifier stability to move along componentwise hsame without changing the route. The displayed two-step path remains the route through f and g, with u serving only as the unit tail inside the same continuation ledger.

Use ledger exactness to identify the composed readback with the continuation route recorded in K and L. Therefore a Kleisli-style consumer is bounded by the named BEDC rows and cannot read quotient Kleisli categories, host functions, host monad equalities, or a general category primitive. □

Theorem 485.20 (ContinuationMonad Kleisli composite scope)**.** *For an accepted* ContinuationMonad$^{\uparrow}$ *packet, any composite consumer that reads*

$$A \xrightarrow{f} B \xrightarrow{g} C$$

must factor through the displayed tails f, g, u, the Cont *route row K, the componentwise* hsame *row H, the ledger row L, the* CategoryHomCarrier *and* ContinuationMorphism *readings,* Pkg *provenance, and the local* NameCert$_{\text{ContinuationMonad}^{\uparrow}}$ *row N. The consumer cannot replace this finite composite by host function composition, quotient Kleisli arrows, or a general category primitive.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier kleisli composite scope`

Proof. Begin with carrier admission. The accepted packet exposes only the histories A, B, C, the tails f, g, u, the transport row H, the continuation route row K, the ledger row L, package provenance, and the local name.

Use classifier stability to move through the componentwise hsame row without changing the displayed two-step route. The CategoryHomCarrier and ContinuationMorphism readings are therefore readings of those same continuation rows, not additional morphism objects.

Apply ledger exactness and the Kleisli composition boundary. They identify the composite readback with the recorded K, L route and confine every consumer of the composite to the displayed BEDC packet.

Since no coordinate names host function composition, quotient Kleisli arrows, or a general category primitive, the composite scope is exhausted by the listed rows. □

Theorem 485.21 (ContinuationMonad scoped route dependencies)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet, the composite consumer route factors through exactly the displayed* BHist*,* Cont*,* hsame*,* CategoryHomCarrier*,* ContinuationMorphism*,* Pkg*, and* NameCert *rows. The dependency surface is the finite route through the histories A, B, C, continuation tails f, g, u, componentwise transports, continuation ledger, package provenance, and local naming row.*

Proof. Start with carrier obligation. It projects the accepted packet to the histories, tails, transport row, continuation route row, ledger, provenance, and local certificate.

Use classifier stability and ledger exactness to keep every read of the composite consumer on those rows. The CategoryHomCarrier and ContinuationMorphism readings are then readings of the same displayed continuation route, not independent categorical data.

Apply the Kleisli boundary and Kleisli composite scope. Together they identify the composite as the finite route through the listed BEDC rows and exhaust the scoped dependencies of the accepted packet. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier scoped route dependencies`

Theorem 485.22 (ContinuationMonad scope non-escape)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet, the scoped composite route exports no quotient Kleisli arrows, no host function composition, and no general category primitive. It exports only the displayed continuation tails,* Cont *route rows, componentwise* hsame *transports, ledger row, package provenance, and local* NameCert *row.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier scope nonescape`

Proof. Project the same packet using carrier obligation. The visible rows are finite continuation data, transport data, ledger data, package provenance, and local naming data.

Classifier stability and ledger exactness keep transport and readback inside that finite route. The Kleisli composition boundary excludes quotient Kleisli arrows, host function composition, and general category primitives from the public boundary.

The Kleisli composite scope supplies the final scope claim: every composite consumer has already factored through the displayed rows, so there is no exported object beyond the scoped route. □

Theorem 485.23 (ContinuationMonad route readback determinacy)**.** *For an accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the displayed* Cont *route row determines the unit readback, first-step readback, second-step readback, and composite readback under componentwise* hsame *transport. Any consumer reading those four results must use the same rows* u, f, g, H, K, L, N *and receives no second host route, host function composition, quotient Kleisli arrow, or host monad equality.*

Proof. Start with carrier obligation and classifier stability. Carrier admission supplies the displayed tails f, g, u and the route row K, while classifier stability keeps componentwise hsame transport on the same histories and continuation tails.

Use ledger exactness to read the unit, first step, second step, and composite from K and L. The ledger records the readbacks as finite continuation data attached to Z, not as host functions or quotient arrows.

Finally apply the Kleisli composition boundary and scope non-escape. The only route available to a public consumer is the displayed Cont route row, so no second host route or host monad equality can be projected. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier route readback determinacy`

Theorem 485.24 (ContinuationMonad route readback totality)**.** *For an accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every public readback of the route is one of the displayed unit, first-step, second-step, or composite rows recorded by* K*,* L*, and* N*. The readback surface is exhausted by the histories* A, B, C*, tails* u, f, g*, componentwise transport* H*, continuation route row* K*, ledger row* L*, and local naming row* N*.*

Proof. Start with the carrier obligation. It projects the accepted packet to exactly $A, B, C, f, g, u, H, K, L, N$, so a public route read has no source coordinate outside the displayed continuation packet.

Use classifier stability and ledger exactness to keep the unit, first-step, second-step, and composite reads on H, K, and L. These rows record the route as finite continuation data rather than as host functions.

Finally apply Definition 485.19, Definition 485.21, and Definition 485.23. The boundary supplies the finite Kleisli-facing route, the dependency theorem restricts all consumers to the listed BEDC rows, and determinacy says the four displayed readbacks exhaust the public route. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier route readback totality`

Theorem 485.25 (ContinuationMonad unit-composite readback totality)**.** *For an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, unit-law consumers and composite-law consumers are jointly exhausted by* u, f, g, H, K, L, N*. They may read the displayed unit row, the two displayed step rows, the displayed composite row, componentwise* hsame *transport, the continuation ledger, and the local* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *row, but they cannot request host monad equalities.*

Proof. Project the packet by carrier obligation. The only unit input is the tail u, and the only composite inputs are the tails f and g together with the route row K.

Apply classifier stability and ledger exactness. Stability keeps all unit and composite reads under the same transport row H, while exactness records their readbacks through K and L.

Now use Definition 485.19, Definition 485.21, and Definition 485.23. The boundary excludes host monad equality, the scoped dependencies leave only u, f, g, H, K, L, N, and determinacy identifies any public unit-law or composite-law read with one of those displayed rows. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier unit composite readback totality`

Theorem 485.26 (ContinuationMonad category-boundary readback totality)**.** *For an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the* CategoryHomCarrier *and* ContinuationMorphism *handoff is total exactly on the same finite route rows* $A, B, C, f, g, u, H, K, L, N$*. A category-boundary consumer receives only the displayed* BHist*,* Cont*,* hsame*,* Pkg*, and* NameCert *surface of that packet, with no independent category object, host function, quotient Kleisli arrow, or host monad equality.*

Proof. First use the carrier obligation to expose the route rows $A, B, C, f, g, u, H, K, L, N$. The category-facing names are attached to those histories, tails, transport, route, ledger, provenance, and naming rows.

Classifier stability and ledger exactness identify the CategoryHomCarrier and ContinuationMorphism readings with the same displayed continuation data. No category-boundary read can leave the transport row H or the ledger rows K and L.

Finally apply Definition 485.19, Definition 485.21, and Definition 485.23. The category boundary is therefore total precisely on the finite route readbacks already determined by Z, and every excluded host or quotient object remains outside the public handoff. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier category boundary readback totality`

Theorem 485.27 (ContinuationMonad unit route non-escape)**.** *Every public unit-law read of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet factors through the unit tail* u*, componentwise transport row* H*, continuation route row* K*, ledger row* L*, and local* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *row* N*. The read may expose the finite* BHist*,* Cont*,* hsame*,* Pkg*, and* NameCert *rows of the packet, but it cannot export host monad equality, a host identity function, or a quotient Kleisli unit.*

Proof. Use carrier obligation to project the unit tail u and the visible package rows. The unit law is therefore attached to the same finite packet as the non-unit continuation tails.

Classifier stability keeps transport through H, and ledger exactness records the unit read through K and L. The public read is a ledger read of the displayed route, not a host equality proof.

The local NameCert package and Kleisli composition boundary give the non-escape conclusion. Since the accepted packet contains no host monad equality coordinate, no host identity-function

coordinate, and no quotient Kleisli unit coordinate, a public unit-law consumer cannot export any of them. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier unit route nonescape`

Theorem 485.28 (ContinuationMonad category handoff exactness)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet, the* CategoryHomCarrier *and* ContinuationMorphism *readings consume exactly the displayed continuation tails f, g, u together with the* Cont *route row K, componentwise* hsame *row H, ledger row L, package provenance, and local naming row. They do not consume quotient Kleisli arrows, host functions, host monad equalities, or an independent category object.*

Proof. Read the handoff through carrier obligation. The only category-facing rows exposed by the packet are the histories, tails, transport, continuation route, ledger, provenance, and local name.

Use classifier stability and ledger exactness to align the CategoryHomCarrier and ContinuationMorphism readings with the same f, g, u, H, K, L, N route. The category-facing names therefore read the continuation packet rather than a separate host category.

Apply the Kleisli composition boundary and scope non-escape. Together they rule out quotient Kleisli arrows, host functions, host monad equalities, and independent category objects as sources for the handoff. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier category handoff exactness`

Theorem 485.29 (ContinuationMonad obligation closure)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *source packet, the carrier source, unit laws, associativity, classifier stability, ledger exactness, local* NameCert *package, and Kleisli composition boundary jointly supply the* obligation *surface for* ContinuationMonad$^{\uparrow}$ *over* BHist*,* Cont*,* hsame*,* CategoryHomCarrier*,* ContinuationMorphism*,* Pkg*, and* NameCert*. The closure surface exports only the displayed continuation tails, route rows, transport rows, ledger rows, package provenance, and naming row.*

Proof. First use the carrier source and carrier obligation. They identify the finite packet rows $A, B, C, f, g, u, H, K, L, N$ and exclude quotient morphisms, host functions, and any general category primitive outside the displayed packet.

Next apply the unit laws and associativity rows. These bind the unit tail and the two-step readback as ledger facts about the displayed Cont routes rather than as host monad equalities.

Use classifier stability and ledger exactness to transport the same route data along componentwise hsame. The CategoryHomCarrier and ContinuationMorphism readings are therefore readings of the same finite continuation rows.

Finally apply the local NameCert package and the Kleisli composition boundary. They repack carrier admission, stability, exactness, provenance, and consumer boundary as the public obligation surface for ContinuationMonad$^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier obligation closure`

Definition 485.30 (ContinuationMonad kernel scope row)**.** *The* ContinuationMonad$^{\uparrow}$ *kernel scope row is the finite list*

BHist, Cont, hsame, CategoryHomCarrier, ContinuationMorphism, Pkg, NameCert.

For a packet $Z = (A, B, C, f, g, u, H, K, L, N)$, every public continuation read must name its source, middle, and target histories, displayed tails, unit tail, transport row, route row, ledger row, package provenance, and local naming row through this list.

Lean4 (definition) `BEDC.Derived.ContinuationMonadUp.ContinuationMonadKernelScopeRow`

Theorem 485.31 (ContinuationMonad route row grounding)**.** *Every route consumer of an accepted* ContinuationMonad$^{\uparrow}$ *packet factors through the finite route data*

$$A, B, C, f, g, u, H, K, L, N.$$

The histories A, B, C, tails f, g, u, componentwise transport row H, continuation route row K, ledger row L, and local naming row N are therefore the complete grounding surface for the kernel scope of Definition 485.30.

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier route row grounding`

Proof. Project the accepted source packet. The carrier source lists exactly $A, B, C, f, g, u, H, K, L, N$, and the kernel scope row lists the only BEDC objects through which those coordinates can be read.

Use carrier obligation and classifier stability to bind all transported reads to H and all continuation reads to K. The CategoryUp hom-carrier and continuation-morphism readings are readings of the same displayed tails, not additional route coordinates.

Apply ledger exactness and the Kleisli composition boundary. The ledger L and local name N package the same finite route for downstream consumers, so no consumer can factor through a quotient Kleisli arrow, host function, or unlisted categorical primitive. □

Theorem 485.32 (ContinuationMonad downstream unblock surface)**.** *The scoped downstream unblock surface for* ContinuationMonad$^{\uparrow}$ *consists of carrier admission for $A, B, C, f, g, u, H, K, L, N$, classifier stability under H, ledger exactness through K and L, package provenance through* Pkg*, and the Kleisli boundary recorded by N. Any downstream Real, completion, category, or unary-continuation consumer must use those rows and cannot replace them by quotient morphisms, host functions, or external monad laws.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier downstream unblock surface`

Proof. Carrier admission supplies the finite continuation packet. Classifier stability then keeps transported histories and tails inside the componentwise hsame row H.

Ledger exactness supplies the unit, associativity, and composed-read facts through K and L. These facts are finite continuation rows, not host monad equalities.

Finally the package provenance and Kleisli boundary expose exactly the rows named in the kernel scope. Downstream consumers may depend on that surface, but they receive no route outside $A, B, C, f, g, u, H, K, L, N$. □

Theorem 485.33 (ContinuationMonad route bridge boundary)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet*

$$Z = (A, B, C, f, g, u, H, K, L, N),$$

the bridge from the displayed finite route

$$A \xrightarrow{f} B \xrightarrow{g} C$$

to the standard monad-reading boundary is mediated only by the rows BHist, Cont, hsame, CategoryHomCarrier, ContinuationMorphism, Pkg, *and* NameCert*. The boundary exports no quotient Kleisli arrow, no host function composition, and no host monad equality.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier route bridge boundary`

Proof. Begin with the public package of Definition 485.9. It supplies carrier admission, classifier stability, ledger exactness, package provenance, and the Kleisli boundary for the same packet Z.

Apply Definition 485.19 to the displayed two-step route. The standard monad-reading boundary can see only the finite continuation route named by $A, B, C, f, g, u, H, K, L, N$.

Finally use Definition 485.21. The CategoryUp hom-carrier and continuation-morphism readings are readings of the same BHist, Cont, and hsame rows, so no quotient arrow, host composition, or host monad equality is exported. □

Theorem 485.34 (ContinuationMonad finite standard handoff)**.** *The public* ContinuationMonad$^{\uparrow}$ *handoff to standard monad notation is finite: the source, middle, and target histories are A, B, C; the displayed non-unit tails are f, g; the unit tail is u; the transport, route, ledger, and naming rows are H, K, L, N. Every standard-looking unit or composite read is a reading of these rows through* BHist*,* Cont*,* hsame*,* CategoryHomCarrier*,* ContinuationMorphism*,* Pkg*, and* NameCert*, not a host-side monad structure.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier finite standard handoff`

Proof. Use Definition 485.20. It identifies every composite consumer with the displayed tails, route row, transport row, ledger row, CategoryUp readings, package provenance, and local certificate.

Next apply Definition 485.21. The standard notation has no separate carrier once the dependency surface has been restricted to the named BEDC rows.

The public package of Definition 485.9 supplies the carrier, stability, exactness, provenance, and boundary obligations for this handoff. Hence the handoff is finite and contains no host monad equality, host function composition, or quotient Kleisli arrow. □

Theorem 485.35 (ContinuationMonad public route bridge totality)**.** *The public* ContinuationMonad$^{\uparrow}$ *route bridge is total on the displayed packet $Z = (A, B, C, f, g, u, H, K, L, N)$. Every downstream Real, completion, category, or unary-continuation consumer that asks for the standard monad-reading boundary receives exactly the finite route surface over* BHist*,* Cont*,* hsame*,* CategoryHomCarrier*,* ContinuationMorphism*,* Pkg*, and* NameCert*; no consumer receives an extra quotient Kleisli arrow, host function composition, or host monad equality.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier public route bridge totality`

Proof. First apply Definition 485.32. It states that each downstream consumer must use carrier admission, classifier stability, ledger exactness, package provenance, and the Kleisli boundary of the same packet.

Then use Definition 485.33. The route bridge has already identified the only rows through which the standard boundary is readable.

Finally apply Definition 485.34. Since the handoff is finite and contains no host-side monad structure, totality holds for all displayed downstream consumers exactly on the route rows $A, B, C, f, g, u, H, K, L, N$ □

Theorem 485.36 (ContinuationMonad bridge package)**.** *The public* ContinuationMonad$^{\uparrow}$ *packet forms a bridge package from its displayed finite route*

$$A \xrightarrow{f} B \xrightarrow{g} C$$

and unit tail u to the standard monad-reading boundary. The package consists precisely of the BHist *rows A, B, C, the* Cont *route row K, the componentwise* hsame *row H, the* CategoryHomCarrier *and*

ContinuationMorphism *readings, the* Pkg *provenance row, and the* $\mathsf{NameCert}_{\mathsf{ContinuationMonad}^{\uparrow}}$ *row* N*. It exports no quotient Kleisli arrow, no host function composition, and no host monad equality.*

Proof. Start with Definition 485.9. It supplies the public NameCert package containing carrier admission, classifier stability, ledger exactness, package provenance, and the Kleisli composition boundary.

Use Definition 485.19 and Definition 485.20 to bind the standard-looking composite read to the displayed route through f and g, with u as the unit tail inside the same packet.

Apply Definition 485.21 to restrict every dependency to BHist, Cont, hsame, CategoryHomCarrier, ContinuationMorphism, Pkg, and NameCert.

Finally use Definition 485.32 and Definition 485.35. They show that downstream consumers receive the complete bridge package and no quotient Kleisli arrow, host function composition, or host monad equality. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier bridge package`

Theorem 485.37 (ContinuationMonad bind-route coverage)**.** *Every accepted bind read of a* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet factors through the displayed source* BHist *row, the continuation route row, the Kleisli composite row, the componentwise* hsame *transport, the* Pkg *provenance row, and the local* NameCert *row. Thus a bind consumer can inspect only the rows* $A, B, C, f, g, u, H, K, L, N$ *named by the bridge package, where* A, B, C *are the* BHist *sources,* K *is the* Cont *route,* L *is the composite ledger,* H *is the* hsame *transport, and* N *is the local* NameCert *certificate with* Pkg *provenance.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier bind route coverage`

Proof. Begin with the unit laws and associativity rows. They identify the accepted bind read as a replay of the displayed unit tail and the two-step Kleisli composite rather than as a host monad operation.

Next use the scoped route dependencies. The only histories visible to the read are the BHist rows A, B, C, and the only continuation data are the displayed Cont route K and ledger L.

Transport is then forced through the componentwise hsame row H. The route bridge boundary and bridge package attach the same read to Pkg provenance and the local NameCert row N, so no hidden evaluator, quotient Kleisli arrow, or host function can supply an additional bind route. □

Theorem 485.38 (ContinuationMonad Kleisli ledger associativity)**.** *Two nested Kleisli composites in an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet have the same consumer-visible ledger exactly when both composites are replayed through the existing associativity row and the same scoped-route dependencies over* BHist*,* Cont*,* hsame*,* Pkg*, and* NameCert*. The comparison is a ledger comparison inside* L*, not an equality supplied by a hidden evaluator or by host-side monad laws.*

Proof. For the forward direction, read the common consumer-visible ledger through the bridge package. The package exposes the source BHist rows, the Cont route row, the hsame transport, the Pkg provenance row, and the local NameCert row, so the common ledger must be the displayed row L.

Apply the associativity row to replay the two nested composites against that same row L. The scoped route dependencies keep both replays inside the route rows $A, B, C, f, g, u, H, K, L, N$.

For the reverse direction, assume both nested composites replay through associativity and the scoped-route dependencies. Since the route bridge boundary exports only the displayed ledger and no host evaluator, the two consumer-visible ledgers coincide exactly as reads of L. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier kleisli ledger associativity`

Theorem 485.39 (ContinuationMonad downstream consumer exhaustion)**.** *Any downstream CategoryUp or generator-closure consumer of the* ContinuationMonad$^{\uparrow}$ *bridge package can inspect only the unit, bind, route, ledger,* hsame*,* Cont*,* Pkg*, and* NameCert *rows already displayed in this chapter. In particular, every such consumer is exhausted by the rows* u, f, g, K, L, H, N *over the source* BHist *rows* A, B, C *with* Pkg *provenance and receives no quotient Kleisli category, ambient evaluator, host function composition, or extra monad law.*

Proof. First expose the consumer through the bridge package. The package has already bound the standard-looking route to the displayed BHist, Cont, hsame, Pkg, and NameCert rows.

Next apply the unit laws, associativity, scoped route dependencies, and route bridge boundary. These rows supply the unit read, bind read, route replay, and ledger comparison by finite continuation data.

The downstream CategoryUp and generator-closure consumers therefore have no remaining coordinate to inspect. Any extra evaluator, quotient Kleisli category, host function composition, or independent monad law would have to be a row outside $A, B, C, f, g, u, H, K, L, N$ and the Pkg provenance surface, which the bridge package does not export. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier downstream consumer exhaustion`

Theorem 485.40 (ContinuationMonad generator-category consumer triad)**.** *For an accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every downstream consumer that jointly reads the generator-closure refusal surface and the* Cat$^{\uparrow}$ *hom route factors through exactly the displayed rows*

$A, B, C, f, g, u, H, K, L, N$, BHist, Cont, hsame, Pkg, NameCert, CategoryHomCarrier, ContinuationMo

The triad consists of the source histories A, B, C*, the continuation tails* f, g, u *with route and ledger rows* K, L*, and the local transport, package, and name rows* H, N*. It exports no quotient Kleisli arrow, host function, or host monad equality.*

Proof. Project the carrier Z. The histories A, B, C and tails f, g, u are the only source and route rows available to a downstream reader.

Route the CategoryUp read through the displayed CategoryHomCarrier and ContinuationMorphism entries in L. These entries read the same finite continuation tails and do not introduce an independent category object.

Route the generator consumer through the refusal surface named by the packet. The refusal surface admits the listed continuation rules and rejects any unlisted continuation rule before the consumer reaches K, L, H, N.

Finally combine the package row with the local NameCert row. Since no coordinate outside $A, B, C, f, g, u, H, K, L, N$ is exported, quotient Kleisli arrows, host functions, and host monad equalities have no consumer-facing route. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier generator category consumer triad`

Theorem 485.41 (ContinuationMonad generator refusal row)**.** *For an accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every generator-closure consumer of the unit or bind surface reads the authorized continuation rows* f, g, u, K, L *through the same refusal ledger before it can inspect* Pkg *provenance or the local* NameCert *row. Any requested continuation rule not displayed by* $A, B, C, f, g, u, H, K, L, N$ *is refused at that ledger and cannot be supplied by a quotient Kleisli arrow, host function, or host monad equality.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier generator refusal certified row`

Proof. Start from the displayed unit and bind rows. The unit tail is u, the non-unit tails are f, g, and the accepted route and ledger are K, L.

Apply the generator-closure refusal surface. It separates authorized displayed continuation rows from unlisted continuation rules before the route reaches the package and local naming coordinates.

Use componentwise hsame transport only through H. The transport preserves the same refusal ledger and does not add a route for a hidden evaluator or a quotient Kleisli arrow.

The Pkg and NameCert rows therefore certify exactly the displayed generator-facing surface, with no host function or host monad equality available to replace the finite route. □

Theorem 485.42 (ContinuationMonad Category hom route totality)**.** *For an accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every* Cat$^{\uparrow}$ *consumer of* CategoryHomCarrier *or* ContinuationMorphism *is total on the displayed route* $A, B, C, f, g, u, H, K, L, N$*. The consumer reads the hom surface only through* BHist*,* Cont*,* hsame*,* Pkg*,* NameCert*, the* CategoryHomCarrier *row, and the* ContinuationMorphism *row, and it receives no independent category object, quotient Kleisli arrow, host function, or host monad equality.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier category hom route totality`

Proof. Project the CategoryUp-facing carrier rows. The hom carrier and continuation morphism readings are stored in the same finite ledger L that records the accepted route through f, g, u and K.

Use classifier stability to transport this read through H. The transported hom route still has endpoints A, B, C and still reads only the displayed continuation rows.

Package provenance and the local NameCert row then close the route for every CategoryUp consumer. Because the packet has no coordinate for an independent category object or host evaluator, the displayed hom route is total on exactly the finite packet. □

Theorem 485.43 (ContinuationMonad category-generator source triad)**.** *Every accepted* ContinuationMonad$^{\uparrow}$ *packet exposes the* Cat$^{\uparrow}$ *hom-carrier row, the* ContinuationMorphism *row, and the generator-closure refusal row before either the public unit read or the public bind read is available. The exposed triad is read from* $A, B, C, f, g, u, H, K, L, N$ *over* BHist*,* Cont*,* hsame*,* Pkg*, and* NameCert*, and not from an independent category object, quotient Kleisli arrow, host function space, or unlisted generator family.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier category generator source triad`

Proof. Begin with carrier admission and the root generator obligation. The carrier obligation identifies $A, B, C, f, g, u, H, K, L, N$ as the available rows, while the root generator obligation places the refusal surface before any generator-facing read can use unit or bind.

Next apply bind-route classifier stability and the Category hom route totality theorem. These results route the Cat$^{\uparrow}$ hom-carrier and ContinuationMorphism entries through the same finite ledger L and the same transport row H.

The unit and bind reads therefore come after the triad is already visible. Since the packet has no coordinate for an independent category object, quotient Kleisli arrow, host function space, or unlisted generator family, no downstream reader can bypass the displayed triad. □

Theorem 485.44 (ContinuationMonad bind readback exhaustion)**.** *Every bind readback exposed by an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet is exhausted by the rows* $A, B, C, f, g, u, H, K, L, N$*. The readback may inspect the source histories* A, B, C*, the displayed continuation tails* f, g, u*, the transport row* H*, the route and ledger rows* K, L*, the* Pkg *provenance, and the local* NameCert *row* N*; it cannot read host functions, quotient Kleisli arrows, unlisted generators, or an external monad evaluator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier bind readback exhaustion`

Proof. First use bind-route classifier stability. It identifies every accepted bind read with the displayed continuation route through f, g, u, K, L and transports that read only through H.

Then use NameCert ledger exactness. The ledger records exactly the finite rows $A, B, C, f, g, u, H, K, L, N$ with Pkg provenance, so any consumer-visible bind readback must be a readback of that finite packet.

Finally apply the Kleisli composite scope and bind-route coverage theorems. They prevent a host function, quotient Kleisli arrow, unlisted generator, or external evaluator from supplying another bind readback outside the listed rows. □

Theorem 485.45 (ContinuationMonad root-unblock package)**.** *The root obligation package of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet consists exactly of carrier admission, classifier stability,* $\mathsf{Cat}^{\uparrow}$ *hom routing, generator refusal, ledger exactness, and the local* NameCert *rows over* $A, B, C, f, g, u, H, K, L, N$*. This package is the surface available to downstream continuation chapters before they read any standard monad boundary, and it exports no quotient Kleisli category, host function composition, ambient effect algebra, or independent generator list.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root unblock package`

Proof. Assemble the package from the existing obligation rows. Carrier admission supplies the packet rows, classifier stability fixes their hsame transport, category hom routing places the $\mathsf{Cat}^{\uparrow}$ read in the finite ledger, and generator refusal excludes unlisted continuation rules.

Add NameCert ledger exactness and Kleisli composite scope. These rows make the visible ledger exact for $A, B, C, f, g, u, H, K, L, N$ and keep every composite read inside the same finite route.

The resulting package is precisely the root obligation surface available to downstream continuation chapters. Any quotient Kleisli category, host function composition, ambient effect algebra, or independent generator list would require a row outside the displayed carrier, and no such row is exported. □

Theorem 485.46 (ContinuationMonad root unit-bind exhaustion)**.** *For an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every root unit read and root bind read is exhausted by the displayed rows* u, f, g, K, L, H, N *together with the source histories* A, B, C*. The unit and bind consumers may inspect only the unit tail, the two continuation tails, componentwise transport, the route and ledger rows, package provenance, and the local* NameCert *row; they receive no quotient Kleisli arrow, host function composition, or host monad equality.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root unit bind exhaustion`

Proof. Start with Definition 485.3 and Definition 485.4. They place the unit and bind laws inside the finite route named by u, f, g, K, L.

Use Definition 485.8 and Definition 485.37. The ledger reads those rows through the same accepted packet and accounts for every public unit or bind request.

Finally apply Definition 485.21 and Definition 485.27. The only remaining transports are the displayed H rows and the local certificate N, so the host and quotient readings have no exported route. □

Theorem 485.47 (ContinuationMonad root generator-category lock)**.** *For an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, generator-closure reads and* $\mathsf{Cat}^{\uparrow}$ *hom reads are locked to the same finite route* $A, B, C, f, g, u, H, K, L, N$*. A downstream consumer cannot separate the generator refusal ledger from the* CategoryHomCarrier *and* ContinuationMorphism *rows, and it cannot replace them by a quotient Kleisli category, an ambient category object, or host-function composition.*

Proof. First apply Definition 485.41. The generator surface reads the continuation tails and route rows through the same refusal ledger before it reaches package provenance or local naming.

Next apply Definition 485.42. The $\mathsf{Cat}^{\uparrow}$ hom carrier and continuation-morphism entries are total exactly on the displayed route and do not supply an independent category object.

The two reads are then combined by Definition 485.43. Since both sides use the same H, K, L, N rows over A, B, C, f, g, u, no downstream consumer can split the generator ledger from the Category hom route. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root generator category lock`

Theorem 485.48 (ContinuationMonad root downstream unblock package)**.** *The root downstream surface of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet is the package formed by Definition 485.46 and Definition 485.47. Downstream continuation chapters receive the finite rows* $A, B, C, f, g, u, H, K, L, N$ *as the complete unit, bind, generator-refusal, and Category hom route surface, and they receive no quotient Kleisli arrows, host-function composition, ambient category completion, or unlisted continuation generators.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root downstream unblock package`

Proof. Use Definition 485.46 to exhaust the unit and bind consumers by the finite rows of Z.

Use Definition 485.47 to attach the generator-refusal and Category hom reads to the same rows. This supplies the generator and category boundary without adding a second route.

Finally apply Definition 485.39 and Definition 485.45. These theorems identify the downstream consumer surface with the finite root obligation package, so every excluded host, quotient, category-completion, or unlisted-generator object remains outside the packet. □

Theorem 485.49 (ContinuationMonad finite bind readback package)**.** *For an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every finite bind readback package is exactly the* BHist *source rows* A, B, C*, the continuation rows* f, g, u*, the* Cont *route row* K*, the ledger row* L*, the componentwise* hsame *row* H*, the* Pkg *provenance, and the local* NameCert *row* N*. A bind consumer reads this package as displayed BEDC data and not as host-function composition, quotient Kleisli equality, a general monad evaluator, or an unlisted continuation generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier finite bind readback package`

Proof. First read bind-route totality. It forces every bind consumer through the displayed Cont route and ledger rows K, L over the same source histories and continuation tails.

Next read bind readback exhaustion. The readback has already been exhausted by $A, B, C, f, g, u, H, K, L, N$, with componentwise transport supplied only by H and with no external evaluator row.

The root downstream package then supplies the Pkg provenance and local NameCert wrapper. Since the package contains exactly the displayed carrier, route, ledger, and naming rows, the finite bind readback cannot be replaced by a host, quotient, or unlisted-generator reading. □

Theorem 485.50 (ContinuationMonad downstream route exhaustion)**.** *Every downstream route exported by an accepted* ContinuationMonad$^{\uparrow}$ *packet is exhausted by the root package rows* $A, B, C, f, g, u, H, K, L, N$ *over* BHist*,* Cont*, componentwise* hsame*,* Pkg*, and the local* NameCert *row. Unit reads, bind reads, generator-boundary reads, and* Cat$^{\uparrow}$ *hom reads all factor through that same package, so no downstream continuation chapter receives a host function, quotient Kleisli arrow, ambient category primitive, or continuation rule outside the displayed packet.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier downstream route exhaustion`

Proof. Begin with the root downstream package. It identifies the downstream surface with the carrier, root generator obligation, bind-route totality, ledger exactness, Pkg provenance, and local NameCert rows of the accepted packet.

Use generator-category lockdown to bind the generator and Cat$^{\uparrow}$ hom reads to the same route. Use the finite bind readback package to bind unit and bind consumers to the same K, L, H, N rows.

It remains only to account for downstream escape routes. The root downstream package already excludes host functions, quotient Kleisli arrows, ambient category completion, and unlisted continuation generators, so the displayed $A, B, C, f, g, u, H, K, L, N$ packet exhausts every downstream route. □

Closure status for NameCert$_{\text{ContinuationMonad}^{\uparrow}}$.

Constructive story: A ContinuationMonad$^{\uparrow}$ packet is generated from source, middle, and target histories, two displayed continuation tails, a unit tail, componentwise hsame transports, displayed Cont routes, CategoryUp continuation-morphism readings, package provenance, and local NameCert evidence.

Theory closure: TheoryGate(NameCert$_{\text{ContinuationMonad}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 485.35 and Definition 485.36 expose the public bridge package from the finite continuation route rows $A, B, C, f, g, u, H, K, L, N$ to the standard monad-reading boundary over BHist, Cont, hsame, CategoryHomCarrier, ContinuationMorphism, Pkg, and NameCert.

Formal verification: FormalStatus(NameCert$_{\text{ContinuationMonad}^{\uparrow}}$, unformalized)

Bridge status: none

Not claimed: This chapter does not close full category theory, quotient Kleisli categories, host functions, standard monad laws as host equalities, arbitrary effects, or bridge checking.

Upgrade path: The theory closure is complete for the finite ContinuationMonad$^{\uparrow}$ bridge package; Lean verification and bridge checking remain separate verification-axis obligations.

Theorem 485.51 (ContinuationMonad root category-generator factorization)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the displayed continuation tails factor every root category-generator read through one finite surface. The* CategoryHomCarrier *and* ContinuationMorphism *rows are read from* f, g, u, K, L, H, N*, while the* GeneratorClosure$^{\uparrow}$ *refusal surface accepts no unit, bind, or continuation generator outside the same packet.*

Thus a downstream root consumer may combine the category face and the generator face only by reading $A, B, C, f, g, u, H, K, L, N$ *over* BHist*,* Cont*,* hsame*,* Pkg*, and* NameCert*.*

Proof. Begin with Definition 485.56. It ties the Cat$^{\uparrow}$ hom-carrier surface and the generator-boundary refusal surface to the same source histories, continuation tails, unit tail, and structural rows.

Next use Definition 485.65. The exhaustion theorem identifies every generator-facing or CategoryHomCarrier-facing read with the displayed continuation tails and rejects independent hom carriers, ambient hom sets, host functions, and quotient Kleisli arrows.

Finally apply Definition 485.47. The lock prevents a downstream consumer from separating the generator refusal ledger from the CategoryHomCarrier and ContinuationMorphism rows, so the factorization is exactly the finite packet surface stated above. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root category generator factorization`

Theorem 485.52 (ContinuationMonad root bind-unit boundary)**.** *For an accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every public unit read and every public bind read requires the displayed rows* u, f, g, H, K, L, N *together with the source histories* A, B, C*. The unit and bind boundary has no coordinate for host function composition, host monad equality, quotient Kleisli arrows, or external evaluator rows.*

Proof. Start with Definition 485.46. It exhausts every root unit read and root bind read by u, f, g, K, L, H, N together with A, B, C.

Use Definition 485.49 to package the bind side as finite BEDC data. The package records the histories, continuation rows, route row, ledger row, transport row, provenance, and local certificate, not a host-side bind operation.

Finally use Definition 485.27. The unit side also stays inside the displayed continuation route, so public unit and bind reads both require the same finite packet rows and cannot be supplied by host or quotient structure. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root bind unit boundary`

Theorem 485.53 (ContinuationMonad root downstream surface exactness)**.** *The downstream root surface of an accepted* ContinuationMonad$^{\uparrow}$ *packet is exactly the finite package assembled from the category row, generator refusal row, carrier rows, classifier stability, ledger exactness, package provenance, and local* NameCert *row over* $A, B, C, f, g, u, H, K, L, N$*. It exports no host function composition, quotient Kleisli arrow, ambient hom set, independent category carrier, or unlisted continuation generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root downstream surface exactness`

Proof. Use Definition 485.48 to identify the downstream surface with the root unit-bind exhaustion and the root generator-category lock.

Add the factorization theorem above. It supplies the category-generator side through CategoryHomCarrier, ContinuationMorphism, and the GeneratorClosure$^{\uparrow}$ refusal surface on the same finite rows.

Add the bind-unit boundary above. It supplies the public unit and bind side through u, f, g, H, K, L, N and the source histories A, B, C.

The carrier, classifier, and ledger rows are already exact by Definition 485.6, Definition 485.7, and Definition 485.8. Repacking these rows with Pkg provenance and the local NameCert row leaves no exported coordinate for host function composition, quotient Kleisli arrows, ambient hom sets, independent category carriers, or unlisted generators. □

Theorem 485.54 (ContinuationMonad root public export)**.** *Every public root export of an accepted* ContinuationMonad$^{\uparrow}$ *packet factors through the combined finite rows*

$$A, B, C, f, g, u, H, K, L, N.$$

On this single BEDC route, category-generator reads, public unit reads, public bind reads, carrier obligations, classifier stability, ledger exactness, package provenance, and local NameCert *naming are all read from the same packet. The export contains no host function composition, quotient Kleisli arrow, ambient hom set, independent category carrier, or unlisted continuation generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public export`

Proof. First assemble the root category-generator side. Apply Definition 485.51 to put the CategoryHomCarrier, ContinuationMorphism, and GeneratorClosure$^{\uparrow}$ refusal surfaces on $A, B, C, f, g, u, H, K, L, N$.

Next assemble the public unit and bind side. Apply Definition 485.52; every public unit read and public bind read uses u, f, g, H, K, L, N together with the source histories A, B, C.

Now use Definition 485.53. It identifies the downstream root surface with the carrier rows, classifier stability, ledger exactness, package provenance, and local NameCert surface over the same finite packet.

Finally cite the carrier, classifier, and ledger theorems: Definition 485.6, Definition 485.7, and Definition 485.8. These rows leave no public coordinate for host function composition, quotient Kleisli arrows, ambient hom sets, independent category carriers, or unlisted continuation generators, so the displayed route is the public root export. □

Lemma 485.55 (ContinuationMonad root category-generator bridge determinacy)**.** *Let* $Z = (A, B, C, f, g, u, H, K, L, N)$ *be an accepted* ContinuationMonad$^{\uparrow}$ *packet. Every consumer-facing use of the root category-generator bridge, whether it is presented as a displayed route, componentwise transport, public readback, or downstream handoff, is determined by the same finite rows*

$$A, B, C, f, g, u, H, K, L, N.$$

The category side may read only the CategoryHomCarrier *and* ContinuationMorphism *rows exposed by the displayed continuation tails and route ledger; the generator side may read only the* GeneratorClosure$^{\uparrow}$ *refusal surface attached to those rows; and the downstream side may read only the* BHist*,* Cont*,* hsame*,* Pkg*, and* NameCert *coordinates already carried by the packet. No bridge coordinate remains for host function composition, quotient Kleisli arrows, ambient hom sets, independent category carriers, external evaluators, detached handoff witnesses, or unlisted continuation generators.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root category generator bridge determinacy`

Proof. Apply Definition 485.51. It places every root category-generator read on one finite surface: the CategoryHomCarrier and ContinuationMorphism rows are read from f, g, u, K, L, H, N, and the GeneratorClosure$^{\uparrow}$ refusal surface accepts no generator outside the same packet. Hence any consumer route that touches the category face or the generator face has already factored through $A, B, C, f, g, u, H, K, L, N$.

Now apply Definition 485.53. The downstream root surface is exactly the package assembled from the category row, generator refusal row, carrier rows, classifier stability, ledger exactness, package provenance, and local NameCert row over the same displayed packet. Thus a transport use is the componentwise hsame row already present in H, a route or replay use is one of the displayed Cont rows carried by f, g, u and K, a readback use is one of the listed carrier, classifier, ledger, category, or generator-refusal rows, and a handoff use is the Pkg provenance together with the local naming row N.

These two exactness statements have the same source rows and the same refusal boundary. Therefore a consumer cannot vary the bridge by changing only an unlisted coordinate: any such

variation would have to be a host composition row, quotient Kleisli arrow, ambient hom set, independent category carrier, external evaluator, detached handoff witness, or unlisted generator, and Definition 485.53 states that none of those coordinates is exported. The bridge is therefore determined by the displayed finite packet. □

Theorem 485.56 (ContinuationMonad generator category triad)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the source histories* A, B, C*, continuation tails* f, g, u*, and structural rows* H, K, L, N *form one generator-category triad. The* $\mathsf{Cat}^{\uparrow}$ *hom-carrier surface reads the displayed tails as* $\mathsf{CategoryHomCarrier}$ *and* $\mathsf{ContinuationMorphism}$ *rows, while the generator-boundary refusal surface of chapter 486 refuses every unit, bind, or continuation generator not already displayed in* Z*.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier generator category triad`

Proof. Start with carrier admission and classifier stability from Definition 485.6 and Definition 485.7. These rows expose $A, B, C, f, g, u, H, K, L, N$ as one finite packet and keep the transported continuation tails on the same histories.

Next read the category side through chapter 61 and Definition 485.16. The hom-carrier and continuation-morphism entries are readings of the displayed tails and ledger, not independent category data.

Finally read the generator side through chapter 486 and Definition 485.17. Since the refusal row accepts only the listed continuation rules, the category and generator faces meet on the same $A, B, C, f, g, u, H, K, L, N$ packet. □

Theorem 485.57 (ContinuationMonad root bind schedule exhaustion)**.** *Let* $Z = (A, B, C, f, g, u, H, K, L, N)$ *be an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet. Every root-level unit or bind schedule read of* Z *is exhausted by the displayed unit tail* u*, continuation tails* f, g*, componentwise transports* H*, route rows* K*, ledger rows* L*, and local name* N*. A downstream read cannot replace this schedule by host function composition, a quotient Kleisli arrow, an ambient hom set, or an unlisted generator rule.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root bind schedule exhaustion`

Proof. First apply Definition 485.3 and Definition 485.4. The unit and bind laws are ledger statements about u, f, g, K, L inside the accepted packet.

Use Definition 485.11 and Definition 485.12 to keep every transported bind read on the same H, K, L, N rows. The schedule is therefore the displayed continuation ledger, not a host composition operation.

Finally attach Definition 485.56. Its category and generator faces account for the only external readings of the schedule, and the refusal surface blocks every unlisted continuation rule. □

Theorem 485.58 (ContinuationMonad downstream unblock route package)**.** *The generator-category triad of Definition 485.56 and the bind schedule exhaustion of Definition 485.57 form the downstream unblock route package for* $\mathsf{ContinuationMonad}^{\uparrow}$*. Any downstream consumer receives exactly* $A, B, C, f, g, u, H, K, L, N$*, the* $\mathsf{Cat}^{\uparrow}$ *hom-carrier reading of those rows, and the generator-boundary refusal of unlisted continuation rules.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier downstream unblock route package`

Proof. Use Definition 485.56 to expose the shared source. It binds the three histories, the continuation tails, the CategoryUp hom-carrier surface of chapter 61, and the generator-boundary refusal surface of chapter 486 to one packet.

Use Definition 485.57 to exhaust unit and bind reads. Every root schedule read factors through u, f, g, H, K, L, N before it can be consumed downstream.

Finally apply Definition 485.39 and Definition 485.45. They identify the downstream surface with the same finite carrier, route, ledger, package, and local naming rows, so no host function composition, quotient Kleisli category, ambient hom set, or unlisted generator is exported. □

Theorem 485.59 (ContinuationMonad formal target handoff)**.** *Any later Lean formal target for* $\mathsf{ContinuationMonad}^{\uparrow}$ *must read the same finite packet*

$$Z = (A, B, C, f, g, u, H, K, L, N)$$

through BHist, hsame, Cont, Pkg, $\mathsf{Cat}^{\uparrow}$, *and* $\mathsf{GeneratorClosure}^{\uparrow}$. *The target may project the packet into carrier, route, ledger, package, hom-carrier, or generator-refusal faces, but it may not introduce a second continuation source or a detached category-generator witness.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier category generator formal handoff`

Proof. Start from Definition 485.56. It identifies the CategoryUp hom-carrier reading and the GeneratorClosureUp refusal reading with the displayed histories, continuation tails, and structural rows of Z.

Next use Definition 485.57. The root unit and bind schedule is exhausted by u, f, g, H, K, L, N, so any formal target that reads a continuation law must pass through the same BHist, hsame, Cont, and Pkg rows.

Finally apply Definition 485.58. It packages the category and generator readings for downstream consumers, leaving no coordinate for a second source, detached witness, or independent formal target carrier. □

Theorem 485.60 (ContinuationMonad Kleisli quotient refusal)**.** *No accepted read of a* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet may replace the displayed continuation tails* f, g, u *and rows* H, K, L, N *by quotient Kleisli arrows, ambient host composition, an unlisted hom set, or a host category law. Every accepted category or generator reading remains a read of the displayed BEDC packet* $Z = (A, B, C, f, g, u, H, K, L, N)$.

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier kleisli quotient refusal`

Proof. Use Definition 485.57 first. It refuses host function composition, quotient Kleisli arrows, ambient hom sets, and unlisted generator rules at the root schedule boundary.

Then apply Definition 485.56. The CategoryUp side reads the displayed tails as hom-carrier and continuation-morphism rows, while the GeneratorClosureUp side refuses every generator not already displayed in Z.

The downstream package of Definition 485.58 carries the same refusal to every consumer. Thus a quotient or host-composition replacement has no accepted row through which it can enter. □

Theorem 485.61 (ContinuationMonad category generator exactness)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$, *the* $\mathsf{Cat}^{\uparrow}$ *hom-carrier face and the* $\mathsf{GeneratorClosure}^{\uparrow}$ *refusal face are exact on the same displayed rows. The category face reads precisely the continuation tails and transport ledger exposed by* Z, *and the generator face refuses precisely the unit, bind, and continuation generators not displayed by those rows.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier category generator exactness`

Proof. Apply Definition 485.56. It already places the CategoryUp hom-carrier surface and the GeneratorClosureUp refusal surface on the same $A, B, C, f, g, u, H, K, L, N$ packet.

Use Definition 485.57 to identify which unit and bind reads are available. The schedule is the displayed continuation ledger, so exactness is measured against u, f, g, H, K, L, N rather than against host composition.

Finally use Definition 485.58. The downstream route exports exactly the category hom-carrier reading and generator refusal reading of the same packet, which proves that the two faces are exact on the displayed rows. □

Theorem 485.62 (ContinuationMonad bind-Cont unit coherence)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the unit tail* u*, bind tails* f, g*,* $\mathsf{Cat}^{\uparrow}$ *hom-carrier face, and* $\mathsf{GeneratorClosure}^{\uparrow}$ *refusal face are coherent exactly when every displayed bind read is a* Cont*-route read through* H, K, L, N*. The packet exports no quotient Kleisli arrow, host function composition, ambient hom set, or detached unit law beyond those displayed routes.*

Proof. Start with root bind schedule exhaustion. It says that every root unit or bind schedule read is exhausted by u, f, g, H, K, L, N and refuses host function composition, quotient Kleisli arrows, ambient hom sets, and unlisted generator rules.

Apply the generator-category triad. The $\mathsf{Cat}^{\uparrow}$ hom-carrier face and the $\mathsf{GeneratorClosure}^{\uparrow}$ refusal face are readings of the same displayed continuation packet, so the category and generator sides do not introduce an extra bind source.

Use category-generator exactness and the downstream unblock route package. They identify the exported downstream surface with the same hom-carrier reading, generator refusal reading, and H, K, L, N route rows. Hence bind-Cont unit coherence is exactly the condition that displayed bind reads pass through those Cont routes. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier bind cont unit coherence`

Theorem 485.63 (ContinuationMonad generator category public factorization)**.** *Every public read of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet factors first through the displayed packet*

$$Z = (A, B, C, f, g, u, H, K, L, N),$$

then through the $\mathsf{Cat}^{\uparrow}$ *hom-carrier face and the* $\mathsf{GeneratorClosure}^{\uparrow}$ *refusal face. The exported public surface contains no quotient Kleisli arrow, host composition operation, detached category witness, or generator not listed by* Z*.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier generator category public factorization`

Proof. Start with category-generator exactness, Definition 485.61. It places the $\mathsf{Cat}^{\uparrow}$ hom-carrier face and the $\mathsf{GeneratorClosure}^{\uparrow}$ refusal face on the same displayed $A, B, C, f, g, u, H, K, L, N$ rows.

Use bind-Cont unit coherence, Definition 485.62. Every displayed bind read passes through the Cont route rows H, K, L, N, and the packet exports no quotient Kleisli arrow, host function composition, ambient hom set, or detached unit law outside those routes.

Finally apply Definition 485.58. It packages the category hom-carrier reading and generator-boundary refusal for every downstream consumer. Hence a public read factors through Z and then through the two displayed faces, with no detached category witness or unlisted generator available to the route. □

Theorem 485.64 (ContinuationMonad triad unit route package)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the triad rows* A, B, C*, the continuation tails* f, g*, the unit tail* u*, and the rows* H, K, L, N *are the complete unit-and-bind route package. The unit route is the displayed* u *row, the bind route is the displayed read through* f, g, K, L*, and the local readback has no coordinate for host function composition, quotient Kleisli arrows, or a general category primitive.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root triad unit route package`

Proof. Start with carrier admission from Definition 485.6. It exposes exactly the three histories, the two continuation tails, the unit tail, the transport row, the route row, the ledger row, and the local naming row.

Apply the unit laws of Definition 485.3 and the associativity theorem of Definition 485.4. The unit route and bind read are therefore ledger routes over u, f, g, K, L, transported componentwise by H.

Use classifier stability and ledger exactness from Definition 485.7 and Definition 485.12. These facts exhaust the consumer-visible route by the displayed packet, so no host function, quotient Kleisli arrow, or external category primitive remains available. □

Theorem 485.65 (ContinuationMonad generator hom route exhaustion)**.** *Every generator-facing or* $\mathsf{CategoryHomCarrier}$*-facing read of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet is exhausted by the displayed continuation tails* f, g, u*, the generator-boundary surface, and the* $\mathsf{Cat}^{\uparrow}$ *hom-carrier surface. The read factors through* A, B, C, H, K, L, N *and cannot introduce an unlisted continuation rule, independent hom carrier, ambient hom set, host function, or quotient Kleisli arrow.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root generator hom route exhaustion`

Proof. First read the generator boundary through Definition 485.17. It refuses every unit row, bind row, continuation rule, or route generator not displayed in the packet.

Next read the category-facing surface through Definition 485.16. The $\mathsf{CategoryHomCarrier}$ and $\mathsf{ContinuationMorphism}$ entries are exposed only as reads of the displayed tails over A, B, C, H, K, L, N.

Finally combine ledger exactness from Definition 485.12 with the Kleisli boundary of Definition 485.19. The generator and hom-carrier readings are therefore exhausted by the continuation rows already present in the packet, with no unlisted rule or external hom object left to read. □

Theorem 485.66 (ContinuationMonad root downstream readback package)**.** *The rows displayed in Definition 485.64 and Definition 485.65 form the downstream root-unblock surface for* $\mathsf{ContinuationMonad}^{\uparrow}$*. A downstream consumer receives precisely* $A, B, C, f, g, u, H, K, L, N$*, the generator-boundary refusal of unlisted continuation rules, and the* $\mathsf{Cat}^{\uparrow}$ *hom-carrier reading of the displayed tails.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root downstream readback package`

Proof. Use the triad unit route package to expose the local source. The downstream surface begins with $A, B, C, f, g, u, H, K, L, N$ and reads unit and bind only through the displayed continuation routes.

Use the generator hom route exhaustion to expose the two external faces. The generator boundary refuses unlisted rules, while the CategoryUp surface reads the hom-carrier and continuation-morphism rows from the same displayed tails.

Together these rows are exactly the carrier, unit, associativity, classifier stability, ledger exactness, generator boundary, category hom exposure, and local NameCert data cited in the core chapter. Since each downstream face is already accounted for by those rows, the readback package exports no host function composition, quotient Kleisli category, ambient hom set, or additional continuation generator. □

Theorem 485.67 (ContinuationMonad root route source exposure)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the root route exposes its source only through the displayed histories* A, B, C*, the continuation tails* f, g*, the unit tail* u*, the transport row* H*, the route row* K*, the ledger row* L*, and the local name row* N*. Any downstream root consumer reads the source through these history, tail, and unit rows before it can read the generator-boundary or* $\mathsf{Cat}^{\uparrow}$ *hom surfaces.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root route source exposure`

Proof. Start with carrier admission from Definition 485.6. It displays exactly $A, B, C, f, g, u, H, K, L, N$ as the accepted source packet and leaves no coordinate for an external source object.

Apply the root route packages already present in Definition 485.58 and Definition 485.66. They route downstream reads through the same packet before the consumer reaches the generator-boundary refusal or the $\mathsf{Cat}^{\uparrow}$ hom-carrier surface.

Finally use Definition 485.16 and Definition 485.17. These theorems read category and generator data from the exposed rows rather than from an independent host source, so the root route source is precisely the displayed history, tail, unit, transport, route, ledger, and local-name surface. □

Theorem 485.68 (ContinuationMonad root continuation rule coverage)**.** *Let* $Z = (A, B, C, f, g, u, H, K, L, N)$ *be an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet. Every root unit read and every root bind read of* Z *is covered by the rows* K, H, L, N *together with the displayed tails* u, f, g *and histories* A, B, C*. The unit laws, associativity read, route provenance, componentwise transport, ledger accounting, and local naming all remain inside this finite row package.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root continuation rule coverage`

Proof. Use Definition 485.3 for unit reads and Definition 485.4 for bind reads. Both theorems state their laws as ledger reads over the displayed unit and continuation tails.

Next apply Definition 485.64 and Definition 485.57. They identify the route row K, transport row H, ledger row L, and local name row N as the finite coverage data for the public unit and bind schedules.

The root downstream packages then provide the handoff to consumers. Since Definition 485.66 and Definition 485.58 expose no rule outside $A, B, C, f, g, u, H, K, L, N$, every unit or bind read is covered by the named rows. □

Theorem 485.69 (ContinuationMonad root downstream consumer separation)**.** *For an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, downstream root consumers are separated from host function composition, quotient Kleisli arrows, ambient hom sets, independent category carriers, and unlisted continuation generators. Their only available reads are the displayed source rows, unit and bind route rows, the generator-boundary refusal, and the* $\mathsf{Cat}^{\uparrow}$ *hom-carrier exposure of the same packet.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root downstream consumer separation`

Proof. Begin with Definition 485.17. It refuses every unit row, bind row, continuation rule, or route generator not displayed in the accepted packet.

Read the category side through Definition 485.16. The CategoryHomCarrier and ContinuationMorphism rows are exposed only as readings of f, g, u over A, B, C, H, K, L, N.

Finally combine the two root-unblock child packages, Definition 485.58 and Definition 485.66. They identify the downstream surface with the finite root route package, so host function composition, quotient Kleisli arrows, ambient hom sets, independent category carriers, and unlisted generators have no consumer-visible coordinate. □

Theorem 485.70 (ContinuationMonad root consumer standard row)**.** *Every root consumer standard row of an accepted* ContinuationMonad$^{\uparrow}$ *packet*

$$Z = (A, B, C, f, g, u, H, K, L, N)$$

is exhausted by the displayed histories A, B, C, continuation tails f, g, unit tail u, transport row H, route row K, ledger row L, and local name row N. Unit reads and bind reads are covered by the root continuation rule package over these rows, while category-facing and generator-facing reads remain separated from host function composition, quotient Kleisli arrows, ambient hom sets, independent category carriers, and unlisted generators.

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root consumer standard row`

Proof. First apply Definition 485.67. It identifies the root source surface with exactly $A, B, C, f, g, u, H, K, L, N$ and leaves no coordinate for an external source object.

Next use Definition 485.68. Unit and bind reads are already covered by the displayed tails, histories, transport, route, ledger, and local naming rows, so the standard row cannot import a second continuation rule package.

Finally apply Definition 485.69. The downstream separation theorem blocks host function composition, quotient Kleisli arrows, ambient hom sets, independent category carriers, and unlisted generators. Therefore the root consumer standard row is precisely the displayed finite packet. □

Theorem 485.71 (ContinuationMonad root formal target surface)**.** *For an accepted* ContinuationMonad$^{\uparrow}$ *packet $Z = (A, B, C, f, g, u, H, K, L, N)$, the formal target surface available at the root consists exactly of the finite rows $A, B, C, f, g, u, H, K, L, N$ together with their displayed* BHist*,* Cont*,* hsame*,* Pkg*,* Cat$^{\uparrow}$ *hom-carrier,* ContinuationMorphism*, and local* NameCert *readings. Downstream formal targets may consume unit, bind, generator-refusal, and Category hom data only through that surface, not through quotient Kleisli arrows, host-function composition, ambient category completion, or unlisted continuation generators.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal target surface`

Proof. Use the root unit-bind exhaustion theorem to account for the unit and bind reads. It restricts those reads to the displayed source histories, continuation tails, unit tail, route rows, ledger rows, transport row, provenance, and local naming row.

Use the root generator-category lock for the generator-refusal and Category hom faces. It ties those faces to the same $A, B, C, f, g, u, H, K, L, N$ route and prevents a separate quotient or ambient category object from entering the surface.

Combine the two readings with the root downstream unblock package. The package is already the complete downstream surface, so the formal target surface is the same finite row list with no additional Kleisli, host-composition, completion, or generator coordinates. □

Theorem 485.72 (ContinuationMonad root route formal handoff)**.** *Every downstream formal target that reads the* $\mathsf{ContinuationMonad}^{\uparrow}$ *root route receives the rows* $A, B, C, f, g, u, H, K, L, N$ *through the root unit-bind exhaustion, generator-category lock, root downstream unblock package, and bind readback exhaustion. The handoff may expose displayed continuation routes and Category hom readings, but it cannot reinterpret them as host Kleisli composition, quotient morphism equality, ambient category completion, or an unlisted continuation-generator rule.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root route formal handoff`

Proof. First apply root unit-bind exhaustion. It makes the public unit and bind entries read u, f, g, K, L, H, N over the source histories A, B, C rather than a host monad operation.

Next apply the generator-category lock. The same finite route carries generator refusal and $\mathsf{Cat}^{\uparrow}$ hom readings, so a downstream target cannot split the generator ledger from the Category hom row.

Now use bind readback exhaustion. It states that every bind readback is already exhausted by the displayed packet rows and cannot be supplied by a quotient Kleisli arrow, host function, unlisted generator, or external evaluator.

The root downstream unblock package then repacks these rows as the formal handoff. Since all consumer-visible data has already been routed through the finite packet, the refused host and quotient readings have no handoff coordinate. □

Theorem 485.73 (ContinuationMonad root ledger formal boundary)**.** *The ledger boundary for root* $\mathsf{ContinuationMonad}^{\uparrow}$ *formal targets is the finite package* $A, B, C, f, g, u, H, K, L, N$*. It records the source, continuation-tail, unit-tail, transport, route, ledger, provenance, generator-refusal, Category hom, and local* NameCert *rows needed by downstream continuation chapters, and it refuses quotient Kleisli arrows, host-function composition, ambient category completion, external monad evaluators, and continuation generators not listed in the packet.*

Proof. Start with the root downstream unblock package. It identifies the rows available before downstream continuation chapters read any standard monad boundary.

Add root unit-bind exhaustion and bind readback exhaustion. These theorems account for every public unit, bind, and bind-readback request through the same packet rows.

Add the generator-category lock. It places generator refusal and Category hom readings on the same ledger, preventing a separate categorical carrier or unlisted generator list from supplying downstream data.

Thus the ledger boundary is precisely the finite root package. Objects outside $A, B, C, f, g, u, H, K, L, N$ are not recorded by the ledger and cannot be consumed as formal-target input. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root ledger formal boundary`

Theorem 485.74 (ContinuationMonad root formal route saturation)**.** *Every downstream formal target consuming* $\mathsf{ContinuationMonad}^{\uparrow}$ *receives exactly the root rows*

$$A, B, C, f, g, u, H, K, L, N$$

through the existing root formal target surface, root route formal handoff, and downstream route exhaustion. The route exports displayed BHist, Cont, hsame, Pkg, $\mathsf{Cat}^{\uparrow}$ *hom-carrier,* ContinuationMorphism, *and local* NameCert *readings only; it exports no quotient Kleisli arrows, host-function composition, ambient category completion, external monad evaluator, or unlisted continuation generator.*

Proof. Start with Definition 485.71. It identifies the formal target surface with the finite root rows $A, B, C, f, g, u, H, K, L, N$ and their displayed BEDC readings.

Next apply Definition 485.72. The handoff keeps downstream formal targets on the same route and refuses host Kleisli composition, quotient morphism equality, ambient category completion, and unlisted continuation-generator rules.

Finally apply Definition 485.50. Since every downstream route is already exhausted by the same root package, the formal route is saturated by exactly those rows and no external evaluator or hidden continuation coordinate can be exported. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal route saturation`

Theorem 485.75 (ContinuationMonad root ledger saturation boundary)**.** *The root ledger boundary for any downstream formal target consuming* $\mathsf{ContinuationMonad}^{\uparrow}$ *is exactly the finite package*

$$A, B, C, f, g, u, H, K, L, N.$$

The boundary is supplied by the existing root ledger formal boundary together with downstream route exhaustion, and it admits no additional ledger entry for quotient Kleisli arrows, host-function composition, ambient category completion, external monad evaluators, or continuation generators outside the packet.

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root ledger saturation boundary`

Proof. First use Definition 485.73. It states that the ledger available to root formal targets is the finite package $A, B, C, f, g, u, H, K, L, N$ with source, tail, unit, transport, route, provenance, generator-refusal, Category hom, and local naming rows.

Then use Definition 485.50. Every downstream unit, bind, generator-boundary, or Category hom read is already routed through that same package.

It remains to exclude extra ledger entries. The root ledger boundary records no coordinate for quotient Kleisli arrows, host-function composition, ambient category completion, external monad evaluators, or unlisted continuation generators, so saturation is exactly the displayed package. □

Theorem 485.76 (ContinuationMonad root formal handoff saturation)**.** *The root formal handoff for* $\mathsf{ContinuationMonad}^{\uparrow}$ *is saturated by the composition of Definition 485.71, Definition 485.72, Definition 485.73, and Definition 485.50. Consequently every downstream formal target receives exactly* $A, B, C, f, g, u, H, K, L, N$ *and receives no quotient Kleisli arrows, host-function composition, ambient category completion, external monad evaluator, or unlisted continuation generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal handoff saturation`

Proof. First compose the formal target surface with the route handoff. The target surface lists the rows available to downstream formal targets, while the handoff states that the target may consume them only along the displayed continuation route.

Next compose the ledger boundary with downstream route exhaustion. The ledger boundary records the finite accounting rows, and route exhaustion shows that unit, bind, generator-refusal, and Category hom consumers cannot leave that accounting surface.

Combining the two compositions saturates the handoff. Every formal consumer receives the same $A, B, C, f, g, u, H, K, L, N$ packet, and the refused host, quotient, ambient, evaluator, and unlisted-generator objects have no exported coordinate. □

Theorem 485.77 (ContinuationMonad root formal audit factorization)**.** *Every downstream formal read of* ContinuationMonad$^{\uparrow}$ *factors through the displayed audit rows*

$$A, B, C, f, g, u, H, K, L, N$$

together with BHist*,* Cont*,* hsame*,* Pkg*, the* Cat$^{\uparrow}$ *hom-carrier, and the local* NameCert *surface. The factorization is the same for unit, bind, generator-refusal, Category hom, and naming consumers, and it uses no route outside the displayed root packet.*

Proof. Start with root formal route saturation. It identifies the downstream formal route with $A, B, C, f, g, u, H, K, L, N$ and the displayed BHist, Cont, hsame, Pkg, Cat$^{\uparrow}$ hom-carrier, ContinuationMorphism, and local NameCert readings.

Apply the root ledger saturation boundary. It records the same finite rows as the audit ledger for source, tail, unit, transport, route, provenance, generator-refusal, Category hom, and local naming.

Finally use root formal handoff saturation together with the sibling formal NameCert handoff of Definition 485.81. The handoff keeps downstream formal targets on the same displayed packet, so every formal read factors through the audit rows and their named BEDC carriers. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal audit factorization`

Theorem 485.78 (ContinuationMonad root formal route budget exhaustion)**.** *The root formal route budget exported by* ContinuationMonad$^{\uparrow}$ *is exhausted by* $A, B, C, f, g, u, H, K, L, N$*,* BHist*,* Cont*,* hsame*,* Pkg*,* Cat$^{\uparrow}$*, and the local* NameCert *surface. It exports no quotient Kleisli arrows, no host-function composition, no ambient category completion, no external evaluator, and no unlisted continuation generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal route budget exhaustion`

Proof. Use root formal route saturation to fix the exported formal surface. The saturation theorem already lists the accepted rows and the allowed BEDC readings for downstream formal targets.

Use the root ledger saturation boundary to read the budget as finite accounting. Since the ledger has entries only for the displayed root rows, there is no remaining coordinate that could encode quotient Kleisli arrows, host-function composition, ambient completion, external evaluation, or another generator.

The sibling formal NameCert handoff confirms the same refusal at the local naming surface. Root formal handoff saturation then transfers the refusal to downstream formal consumers, exhausting the route budget. □

Theorem 485.79 (ContinuationMonad root formal NameCert consumer lock)**.** *The downstream formal consumers of* ContinuationMonad$^{\uparrow}$ *are locked to the audit factorization of Definition 485.77 and the route-budget exhaustion of Definition 485.78. Together with root formal handoff saturation and the root formal NameCert handoff, this lock permits only reads through* $A, B, C, f, g, u, H, K, L, N$*,* BHist*,* Cont*,* hsame*,* Pkg*,* Cat$^{\uparrow}$*, and local* NameCert*, and refuses all quotient, host-composition, ambient-completion, evaluator, and unlisted-generator reads.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal namecert consumer lock`

Proof. First apply the audit factorization theorem. It routes every downstream formal read through the finite audit rows and their displayed BEDC carriers.

Next apply route-budget exhaustion. It removes the quotient Kleisli, host-composition, ambient-completion, evaluator, and unlisted-generator alternatives from the exported route budget.

Finally combine root formal handoff saturation with Definition 485.81. The handoff and local NameCert route read the same finite packet, so a downstream formal consumer has no accepted route outside the audit factorization and no leftover route budget for the refused objects. □

Theorem 485.80 (ContinuationMonad root formal downstream coverage)**.** *For an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every accepted local consumer of the root formal target is exhausted by the finite downstream coverage surface*

$$A, B, C, f, g, u, H, K, L, N.$$

The coverage surface consists of the displayed BHist *source histories,* Cont *continuation tails, componentwise* hsame *transports,* Pkg *provenance, the* $\mathsf{Cat}^{\uparrow}$ *hom-carrier row, the ContinuationMorphism row, the local* NameCert *row, and the ledger and readback rows named by the root formal route. Unit and bind consumers factor through the unit-bind and bind-readback rows, generator and Category consumers factor through the generator-category rows, and local naming or handoff consumers factor through the root formal handoff rows. Quotient Kleisli arrows, host-function composition, ambient category completion, external monad evaluators, and unlisted continuation-generator rules remain outside the packet.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal downstream coverage`

Proof. Start with Definition 485.72. It states that every downstream formal target reading the root route receives $A, B, C, f, g, u, H, K, L, N$ through root unit-bind exhaustion, generator-category lock, the root downstream unblock package, and bind readback exhaustion. Thus the accepted local consumers are already sorted into the unit-bind face, the generator-Category face, and the bind-readback or handoff face.

Apply Definition 485.74. The saturation theorem identifies the exported formal route with the same finite rows and lists the only readings exported by that route: BHist, Cont, hsame, Pkg, the $\mathsf{Cat}^{\uparrow}$ hom-carrier, the ContinuationMorphism row, and local NameCert. Therefore any consumer-facing use of the formal target must factor through one of those displayed rows.

It remains to check that no local consumer can enter through an accounting side door. The ledger side is closed by Definition 485.75, which records no extra entry beyond $A, B, C, f, g, u, H, K, L, N$. The coverage side is closed by Definition 485.77 and Definition 485.78, which route audit, naming, Category, unit, bind, and generator-facing reads through the same packet and exhaust the route budget. Finally Definition 485.79 transfers that exhaustion to local formal consumers. Since none of these rows contains a coordinate for quotient Kleisli arrows, host-function composition, ambient category completion, external monad evaluators, or unlisted continuation-generator rules, all excluded alternatives remain outside the BEDC packet. □

Theorem 485.81 (ContinuationMonad root formal NameCert handoff)**.** *Every downstream formal target consuming* $\mathsf{ContinuationMonad}^{\uparrow}$ *receives the local* NameCert *row only through the finite packet*

$$A, B, C, f, g, u, H, K, L, N.$$

The received readings are exactly the displayed BHist *source histories,* Cont *unit and bind tails,* hsame *transports,* Pkg *provenance,* $\mathsf{Cat}^{\uparrow}$ *hom-carrier row,* ContinuationMorphism *row, and local*

NameCert *row. No quotient Kleisli arrow, host-function composition, ambient category completion, external monad evaluator, or unlisted continuation generator is exported.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal namecert handoff`

Proof. First apply Definition 485.87. It forces root consumers to read the source histories A, B, C and continuation tails f, g, u through the displayed BHist, hsame, Cont, Pkg, and NameCert surface of the packet.

Next use Definition 485.74. Downstream formal targets receive exactly $A, B, C, f, g, u, H, K, L, N$ through the formal route, together with the displayed Category hom-carrier and ContinuationMorphism readings.

Finally compose with Definition 485.75. The ledger boundary is the same finite packet and admits no extra entry for quotient Kleisli arrows, host-function composition, ambient category completion, external evaluators, or unlisted continuation generators. Hence the local NameCert row reaches downstream formal targets only through the named packet and not through an external monad schema. □

Theorem 485.82 (Category ContinuationMonad hom-carrier route)**.** *Every downstream formal target reading a* ContinuationMonad$^{\uparrow}$ *packet through* $A, B, C, f, g, u, H, K, L, N$ *receives its* Cat$^{\uparrow}$ *hom-carrier exposure exactly through the displayed* CategoryHomCarrier *and* ContinuationMorphism *rows. The route is the finite continuation packet route; it is not host function composition, a quotient Kleisli arrow, an ambient category completion, or an external monad evaluator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier category hom carrier route`

Proof. Start with Definition 485.81. It fixes the downstream formal handoff to the finite packet $A, B, C, f, g, u, H, K, L, N$ and already names the Category hom-carrier and ContinuationMorphism readings as packet rows.

Next apply Definition 61.317. The Category side reads a hom carrier exactly as unary endpoint rows together with a continuation morphism whose displayed tail is the morphism history. Thus the CategoryHomCarrier row consumed downstream is the continuation-tail row of the same packet.

Finally use Definition 485.87, Definition 485.74, and Definition 485.75. These root source and ledger saturation results leave no additional coordinate for host composition, quotient Kleisli arrows, ambient category completion, external evaluators, or unlisted continuation generators, so the Category hom-carrier route is exactly the displayed continuation packet route. □

Theorem 485.83 (ContinuationMonad Category hom readback correspondence)**.** *Any* Cat$^{\uparrow}$ *hom-carrier read consumed by the* ContinuationMonad$^{\uparrow}$ *formal target is exactly the readback of the finite packet rows*

$$A, B, C, f, g, u, H, K, L, N.$$

The correspondence is carried by the displayed CategoryHomCarrier *and* ContinuationMorphism *rows of the packet. It cannot be replaced by quotient Kleisli arrows, host-function composition, ambient category completion, an external monad evaluator, or an unlisted continuation generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier category hom readback correspondence`

Proof. First apply Definition 485.81. It fixes the formal target handoff to the finite packet $A, B, C, f, g, u, H, K, L, N$ and names the Category hom-carrier and ContinuationMorphism rows as part of that packet.

Next use Definition 485.82. The Category hom-carrier exposure reaches the formal target only through the displayed CategoryHomCarrier and ContinuationMorphism readings, so the Category-side readback is already the continuation packet readback.

Finally compose with Definition 485.84. The formal target has no remaining coordinate for quotient Kleisli arrows, host-function composition, ambient category completion, external monad evaluators, or unlisted generators. Hence every consumed $\mathsf{Cat}^{\uparrow}$ hom-carrier read corresponds exactly to the finite continuation packet rows. □

Theorem 485.84 (ContinuationMonad formal target readback exhaustion)**.** *Every downstream formal target consuming the* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet through*

$$A, B, C, f, g, u, H, K, L, N$$

must first read the root formal NameCert *handoff and the* $\mathsf{Cat}^{\uparrow}$ *hom-carrier route. Therefore the target receives only the displayed* BHist *source histories,* Cont *continuation tails,* hsame *transports,* Pkg *provenance, Category hom-carrier row,* ContinuationMorphism *row, and local* NameCert *row; it receives no quotient Kleisli arrow, host-function composition, ambient category completion, external monad evaluator, or unlisted continuation generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier formal target readback exhaustion`

Proof. Start with Definition 485.81. It fixes the formal handoff to $A, B, C, f, g, u, H, K, L, N$ and excludes quotient Kleisli arrows, host composition, ambient category completion, external evaluators, and unlisted generators from the local NameCert route.

Next apply Definition 485.82. The Category hom-carrier exposure is not an ambient category completion; it is the displayed CategoryHomCarrier and ContinuationMorphism reading of the same finite continuation packet.

Finally compose with Definition 485.87, Definition 485.74, and Definition 485.75. These root source, route, and ledger boundaries exhaust the readback surface, so every formal target consumes the finite packet and no external monad semantics. □

Theorem 485.85 (ContinuationMonad formal route target exhaustion)**.** *Any formal target that reads the displayed continuation packet*

$$A, B, C, f, g, u, H, K, L, N$$

must factor through the root formal NameCert *handoff, the* $\mathsf{Cat}^{\uparrow}$ *hom-carrier route, and the formal-target readback exhaustion. Therefore the target receives only the displayed* BHist *source histories,* Cont *continuation tails,* hsame *transports,* Pkg *provenance, Category hom-carrier row,* ContinuationMorphism *row, and local* NameCert *row. It cannot obtain quotient Kleisli arrows, host-function composition, ambient category completion, external monad evaluators, or unlisted generators.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier formal route target exhaustion`

Proof. First apply Definition 485.81. It fixes the formal route to the finite packet $A, B, C, f, g, u, H, K, L, N$ and excludes quotient Kleisli arrows, host composition, ambient category completion, external evaluators, and unlisted generators from the local NameCert handoff.

Next use Definition 485.82. The Category hom-carrier exposure is the displayed CategoryHomCarrier and ContinuationMorphism reading of the same continuation packet, not an external category-completion route.

Finally compose with Definition 485.84. The formal target has already read the root handoff and the Category route, and the readback theorem exhausts the remaining consumer surface. Hence every formal consumer factors through those three routes and receives no unlisted continuation or monad data. □

Theorem 485.86 (ContinuationMonad root formal handoff downstream coverage)**.** *Every accepted local consumer of the* $\mathsf{ContinuationMonad}^{\uparrow}$ *root formal handoff is exhausted by the displayed finite route*

$$A, B, C, f, g, u, H, K, L, N.$$

Its consumer-facing use factors through one of the already enumerated rows: the BHist *source histories* A, B, C*, the* Cont *unit and bind tails* f, g, u*, the componentwise* hsame *transport row* H*, the formal route and ledger rows* K, L*, the* Pkg *provenance row, the* $\mathsf{Cat}^{\uparrow}$ *hom-carrier row, the* ContinuationMorphism *row, or the local* NameCert *row* N*. No quotient Kleisli arrow, host-function composition, ambient category completion, external monad evaluator, or unlisted continuation generator becomes an accepted alternative of the BEDC packet.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal handoff downstream coverage`

Proof. Start with Definition 485.81. It fixes the local handoff to the finite packet $A, B, C, f, g, u, H, K, L, N$ and states that downstream formal targets receive the local NameCert row only through the displayed source-history, continuation-tail, transport, provenance, Category hom-carrier, ContinuationMorphism, and naming rows. Thus an accepted local consumer has no entry point before the finite handoff packet is read.

Apply Definition 485.84. The readback theorem forces any downstream formal target consuming the packet to read the root formal NameCert handoff together with the $\mathsf{Cat}^{\uparrow}$ hom-carrier route. It also identifies the remaining readback surface with exactly the displayed BHist, Cont, hsame, Pkg, Category hom-carrier, ContinuationMorphism, and local NameCert rows.

The ledger and coverage coordinates are therefore the same finite list. The route rows K, L account for the formal route and ledger boundary, while H transports only the displayed components and N names only that packet. Since the handoff theorem excludes the quotient, host-composition, ambient-completion, external-evaluator, and unlisted-generator alternatives from the local export, and the readback-exhaustion theorem leaves no further downstream coordinate after the handoff and Category route are read, every accepted local consumer is exhausted by the enumerated rows and every excluded alternative remains outside the BEDC packet. □

Theorem 485.87 (ContinuationMonad root source coverage)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every root consumer must read the displayed source histories* A, B, C *and the displayed continuation tails* f, g, u *before any unit or bind law can be consumed. The source coverage is exactly the finite* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *surface of* Z*; it does not pass through host functions, quotient Kleisli arrows, ambient hom sets, or unlisted generators.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root source coverage`

Proof. Start with Definition 485.67. It identifies the source of a root read with $A, B, C, f, g, u, H, K, L, N$ and leaves no coordinate for an external source object.

Next use Definition 485.68. Unit and bind reads are covered only after the displayed histories, tails, route row, transport row, ledger row, and local name have been read.

Finally apply Definition 485.69. This excludes host functions, quotient Kleisli arrows, ambient hom sets, independent category carriers, and unlisted continuation generators from the root source route, so coverage is exactly the displayed packet. □

Theorem 485.88 (ContinuationMonad root source triad exactness)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every root consumer route is exactly the joint surface obtained from source exposure, continuation-rule coverage, and downstream consumer separation. The route consists of the displayed source histories* A, B, C*, continuation tails* f, g, u*, route row, transport row, ledger row, package provenance, and local naming row of* Z*; it contains no host function, quotient Kleisli arrow, ambient hom set, or unlisted continuation generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root source triad exactness`

Proof. Apply Definition 485.67. It identifies the root route source with the displayed packet $Z = (A, B, C, f, g, u, H, K, L, N)$ and supplies no external source coordinate.

Next use Definition 485.68. The unit and bind laws are readable only through the displayed histories, tails, route row, transport row, ledger row, and local name.

Finally apply Definition 485.69. Downstream consumers cannot receive host functions, quotient Kleisli arrows, ambient hom sets, or unlisted continuation generators, so the three component surfaces exhaust the root consumer route exactly. □

Theorem 485.89 (ContinuationMonad root generator consumer lock)**.** *For an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every generator-facing root consumer is locked to the generator closure surface of chapter 486 and to the existing generator-boundary refusal of* Z*. A consumer may read only the displayed source histories, continuation tails, transport rows, route rows, ledger rows, package rows, and local name rows; it may not introduce host functions, quotient Kleisli arrows, ambient hom sets, or continuation generators not listed in the packet.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root generator consumer lock`

Proof. Read the generator side through Definition 485.56. It routes the generator face of Z through chapter 486 and the same $A, B, C, f, g, u, H, K, L, N$ packet.

Then apply Definition 485.17. The refusal row blocks every unit, bind, continuation rule, or route generator that is not already displayed in the accepted packet.

Combine this with Definition 485.58. Downstream consumers receive the generator-boundary refusal as part of the finite route package, so no host function, quotient Kleisli arrow, ambient hom set, or unlisted generator can be added at the consumer boundary. □

Theorem 485.90 (ContinuationMonad root category generator obligation surface)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the root category-generator obligation surface is the shared finite package read through chapter 61, Definition 485.56, Definition 485.57, and Definition 485.58. The surface consists only of the displayed* BHist *source rows,* Cont *unit and bind tails, componentwise* hsame *transports,* Pkg *provenance,* NameCert *rows, generator-boundary refusal, and* $\mathsf{Cat}^{\uparrow}$ *hom-carrier readings.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root category generator obligation surface`

↪ variant `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root kleisli associativity surface`

Proof. First apply Definition 485.56. It binds the $\mathsf{Cat}^{\uparrow}$ hom-carrier surface of chapter 61 and the generator-boundary surface to the same accepted packet Z.

Next use Definition 485.57. The root unit and bind schedules are exhausted by u, f, g, H, K, L, N, so category and generator consumers cannot replace the schedule by host composition or quotient Kleisli arrows.

Finally apply Definition 485.58. It packages the triad and schedule exhaustion for downstream use, with no coordinate for ambient hom sets, external category completion, host functions, or unlisted generators. □

Theorem 485.91 (ContinuationMonad root NameCert ledger exactness)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every root consumer receives exactly the source histories* A, B, C*, continuation tails* f, g, u*, unit and bind rows, generator-boundary refusal,* $\mathsf{Cat}^{\uparrow}$ *hom-carrier readings, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *rows assembled by Definition 485.87, Definition 485.89, and Definition 485.90. The same root consumer receives no host function, quotient Kleisli arrow, ambient hom set, or unlisted continuation generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root namecert ledger exactness`

Proof. First apply Definition 485.87. It fixes the root source route to the displayed histories A, B, C, tails f, g, u, and the finite BHist, hsame, Cont, Pkg, and NameCert surface of Z.

Next apply Definition 485.89. It adds the generator-boundary refusal to the same accepted packet and blocks host functions, quotient Kleisli arrows, ambient hom sets, and unlisted continuation generators at every generator-facing root consumer.

Then apply Definition 485.90. It contributes the $\mathsf{Cat}^{\uparrow}$ hom-carrier readings and confirms that the unit and bind schedules are read through the displayed continuation rows rather than through an external category or quotient Kleisli object.

The carrier coordinates are exhausted by $A, B, C, f, g, u, H, K, L, N$ together with the named source, continuation, generator, category, transport, route, provenance, and local naming readings supplied by these three theorems. No remaining coordinate can export a host function, quotient Kleisli arrow, ambient hom set, or unlisted continuation generator, so the root NameCert ledger is exact. □

Theorem 485.92 (ContinuationMonad root source public contract)**.** *For every accepted root-source public consumer of* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the public read factors through Definition 485.87, Definition 485.89, Definition 485.90, and Definition 485.91 before any unit, bind, generator, or category surface is consumed. The resulting contract exposes only the displayed source histories, continuation tails, unit and bind rows, generator-boundary refusal, category-generator obligation surface, componentwise* hsame*,* Cont*,* Pkg*, and local* NameCert *rows of* Z*; it refuses host functions, quotient Kleisli arrows, ambient hom sets, and unlisted continuation generators.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root source public contract`

Proof. First apply root source coverage. The public consumer must enter through the displayed histories A, B, C, continuation tails f, g, u, and finite BHist, hsame, Cont, Pkg, and NameCert rows of Z.

Next apply the generator consumer lock. This makes the generator-facing route pass through the displayed generator-boundary refusal before any generator surface can be consumed.

Then apply the category-generator obligation surface. Category readings are available only through the named finite package and its $\mathsf{Cat}^{\uparrow}$ hom-carrier readings, not through ambient hom sets or quotient Kleisli arrows.

Finally apply root NameCert ledger exactness. It assembles the four public readings into one ledgered route and leaves no coordinate for host functions, quotient Kleisli arrows, ambient hom sets, or unlisted continuation generators. □

Theorem 485.93 (ContinuationMonad root public contract factorization)**.** *For every accepted root-source public consumer of* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the public contract factors through exactly the ordered chain of root source coverage, generator consumer lock, category-generator obligation surface, and root* NameCert *ledger exactness before any unit, bind, generator, or category reading is exposed. The factorization refuses host functions, quotient Kleisli arrows, ambient hom sets, and unlisted continuation generators at each public read boundary.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public contract factorization`

Proof. First apply Definition 485.87. It fixes the source part of the public route to the displayed histories A, B, C, continuation tails f, g, u, and the finite BHist, hsame, Cont, Pkg, and NameCert surface of Z.

Next apply Definition 485.89. The generator-facing read is then locked to the displayed generator-boundary refusal, so no host function, quotient Kleisli arrow, ambient hom set, or unlisted continuation generator can be inserted before generator exposure.

Then apply Definition 485.90. This makes the category-facing part a read of the displayed $\mathsf{Cat}^{\uparrow}$ hom-carrier and continuation rows rather than a read of an ambient category or quotient Kleisli object.

Finally apply Definition 485.91 and then Definition 485.92. The ledger assembles the three prior surfaces in the stated order, and the public-contract endpoint exposes only the resulting unit, bind, generator, and category readings. Since every excluded coordinate has already been refused along the chain, the public contract has exactly this factorization. □

Theorem 485.94 (ContinuationMonad root formal target exactness)**.** *For every root public and formal consumer of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the accepted read factors through the source histories* A, B, C*, continuation tails* f, g, u*, unit and bind rows, category row, generator row, public read, formal read,* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *support displayed by* Z*. It does not factor through host Kleisli composition, quotient morphism equality, ambient category completion, or any generator absent from the packet.*

↪variant `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root kleisli formal target package`

Proof. Start with root source coverage, Definition 485.87. It fixes the consumer source to the displayed histories, continuation tails, and finite BHist, hsame, Cont, Pkg, and NameCert surface.

Next apply the generator consumer lock and the category-generator obligation surface, Definition 485.89 and Definition 485.90. These expose the generator and category rows without admitting host Kleisli composition, quotient morphism equality, ambient category completion, or an unlisted generator.

Finally use root NameCert ledger exactness and root public contract factorization, Definition 485.91 and Definition 485.93. The first assembles the formal ledger support, and the second makes the public read pass through the same ordered finite route. Thus the public/formal consumer has exactly the displayed target surface. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal target exactness`

Theorem 485.95 (ContinuationMonad root formal-public readback terminality)**.** *Every root public/formal consumer of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$ *factors through the existing root source coverage, generator consumer lock, category-generator obligation surface, root* NameCert *ledger exactness, public contract factorization, and formal target exactness before it can read unit, bind, generator, category, or formal rows. After those factorizations, no host Kleisli composition, quotient morphism equality, ambient category completion, external monad evaluator, or unlisted continuation generator remains available.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root formal public readback terminality`

Proof. First apply Definition 485.87. It fixes the root public/formal source to the displayed histories A, B, C, continuation tails f, g, u, and the finite BHist, hsame, Cont, Pkg, and NameCert support of Z.

Next apply Definition 485.89 and Definition 485.90. These force generator and category readings to pass through the displayed generator-boundary refusal and $\mathsf{Cat}^{\uparrow}$ hom-carrier rows, so the route has no host Kleisli composition, quotient morphism equality, ambient category completion, external evaluator, or unlisted generator at those boundaries.

Then use Definition 485.91 and Definition 485.93. The ledger assembles the root rows into one ordered public route, and the public contract exposes unit, bind, generator, and category readings only through that route.

Finally apply Definition 485.94. The formal target is already the same finite public/formal surface, so the consumer is terminal at the displayed readback boundary and no unlisted continuation or external monad semantics remains to be read. □

Theorem 485.96 (ContinuationMonad root terminal readback coverage)**.** *Every terminal root readback of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$ *is covered exactly by the ordered root surface consisting of root source coverage, generator consumer lock, category-generator obligation surface, root* NameCert *ledger exactness, public contract factorization, formal target exactness, and formal-public readback terminality. The terminal readback exposes only the displayed source histories, continuation tails, unit and bind rows, generator-boundary refusal,* $\mathsf{Cat}^{\uparrow}$ *hom-carrier readings, formal/public rows,* BHist, hsame, Cont, Pkg, *and local* NameCert *support of* Z.

It excludes host Kleisli composition, quotient morphism equality, ambient category completion, external monad evaluator, and every continuation generator not displayed in the packet.

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root terminal readback coverage`

Proof. First apply Definition 485.87. It fixes the terminal readback source to the displayed histories A, B, C, continuation tails f, g, u, and finite BHist, hsame, Cont, Pkg, and NameCert support.

Next apply Definition 485.89 and Definition 485.90. These identify the generator-boundary refusal and the category-generator surface without allowing host Kleisli composition, quotient morphism equality, ambient category completion, or unlisted generators.

Then use Definition 485.91 and Definition 485.93. The ledger collects the root rows into the local NameCert surface, and the public contract forces the terminal readback to pass through that ordered public route before any public unit, bind, generator, or category row is exposed.

Finally apply Definition 485.94 and Definition 485.95. The formal target and formal-public terminality make the same finite route the terminal readback boundary. Hence every covered row

is one of the displayed rows named in the statement, and every host, quotient, ambient-completion, external-evaluator, or unlisted-generator coordinate is outside the terminal coverage surface. □

Theorem 485.97 (ContinuationMonad generator category route totality)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the public generator-category route is total exactly on the displayed carrier rows* $A, B, C, f, g, u, H, K, L, N$*. The* $\mathsf{Cat}^{\uparrow}$ *hom-carrier surface reads the continuation tails as* CategoryHomCarrier *and* ContinuationMorphism *rows, the* $\mathsf{GeneratorClosure}^{\uparrow}$ *refusal surface blocks every unlisted continuation generator, and the* Cont*,* hsame*,* Pkg*, and* NameCert *rows supply the only route, transport, provenance, and naming data available to downstream consumers.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier generator category route totality`

Proof. Begin with the root category-generator factorization. By Definition 485.51, the category face and generator face already share the finite packet $A, B, C, f, g, u, H, K, L, N$.

Use the root CategoryHomCarrier consumer totality theorem next. It places every hom-carrier read on the displayed continuation tails and the $\mathsf{Cat}^{\uparrow}$ surface, with no ambient hom set or external category completion.

Finally apply the root generator boundary readback theorem and the generator-boundary refusal surface. They block unlisted unit, bind, continuation, or route generators. Since the carrier rows, hsame transports, Cont routes, Pkg provenance, and local NameCert row have already been listed, the route is total on the displayed packet and nowhere else. □

Theorem 485.98 (ContinuationMonad generator-category lockdown)**.** *For an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the generator boundary and the* $\mathsf{Cat}^{\uparrow}$ *hom route form one locked root obligation surface over* BHist*,* Cont*, componentwise* hsame*,* Pkg*, and the local* NameCert *row. Every downstream read of the authorized generator row, the* CategoryHomCarrier *row, or the* ContinuationMorphism *row factors through the same displayed rows* $A, B, C, f, g, u, H, K, L, N$*, and no host function space, quotient Kleisli category, ambient category carrier, or independent generator list is exported.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier generator category lockdown`

Proof. Start with the carrier and root generator obligation. Carrier admission fixes the readable rows $A, B, C, f, g, u, H, K, L, N$, while the root generator obligation places every authorized continuation generator inside the same finite packet before unit or bind data is consumed.

Use the bind-route totality and Category hom route totality theorems. They route the Cont reads and the $\mathsf{Cat}^{\uparrow}$ hom-carrier readings through K, L and transport them only by the componentwise hsame row H.

Finally apply the root downstream package. Its Pkg provenance and local NameCert row repack the generator and Category readings as one obligation surface, so a downstream continuation consumer has no coordinate for a separate host, quotient, ambient category, or generator object. □

Theorem 485.99 (ContinuationMonad displayed bind readback exhaustion)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, each displayed bind readback is exhausted by* $A, B, C, f, g, u, H, K, L, N$ *together with the* $\mathsf{Cat}^{\uparrow}$ *hom-carrier surface, the* $\mathsf{GeneratorClosure}^{\uparrow}$ *refusal surface, and the* Cont*,* hsame*,* Pkg*, and* NameCert *rows. The readback does not export host function composition, host monad equality, quotient Kleisli arrows, ambient hom sets, or external evaluator rows.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier displayed bind readback exhaustion`

Proof. Start from the root bind-unit boundary of Definition 485.52. It identifies public bind and unit reads with u, f, g, H, K, L, N over the source histories A, B, C.

Next attach the finite bind readback package and root downstream surface exactness. These package the bind read as BEDC data and keep the category and generator faces on the same finite source.

The exclusion clauses come from the Kleisli composition boundary and the root ledger saturation boundary. They admit no coordinate for host function composition, quotient Kleisli arrows, ambient hom sets, or external evaluator rows, so the displayed bind readback is exhausted by the accepted packet and its named consumer surfaces. □

Theorem 485.100 (ContinuationMonad root consumer non-escape)**.** *Every root consumer of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$ *reads through the same finite generator-category route, the same displayed bind readback, and the same* Cont, hsame, Pkg, *and* NameCert *support rows. No root consumer can escape to host function composition, quotient Kleisli arrows, host monad equality, ambient category completion, an independent* $\mathsf{Cat}^{\uparrow}$ *hom carrier, or a generator outside the* $\mathsf{GeneratorClosure}^{\uparrow}$ *refusal surface.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root consumer nonescape`

Proof. First combine Definition 485.97 with Definition 485.99. The first theorem fixes the generator-category route, and the second fixes the bind readback.

Next use the root downstream unblock package and root Kleisli source totality. They identify downstream and Kleisli-facing reads with the carrier rows $A, B, C, f, g, u, H, K, L, N$ and the structural rows already displayed by the packet.

Finally apply the generator boundary readback and CategoryHomCarrier consumer totality surfaces. Since both root consumer faces are already routed through the accepted packet, there is no remaining route to host composition, quotient Kleisli arrows, host equality, ambient category completion, independent hom carriers, or unlisted generators. □

Theorem 485.101 (ContinuationMonad root Kleisli source totality)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the Kleisli source exposed to any root consumer is exhausted by the displayed* BHist *source histories* A, B, C*, the continuation tails* f, g*, the unit tail* u*, the componentwise* hsame *transport row* H*, the displayed* Cont *route row* K*, the ledger row* L*, and the local* NameCert *row* N*.*

No host function, quotient Kleisli arrow, ambient hom set, external monad evaluator, or continuation rule outside Z *is part of that source.*

Proof. Start with carrier admission from Definition 485.6. It displays exactly $A, B, C, f, g, u, H, K, L, N$ as the accepted source packet.

Next use Definition 485.87. Every root read must pass through the displayed histories and continuation tails before unit or bind data can be consumed.

Finally apply ledger exactness from Definition 485.12. The consumer-visible Kleisli read is exhausted by the carrier, classifier, unit, bind, associativity, Cont, Pkg, and NameCert rows of the same finite packet, so no external source coordinate remains. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root kleisli source totality`

Theorem 485.102 (ContinuationMonad root generator boundary readback)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every generator-facing readback of the root Kleisli source factors through the authorized generator boundary named by chapter 486 and the displayed generator-boundary refusal for* Z*.*

Such a readback may replay only the listed histories, continuation tails, unit tail, transport rows, route rows, ledger rows, package rows, and local name rows. It cannot introduce an unlisted continuation rule or a second generator route.

Proof. Read the generator face through Definition 485.56. It attaches the generator boundary to the same packet $A, B, C, f, g, u, H, K, L, N$.

Apply Definition 485.17. The refusal row blocks every unit row, bind row, continuation rule, or route generator that is not already displayed in the accepted packet.

Close the readback with Definition 485.89. Generator-facing consumers inherit the same refusal and the same finite source surface, so the readback has no coordinate for an unlisted continuation rule. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root generator boundary readback`

Theorem 485.103 (ContinuationMonad root CategoryHomCarrier consumer totality)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every* CategoryHomCarrier*-facing consumer of the root Kleisli source is exhausted by the displayed continuation tails* f, g, u *and the* $\mathsf{Cat}^{\uparrow}$ *hom-row reading over* A, B, C, H, K, L, N*.*

The consumer may use the componentwise hsame *transports, displayed* Cont *routes, ledger, package provenance, and local* NameCert *row of* Z*, but it receives no ambient hom set, host composition operation, quotient Kleisli arrow, or external category completion.*

Proof. Begin with Definition 485.16. The CategoryHomCarrier and ContinuationMorphism entries are exposed only as reads of the displayed continuation tails over the same histories, transports, routes, ledger, and local name.

Next use Definition 485.90. It places the $\mathsf{Cat}^{\uparrow}$ hom-carrier reading on the shared finite root package and excludes independent category data.

Finally apply Definition 485.57 and Definition 485.75. Unit and bind schedules are exhausted by u, f, g, H, K, L, N, while the ledger boundary admits no quotient Kleisli arrow, host-function composition, ambient category completion, external evaluator, or unlisted generator. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root category hom consumer totality`

Theorem 485.104 (ContinuationMonad root Kleisli source route exhaustion)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every root Kleisli consumer factors through the displayed source histories* A, B, C*, continuation tails* f, g*, unit row* u*, generator boundary,* CategoryHomCarrier *row, componentwise* hsame *transport* H*,* Cont *replay row* K*,* Pkg *provenance row* L*, and local* NameCert *row* N*.*

The resulting source route is exhausted by the finite packet Z *and by the downstream readback surface of Definition 485.66. It contains no host evaluator, quotient Kleisli arrow, ambient hom set, or unlisted continuation generator.*

Proof. Start with Definition 485.101. It displays the source histories, continuation tails, unit row, componentwise hsame transport, Cont route, ledger row, and local NameCert row as the complete root Kleisli source for Z.

Apply Definition 485.102. The generator-facing part of the same source route is forced through the authorized boundary and cannot introduce a second continuation rule or generator route.

Next use Definition 485.103. CategoryHom-facing consumers read only the displayed continuation tails and the $\mathsf{Cat}^{\uparrow}$ hom row over the same histories, transports, routes, ledger, package, and local name.

Finally cite Definition 485.66. Its formal target surface packages the downstream readback over the same finite carrier, so composing the three local theorems leaves no coordinate for a host evaluator, quotient Kleisli arrow, ambient hom set, or unlisted continuation generator. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root kleisli source route exhaustion`

Theorem 485.105 (ContinuationMonad root unit-bind coverage)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet*

$$Z = (A, B, C, f, g, u, H, K, L, N),$$

every root consumer reads the unit row and bind rows only through the displayed histories A, B, C*, continuation tails* f, g*, unit tail* u*, componentwise* hsame *transport row* H*, displayed* Cont *route row* K*, ledger row* L*, and local* NameCert *row* N*. No unit or bind reading is available as a host function, quotient Kleisli arrow, ambient monad evaluator, or continuation rule outside this finite packet.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root unit bind coverage`

Proof. Start with carrier admission from Definition 485.6. It identifies the accepted packet with exactly the displayed rows $A, B, C, f, g, u, H, K, L, N$.

Use the root Kleisli source totality of Definition 485.101. That source exposes the histories and continuation tails before any root consumer can read unit or bind data.

Finally apply the root bind-unit boundary of Definition 485.52. It forces public unit and bind reads through u, f, g, H, K, L, N over the same histories A, B, C, leaving no coordinate for a host or quotient-level operation. □

Theorem 485.106 (ContinuationMonad root Kleisli associativity scope)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, Kleisli associativity at the root is scoped exactly by the displayed* Cont *rows in* K*, the componentwise* hsame *transports in* H*, the ledger row* L*, and the* CategoryHomCarrier *readings attached to* f, g, u *over* A, B, C*. The associativity surface is therefore a finite BEDC route reading of* Z*, not a host composition law or quotient Kleisli equality.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root kleisli associativity scope`

Proof. Begin with Definition 485.4. The associativity row is recorded in L, transported by H, and read through the displayed Cont row K.

Attach the category face through Definition 485.16. The CategoryHomCarrier and ContinuationMorphism readings are only readings of the displayed tails f, g, u over the same histories and structural rows.

Now combine Definition 485.113 with the unit-bind coverage theorem above. The root associativity surface has exactly the displayed scope and cannot be enlarged into host function composition or quotient Kleisli equality. □

Theorem 485.107 (ContinuationMonad root downstream generator package)**.** *The downstream* $\mathsf{Cat}^{\uparrow}$ *and generator-boundary consumers of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet receive exactly the finite package* $A, B, C, f, g, u, H, K, L, N$ *together with the displayed* CategoryHomCarrier *readings, generator-boundary refusal,* Cont *routes,* hsame *transports, ledger, provenance, and local naming rows. They receive no host function composition, quotient Kleisli arrow, ambient category completion, external evaluator, or unlisted continuation rule.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root downstream generator package`

Proof. First use Definition 485.53. It identifies the downstream root surface with the category row, generator refusal row, carrier rows, classifier stability, ledger exactness, package provenance, and local NameCert row over $A, B, C, f, g, u, H, K, L, N$.

Next use Definition 485.115. The generator-facing consumer must pass through the same source, bind schedule, unit row, transport row, route row, provenance, and local name before any category or Kleisli surface is exported.

Finally apply Definition 485.100. Since every root consumer is routed through the finite generator-category route and displayed bind readback, the downstream package exports none of the listed host, quotient, completion, evaluator, or unlisted-rule objects. □

Theorem 485.108 (ContinuationMonad unit-bind terminal route)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet*

$$Z = (A, B, C, f, g, u, H, K, L, N),$$

every terminal unit-bind read routes through the histories A, B, C*, continuation tails* f, g*, unit tail* u*, componentwise* hsame *transport row* H*, displayed* Cont *route row* K*, ledger row* L*, local* NameCert *row* N*, and the attached* CategoryHomCarrier *and Kleisli readings. The terminal route is a finite BEDC packet route, not host function composition or quotient Kleisli equality.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier unit bind terminal route`

Proof. Start with the root unit-bind coverage of Definition 485.105. It identifies every root unit or bind read with the displayed rows $A, B, C, f, g, u, H, K, L, N$.

Next apply the root Kleisli associativity scope of Definition 485.106. That theorem attaches the CategoryHomCarrier and Kleisli readings to the same displayed continuation rows rather than to host composition.

Finally use the downstream generator package of Definition 485.107. The terminal consumer receives exactly that finite package, so the unit-bind route remains the displayed packet route. □

Theorem 485.109 (ContinuationMonad unit-bind completion nonescape)**.** *No accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *consumer can replace the unit-bind terminal route of Definition 485.108 by host function composition, quotient Kleisli equality, ambient monad completion, or an evaluator outside the packet. Any such replacement would require a coordinate not present among* $A, B, C, f, g, u, H, K, L, N$ *or among the displayed* CategoryHomCarrier *and Kleisli rows.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier unit bind completion nonescape`

Proof. Use Definition 485.100. It excludes host function composition, quotient Kleisli arrows, ambient category completion, external evaluators, and unlisted continuation rules from every root consumer route.

Then apply Definition 485.108. The terminal unit-bind read has already been identified with the displayed histories, continuation tails, unit row, transport row, route row, ledger, local name, and category/Kleisli readings.

Since none of the excluded objects appears in those rows, no accepted consumer can replace the terminal route by an external completion or evaluator. □

Theorem 485.110 (ContinuationMonad unit-bind Kleisli consumer handoff)**.** *Every* $\mathsf{Cat}^{\uparrow}$ *or generator-closure consumer of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet receives only the terminal unit-bind route displayed in Definition 485.108 and the local* NameCert *row. The consumer may replay the* CategoryHomCarrier *and Kleisli readings attached to* $A, B, C, f, g, u, H, K, L, N$*, but it receives no host composition law, quotient Kleisli equality, ambient monad completion, or external evaluator.*

Proof. Begin with Definition 485.107. It identifies the downstream $\mathsf{Cat}^{\uparrow}$ and generator-boundary package with the finite route $A, B, C, f, g, u, H, K, L, N$ plus the displayed category, generator, transport, ledger, provenance, and local naming rows.

Use Definition 485.108 to specialize that package to terminal unit-bind reads. The same rows supply the unit tail, bind tails, CategoryHomCarrier readings, and Kleisli route.

Finally apply Definition 485.109. The handoff therefore exports only the finite packet route and refuses host composition, quotient Kleisli equality, ambient completion, and external evaluators. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier unit bind kleisli consumer handoff`

Theorem 485.111 (ContinuationMonad unit-bind KernelMorphism compiler coherence)**.** *Every* KernelMorphismUp *or* $\mathsf{CertificateCompiler}^{\uparrow}$ *consumer of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *unit-bind terminal route reads the same finite packet*

$$A, B, C, f, g, u, H, K, L, N$$

and the attached CategoryHomCarrier *and Kleisli rows. Such a consumer cannot replace the route by host function composition, quotient Kleisli equality, ambient monad completion, or an external evaluator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier unit bind kernelmorphism compiler coherence`

Proof. First apply root unit-bind coverage, Definition 485.105. It identifies every accepted unit or bind read with the displayed histories A, B, C, continuation tails f, g, unit tail u, transport row H, route row K, ledger L, and local naming row N.

Next use the root downstream generator package of Definition 485.107. This is the package available to downstream route consumers, so a kernel-morphism or compiler consumer receives the same displayed packet together with the category, generator, transport, ledger, provenance, and local naming rows.

Apply the terminal route theorem Definition 485.108. The CategoryHomCarrier and Kleisli rows are attached to the same packet rather than to a host operation.

Finally invoke completion nonescape, Definition 485.109. Host function composition, quotient Kleisli equality, ambient monad completion, and external evaluators are not coordinates of $A, B, C, f, g, u, H, K, L, N$, so the KernelMorphism and CertificateCompiler consumers preserve the displayed terminal route. □

Theorem 485.112 (ContinuationMonad root bind completion classifier)**.** *For every completion-facing root read of an accepted* ContinuationMonad$^{\uparrow}$ *packet*

$$Z = (A, B, C, f, g, u, H, K, L, N),$$

the classifier surface is the same as the displayed unit-bind terminal route: histories A, B, C, continuation tails f, g, unit tail u, componentwise hsame *row H, displayed* Cont *row K, ledger L, local* NameCert *row N, and the attached* CategoryHomCarrier *and Kleisli readings. No completion-facing root consumer can reread the packet as host function composition, quotient Kleisli equality, ambient monad completion, or an external evaluator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root bind completion classifier`

Proof. First use Definition 485.108. It fixes the unit-bind terminal route as the rows $A, B, C, f, g, u, H, K, L, N$ together with the attached CategoryHomCarrier and Kleisli readings.

Next apply Definition 485.109. Any completion-facing root read that tried to use host composition, quotient Kleisli equality, ambient monad completion, or an external evaluator would require a coordinate outside the displayed packet.

Finally use Definition 485.111. KernelMorphism and CertificateCompiler consumers preserve the same finite terminal route, so the completion-facing classifier surface is exactly the displayed unit-bind packet and the attached category and Kleisli readings. □

Theorem 485.113 (ContinuationMonad root Kleisli associativity surface)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet $Z = (A, B, C, f, g, u, H, K, L, N)$, the displayed unit rows and bind rows replay through one Kleisli associativity surface over* BHist, hsame, Cont, Pkg, *and* NameCert. *The surface is the route carried by $A, B, C, f, g, u, H, K, L, N$, with the* Cat$^{\uparrow}$ *hom-carrier and* ContinuationMorphism *readings attached to those rows, and it exports no host function composition, quotient Kleisli arrow, ambient category completion, external evaluator, or unlisted continuation generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier kleisli associativity surface`

Proof. Begin with Definition 485.3 and Definition 485.4. The unit rows and nested bind rows are read as finite ledger rows over u, f, g, K, L rather than as host monad equations.

Use Definition 485.101 to expose the source histories and continuation tails before any Kleisli-facing consumer reads them. The source remains the displayed BHist, hsame, Cont, Pkg, and local NameCert surface of Z.

Finally combine Definition 485.67, Definition 485.97, and Definition 485.99. These theorems attach the Category hom and generator-boundary faces to the same route, so associativity is visible as one replay surface and not as a quotient or host-composition object. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root kleisli associativity surface`

Theorem 485.114 (ContinuationMonad BHist bind associativity induction)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet $Z = (A, B, C, f, g, u, H, K, L, N)$, nested bind replay over the displayed finite source rows is associative by induction on the finite continuation schedule. The induction uses only the* BHist *source rows A, B, C, the displayed bind schedule f, g, K, L, the unit row u, componentwise* hsame *transport H,* Cont *replay through K,* Pkg *provenance through L, and the local* NameCert *row N. It exports no quotient Kleisli arrow, host function composition, ambient category completion, or evaluator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadBHistBindAssociativityInduction`

Proof. Induct on the displayed finite continuation schedule. In the base case the schedule has only the source and unit rows, so Definition 485.3 and the root unit-bind exhaustion identify the two nested bind replays through u, H, K, L, N.

For the step, expose the next continuation row in the finite schedule. The existing associativity surface of Definition 485.113 rewrites the two displayed nesting orders through the same BHist, hsame, Cont, Pkg, and local NameCert rows.

Transport preserves the induction hypothesis componentwise through H, and replay composes the displayed continuation rows through K without leaving the packet. Provenance through L and local naming through N record the same finite schedule after each step.

Thus the accepted packet proves associativity only as a BEDC finite replay induction. Since no induction step introduces a quotient Kleisli arrow, host function composition, ambient category completion, or evaluator, none of those objects is exported. □

Theorem 485.115 (ContinuationMonad root generator bind coverage)**.** *Every root generator consumer of an accepted* ContinuationMonad$^{\uparrow}$ *packet reads the source rows A, B, C, bind schedule f, g, K, L, unit row u, componentwise transport H, displayed route K, provenance through* Pkg*, and local naming row N before any* Cat$^{\uparrow}$ *or Kleisli surface is exported. The consumer receives no generator, bind evaluator, quotient Kleisli arrow, host function composition, ambient category object, or monad law outside the displayed packet.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root generator bind coverage`

Proof. Start from Definition 485.67 and Definition 485.87. They force every root read to pass through the displayed histories, continuation tails, unit tail, transport row, route row, ledger row, and local name.

Apply Definition 485.101. The Kleisli-facing source is exhausted by $A, B, C, f, g, u, H, K, L, N$, so a generator consumer cannot skip directly to an external Category or Kleisli object.

Use Definition 485.97 and Definition 485.102 to account for the generator face. The generator refusal is attached to the same finite route before any category-facing read is visible, leaving no coordinate for an unlisted continuation generator or external evaluator. □

Theorem 485.116 (ContinuationMonad root downstream monad package)**.** *The root downstream monad package for an accepted* ContinuationMonad$^{\uparrow}$ *packet is assembled from the displayed source rows, unit rows, bind schedule, componentwise* hsame *transport,* Cont *routes,* Pkg *provenance,* Cat$^{\uparrow}$ *hom-carrier readings, generator-boundary refusal, and local* NameCert *row carried by $A, B, C, f, g, u, H, K, L, N$. Downstream continuation chapters may consume this package as the finite monad-reading boundary, and no quotient Kleisli category, host function composition, ambient category completion, external evaluator, or unlisted continuation generator is exported.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root downstream monad package`

Proof. First use Definition 485.46 and Definition 485.113. They cover the unit, bind, and associativity readings through u, f, g, K, L, H, N over the source histories A, B, C.

Next use Definition 485.115. It places the generator-facing consumer behind the same source, route, transport, provenance, and naming rows before any category or Kleisli surface can be consumed.

Finally apply Definition 485.48 and Definition 485.97. These package the unit, bind, generator-boundary, and Category hom faces as one downstream surface, so all external host, quotient, completion, evaluator, and unlisted-generator readings remain outside the packet. □

Theorem 485.117 (ContinuationMonad root public obligation triad)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the root public surface exposes one obligation triad: the source histories* A, B, C*, the continuation tails* f, g, u*, and the NameCert rows* H, K, L, N*. Any downstream root consumer that reads the* BHist*,* Cont*,* Pkg*, or* NameCert *face of* Z *receives that triad before it can consume a Category, generator-boundary, or Kleisli route.*

Proof. Start with Definition 485.6 and Definition 485.87. They expose $A, B, C, f, g, u, H, K, L, N$ as the finite source read of the accepted packet.

Next use Definition 485.56. It identifies the Category and generator-boundary faces as readings of the same displayed source histories, continuation tails, transports, routes, ledger, and local name.

Finally apply Definition 485.58. Since every public root consumer is routed through the same BHist, Cont, Pkg, and NameCert rows, the triad is the public obligation surface and not a host Kleisli object or an ambient category object. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public obligation triad`

Theorem 485.118 (ContinuationMonad root public generator boundary)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, a public root generator read is admitted only through the displayed continuation tails* f, g, u*, route row* K*, ledger row* L*, package provenance, and local* NameCert *row* N*. The boundary exports no unit rule, bind rule, continuation generator, host evaluator, quotient Kleisli arrow, or ambient hom set outside the displayed packet.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public generator boundary`

Proof. Read the root source through Definition 485.101. It exhausts the source by $A, B, C, f, g, u, H, K, L, N$ before any generator-facing route is visible.

Apply the generator boundary readback of Definition 485.102. The generator face is the authorized refusal boundary attached to the same finite packet.

Use Definition 485.115 to close the public boundary. It places generator consumers behind the displayed source, bind schedule, unit row, transports, route, provenance, and local name, leaving no coordinate for an unlisted generator or host Kleisli operation. □

Theorem 485.119 (ContinuationMonad root public Kleisli readback)**.** *Every root public Kleisli readback of an accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$ *is total on the displayed finite packet: it reads the source histories, continuation tails, unit tail, componentwise* hsame *transport, displayed* Cont *route,* Pkg *provenance, ledger, and local* NameCert *row before any downstream monad consumer receives the surface. It exports no host function composition, quotient Kleisli category, ambient category completion, external evaluator, or unlisted continuation rule.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public kleisli readback`

Proof. Begin with Definition 485.113. It identifies unit, bind, and associativity reads as the finite replay surface over $A, B, C, f, g, u, H, K, L, N$.

Next use Definition 485.117. The public source exposure, continuation tails, and NameCert rows are already fixed before a downstream consumer reads the Kleisli face.

Finally apply Definition 485.116. The package consumes the same finite BHist, hsame, Cont, Pkg, Category hom, generator boundary, and local NameCert rows, so the public Kleisli readback is total on the displayed packet and has no external evaluator or quotient-category coordinate. □

Theorem 485.120 (ContinuationMonad root Cont-associativity ledger)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, any root public consumer that reads a composite Kleisli route must ledger associativity only through the displayed continuation tails* f, g, u*, source histories* A, B, C*, transport row* H*, route row* K*, ledger row* L*, and local name* N*. The route exports no host function composition, quotient Kleisli category, ambient hom set, or external evaluator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root cont associativity ledger`

Proof. Begin with Definition 485.117. It places every root public consumer behind the displayed source histories, continuation tails, and local NameCert rows of Z.

Next apply Definition 485.118. The generator-facing route is admitted only through the same displayed tails, route row, ledger row, provenance, and local name, so the public consumer has no independent generator or host evaluator coordinate.

Use Definition 485.119 to read the composite Kleisli surface. It makes the unit row, bind row, componentwise hsame transport, displayed Cont route, Pkg provenance, ledger, and local NameCert row total on the finite packet.

Finally invoke Definition 485.116. The downstream monad package consumes the same finite BHist, hsame, Cont, Pkg, Category hom, generator boundary, and local NameCert rows. Therefore associativity is a ledger row inside $A, B, C, f, g, u, H, K, L, N$, not an export of host function composition, a quotient Kleisli category, an ambient hom set, or an external evaluator. □

Theorem 485.121 (ContinuationMonad root public route exactness)**.** *For every accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the root public route exposed to downstream readers is exactly the displayed source histories, continuation tails, unit tail, transport row, route row, ledger row, package provenance, and local naming row. It has no additional coordinate for host function composition, quotient Kleisli arrows, ambient hom sets, or external evaluators.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public route exactness`

Proof. Begin with the root public obligation triad, Definition 485.117. It exposes $A, B, C, f, g, u, H, K, L, N$ before any Category, generator, or Kleisli read is available.

Next use the generator boundary and Kleisli readback theorems, Definition 485.118 and Definition 485.119. They place both generator-facing and Kleisli-facing consumers behind the same finite root packet.

Finally apply the Cont-associativity ledger, Definition 485.120. Since associativity is recorded inside the displayed continuation and ledger rows, the public route is exact on $A, B, C, f, g, u, H, K, L, N$ and exports none of the excluded host or quotient surfaces. □

Theorem 485.122 (ContinuationMonad root consumer totality)**.** *Every downstream consumer that reads the root public face of an accepted* ContinuationMonad$^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$ *first consumes the displayed* BHist*,* hsame*,* Cont*,* Pkg*, ledger, and local* NameCert *rows. Category reads, generator-boundary reads, and Kleisli readbacks are therefore total only after the route* $A, B, C, f, g, u, H, K, L, N$ *is available.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root consumer totality`

Proof. Start from root public route exactness, Definition 485.121. It identifies the complete finite route exposed by the packet.

The generator-boundary side is handled by Definition 485.118; the Kleisli-readback side is handled by Definition 485.119. Together they show that no downstream consumer can read Category, generator, or Kleisli data before the root packet has supplied the displayed rows.

Finally use Definition 485.116. The downstream monad package consumes the same route, so consumer totality is a property of the public packet itself rather than of an ambient category or host evaluator. □

Theorem 485.123 (ContinuationMonad root public formal-target boundary)**.** *Any formal target for the root public face of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet must use exactly the displayed tuple* $Z = (A, B, C, f, g, u, H, K, L, N)$*. The tuple supplies the source histories, continuation tails, unit row, componentwise* hsame *transport, displayed* Cont *route,* Pkg *provenance, ledger row, and local* NameCert *row needed by the public face.*

The formal target may not introduce host function composition, quotient Kleisli arrows, ambient hom sets, or an external evaluator.

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public formal target boundary`

Proof. First apply the root public obligation triad. It names the full public tuple $A, B, C, f, g, u, H, K, L, N$ and exposes the source histories, continuation tails, unit row, transport row, route row, package row, ledger row, and local naming row as the available formal surface.

Next use the generator boundary and Kleisli readback theorems. They show that generator-facing and Kleisli-facing reads are read back through the same tuple, not through host composition, quotient arrows, ambient hom sets, or an external evaluator.

Finally combine the Cont-associativity ledger, route exactness, and consumer totality. These results keep associativity, public routing, and downstream consumption inside the displayed BHist, hsame, Cont, Pkg, ledger, and local NameCert rows. Hence any Lean-facing formal target for the root public face is bounded by exactly the tuple stated above. □

Theorem 485.124 (ContinuationMonad root refusal exhaustion)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, every refused root public read is exhausted by absence of one of the displayed source-history, continuation-tail, transport, route, ledger, package, or local naming rows. The refusal surface cannot be discharged by host function composition, quotient Kleisli arrows, ambient hom sets, external evaluators, or an unlisted continuation rule.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root refusal exhaustion`

Proof. First bind refusals to the public route. By Definition 485.121, the only admitted route is the displayed packet $A, B, C, f, g, u, H, K, L, N$.

Next account for the two root readers. The generator boundary theorem, Definition 485.118, refuses unlisted generator data, while the Kleisli readback theorem, Definition 485.119, refuses host or quotient Kleisli data outside the finite packet.

Finally apply the Cont-associativity ledger and downstream package theorems, Definition 485.120 and Definition 485.116. They keep associativity and downstream monad consumption inside the same public route, so every failed read is exhausted by the displayed refusal surface. □

Theorem 485.125 (ContinuationMonad root public readiness package)**.** *For every accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$*, the root public obligation triad, generator boundary, Kleisli readback,* Cont*-associativity ledger, route exactness, consumer totality, and refusal exhaustion assemble a public readiness package over* $A, B, C, f, g, u, H, K, L, N$*. Downstream monad,*

category, and generator-boundary consumers therefore receive one finite public packet, not separate host composition, quotient-arrow, or evaluator surfaces.

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public readiness package`

Proof. Start with the root public obligation triad, Definition 485.117. It exposes the source histories, continuation tail, generator row, unit row, transport row, route row, ledger row, package row, and local NameCert row.

Next combine the public readers. The generator boundary theorem, Definition 485.118, and the Kleisli readback theorem, Definition 485.119, place both advertised reads behind the same finite packet.

Apply the Cont-associativity ledger, Definition 485.120, together with route exactness, Definition 485.121. These results keep associativity and route consumption on $A, B, C, f, g, u, H, K, L, N$.

Finally use consumer totality and refusal exhaustion, Definition 485.122 and Definition 485.124. Successful reads and failed reads are both classified by displayed rows of the same packet, which is the advertised readiness package. □

Theorem 485.126 (ContinuationMonad root public refusal totality)**.** *Every failed public read of an accepted* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet* $Z = (A, B, C, f, g, u, H, K, L, N)$ *is exactly the absence of a displayed row among* $A, B, C, f, g, u, H, K, L, N$*. It is not a route through host function composition, quotient Kleisli arrows, ambient hom sets, external evaluators, or unlisted continuation rules.*

Proof. Use Definition 485.125 to reduce a public read to the single readiness packet. The only admissible surface is $A, B, C, f, g, u, H, K, L, N$.

Apply Definition 485.124. Its refusal classification already lists the displayed source-history, continuation-tail, transport, route, ledger, package, and naming rows as the exhaustive failure surface.

The excluded routes are not rows of the packet. Host function composition, quotient Kleisli arrows, ambient hom sets, external evaluators, and unlisted continuation rules therefore cannot turn a failed public read into an accepted one. □

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public refusal totality`

Theorem 485.127 (ContinuationMonad root public consumer totality)**.** *Every public* $\mathsf{ContinuationMonad}^{\uparrow}$ *consumer of an accepted packet* $Z = (A, B, C, f, g, u, H, K, L, N)$ *must pass through the* $\mathsf{Cat}^{\uparrow}$ *hom row, the* $\mathsf{GeneratorClosure}^{\uparrow}$ *source row, the unit row, the bind row, the Kleisli composite row, the componentwise* hsame *transport, the* Cont *replay, the* Pkg *provenance, and the local* NameCert *row before it receives the public continuation-monad surface. It exports no host evaluator, quotient Kleisli category, ambient category completion, unlisted continuation generator, or monad law outside those displayed rows.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public consumer totality`

Proof. Begin with the root public obligation triad Definition 485.117. It fixes the public source histories, continuation tails, and NameCert rows of Z before any downstream consumer reads the monad-facing surface.

Use the root public generator boundary Definition 485.118 and the root category-generator factorization Definition 485.51. These place the $\mathsf{Cat}^{\uparrow}$ hom row and $\mathsf{GeneratorClosure}^{\uparrow}$ source row on the same displayed route as the source histories, routes, provenance, and local name.

Apply the root public Kleisli readback Definition 485.119. It routes the unit row, bind row, Kleisli composite row, componentwise hsame transport, Cont replay, Pkg provenance, and local NameCert row through the same finite packet.

The exclusions follow by row exhaustion. Since the public consumer has only the displayed rows of Z, host evaluators, quotient Kleisli categories, ambient completions, unlisted generators, and external monad-law objects remain outside the carrier. □

Theorem 485.128 (ContinuationMonad root public source lock)**.** *Any public* ContinuationMonad$^{\uparrow}$ *consumer that preserves the* Cat$^{\uparrow}$ *hom row and the* GeneratorClosure$^{\uparrow}$ *source row must preserve the same packet*

$$Z = (A, B, C, f, g, u, H, K, L, N)$$

before reading the unit, bind, or Kleisli composite rows. Changing either source lock invalidates the public ContinuationMonad$^{\uparrow}$ *consumer route and cannot be repaired by host function composition, quotient Kleisli arrows, or an ambient category completion.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root public source lock`

Proof. Begin with root public consumer totality. It places every public consumer of Z behind the Category hom row, GeneratorClosure source row, unit row, bind row, Kleisli row, componentwise hsame transport, Cont replay, Pkg provenance, and local NameCert row.

Apply the category-generator NameCert source lock. The Category and generator faces are source locks for the same $A, B, C, f, g, u, H, K, L, N$ packet, so preserving both rows also preserves the source histories, continuation tails, transport, route, provenance, and local name before any monad-facing read.

Finally use the root Kleisli formal target package. The formal target has no coordinate for host composition, quotient Kleisli arrows, ambient completion, external evaluation, or an unlisted generator. Therefore changing either source lock leaves the displayed package and is not a public ContinuationMonad$^{\uparrow}$ consumer route. □

Theorem 485.129 (ContinuationMonad root category-generator NameCert source lock)**.** *The* Cat$^{\uparrow}$ *and* GeneratorClosure$^{\uparrow}$ *rows of an accepted* ContinuationMonad$^{\uparrow}$ *packet are source locks for the public Kleisli readback: before a consumer reads the unit, bind, or Kleisli composite surface, it must preserve the same source histories A, B, C, continuation tails f, g, u, transport row H, route row K, provenance row L, and local* NameCert *row N. A route that changes either source lock is not a public* ContinuationMonad$^{\uparrow}$ *consumer route.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root category generator namecert source lock`

Proof. First read the root category-generator factorization. It identifies the Cat$^{\uparrow}$ hom row and GeneratorClosure$^{\uparrow}$ source row as two faces of the same finite source route over $A, B, C, f, g, u, H, K, L, N$.

Next apply the root public generator boundary. Generator-facing consumers must remain behind the displayed continuation tails, route row, provenance, and local name, so the generator source cannot be swapped after the category row is public.

Use the root public Kleisli readback to reach the monad-facing rows. The unit, bind, and Kleisli composite surface is read only after the same source, transport, route, package, and naming rows have been preserved.

Therefore the Category and generator rows are source locks for the public readback. Any route changing one of them no longer follows the displayed packet and cannot be a public ContinuationMonad$^{\uparrow}$ route. □

Theorem 485.130 (ContinuationMonad root Kleisli formal target package)**.** *The formal target surface for root* $\mathsf{ContinuationMonad}^{\uparrow}$ *consumers is the finite package consisting of the unit row, bind row, Kleisli associativity row, public consumer row, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance,* $\mathsf{Cat}^{\uparrow}$ *hom row,* $\mathsf{GeneratorClosure}^{\uparrow}$ *source row, and local* NameCert *row carried by* $Z = (A, B, C, f, g, u, H, K, L, N)$*. This package has no coordinate for host composition, quotient Kleisli arrows, ambient category completion, external continuation evaluation, or an unlisted generator.*

Lean4 ✓ `BEDC.Derived.ContinuationMonadUp.ContinuationMonadCarrier root kleisli formal target package`

Proof. Start with the root Kleisli associativity surface Definition 485.113. It reads unit, bind, and associativity as finite rows over the displayed packet rather than as host monad equations.

Combine it with the root public consumer totality above. The public consumer row is forced through the Category hom, generator source, transport, replay, provenance, and local naming rows before any downstream read is available.

Finally use the category-generator source lock above. It keeps the Category and generator faces tied to the same $A, B, C, f, g, u, H, K, L, N$ packet, so the formal target surface is exactly the finite package listed in the statement.

Row exhaustion gives the negative clauses. There is no displayed coordinate for host composition, quotient Kleisli arrows, ambient completion, external evaluation, or an unlisted generator. □

Chapter 486

A Concrete Naming Certificate for $\mathsf{GeneratorClosure}^{\uparrow}$

The $\mathsf{GeneratorClosure}^{\uparrow}$ interface records the finite naming surface for an authorized generator together with the classifier that refuses continuations outside the generator's constructor list. It is the concrete BEDC certificate side of the generator-closure classifier in Definition 9389.7: the packet exposes the generator rows, the constructor-list provenance, the continuation witnesses, and the GAP ledger that records every attempted escape from the authorized closure.

Definition 486.1 (GeneratorClosure NameCert carrier)**.** *A* $\mathsf{GeneratorClosure}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (G, L, A, Q, W, H, C, P, N)$$

with the following visible coordinates:

1. *G is the authorized generator row naming the closed inductive source whose outputs are admitted;*
2. *L is the finite constructor-list provenance row for G, including the displayed closure witness for each constructor;*
3. *A is the authorized-row ledger stating which observed rows are generated by L;*
4. *Q is the generator-closure classifier row comparing authorized generator rows componentwise;*
5. *W is the continuation-witness ledger, recording for each finite continuation read whether the same constructor-list witness remains present;*
6. *H stores displayed* hsame *transports for G, L, A, Q, W and the local naming rows;*
7. *C stores the finite* Cont *routes by which consumers read authorized rows, constructor provenance, continuation witnesses, and rejected non-closure attempts;*
8. *P is the* Pkg *provenance over* BHist*, authorized generator rows, constructor-list provenance,* hsame*,* Cont*, and the* GAP *ledger;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{GeneratorClosure}^{\uparrow}}$ *row.*

The carrier exports only the finite generator row, constructor-list provenance, authorized-row ledger, classifier row, continuation witnesses, transport rows, continuation routes, package provenance, local naming row, and GAP *non-escape evidence. It contains no free-floating induction principle and no universal closure over objects outside the displayed generator.*

Theorem 486.2 (GeneratorClosure classifier stability)**.** *Displayed* hsame *transport preserving the authorized generator row G, constructor-list provenance L, authorized-row ledger A, continuation ledger W, transport rows H, continuation routes C, package provenance P, and local* NameCert *row N preserves the* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier Q. In particular, two authorized generator rows classified through the same constructor-list provenance retain the same accepted-row and rejected-continuation boundary.*

Proof. The carrier of Definition 486.1 makes the classifier componentwise. Transport of G and L preserves the generator source and its closed constructor list, so the authorized-row ledger A is read against the same generating surface.

Transport of W preserves the witness attached to each finite continuation read. The routes H and C then replay the same classifier reads, and the package and local naming rows repack the transported packet without adding an external induction rule. □

Theorem 486.3 (GeneratorClosure continuation witness preservation)**.** *Let K be an accepted* $\mathsf{GeneratorClosure}^{\uparrow}$ *carrier. Every finite* Cont *extension that reads only the displayed authorized generator row, constructor-list provenance, authorized-row ledger, classifier row, and local naming row preserves the continuation witness in W. If the extension asks for a row without the constructor-list witness required by L, the read is recorded as a* GAP *ledger boundary rather than as a continuation of K.*

Proof. Read the extension through the displayed Cont route C. If the route lands in $G, L, A, Q, W, H, C, P, N$, the continuation witness is already one of the stored rows, so extending the read only appends a finite access path to the same witness.

If the route asks for a row outside the constructor-list provenance, the carrier has no coordinate that can supply a closure witness. The only visible output is the GAP non-escape row in the package provenance, so the attempted read is recorded as a boundary and not as a generated continuation. □

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket continuation witness preservation`

Theorem 486.4 (GeneratorClosure NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{GeneratorClosure}^{\uparrow}}$ *surface for Definition 486.1 consists of five BEDC-native rows:*

1. *carrier admission over the finite* BHist *packet K;*
2. Pkg *provenance naming the authorized generator row, constructor-list provenance, classifier row, continuation-witness ledger,* hsame *transports,* Cont *routes, and local naming row;*
3. NameCert *exactness stating that the local certificate classifies exactly the displayed generator-closure packet;*
4. *constructor-list provenance stating that every accepted row is generated by the finite constructor list L and every continuation witness is read against that same list;*
5. GAP *ledger non-escape stating that rows without the required constructor-list witness are recorded as boundary attempts and are not exported as generator-internal continuations.*

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket namecert obligations`

Proof. Carrier admission is projection of the tuple in Definition 486.1. The generator row, constructor list, authorized ledger, classifier row, continuation witnesses, transports, routes, provenance, and local naming row are all visible coordinates of one finite BHist packet.

The package and naming rows identify the same packet. Classifier stability from Definition 486.2 supplies the transport behavior, while continuation witness preservation from Definition 486.3 supplies the finite extension behavior.

The constructor-list and GAP clauses are the two remaining projections. The former says every accepted row is read through L; the latter says a read lacking that witness is recorded as non-escape evidence rather than as an admitted continuation. □

Theorem 486.5 (GeneratorClosure carrier obligation)**.** *For a finite* BHist *packet* $K = (G, L, A, Q, W, H, C, P, N)$ *as in Definition 486.1, carrier admission for* GeneratorClosure$^{\uparrow}$ *is exactly the displayed generator row* G*, constructor-list provenance* L*, authorized-row ledger* A*, generator-closure classifier row* Q*, continuation-witness ledger* W*, displayed* hsame *transports* H*, finite* Cont *routes* C*,* Pkg *provenance* P*, and local* NameCert *row* N*. Every generated closure witness exported by the carrier is produced by a row of* L *and recorded in* A *or* W*.*

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket carrier obligation`

Proof. Project the tuple in Definition 486.1. The only generator source is G, the only constructor-list provenance is L, and the only accepted-row ledger is A.

Now read any exported closure witness through the displayed route C. If the read is accepted, the route reaches L and records the result in A or W; if it is not accepted, the carrier has no other row that can supply generated closure data.

The rows H, P, N transport and name the same packet. They do not add a second generator, an external induction rule, or a closure witness outside the displayed constructor list. □

Theorem 486.6 (GeneratorClosure classifier obligation)**.** *Displayed* hsame *transport for an accepted* GeneratorClosure$^{\uparrow}$ *carrier preserves generator endpoints and generated closure rows. In particular, if two packets transport the same* $G, L, A, Q, W, H, C, P, N$ *surface, then the* GeneratorClosure$^{\uparrow}$ *classifier preserves the endpoints named by* G *and the generated rows recorded by* A *and* W*.*

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket classifier obligation`

Proof. Apply the classifier stability theorem Definition 486.2. Transport of G preserves the generator endpoint, and transport of L preserves the constructor-list provenance against which generated rows are checked.

The accepted rows in A and the continuation witnesses in W are transported along the same displayed hsame rows H. The continuation routes C, package provenance P, and local naming row N then repack the transported data as the same classifier-facing packet.

Thus the classifier can move only the displayed generator endpoint and generated closure rows; it cannot introduce an endpoint or generated row outside the transported carrier. □

Theorem 486.7 (GeneratorClosure ledger obligation)**.** *Every exported* GeneratorClosure$^{\uparrow}$ *read factors through the displayed generator row* G*, constructor-list provenance* L*, authorized-row ledger* A*, continuation-witness ledger* W*, displayed* hsame *transport* H*, finite* Cont *route* C*,* Pkg *provenance* P*, and local* NameCert *row* N*. A read without the constructor-list witness required by* L *is recorded by the* GAP *non-escape boundary and is not exported as a generated closure row.*

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket ledger obligation`

Proof. Start with the carrier obligation of Definition 486.5. It identifies every exported closure witness with a finite read through $G, L, A, Q, W, H, C, P, N$.

Use continuation witness preservation from Definition 486.3. A route that keeps the constructor-list witness remains inside W and is therefore exported through the same packet.

For a route without that witness, the carrier exposes no generated closure coordinate. The read is therefore recorded as a GAP boundary by the package provenance and cannot be repacked by N as an accepted generated row. □

Theorem 486.8 (GeneratorClosure authorized-row exhaustion)**.** *Every exported generated row of an accepted* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet factors through the displayed generator row G, constructor-list provenance L, authorized-row ledger A, continuation-witness ledger W, and the finite constructor-list provenance carried by L. No generated row is exported from a rule outside the displayed constructor list.*

Proof. Begin with Definition 486.5. It identifies the only carrier rows that can export generated closure data and places every exported closure witness in the finite packet $G, L, A, Q, W, H, C, P, N$.

Use Definition 486.2 to transport the authorized generator row and constructor-list provenance componentwise. Since classifier transport preserves the same G and L surface, it cannot create a second source of generated rows.

Finally apply Definition 486.7. Its ledger boundary sends every accepted read through A or W and records every read without the required constructor-list witness as a GAP boundary. □

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket authorized row exhaustion`

Theorem 486.9 (GeneratorClosure Cont route GAP separation)**.** *Every displayed* Cont *route of an accepted* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet either preserves the constructor-list witness carried by L or lands in the displayed* GAP *boundary. A continuation route never becomes a free induction rule and never exports a generated row without the constructor-list witness.*

Proof. Read the route through Definition 486.3. A finite extension that keeps the displayed generator row, constructor-list provenance, authorized ledger, classifier row, and local name preserves the witness already stored in W.

If the route lacks that witness, the same theorem records the attempted read as a GAP ledger boundary. The carrier has no coordinate for an external induction rule, so the missing witness cannot be recovered from another row.

Apply Definition 486.4 to repack the two outcomes as the local certificate surface. The Cont route is therefore separated into witness-preserving reads and displayed GAP reads. □

Theorem 486.10 (GeneratorClosure NameCert public consumer boundary)**.** *The public consumer boundary for an accepted* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet is exhausted by the displayed* BHist *carrier, componentwise* hsame *transports, finite* Cont *routes,* Pkg *provenance,* GAP *non-escape rows, and the local* $\mathsf{NameCert}_{\mathsf{GeneratorClosure}^{\uparrow}}$ *row. Every public read of a generated row factors through the authorized generator row G, constructor-list provenance L, authorized-row ledger A, continuation witness W, and the separated* GAP *boundary.*

Proof. First use Definition 486.8. It fixes the generated-row surface to G, L, A, W and the finite constructor-list provenance, so a public consumer has no generated-row source outside the displayed packet.

Next use Definition 486.9. It separates every continuation read into a witness-preserving route or a displayed GAP boundary, excluding free induction rules from the consumer surface.

Now combine Definition 486.4 with Definition 486.7. The NameCert rows package carrier admission, provenance, exactness, constructor-list reads, and GAP non-escape, while the ledger theorem routes every exported read through the same finite rows. □

Theorem 486.11 (GeneratorClosure public bridge schema handoff)**.** *The public* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet hands off to downstream schema readers only through the displayed rows* $G, L, A, Q, W, H, C, P, N$*. Thus a downstream schema may read the authorized generator row, constructor-list provenance, authorized-row ledger, classifier row, continuation-witness ledger, displayed* hsame *transports, finite* Cont *routes,* Pkg *provenance, local* NameCert *row, and displayed* GAP *boundary, but it receives no second generator source, no independent constructor rule, and no host-side recursor.*

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket public bridge schema handoff`

Proof. Start from the carrier obligation in Definition 486.5. It identifies the public packet with the finite BHist coordinates $G, L, A, Q, W, H, C, P, N$, so every schema-facing read begins from the displayed carrier.

Apply the classifier obligation in Definition 486.6. The classifier preserves only the endpoints named by G and the generated rows recorded by A and W under the same constructor-list provenance L.

Use Definition 486.3 for finite continuation reads, and then apply the ledger obligation in Definition 486.7. A read that carries the required constructor-list witness remains inside W; a read without that witness is recorded by the displayed GAP boundary. These are exactly the rows available to the downstream schema. □

Theorem 486.12 (GeneratorClosure bridge carrier obligation)**.** *The public bridge out of an accepted* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet consumes exactly the carrier row already fixed by the chapter. Its carrier-facing read is the authorized generator row* G*, constructor-list provenance* L*, authorized-row ledger* A*, classifier row* Q*, continuation-witness ledger* W*, componentwise* hsame *rows* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, local* $\mathsf{NameCert}_{\mathsf{GeneratorClosure}^{\uparrow}}$ *row* N*, and the displayed* GAP *boundary; it receives no second generator source, independent constructor rule, or host-side recursor.*

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosureUp StdBridge`

Proof. Begin with the carrier obligation Definition 486.5. It identifies the public packet with the finite carrier rows $G, L, A, Q, W, H, C, P, N$ and leaves no coordinate for a second generator source.

Apply the public bridge schema handoff Definition 486.11. The handoff permits downstream schema readers to consume only the same displayed carrier, transport, continuation, provenance, local name, and boundary rows.

Thus the bridge carrier obligation is not an additional carrier construction. It is the carrier obligation read through the public bridge boundary, with the same constructor-list provenance and the same GAP non-escape row. □

Theorem 486.13 (GeneratorClosure bridge classifier obligation)**.** *The public bridge classifier for an accepted* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet consumes exactly the authorized generator row, constructor-list provenance, classifier row, continuation-witness ledger, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, local* $\mathsf{NameCert}_{\mathsf{GeneratorClosure}^{\uparrow}}$ *row, and* GAP *rows already fixed by the chapter. Every accepted bridge classification factors through* G, L, Q, W, H, C, P, N*, and every read without the constructor-list witness remains a displayed* GAP *boundary.*

Proof. Use the classifier obligation Definition 486.6. It transports the accepted generator endpoint and generated-row surface through the same displayed constructor-list provenance and carrier rows.

The public bridge schema handoff Definition 486.11 exposes no classifier row other than Q and no constructor provenance other than L. Hence a bridge classification cannot be read from an external predicate or host recursor.

Finally use Definition 486.3 to separate witnessed and unwitnessed continuation reads. Witnessed reads remain in the continuation-witness ledger W, while unwitnessed reads stay in the displayed GAP boundary. □

Theorem 486.14 (GeneratorClosure bridge ledger obligation)**.** *The public bridge ledger for an accepted* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet consumes exactly the authorized-row ledger, continuation-witness ledger, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, local* $\mathsf{NameCert}_{\mathsf{GeneratorClosure}^{\uparrow}}$ *row, and* GAP *rows already fixed by the chapter. A bridge read is accepted only through A or W with the constructor-list provenance supplied by L; otherwise the read is recorded as a displayed* GAP *row and is not exported as generated data.*

Proof. Start from the ledger obligation Definition 486.7. It records the accepted generated rows and continuation witnesses in A and W, and it sends reads lacking the constructor-list witness to the displayed boundary.

Combine this with the public bridge schema handoff Definition 486.11. The bridge reads only the authorized generator row, constructor-list provenance, classifier, continuation ledger, transport, continuation routes, package provenance, local name, and GAP rows named there.

Therefore the ledger exported to downstream bridge consumers is exactly the chapter ledger. The bridge does not introduce an unledgered generator continuation, a free induction rule, or an additional row from which generated data could be recovered. □

Theorem 486.15 (GeneratorClosure fixed-point consumer obligation)**.** *Every* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *consumer of a* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet must read the fixed witness through the* $\mathsf{GeneratorClosure}^{\uparrow}$ *constructor-list provenance and classifier surface. Concretely, the fixed witness is admissible only when its read factors through $G, L, A, Q, W, H, C, P, N$ and the constructor-list row L supplies the witness required by the classifier row Q.*

This fixed-witness consumer surface is the sibling handoff to chapter 556; the $\mathsf{GeneratorClosure}^{\uparrow}$ *constructor-list provenance and classifier rows are the specific dependency consumed by that chapter.*

Proof. The carrier obligation Definition 486.5 fixes the generator-closure packet available to the consumer. Hence the consumer cannot obtain a fixed witness from a row outside $G, L, A, Q, W, H, C, P, N$.

The classifier obligation Definition 486.6 transports the generator endpoint and generated rows along the same displayed surface. A fixed-point read therefore uses the classifier row Q only together with the constructor-list provenance L and the accepted-row or continuation-witness ledgers A and W.

Finally, continuation witness preservation from Definition 486.3 and the ledger obligation Definition 486.7 separate the two possible outcomes. With the constructor-list witness, the fixed witness is read from the displayed continuation surface; without that witness, the attempted read is a GAP boundary and is not a fixed witness for $\mathsf{GeneratorFixedPoint}^{\uparrow}$. □

Theorem 486.16 (GeneratorClosure downstream ledger exhaustion)**.** *Every downstream generator consumer of the public* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet factors through the displayed* BHist *carrier,* hsame *transport rows,* Cont *routes,* Pkg *provenance, local* NameCert *row, constructor-list provenance, and* GAP *ledger. No downstream consumer receives a free-floating induction principle, an unledgered generator continuation, or a host recursor exported outside those rows.*

Proof. Use Definition 486.5 to place the consumer read in the finite BHist packet. The only visible generator source is G, the only constructor-list provenance is L, and the only public ledgers for generated rows and continuation witnesses are A and W.

Apply Definition 486.6 to transport the classifier-facing endpoints and generated rows along H. The Cont routes C, package provenance P, and local certificate row N repack the same transported rows and do not expose another induction principle.

It remains to exhaust failed or boundary reads. By Definition 486.3, a continuation lacking the constructor-list witness cannot remain a generated continuation. The ledger obligation Definition 486.7 records such a read as a displayed GAP boundary, so every downstream read is accounted for by the public ledger surface. □

Theorem 486.17 (GeneratorClosure fixed-point acceptance route)**.** *Every accepted fixed witness consumed by* GeneratorFixedPoint$^{\uparrow}$ *from the public* GeneratorClosure$^{\uparrow}$ *packet routes through the displayed rows $G, L, A, Q, W, H, C, P, N$. The constructor-list provenance row L supplies the witness that the fixed point is generated by the authorized constructor list, and the classifier row Q is the only row that classifies the fixed witness as accepted rather than as a* GAP *boundary.*

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket fixedpoint acceptance route`

Proof. Begin with the fixed-point consumer obligation of Definition 486.15. It already restricts every GeneratorFixedPoint$^{\uparrow}$ read to the carrier rows $G, L, A, Q, W, H, C, P, N$ and requires L and Q to be read together.

Use the carrier, classifier, and ledger obligations of Definition 486.5, Definition 486.6, and Definition 486.7. The carrier identifies the only available rows, the classifier preserves the generated endpoint and fixed-witness surface, and the ledger sends reads without the constructor-list witness to the displayed GAP boundary.

Finally apply Definition 486.8 and Definition 486.9. These exhaust the authorized generated rows and separate witness-preserving routes from rejected routes, so an accepted fixed witness has exactly the stated acceptance route. □

Theorem 486.18 (GeneratorClosure fixed-point continuation-route exhaustion)**.** *Every* GeneratorFixedPoint$^{\uparrow}$ *read through a public* GeneratorClosure$^{\uparrow}$ *packet factors through the displayed surface*

$$G, L, A, Q, W, H, C, P, N.$$

If the continuation route carries the constructor-list witness supplied by L, then the read is accepted through the authorized-row ledger A or the continuation-witness ledger W. Otherwise the read is recorded as the displayed GAP *boundary and is not exported as a fixed-point continuation.*

Proof. Begin with Definition 486.15. It places every GeneratorFixedPoint$^{\uparrow}$ consumer inside the constructor-list provenance and classifier surface of the public GeneratorClosure$^{\uparrow}$ packet.

Use Definition 486.17. When the route carries the constructor-list witness from L, the fixed witness is classified through Q and read through the accepted ledgers A or W.

It remains to account for routes without that witness. Apply Definition 486.9 to separate witness-preserving routes from rejected routes, and then apply Definition 486.16 to place every rejected read in the displayed GAP boundary of the same public ledger. □

Theorem 486.19 (GeneratorClosure induction non-escape boundary)**.** *Every downstream generator consumer receives displayed constructor-list provenance and displayed* GAP *rejection rows from* GeneratorClosure$^{\uparrow}$*. It receives neither a free induction principle, nor a host recursor, nor an unledgered generator continuation outside $G, L, A, Q, W, H, C, P, N$.*

Proof. Start from downstream ledger exhaustion in Definition 486.16. It places every downstream consumer inside the displayed carrier, transport rows, continuation routes, package provenance, local certificate row, constructor-list provenance, and GAP ledger.

The carrier and ledger obligations of Definition 486.5 and Definition 486.7 identify the constructive boundary. Accepted generated rows are read through L, A, W, while reads lacking the constructor-list witness are recorded by the boundary ledger.

The route separation theorem Definition 486.9 excludes the remaining escape. A continuation route either preserves the displayed witness or lands in GAP, so the consumer cannot turn the route into a free induction principle or host-side recursor. □

Theorem 486.20 (GeneratorClosure authorized consumer factorization)**.** *Every authorized generator consumer of the public* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet factors through the carrier, the classifier row, the continuation-witness surface, the* GAP *ledger, the package provenance, and the local* $\mathsf{NameCert}_{\mathsf{GeneratorClosure}^{\uparrow}}$ *rows. Concretely, its read is a finite route through* $G, L, A, Q, W, H, C, P, N$*, with* L *witnessing constructor-list provenance,* Q *classifying accepted generated rows,* W *recording accepted continuations,* P *recording package provenance, and* N *naming the local certificate.*

Proof. Use the authorized-row exhaustion theorem Definition 486.8. It fixes the generated-row source to the displayed generator row, constructor-list provenance, authorized-row ledger, and continuation-witness ledger.

Apply Definition 486.15 for fixed-witness consumers and Definition 486.16 for downstream consumers. Both routes pass through the same finite packet, so there is no separate consumer interface outside $G, L, A, Q, W, H, C, P, N$.

It remains only to name the factors. The classifier obligation Definition 486.6 supplies Q, the ledger obligation Definition 486.7 supplies the GAP boundary, and the carrier obligation Definition 486.5 supplies H, C, P, N as displayed support rows. Hence every authorized consumer factors through the stated public surface. □

Theorem 486.21 (GeneratorClosure constructor provenance determinacy)**.** *For an accepted* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet, the constructor-list provenance row* L *determines the admitted generator endpoint and the generated rows recorded in* A *and* W*. Hence two accepted reads with the same displayed* L *cannot disagree about the authorized constructor provenance while remaining inside the carrier; any unwitnessed route is recorded at the displayed* GAP *boundary.*

Proof. Project the carrier by Definition 486.5. The packet exposes the generator row G, constructor-list provenance row L, authorized generated-row ledger A, continuation-witness ledger W, classifier row Q, transport row H, continuation routes C, package provenance P, and local certificate row N.

Apply the classifier obligation Definition 486.6 and authorized-row exhaustion Definition 486.8. Once L is fixed, the accepted generator endpoint and generated rows are read through the same displayed A and W ledgers.

Finally apply the ledger obligation Definition 486.7. A route that lacks the displayed constructor-list witness is not an alternate accepted provenance read; it is forced into the GAP boundary. Therefore equal displayed L rows cannot support two different authorized constructor provenances inside the accepted packet. □

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket constructor provenance determinacy`

Theorem 486.22 (GeneratorClosure GAP boundary absorbs unwitnessed route)**.** *Every* Cont *route of the public* $\mathsf{GeneratorClosure}^{\uparrow}$ *packet that lacks the constructor-list witness supplied by* L

is absorbed by the displayed GAP *boundary. Such a route cannot later be exported as an accepted generated-row read through A or as an accepted continuation-witness read through W.*

Proof. Use the carrier obligation Definition 486.5 to confine the route to the displayed rows $G, L, A, Q, W, H, C, P, N$. There is no independent continuation surface outside the carrier packet.

The classifier obligation Definition 486.6 and ledger obligation Definition 486.7 separate witnessed and unwitnessed routes. A route with the L witness may be read by the accepted ledgers, while a route without that witness is recorded at the displayed GAP boundary.

It remains to exclude later export. The fixed-point consumer obligation Definition 486.15 and authorized consumer factorization Definition 486.20 require any downstream accepted read through A or W to carry the same displayed constructor-list provenance. The unwitnessed route has already been classified as boundary evidence, so it cannot be repacked as an accepted generated row or accepted continuation witness. □

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket gap boundary absorbs unwitnessed route`

Theorem 486.23 (GeneratorClosure fixed-point consumer route determinacy)**.** *Every* GeneratorFixedPoint$^{\uparrow}$ *witness consumed from the public* GeneratorClosure$^{\uparrow}$ *packet is determined by the displayed route through G, L, Q, W. Once the generator row G, constructor-list provenance row L, classifier row Q, and continuation-witness ledger W are fixed up to componentwise* hsame*, neither a host recursor nor a second generator can vary the consumed fixed witness.*

Proof. Start from Definition 486.15. It states that a GeneratorFixedPoint$^{\uparrow}$ consumer reads the fixed witness only through the constructor-list provenance and classifier surface of GeneratorClosure$^{\uparrow}$.

The carrier, classifier, and ledger obligations in Definition 486.5, Definition 486.6, and Definition 486.7 identify the visible route. The row G supplies the generator source, L supplies the constructor-list witness, Q classifies the accepted fixed witness, and W records the continuation witness that remains outside GAP.

Apply authorized consumer factorization Definition 486.20. Since every authorized consumer factors through the same public surface, a host recursor or second generator would have to appear as an additional public factor. No such factor is present, so the consumed witness is determined by the displayed G, L, Q, W route. □

Lean4 ✓ `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket fixedpoint consumer route determinacy`

Theorem 486.24 (GeneratorClosure mature consumer inventory)**.** *The mature public consumer inventory of the* GeneratorClosure$^{\uparrow}$ *packet consists exactly of authorized-row consumers, bridge schema consumers, fixed-point consumers, constructor-provenance consumers, and* GAP*-boundary consumers. Each such consumer is routed through the same displayed surface $G, L, A, Q, W, H, C, P, N$: G supplies the authorized generator row, L supplies constructor-list provenance, A records accepted generated rows, Q classifies the generator-closure read, W records fixed-point and continuation witnesses, H transports componentwise* hsame *evidence, C exposes finite* Cont *routes, P records package provenance, and N names the local certificate. No other public consumer kind is admitted by the chapter surface.*

Proof. Apply authorized consumer factorization Definition 486.20. It places every authorized-row consumer on the displayed route $G, L, A, Q, W, H, C, P, N$, and it leaves no independent consumer port outside the carrier, classifier, continuation-witness, provenance, and local certificate rows.

Bridge schema consumers use the same public surface. Their bridge-facing read must pass through the accepted generated-row ledger A, the classifier row Q, the continuation route ledger C, package provenance P, and the local naming row N, so they are not a separate carrier family.

For constructor-provenance consumers, use Definition 486.21. Once L is fixed, the admitted generator endpoint and the generated rows recorded in A and W are fixed inside the accepted packet.

For GAP-boundary consumers, use Definition 486.22. A route lacking the constructor-list witness is absorbed by the displayed boundary and cannot later become an accepted generated-row read or accepted continuation-witness read.

For fixed-point consumers, use Definition 486.23. The consumed fixed witness is determined by the displayed G, L, Q, W route, with H, C, P, N carrying transport, route exposure, package provenance, and the local certificate. These five cases exhaust the public consumer inventory because every admitted read has already been factored through the same packet surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{GeneratorClosure}\uparrow}$.

Constructive story: A $\mathsf{GeneratorClosure}^{\uparrow}$ packet is generated from an authorized generator row, finite constructor-list provenance, authorized-row ledger, generator-closure classifier row, continuation-witness ledger, displayed hsame transport, finite Cont routes, Pkg provenance, a local NameCert row, and GAP non-escape evidence.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{GeneratorClosure}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: The scoped surface binds the displayed BHist carrier, authorized generator rows, constructor-list provenance, hsame transport, Cont routes, Pkg provenance, local $\mathsf{NameCert}_{\mathsf{GeneratorClosure}\uparrow}$ rows, classifier stability, continuation witness preservation, and GAP non-escape evidence for authorized generator rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{GeneratorClosure}\uparrow}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.GeneratorClosureUp.GeneratorClosurePacket\_namecert\_obligations`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close free-floating induction, universal quantification over objects outside the displayed generator, host recursor correctness, or bridge checking.

Upgrade path: No further formal-axis bridge upgrade is pending for the authorized generator packet.

Chapter 487

A Concrete Naming Certificate for $\mathsf{ClosureWitnessLedger}^{\uparrow}$

The $\mathsf{ClosureWitnessLedger}^{\uparrow}$ interface records the finite ledger side of generator-internal closure. Where $\mathsf{GeneratorClosure}^{\uparrow}$ of chapter 486 supplies the authorized generator and classifier surface, $\mathsf{ClosureWitnessLedger}^{\uparrow}$ isolates the witness packets and GAP non-escape rows consumed by that surface: each accepted continuation row names the constructor-list witness it reuses, and each read without such a witness is stored as a GAP non-escape row.

Definition 487.1 (ClosureWitnessLedger carrier)**.** *A* $\mathsf{ClosureWitnessLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (G, L, W, Q, E, H, C, P, N)$$

with the following visible coordinates:

1. *G is the authorized generator row whose closure supplies the admissible constructor surface;*
2. *L is the finite constructor-list provenance row for G;*
3. *W is the closure-witness ledger, with one finite witness packet for each continuation read that remains inside L;*
4. *Q is the witness-classifier row comparing continuation reads by the displayed generator row, constructor-list provenance, and witness packet;*
5. *E is the* GAP *non-escape ledger, recording every attempted continuation read that lacks the constructor-list witness required by L;*
6. *H stores displayed* hsame *transports for G, L, W, Q, E and the local naming rows;*
7. *C stores the finite* Cont *routes by which consumers read generator rows, constructor-list provenance, witness packets, classifier rows, and non-escape rows;*
8. *P is the* Pkg *provenance over* BHist*, generator rows, constructor-list provenance, closure-witness packets,* hsame*,* Cont*, and* GAP *boundaries;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ClosureWitnessLedger}^{\uparrow}}$ *row.*

The carrier exports only the displayed generator row, constructor-list provenance, finite witness ledger, classifier row, non-escape ledger, transport rows, continuation routes, package provenance, and local naming row. It does not export an induction rule over all future continuations.

Lean4 (definition) `BEDC.Derived.ClosureWitnessLedgerUp.ClosureWitnessLedgerCarrier`

Theorem 487.2 (ClosureWitnessLedger classifier stability)**.** *Displayed* hsame *transport preserving the generator row G, constructor-list provenance L, closure-witness ledger W, non-escape ledger E, transport rows H, continuation routes C, package provenance P, and local* NameCert *row N preserves the* $\mathsf{ClosureWitnessLedger}^{\uparrow}$ *classifier Q. Thus two finite continuation reads classified through the same displayed generator and constructor-list provenance retain the same witness-present or* GAP*-boundary status.*

Lean4 ✓ `BEDC.Derived.ClosureWitnessLedgerUp.ClosureWitnessLedgerCarrier classifier stability`

Proof. The classifier is componentwise over the packet in Definition 487.1. Transport of G and L preserves the authorized generator surface and the finite constructor-list provenance against which every witness packet is read.

Transport of W preserves the witness attached to an accepted continuation read. Transport of E preserves the corresponding absence row for a read without the required constructor-list witness, and H, C, P, N repack the same finite routes and naming row without adding any external closure principle. □

Theorem 487.3 (ClosureWitnessLedger NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ClosureWitnessLedger}^{\uparrow}}$ *surface for Definition 487.1 consists of five BEDC-native rows:*

1. *carrier admission over the finite* BHist *packet K;*
2. Pkg *provenance naming the generator row, constructor-list provenance, witness ledger, classifier row, non-escape ledger,* hsame *transports,* Cont *routes, and local naming row;*
3. NameCert *exactness stating that the local certificate classifies exactly the displayed closure-witness ledger packet;*
4. *witness coverage stating that each accepted continuation read in W carries a constructor-list witness from L for the same generator row G;*
5. GAP *ledger non-escape stating that each read in E lacks the displayed witness required by L and is not exported as a generator-internal continuation.*

Proof. Carrier admission is projection of the displayed tuple. The generator row, constructor-list provenance, witness ledger, classifier row, non-escape ledger, transports, routes, provenance, and local naming row are coordinates of one finite BHist packet.

The package and naming rows identify that same packet. Classifier stability from Definition 487.2 supplies the transport behavior required by the NameCert surface.

The remaining rows are direct ledger projections. The witness-coverage row reads accepted continuations through W and L, while the GAP row reads rejected continuations through E and records them as boundaries rather than as generated closure content. □

Theorem 487.4 (ClosureWitnessLedger handoff to GeneratorClosure)**.** *Let K be an accepted* $\mathsf{ClosureWitnessLedger}^{\uparrow}$ *carrier and let J be a* $\mathsf{GeneratorClosure}^{\uparrow}$ *carrier with the same displayed generator row G and constructor-list provenance L. If the* Cont *route of J asks for a continuation witness, then the answer is read from W when the witness is present and from E as a* GAP *boundary when it is absent. Therefore the* $\mathsf{GeneratorClosure}^{\uparrow}$ *continuation-witness coordinate can be supplied by the concrete* $\mathsf{ClosureWitnessLedger}^{\uparrow}$ *packet without changing the generator classifier.*

Proof. The shared G and L make both packets read continuation rows against the same finite constructor-list provenance. A Cont route in J that requests a continuation witness is therefore a route of the same displayed shape as the corresponding route in K.

If the route has a witness packet, the coordinate W supplies it and the classifier row Q records that the read remains inside the generator closure. If the route lacks the witness required by L, the coordinate E supplies the only visible row, namely the GAP boundary.

Repacking these two cases into the continuation-witness coordinate of J changes no generator row and no constructor-list provenance. The handoff is a finite ledger substitution, not an additional induction principle. □

Theorem 487.5 (ClosureWitnessLedger GAP non-escape)**.** *For any accepted* $\mathsf{ClosureWitnessLedger}^{\uparrow}$ *carrier K, a finite continuation read recorded in the* GAP *ledger E cannot also be exported by K as an accepted witness packet in W for the same generator row G and constructor-list provenance L. Consequently every rejected read remains a boundary row and never becomes generator-internal closure content by certificate transport alone.*

Proof. Read the attempted continuation through its displayed route in C. The carrier has exactly two ledger outputs for such a route: a witness packet in W when the constructor-list witness from L is present, or a GAP row in E when that witness is absent.

The classifier stability theorem transports this distinction without changing G or L. A row already classified through E has no witness coordinate to project, so package provenance can only preserve it as a boundary row.

Thus certificate transport cannot move an absent-witness read from E into W. Such a move would require a new constructor-list witness not present in the finite packet, and the carrier exposes no coordinate that can create one. □

Theorem 487.6 (ClosureWitnessLedger continuation-witness exactness)**.** *For an accepted* $\mathsf{ClosureWitnessLedger}^{\uparrow}$ *packet $K = (G, L, W, Q, E, H, C, P, N)$, every finite continuation read through C has exactly one public classification: either a witness packet in W against the displayed constructor-list provenance L, or a* GAP *row in E. Componentwise* hsame *transport through H preserves this split, and no certificate transport can move a row from E to W without a displayed witness from L.*

Proof. Project the carrier of Definition 487.1. The continuation routes in C read against the same generator row G and constructor-list provenance L, so the classifier row Q is evaluated on one displayed ledger surface.

Apply Definition 487.4. A continuation read with the required constructor-list witness is supplied from W, while a read without that witness is supplied from E as a GAP boundary.

The two cases are exclusive by Definition 487.5. A row already recorded in E cannot also be exported as a witness packet in W for the same G and L.

Transport through H is componentwise over G, L, W, Q, E and the local naming rows. It preserves the witness-vs-boundary split and provides no coordinate that can create the missing constructor-list witness. □

Closure status for $\mathsf{NameCert}_{\mathsf{ClosureWitnessLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{ClosureWitnessLedger}^{\uparrow}$ packet is generated from an authorized generator row, finite constructor-list provenance, a closure-witness ledger, a witness classifier row, a GAP non-escape ledger, displayed hsame transport, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ClosureWitnessLedger}^{\uparrow}}, \mathsf{seed})$

Scope closed: The seed scope records the carrier, classifier stability, NameCert obligations, generator-closure handoff, and GAP non-escape boundary for finite closure-witness ledgers.

Formal verification: FormalStatus(NameCert$_{\mathsf{ClosureWitnessLedger}\uparrow}$, unformalized)
Bridge status: none
Origin: human
Not claimed: This chapter does not close general induction, host recursor correctness, public bridge checking, or closure over continuations outside the displayed generator and constructor-list provenance.
Upgrade path: Obligation closure requires checked carrier admission, classifier stability, NameCert exactness, generator-closure handoff, and GAP non-escape for the same finite packet.

Chapter 488

A Continuation-Ledger Certificate for $\mathsf{KernelCategory}^{\uparrow}$

The $\mathsf{KernelCategory}^{\uparrow}$ packet records the category-shaped reading of the BEDC kernel without importing a host category object. Its data are finite BHist rows: unary object histories, continuation-ledger hom histories, empty continuation identities, displayed Cont composition ledgers, hsame law transports, package provenance, and one local naming row.

This packet is the kernel-level specialization of the concrete $\mathsf{Cat}^{\uparrow}$ hom-carrier surface in chapter 61. It consumes the continuation unit and associativity surface of chapter 931 and the displayed continuation identity and composition route already packaged by $\mathsf{ContinuationMonad}^{\uparrow}$ in chapter 485. Thus $\mathsf{KernelCategory}^{\uparrow}$ reuses the sibling carrier and route rows while refusing host category objects, quotient morphisms, and any morphism equality not expressed as finite continuation-ledger history.

Definition 488.1 (KernelCategory carrier)**.** *A* $\mathsf{KernelCategory}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (O, H, I, C, A, U, P, N)$$

with the following visible coordinates:

1. *O is the object table, whose rows are exactly the histories admitted by* UnaryHistory*.*
2. *H is the hom table, whose rows are continuation-ledger histories presented as* CategoryHomCarrier *and* ContinuationMorphism *data between rows of O.*
3. *I records identity rows, and these are precisely the empty continuation rows over each unary object history.*
4. *C records displayed composition rows, and each row is a* Cont*-composite ledger from composable continuation-ledger hom histories.*
5. *A records associativity rows as* hsame *transports between the two displayed triple-composite ledgers with the same endpoints.*
6. *U records left and right unit rows as* hsame *transports from the empty-continuation composites back to the displayed hom row.*
7. *P names* BHist*,* UnaryHistory*,* Cont*,* hsame*,* Pkg*,* NameCert*, and* $\mathsf{Cat}^{\uparrow}$ *as the only dependency rows used by the packet.*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{KernelCategory}^{\uparrow}}$ *row.*

The classifier for accepted packets compares only these rows, their endpoint ledgers, their displayed transports, their continuation routes, and their package and naming provenance.

Theorem 488.2 (KernelCategory identity continuations)**.** *In an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *carrier, identity homs are exactly the empty continuation rows in* I*. If endpoint rows are transported by the componentwise* hsame *data of the carrier, the transported identity row is again the empty continuation row over the transported endpoint, and it remains classified as an identity hom in the same packet.*

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier identity continuation`

Proof. Project the object and identity coordinates from Definition 488.1. The object coordinate admits endpoints only through UnaryHistory, and the identity coordinate has no row other than the empty continuation row over such an endpoint.

Transport an endpoint by the displayed hsame rows. Since the identity row is defined by the empty continuation ledger and has no independent tail data, transporting the endpoint transports the whole identity row to the empty continuation row over the transported object.

The package and local naming rows are unchanged by this componentwise transport. Thus the transported row is still classified by the same $\mathsf{NameCert}_{\mathsf{KernelCategory}^{\uparrow}}$ identity coordinate. □

Theorem 488.3 (KernelCategory composition continuations)**.** *Composable hom rows in an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *carrier close under the displayed* Cont *composition rows in* C*. The resulting hom row has the source endpoint of the first input row, the target endpoint of the second input row, and no endpoint ledger outside the two input ledgers and the displayed composite route.*

Proof. Read two composable hom rows from H. By the carrier definition, each is a continuation-ledger history with endpoints already listed in the unary object table O.

The composition coordinate C records exactly the displayed Cont-composite ledger for such a composable pair. Applying that row produces a hom history whose source is inherited from the first row and whose target is inherited from the second row.

No additional endpoint source is present in K. The associativity and unit rows in A and U may transport composite ledgers by hsame, but they do not introduce new object histories or quotient morphisms. Hence composition preserves the displayed endpoint ledger. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier composition continuation`

Theorem 488.4 (KernelCategory certificate surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{KernelCategory}^{\uparrow}}$ *surface consists exactly of five obligation families:*

1. *carrier admission for the finite packet* $K = (O, H, I, C, A, U, P, N)$*;*
2. *hom classifier stability under componentwise* hsame *transport of endpoints and continuation-ledger hom rows;*
3. *identity law rows asserting that the empty continuation rows in* I *are the left and right unit ledgers;*
4. *composition and associativity law rows asserting closure under* C *and triple-composite transport by* A*;*
5. *ledger non-escape, excluding host category objects, quotient morphisms, external equality of arrows, and any category primitive not named by* O, H, I, C, A, U, P, N*.*

Proof. Carrier admission is the tuple projection of Definition 488.1. It supplies the object table, hom table, identity rows, composition rows, associativity rows, unit rows, package provenance, and local naming row.

Hom classifier stability follows by componentwise transport: endpoint rows are transported inside O, hom histories are transported inside H, and the displayed continuation routes in C replay the same source and target ledgers.

Use Definition 488.2 for the identity law rows and Definition 488.3 for composition closure. The remaining associativity and unit law rows are precisely the hsame transports stored in A and U.

Finally inspect the package row P and the naming row N. They name only the BEDC history, continuation, transport, package, NameCert, and $\mathsf{Cat}^{\uparrow}$ rows listed in the carrier. A host category object or quotient morphism would require an additional coordinate, so it is outside the certificate surface. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCertificateSurface`

Theorem 488.5 (KernelCategory associativity scope)**.** *Every triple composite admitted by a* $\mathsf{KernelCategory}^{\uparrow}$ *packet is scoped by the displayed* Cont *rows in C together with the* hsame *associativity row in A. The packet reads both parenthesized composites as finite continuation-ledger histories with the same endpoints, and it has no row for a host category object, quotient morphism, or external arrow equality.*

Proof. Start with the finite packet of Definition 488.1. Its hom rows live in H, its displayed binary composite rows live in C, and its associativity transports live in A.

Apply Definition 488.3 twice. The two applications build the two parenthesized triple composites using only the displayed Cont ledgers in C, so the source and target endpoints remain the ones inherited from the three input hom rows.

The comparison between the two readings is then exactly the hsame row named in A. By Definition 488.4, the certificate has no additional coordinate for a host category primitive, quotient morphism, or external equality of arrows. Thus associativity is scoped only by the displayed continuation rows and the named transport row. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier associativity scope`

Theorem 488.6 (KernelCategory unit scope)**.** *Every left or right unit read admitted by a* $\mathsf{KernelCategory}^{\uparrow}$ *packet is exhausted by the empty-continuation identity rows in I and the unit transports in U. The read never imports a host identity arrow, quotient morphism, or external arrow equality beyond the finite continuation-ledger rows already present in K.*

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier unit scope`

Proof. The identity surface is fixed by Definition 488.2: identities are exactly the empty continuation rows over unary object histories. Thus a unit read can begin only with the displayed identity row in I.

Compose the displayed identity row with the displayed hom row through Definition 488.3. The resulting ledger is again a finite continuation-ledger hom row whose endpoints are inherited from the input rows.

The return from this composite ledger to the original hom row is precisely the left or right unit hsame transport listed in U. The non-escape clause of Definition 488.4 excludes host category objects, quotient morphisms, and external arrow equality, so no further unit principle is available. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryUnitScope`

Theorem 488.7 (KernelCategory public NameCert surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{KernelCategory}^{\uparrow}}$ *surface is exactly the carrier, hom classifier, identity, composition, associativity, unit, package, and non-escape rows named by* $K = (O, H, I, C, A, U, P, N)$*. Public consumers may cite the rows exposed by Definition 488.1, Definition 488.2, Definition 488.3, Definition 488.5, Definition 488.6, and Definition 488.4, but they cannot add host category objects, quotient morphisms, or external arrow equality.*

Proof. Project the tuple $K = (O, H, I, C, A, U, P, N)$ from Definition 488.1. These coordinates supply the object table, hom classifier, identity rows, composition rows, associativity transports, unit transports, package provenance, and local naming row.

Definition 488.2 and Definition 488.3 expose the identity and composition readings. Definition 488.5 and Definition 488.6 expose the law transports without adding any host-side category structure.

Finally, Definition 488.4 states the ledger non-escape boundary. Since the public surface is the displayed NameCert surface of the same packet, a consumer receives exactly those rows and no quotient morphism, external arrow equality, or host category object. □

Theorem 488.8 (KernelCategory root NameCert obligation triad)**.** *The root* $\mathsf{NameCert}_{\mathsf{KernelCategory}^{\uparrow}}$ *surface is generated by three displayed obligations: carrier admission for* $K = (O, H, I, C, A, U, P, N)$*, identity-continuation admission for the empty rows in* I*, and composition-continuation admission for the displayed* Cont *rows in* C*. Any accepted kernel-category read must cite all three obligations before it can consume associativity, unit, package, or local naming rows.*

Proof. Carrier admission is the tuple projection of Definition 488.1. It exposes the object, hom, identity, composition, transport, provenance, and local naming rows as the finite packet.

Identity-continuation admission is supplied by Definition 488.2. It identifies the identity rows with empty continuation rows over unary object histories.

Composition-continuation admission is supplied by Definition 488.3. It identifies the composable hom rows with displayed Cont composites whose endpoints remain inside the input ledgers.

The certificate surface theorem, Definition 488.4, then reads the associativity, unit, package, and non-escape rows as downstream rows of the same packet. Thus the root obligation surface is exactly the carrier, identity-continuation, and composition-continuation triad. □

Theorem 488.9 (KernelCategory composition locality)**.** *Every composition read admitted by a* $\mathsf{KernelCategory}^{\uparrow}$ *packet factors through the displayed* Cont *rows in* C *and the endpoint ledgers already present in* O *and* H*. No composition read may consult a host category composition, quotient morphism, external arrow equality, or endpoint object outside the finite carrier* $K = (O, H, I, C, A, U, P, N)$*.*

Proof. Start with the carrier of Definition 488.1. Hom rows live in H, endpoints live in O, and displayed composition rows live in C.

Apply Definition 488.3. It constructs the composite hom row from two displayed continuation-ledger hom rows and the Cont composite row that joins them.

The endpoint ledgers of the composite are therefore inherited from the two input hom rows. The associativity and unit transports in A and U compare displayed continuation ledgers, while the package and naming rows P, N certify the same finite packet.

Finally apply Definition 488.4. Its non-escape clause excludes host category objects, quotient morphisms, and external equality of arrows, so composition is local to C and the endpoint ledgers in O, H. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier cont composition locality`

Theorem 488.10 (KernelCategory package provenance non-escape)**.** *The provenance row P of a* $\mathsf{KernelCategory}^{\uparrow}$ *packet exports no host category object, quotient morphism, external arrow equality, functor semantics, or limit object outside O, H, I, C, A, U, P, N. It only records the BEDC history, unary-history, continuation, transport, package, NameCert, and category-surface rows needed to replay the finite carrier.*

Proof. Project the package row from Definition 488.1. It names BHist, $\mathsf{UnaryHistory}$, Cont, hsame, Pkg, $\mathsf{NameCert}$, and $\mathsf{Cat}^{\uparrow}$ as dependency rows for the finite packet.

Use Definition 488.2 and Definition 488.3 to identify the only identity and composition routes available to consumers. Both routes remain inside the displayed continuation-ledger rows.

Apply Definition 488.4. The ledger non-escape obligation says that a host category object, quotient morphism, external equality of arrows, or category primitive not named by O, H, I, C, A, U, P, N is outside the certificate surface.

Functor semantics and limit objects would require additional carrier rows and additional laws. Since P records only provenance for the displayed finite packet, it cannot export those structures. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier package provenance nonescape`

Theorem 488.11 (KernelCategory endpoint transport closure)**.** *For a* $\mathsf{KernelCategory}^{\uparrow}$ *packet $K = (O, H, I, C, A, U, P, N)$, componentwise endpoint* hsame *transport preserves the unary object table O and the empty-continuation identity row I. Thus an endpoint read transported along O remains an admitted object row, and the corresponding identity read remains the same local empty* Cont *row rather than a host identity arrow.*

Proof. Start from the carrier in Definition 488.1. It places object endpoints in the unary table O and identity witnesses in the empty-continuation row I.

Apply Definition 488.2. The identity row is not a host identity operation; it is the displayed empty Cont route attached to the unary object history.

The certificate surface of Definition 488.4 supplies the componentwise hsame transport rows. Transporting an endpoint therefore moves only the displayed unary object row and its empty-continuation identity row, while the non-escape clauses exclude host category objects, quotient morphisms, and external arrow equality. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier endpoint transport closure`

Theorem 488.12 (KernelCategory composite endpoint determinacy)**.** *For a* $\mathsf{KernelCategory}^{\uparrow}$ *packet $K = (O, H, I, C, A, U, P, N)$, any displayed* Cont *composite admitted by C has exactly the source endpoint of the first continuation-ledger hom row and the target endpoint of the second continuation-ledger hom row. No host endpoint coordinate, quotient morphism endpoint, or external equality of arrows is available to alter those two displayed endpoints.*

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier composite endpoint determinacy`

Proof. Read the composite through Definition 488.3. It constructs the composite only from two hom rows in H and the displayed Cont composite row in C.

The first hom row supplies the source endpoint and the second hom row supplies the target endpoint. The carrier of Definition 488.1 has no further endpoint coordinate outside O, H, C.

Finally apply Definition 488.5, Definition 488.6, and Definition 488.4. The law transports compare displayed continuation ledgers, and the certificate surface blocks host category endpoints, quotient morphism endpoints, and external arrow equality from participating in the endpoint read. □

Theorem 488.13 (KernelCategory law transport exhaustion)**.** *Once the carrier row O, H, I, C, P, N, the identity row I, and the composition row C of a* $\mathsf{KernelCategory}^{\uparrow}$ *packet are fixed, every associativity or unit read is exhausted by the law-transport rows A and U. These law reads do not import host associativity, host unit equality, quotient morphisms, functor semantics, natural transformations, or limit objects.*

Proof. Fix the carrier with Definition 488.1. The rows O, H, I, C, P, N determine the displayed object table, hom ledger, identity route, composition route, provenance, and local name.

Use Definition 488.2 and Definition 488.3. They ensure that identity and composition reads are already local to empty-continuation identity rows and displayed Cont composites.

The remaining category-shaped laws are exactly the rows described by Definition 488.5 and Definition 488.6. Associativity reads pass through A, and unit reads pass through U.

Finally apply Definition 488.4. Its public surface and non-escape clauses show that no host category law, quotient morphism, external equality of arrows, functorial semantics, natural transformation, or limit object remains after A and U have been read. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier law transport exhaustion`

Theorem 488.14 (KernelCategory route totality)**.** *Every accepted* $\mathsf{KernelCategory}^{\uparrow}$ *route factors through exactly the displayed rows O, H, I, C, A, U, P, N: unary* BHist *endpoints in O, continuation-ledger hom histories in H, empty* Cont *identity rows in I, displayed* Cont *composition rows in C, componentwise* hsame *law transports in A, U,* Pkg *provenance in P, and the local* NameCert *row N. No host category object, quotient morphism, external arrow equality, host composition, functorial semantic row, natural transformation, or limit object is part of the accepted route.*

Proof. Project the carrier in Definition 488.1. It exposes the finite packet O, H, I, C, A, U, P, N as the entire KernelCategory surface, so an accepted route begins with displayed BHist endpoints, continuation-ledger hom rows, provenance, and local naming.

Use Definition 488.2 and Definition 488.3. They place identity and composition reads in the empty Cont identity row and the displayed Cont composite row, rather than in a host category operation.

Finally combine Definition 488.5, Definition 488.6, Definition 488.13, Definition 488.4, and Definition 488.10. The law theorems exhaust the componentwise hsame rows, while the certificate and package rows block host objects, quotient morphisms, external arrow equality, and detached category structure outside the displayed packet. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier route totality`

Theorem 488.15 (KernelCategory law row exactness)**.** *After the identity row I and composition row C of a* $\mathsf{KernelCategory}^{\uparrow}$ *packet have been exposed, every law read is exactly one of the associativity row A or the unit row U. There is no third law row for host associativity, host unit equality, quotient morphism equality, external arrow equality, functorial semantics, natural transformations, or limits.*

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier law row exactness`

Proof. First expose identity and composition with Definition 488.2 and Definition 488.3. These theorems identify the operational rows available before any law read occurs.

Next apply Definition 488.5 and Definition 488.6. The associativity comparison is read from A, and the unit comparison is read from U.

It remains to rule out further law sources. Use Definition 488.13 and Definition 488.4. Together they say that every category-shaped law comparison has already been exhausted by A and U, and that the public surface has no coordinate for host laws, quotient equality, external arrow equality, functorial semantics, natural transformations, or limits. □

Theorem 488.16 (KernelCategory downstream NameCert readiness)**.** *Every downstream* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, or* $\mathsf{ContinuationMonad}^{\uparrow}$*-facing consumer of a* $\mathsf{KernelCategory}^{\uparrow}$ *route receives only the displayed* $\mathsf{KernelCategory}^{\uparrow}$ $\mathsf{NameCert}$ *surface* O, H, I, C, A, U, P, N*. Such a consumer may read unary* BHist *endpoints, displayed* Cont *identity and composition rows, componentwise* hsame *law transports,* Pkg *provenance, and the local name, but it cannot import external arrow equality, host object equality, quotient morphisms, host composition, functor semantics, natural transformations, or limit data.*

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier downstream namecert readiness`

Proof. Start from Definition 488.1. The downstream consumer is handed the same finite tuple O, H, I, C, A, U, P, N, not a separate host category carrier.

Use Definition 488.22 to identify this tuple as the NameCert root surface for category-shaped consumers. Then apply Definition 488.4 and Definition 488.10 to keep provenance and naming inside the displayed packet.

Finally apply Definition 488.2, Definition 488.3, Definition 488.5, Definition 488.6, and Definition 488.13. These results account for the operation and law rows read by downstream category-shaped consumers, leaving no route by which external arrow equality or host category structure can enter the NameCert surface. □

Theorem 488.17 (KernelCategory identity Cont route exhaustion)**.** *For a* $\mathsf{KernelCategory}^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$*, every identity read factors through the unary object row* O*, the empty* Cont *identity row* I*, componentwise* hsame *transport,* Pkg *provenance in* P*, and the local* $\mathsf{NameCert}$ *row* N*. The identity route has no coordinate for host identities, quotient morphisms, external arrow equality, functorial semantics, natural transformations, limits, or a second naming source outside the displayed packet.*

Proof. Project the packet from Definition 488.1. The only object data available to an identity read are the unary object histories in O, with package and naming support confined to P, N.

Apply Definition 488.2. It identifies the identity row as the empty Cont route over the displayed unary object history, not as a host identity arrow.

Use Definition 488.4 together with Definition 488.13. The componentwise hsame rows and law transports are already local to A and U, so identity transport does not create a new category-shaped equality source.

Finally use Definition 488.5 and Definition 488.6 only as law-boundary checks. They keep later law reads attached to the displayed continuation packet, while the identity route remains exhausted by O, I, P, N and the local certificate surface. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier identity cont route exhaustion`

Theorem 488.18 (KernelCategory composition Cont route exactness)**.** *For a* $\mathsf{KernelCategory}^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$*, a composable pair of displayed hom rows is accepted exactly through the* Cont *composite row* C *whose source endpoint is inherited from the first hom row and whose target endpoint is inherited from the second hom row. This exact route uses the hom ledger* H*, componentwise* hsame *law transports in* A, U*,* Pkg *provenance in* P*, and local* NameCert *naming in* N*, and it imports no external arrow equality or host composition operation.*

Proof. Start from Definition 488.1. The carrier gives only the unary endpoint row O, hom ledger H, composition row C, law transports A, U, package row P, and local naming row N for a composite read.

Apply Definition 488.3. The accepted composite is the displayed Cont row in C, and its endpoints are inherited from the two continuation-ledger hom rows rather than supplied by a host category.

Use Definition 488.5 and Definition 488.6. They place subsequent associativity and unit comparisons in componentwise hsame rows over the same displayed continuation data.

Finally apply Definition 488.4 and Definition 488.13. The certificate and transport exhaustion clauses leave no coordinate for quotient morphisms, external arrow equality, host composition, functorial semantics, natural transformations, or limits. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier composition cont route exactness`

Theorem 488.19 (KernelCategory Functor continuation handoff)**.** *Every* $\mathsf{Functor}^{\uparrow}$*-facing consumer of a* $\mathsf{KernelCategory}^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$ *receives hom transport only through the displayed rows of* K*: unary object histories in* O*, continuation-ledger hom rows in* H*, empty-continuation identities in* I*, displayed* Cont *composites in* C*, componentwise* hsame *law transports in* A, U*,* Pkg *provenance in* P*, and local naming in* N*. The handoff to chapter 62 carries no host category object, quotient morphism, or external arrow equality.*

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier functor continuation handoff`

Proof. Read the finite packet through Definition 488.1. The only hom data available to a functor-facing consumer are the hom ledger H and the displayed operation rows attached to it.

Use Definition 488.18. It fixes each composite as a displayed Cont route whose endpoints are inherited from the accepted hom rows, so functorial transport has no host composition source.

Now apply Definition 488.16. Together with the sibling surfaces of chapter 61, chapter 62, and chapter 485, it presents the same finite NameCert route as the consumer handoff. □

Theorem 488.20 (KernelCategory ContinuationMonad route coverage)**.** *The* $\mathsf{ContinuationMonad}^{\uparrow}$ *unit and bind coverage read by* $\mathsf{KernelCategory}^{\uparrow}$ *is exhausted by the identity row* I *and composition row* C *of the packet* $K = (O, H, I, C, A, U, P, N)$*. Unit coverage is the empty-continuation route over unary object histories, bind coverage is displayed* Cont *composition over hom ledgers, and neither coverage route imports a host monad, host category composition, quotient morphism, or external equality.*

Proof. Start from Definition 488.1. The carrier separates identity and composition as the packet rows I and C, with endpoints and hom inputs already present in O and H.

The exactness theorem Definition 488.18 fixes the bind-shaped route as displayed Cont composition. The same packet's identity-continuation rows supply the empty-continuation unit side used by the continuation sibling.

Finally use Definition 488.16. It routes downstream reads through the local NameCert packet and through chapter 485, leaving no off-packet monad or category law to supply coverage. □

Theorem 488.21 (KernelCategory Category surface readiness)**.** *The public* $\mathsf{Cat}^{\uparrow}$ *surface read from a* $\mathsf{KernelCategory}^{\uparrow}$ *packet is ready exactly when carrier admission, displayed identity, displayed composition, law transport,* Pkg *provenance, and local* NameCert *naming have all been read from* O, H, I, C, A, U, P, N*. The readiness route cites chapter 61 only through those finite BEDC rows and admits no host category carrier, quotient arrow class, global equality of morphisms, or detached categorical semantics.*

Proof. Begin with Definition 488.1. It supplies the object, hom, identity, composition, law, provenance, and naming coordinates of the category-shaped packet.

Use Definition 488.18 for the composition side. The exact route is already a displayed continuation composite, not a host operation.

Close the readiness claim with Definition 488.16. Its downstream handoff, read together with chapter 61, chapter 62, and chapter 485, keeps every consumer route inside the finite packet and excludes the host category surface. □

Theorem 488.22 (KernelCategory NameCert root route readiness)**.** *The local* NameCert *root surface of a* $\mathsf{KernelCategory}^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$ *is route-ready exactly through the displayed rows: unary* BHist *object histories in* O*, continuation-ledger hom histories in* H*, empty* Cont *identities in* I*, displayed* Cont *composites in* C*, componentwise* hsame *associativity and unit transports in* A, U*,* Pkg *provenance in* P*, and the local naming row* N*. This root surface is the one consumed by downstream category-shaped BEDC packets, and it contains no host category object, quotient morphism, external arrow equality, functorial semantic row, natural transformation, limit object, or detached global certificate.*

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier namecert root route readiness`

Proof. Read the packet through Definition 488.1. It presents the complete root surface as the finite tuple O, H, I, C, A, U, P, N, so downstream consumers begin from displayed BEDC rows rather than a host category carrier.

Use Definition 488.2 for identity readiness and Definition 488.3 for composition readiness. These two theorems provide the empty Cont identity route and the displayed Cont composite route needed by category-shaped consumers.

Add the law rows with Definition 488.5, Definition 488.6, and Definition 488.13. They ensure that associativity and unit reads remain componentwise hsame transports over the displayed identity and composition routes.

Finish with Definition 488.4. The certificate surface combines the local NameCert row with the Pkg provenance row, and its non-escape clauses exclude every host, quotient, external-equality, functorial, natural-transformation, limit, or global-certificate route outside the packet. □

Theorem 488.23 (KernelCategory inductive object route)**.** *Every object-facing* $\mathsf{KernelCategory}^{\uparrow}$ *consumer is generated by induction over the displayed unary object histories in* O *and the continuation-ledger hom rows in* H *of the packet* $K = (O, H, I, C, A, U, P, N)$*. The base object route is the empty-continuation identity row in* I*, and the inductive step appends a displayed hom row through the* Cont *composition row in* C*. The resulting route may use only the law transports in* A, U*, package provenance in* P*, and local naming in* N*; it never imports quotient morphisms, host category equality, or an external object classifier.*

Proof. Induct on the visible route rows read by the consumer. In the base case the route exposes only a unary object history from O. Apply Definition 488.2: the corresponding object-facing identity is exactly the empty continuation row in I, not a host identity arrow.

For the inductive step, assume the already-read route is generated from displayed unary histories and continuation-ledger hom rows. Appending one more displayed hom row is possible only through the composition coordinate C. Apply Definition 488.3 to identify this append as the displayed Cont composite whose endpoints are inherited from the input ledgers.

The law rows do not enlarge the object route. Use Definition 488.13, Definition 488.14, and Definition 488.22: associativity and unit comparisons are the rows A, U, while provenance and naming remain P, N. Thus every object-facing read is generated by the finite induction over O, H, I, C, A, U, P, N, and no quotient morphism, host category equality, or external object classifier is available. □

Theorem 488.24 (KernelCategory carrier admission obligation)**.** *For a* KernelCategory$^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$*, carrier admission is exactly the finite obligation surface consisting of unary object histories in* O*, continuation-ledger hom rows in* H*, empty-continuation identity rows in* I*, displayed* Cont *composites in* C*, componentwise* hsame *law transports in* A *and* U*, provenance in* P*, and local* NameCert *in* N*. It admits no host category object, quotient morphism, external arrow equality, functor semantics, natural transformation, limit object, or global naming row outside that tuple.*

Proof. Start with Definition 488.1. Its carrier tuple exposes the object, hom, identity, composition, law-transport, provenance, and local naming rows as the available finite packet.

Use Definition 488.2 for the identity side. It identifies identity admission with empty continuation rows over unary object histories already present in O.

Use Definition 488.3 for the hom side. It identifies composition admission with displayed Cont composites whose endpoints remain in the continuation-ledger hom rows of H.

Finally apply Definition 488.4 and Definition 488.10. The certificate and provenance rows expose the hsame law transports, package row, and local naming row, while their non-escape clauses exclude all host category and quotient coordinates outside K. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier carrier admission obligation`

Theorem 488.25 (KernelCategory continuation route factorization)**.** *For a* KernelCategory$^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$*, every admitted composition route factors through unary object histories in* O*, continuation-ledger hom rows in* H*, displayed* Cont *composites in* C*, componentwise* hsame *transports in* A *and* U*,* Pkg *provenance in* P*, and the local* NameCert *row* N*. It has no factor through host category composition, quotient morphisms, external arrow equality, functorial semantics, natural transformations, limits, or a second naming source.*

Proof. Start with Definition 488.24. It fixes O, H, I, C, A, U, P, N as the complete carrier-admission surface and leaves no composition-shaped coordinate outside that tuple.

Use Definition 488.3. Any composition read is a displayed Cont composite whose endpoints and inputs already live in the unary object and continuation-ledger hom rows.

The law part of the factorization is supplied by Definition 488.4. Associativity and unit comparisons are componentwise hsame transports over the displayed rows, not host arrow equalities.

Finally apply Definition 488.10. The Pkg and local NameCert rows record only provenance and naming for the finite BEDC packet, so every admitted route has the displayed factorization and no external category route remains. □

Theorem 488.26 (KernelCategory continuation handoff for CategoryUp)**.** *Any* Cat$^{\uparrow}$ *consumer of the* KernelCategory$^{\uparrow}$ *packet receives only the finite continuation rows already displayed in the*

category, unary continuation-monoid, and continuation-monad constructions of chapter 61, chapter 931, and chapter 485. The handoff exports object histories, hom ledgers, empty-continuation identity rows, displayed Cont *composites,* hsame *law transports,* Pkg *provenance, and local* NameCert *naming, but not host category objects, quotient morphisms, or external arrow equality.*

Proof. Begin with Definition 488.24. The consumer can read only the finite packet rows O, H, I, C, A, U, P, N.

Apply Definition 488.2. The identity rows handed to the consumer are empty-continuation rows over unary object histories, matching the unary continuation-monoid and continuation-monad sources.

Apply Definition 488.3. The composition rows handed to the consumer are displayed Cont composites of continuation-ledger hom rows, matching the category-side finite continuation surface.

Finally use Definition 488.4 and Definition 488.10. These rows package the hsame law transports, provenance, and local naming while blocking any host category object, quotient morphism, or external arrow equality from entering the $\mathsf{Cat}^{\uparrow}$ read. □

Theorem 488.27 (KernelCategory downstream consumer readiness)**.** *Downstream Functor, NatTrans, and Category consumers may cite the* $\mathsf{KernelCategory}^{\uparrow}$ *carrier, identity rows, composition rows, law-transport rows, package provenance, and non-escape rows as a complete BEDC kernel surface. Such consumers need not import host category objects, quotient morphisms, external arrow equality, functorial semantics, natural transformation objects, limit objects, adjunction data, or a global naming row beyond the local* NameCert *row.*

Proof. First read the carrier through Definition 488.1 and Definition 488.24. These fix the finite rows available to every downstream consumer.

Next use Definition 488.2 and Definition 488.3. Identity and composition are already displayed as empty-continuation rows and Cont composites, so a downstream consumer has the operation rows it needs without a host category object.

The law rows are supplied by Definition 488.4. They transport associativity and units through componentwise hsame rows, which is enough for Category, Functor, and NatTrans consumers to cite the kernel packet as their operation surface.

Finally apply Definition 488.10. The package and non-escape rows keep provenance and naming local to P, N, so the consumer has no route to quotient morphisms, external arrow equality, limits, adjunctions, or a global naming row. □

Theorem 488.28 (KernelCategory root hom-law triad)**.** *Every root consumer of a* $\mathsf{KernelCategory}^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$ *must read the hom ledger* H*, the identity row* I*, and the composition row* C *before it reads associativity or unit law rows in* A *and* U*. The law rows therefore compare already displayed continuation-ledger operations; they do not introduce host category composition, quotient morphisms, external arrow equality, functorial semantics, natural transformations, or limit objects.*

Proof. Start with Definition 488.24. It fixes O, H, I, C, A, U, P, N as the full root admission surface and places hom, identity, and composition data in the displayed packet before the law transports are consumed.

Apply Definition 488.2. Identity rows are empty-continuation reads over unary object histories, so a unit-law read has no host identity operation to import.

Apply Definition 488.3. Composition rows are displayed Cont composites between continuation-ledger hom rows, so an associativity read must already have passed through H and C.

Finally use Definition 488.4. It supplies A and U as componentwise hsame law transports over those displayed rows, while Definition 488.10 removes every host or quotient category coordinate outside the packet. □

Theorem 488.29 (KernelCategory root endpoint exhaustion)**.** *For a* $\mathsf{KernelCategory}^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$*, every displayed* Cont *composite through the object row* O*, hom ledger* H*, identity row* I*, and composition row* C *has endpoints exhausted by the unary object histories in* O *and the continuation-ledger hom rows in* H*. No endpoint can be supplied by a host category object, quotient morphism, external arrow equality, functor semantic row, natural transformation, or limit object.*

Proof. Read the composite through Definition 488.3. It builds each composite from continuation-ledger hom rows in H and a displayed Cont composition row in C.

Use Definition 488.2 for endpoint identities. The identity rows in I are empty-continuation reads over unary object histories, so their endpoints are already in O.

Apply Definition 488.9. Locality keeps the displayed composite inside the same endpoint and hom ledgers rather than moving through a host category composition operation.

Finish with Definition 488.4 and Definition 488.10. Their non-escape clauses exclude host endpoints, quotient endpoints, external arrow equality, functor semantics, natural transformations, and limits from the root endpoint surface. □

Theorem 488.30 (KernelCategory root non-escape surface)**.** *The root public surface of a* $\mathsf{KernelCategory}^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$ *is exhausted by unary object histories, continuation-ledger hom rows, empty-continuation identities, displayed* Cont *composites, componentwise* hsame *law transports,* Pkg *provenance, and the local* NameCert *row. It exports no host category object, quotient morphism, external arrow equality, functor semantics, natural transformation, limit object, or detached global category certificate.*

Proof. Begin with Definition 488.24. The theorem identifies the displayed packet rows O, H, I, C, A, U, P, N and excludes additional category-shaped coordinates from carrier admission.

Use Definition 488.4. The certificate surface supplies exactly the local naming and law-transport reads needed by the root packet.

Use Definition 488.9. Any composite that reaches the public surface remains a displayed Cont composite over local endpoint and hom rows.

Finally apply Definition 488.10. The provenance row is local to the packet and cannot be reread as host category data, quotient morphism data, functorial semantics, natural transformations, limits, or a second global naming source. □

Theorem 488.31 (KernelCategory root public readiness)**.** *For a* $\mathsf{KernelCategory}^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$*, the public root surface is ready exactly when every root read is a displayed* BHist *read of unary object histories in* O*, continuation-ledger hom rows in* H*, empty-continuation identity rows in* I*, displayed* Cont *composites in* C*, componentwise* hsame *law transports in* A *and* U*,* Pkg *provenance in* P*, and the local* NameCert *row in* N*. The surface contains no host category object, quotient morphism, external arrow equality, functorial semantics, natural transformation, limit object, or global naming source outside those rows.*

Proof. Project from Definition 488.1. The carrier exposes only the rows O, H, I, C, A, U, P, N, with object reads carried by unary BHist histories and hom reads carried by continuation ledgers.

Apply Definition 488.2 and Definition 488.3. Identity readiness is the empty Cont route over a unary history, and composition readiness is the displayed Cont composite over hom ledger rows.

Use Definition 488.5 and Definition 488.6 for the law rows. These theorems place associativity and unit comparisons in the componentwise hsame transports A and U.

Finally apply Definition 488.4, Definition 488.10, and Definition 488.24. The package and naming rows are therefore local to P, N, and every public root read is already accounted for by the displayed packet. □

Theorem 488.32 (KernelCategory downstream consumer totality)**.** *Every downstream consumer of a* KernelCategory$^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$ *is total on the displayed BEDC rows of* K *precisely by reading unary* BHist *object histories, continuation-ledger hom histories, displayed* Cont *identity and composition routes, componentwise* hsame *law transports,* Pkg *provenance, and the local* NameCert *row. No downstream consumer may demand a host category carrier, quotient morphism, external equality of arrows, natural-transformation coordinate, limit object, or second certificate before it can read the packet.*

Proof. Start with Definition 488.24. It gives the finite admission surface on which a consumer may be total: O, H, I, C, A, U, P, N and no additional category-shaped row.

Read the operation rows next. By Definition 488.2, identity consumption is total for empty continuation rows over unary object histories. By Definition 488.3, composition consumption is total for displayed Cont composites over continuation-ledger hom rows.

The law rows are then supplied by Definition 488.5, Definition 488.6, and Definition 488.13. They make the consumer read only the componentwise hsame transports A and U.

Finally use Definition 488.4 and Definition 488.10. Since Pkg provenance and the local NameCert row are the only certificate endpoints, the downstream route is total on the displayed packet and nowhere else. □

Theorem 488.33 (KernelCategory formal-target frontier)**.** *The formal target frontier for* KernelCategory$^{\uparrow}$ *is the concrete packet* $K = (O, H, I, C, A, U, P, N)$ *together with its BEDC rows:* BHist *unary object histories, continuation-ledger hom histories, displayed* Cont *identity and composition routes, componentwise* hsame *associativity and unit transports,* Pkg *provenance, and local* NameCert *naming. Formalization of the public root claim needs exactly carrier admission, identity continuation, composition continuation, law transport, provenance non-escape, and local certificate exhaustion for those rows, and it needs no host category semantics or quotient arrow equality.*

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryUp StdBridge`

Proof. The frontier begins at Definition 488.1: the only data offered to Lean-side reconstruction is the packet O, H, I, C, A, U, P, N.

Use Definition 488.24 to identify the admission clauses. This separates unary object histories, hom ledgers, identity rows, composition rows, law transports, provenance, and local naming as the proof obligations.

Then compose the existing operation and law theorems. The identity and composition clauses are Definition 488.2 and Definition 488.3; the law clauses are Definition 488.5, Definition 488.6, and Definition 488.13.

The frontier closes with Definition 488.4 and Definition 488.10. These show that Pkg provenance and the local NameCert row are the final public coordinates, while every host or quotient category object remains outside the formal target. □

Theorem 488.34 (KernelCategory root transport non-escape)**.** *For a* KernelCategory$^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$*, every endpoint and hom transport remains inside the displayed rows* O, H, I, C, A, U, P, N*. Endpoint transport reads unary object histories in* O*, hom transport reads*

continuation-ledger hom rows in H, and law transport reads only the componentwise hsame *rows in A and U together with the displayed* Cont, Pkg, *and local* NameCert *support. No host category object, quotient morphism, external arrow equality, functorial semantic row, natural transformation, or limit object is available.*

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier root transport nonescape`

Proof. Start with the carrier admission obligation, Definition 488.24. It fixes the finite packet rows O, H, I, C, A, U, P, N as the full admission surface.

Apply Definition 488.2 to endpoint identities and Definition 488.3 to hom composites. These theorems keep identity and composition reads in unary object histories, continuation-ledger hom rows, and displayed Cont composites.

Finally use Definition 488.4 and Definition 488.10. The certificate rows supply the componentwise law transports, and the provenance theorem removes host category objects, quotient morphisms, external equality, and all category-shaped structure outside the packet. □

Theorem 488.35 (KernelCategory public consumer triad)**.** *Every public consumer of a* $\mathsf{KernelCategory}^{\uparrow}$ *packet must pass through three admission gates before reading associativity or unit law rows:*

1. *carrier admission for the object, hom, identity, composition, law-transport, provenance, and local naming rows;*
2. *identity-continuation admission for empty-continuation identity rows over unary object histories;*
3. *composition-continuation admission for displayed* Cont *composites between continuation-ledger hom rows.*

Only after these three gates may the consumer read the A and U law-transport rows. The route imports no host category object, quotient morphism, external arrow equality, functorial semantics, natural transformation, limit object, or second naming source.

Proof. First use Definition 488.24. It exposes the finite carrier surface and blocks public reads outside O, H, I, C, A, U, P, N.

Next apply Definition 488.2. The identity side of a public consumer is admitted only through empty Cont rows attached to unary object histories.

Then apply Definition 488.3. The composition side is admitted only through displayed Cont composites built from continuation-ledger hom rows.

With the three gates in place, Definition 488.4 supplies the associativity and unit transports, and Definition 488.10 supplies the provenance non-escape clause. Thus the law rows are consumed only after carrier, identity, and composition admission, with no host or quotient route added. □

Theorem 488.36 (KernelCategory hom ledger exhaustion)**.** *For a* $\mathsf{KernelCategory}^{\uparrow}$ *packet $K = (O, H, I, C, A, U, P, N)$, every hom read is exhausted by unary endpoints in O, continuation-ledger hom rows in H, displayed* Cont *composites in C, componentwise* hsame *transports in A and U,* Pkg *provenance in P, and the local* NameCert *row N. A hom consumer has no extra coordinate for host morphisms, quotient morphisms, external equality of arrows, functorial semantics, natural transformations, limits, or a detached global category.*

Proof. Begin with Definition 488.24. It identifies the hom ledger as part of the same finite packet as the unary object endpoints, law transports, provenance, and local naming row.

Use Definition 488.3. Every composite hom read is a displayed Cont composite of continuation-ledger hom rows whose endpoints are already in O and H.

Use Definition 488.2 for identity hom rows. These are empty-continuation reads over unary object histories, so they add no host identity morphism.

Finally apply Definition 488.4 and Definition 488.10. The hsame, Pkg, and local NameCert rows exhaust the public certificate surface and exclude every host, quotient, functorial, limit, or detached category coordinate. □

Theorem 488.37 (KernelCategory continuation composition stability)**.** *Let $K = (O, H, I, C, A, U, P, N)$ and $K' = (O', H', I', C', A', U', P', N')$ be* $\mathsf{KernelCategory}^{\uparrow}$ *packets whose endpoints and hom rows are related by componentwise* hsame *transports. Any displayed* Cont *composite admitted by C transports to the corresponding displayed* Cont *composite admitted by C' using only the endpoint rows, hom rows, and law transports of the two packets. The stability statement has no coordinate for host category composition, quotient morphism, or external equality of arrows.*

Proof. Read composition through Definition 488.9. It says that a composition read is local to displayed Cont rows and the endpoint ledgers already present in O and H.

Apply Definition 488.3. The composite hom row is constructed from the two input continuation-ledger hom rows and the displayed Cont composite row joining them.

The componentwise hsame endpoint and hom transports move those input rows from K to K'. The associativity and unit transports in A, U, A', U' compare only displayed continuation ledgers, so the transported composite remains a displayed Cont composite rather than a host category composition.

Finally use Definition 488.4. Its non-escape clause removes quotient morphisms and external arrow equality, leaving the displayed continuation route as the entire stability witness. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier cont composition stability`

Theorem 488.38 (KernelCategory NameCert route exhaustion)**.** *Every public read of a* $\mathsf{KernelCategory}^{\uparrow}$ *packet factors through carrier admission, identity continuation, composition continuation, associativity and unit transports, package provenance, and local naming. Thus the local* NameCert *route is exhausted by the rows O, H, I, C, A, U, P, N and exports no host category universe, quotient morphism, external arrow equality, functorial semantics, natural transformation, limit object, adjunction, or second naming source.*

Proof. First apply Definition 488.24. It fixes the available carrier rows as unary object histories, continuation-ledger hom rows, identity rows, displayed composites, law transports, provenance, and local naming.

Next use Definition 488.2 and Definition 488.3. These identify the two operation routes available to a public read and keep both routes inside the displayed continuation ledger.

The law rows are supplied by Definition 488.4. They transport associativity and unit comparisons through hsame rows rather than through external equality of arrows.

Finally apply Definition 488.10. The provenance row records only the finite BEDC carrier and local NameCert route, so all host category, quotient, functorial, limit, adjunction, and second naming coordinates are outside the public read. □

Theorem 488.39 (KernelCategory scoped endpoint transport surface)**.** *Let $K = (O, H, I, C, A, U, P, N)$ be an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *packet. Every endpoint transport available to a kernel-category consumer is exhausted by the unary object histories in O, the continuation-ledger hom histories in H, the empty-continuation identity rows in I, the displayed* Cont *composition rows in C, the componentwise* hsame *associativity rows in A, and the componentwise* hsame *unit rows in U. Transport*

can therefore move object endpoints, hom endpoints, identity rows, composite rows, and law rows only by the componentwise hsame *data already listed in* K.

Proof. Start with carrier admission. By Definition 488.1 and Definition 488.24, the only endpoint-bearing rows of K are the unary object rows, continuation-ledger hom rows, identity rows, displayed composites, and law-transport rows.

Use the operation rows next. Definition 488.2 identifies identities with empty Cont rows over the transported unary histories, while Definition 488.3 and Definition 488.37 keep composite endpoints inside the displayed hom and composition ledgers.

It remains to account for law transport. Definition 488.5, Definition 488.6, and Definition 488.13 place every associativity or unit comparison in the componentwise hsame rows A and U. The non-escape surface of Definition 488.30 then removes host endpoints, quotient endpoints, and external arrow equality from the scoped endpoint surface. □

Theorem 488.40 (KernelCategory scoped package provenance surface)**.** *Let* $K = (O, H, I, C, A, U, P, N)$ *be an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *packet. The package provenance exposed by* P *is exhausted by* BHist *rows, UnaryHistory object histories, displayed* Cont *routes, componentwise* hsame *transports, the* Pkg *row, the local* NameCert *row, the concrete* $\mathsf{Cat}^{\uparrow}$ *surface, and the sibling ContinuationMonad and UnaryContMonoid surfaces used to read identity, composition, associativity, and unit routes. No provenance read may pass to a second package source or to a host category carrier outside those displayed rows.*

Proof. Project the packet through the certificate surface. Definition 488.4 and Definition 488.8 list exactly the carrier, identity, composition, law, package, and local naming obligations available to P.

Now bind the category-shaped rows to BEDC primitives. Definition 488.7, Definition 488.31, and Definition 488.32 show that downstream CategoryUp, ContinuationMonad, and UnaryContMonoid consumers read only unary histories, continuation-ledger homs, displayed Cont routes, and componentwise hsame transports.

Finally apply Definition 488.10 and Definition 488.38. The provenance and naming rows are local to P, N, so no second package source, host category carrier, quotient morphism, or detached global certificate can be appended to the scoped package surface. □

Theorem 488.41 (KernelCategory scoped non-escape surface)**.** *For an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$*, the scoped obligation surface exports no host category object, quotient morphism, external arrow equality, functor semantics, natural transformation, limit object, adjunction, or detached category certificate. All category-shaped laws are read as BEDC rows: unary object histories, continuation-ledger hom histories, empty-continuation identities, displayed* Cont *composites, componentwise* hsame *law transports,* Pkg *provenance, and local* NameCert *naming.*

Proof. First combine the operation and law rows. Definition 488.2, Definition 488.3, Definition 488.5, and Definition 488.6 account for the category-shaped identity, composition, associativity, and unit readings without leaving the displayed packet.

Next use the public route theorems. Definition 488.28, Definition 488.29, and Definition 488.32 show that every downstream consumer receives the same rows O, H, I, C, A, U, P, N and no unlisted semantic coordinate.

The remaining exclusions are exactly the provenance and readiness exclusions. Definition 488.10, Definition 488.30, and Definition 488.33 remove host category objects, quotient morphisms, ex-

ternal equality of arrows, functor semantics, natural transformations, limits, adjunctions, and detached certificates from the scoped surface. □

Theorem 488.42 (KernelCategory downstream functor route boundary)**.** *Let $K = (O, H, I, C, A, U, P, N)$ be an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *packet. Every* $\mathsf{Functor}^{\uparrow}$*-facing read of a KernelCategory route factors through the displayed rows O, H, I, C, A, U, P, N: unary object histories, continuation-ledger hom rows, empty-continuation identities, displayed* Cont *composites, componentwise* hsame *law transports, package provenance, and local naming. It cannot import host arrow equality, quotient morphisms, host composition, functor semantics, natural transformations, or limit data.*

Proof. Start with the carrier and certificate surface. The carrier Definition 488.1 fixes O, H, I, C, A, U, P, N as the packet, while Definition 488.4 exposes only the local certificate rows over that packet.

Use the operation routes. The identity theorem Definition 488.2 and composition theorem Definition 488.3 place the functor-facing source and target reads inside empty-continuation identities and displayed Cont composites.

Finally apply route totality and downstream readiness. By Definition 488.14 and Definition 488.16, the downstream functor handoff receives exactly the displayed KernelCategory NameCert route and has no host arrow equality, quotient morphism, host composition, semantic functor row, natural transformation, or limit coordinate to read. □

Theorem 488.43 (KernelCategory ContinuationMonad consumer exhaustion)**.** *For an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *packet $K = (O, H, I, C, A, U, P, N)$, every* $\mathsf{ContinuationMonad}^{\uparrow}$ *consumer exhausts its unit and bind reads through the empty* Cont *identity rows in I and the displayed* Cont *composition rows in C. The consumer may also read the endpoint, hom-ledger, law-transport, provenance, and local naming rows O, H, A, U, P, N, but it cannot add a host monad, host category composition, quotient morphism, external arrow equality, or detached continuation semantics.*

Proof. Read the finite packet first. The carrier Definition 488.1 supplies the only object, hom, operation, law, provenance, and naming rows available to a continuation consumer, and Definition 488.4 keeps the certificate local to those rows.

Apply the identity and composition routes. By Definition 488.2, unit reads are empty Cont identity rows in I. By Definition 488.3, bind-shaped reads are displayed Cont composites in C over the hom ledger H.

Close with totality and readiness. The route totality theorem Definition 488.14 and downstream readiness theorem Definition 488.16 exhaust every continuation-monad consumer on O, H, I, C, A, U, P, N, excluding host monads, host composition, quotient morphisms, external equality, and detached continuation semantics. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier continuation monad consumer exhaustion`

Theorem 488.44 (KernelCategory CategoryUp public export lock)**.** *For an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *packet $K = (O, H, I, C, A, U, P, N)$, the public export to* $\mathsf{Cat}^{\uparrow}$ *is exactly the carrier, identity, composition, law transport, package, and local* NameCert *rows displayed by K. No public export adds a host category carrier, quotient arrow class, global equality of morphisms, functor semantic row, natural transformation, limit object, or detached public certificate.*

Proof. Begin with carrier and certificate. The carrier Definition 488.1 lists the finite export rows, and Definition 488.4 makes package provenance and local naming part of the same public surface.

Attach identity, composition, and law transport. The identity theorem Definition 488.2 supplies the empty-continuation identity rows, while Definition 488.3 supplies displayed composition rows.

The law transport rows are the same componentwise hsame rows accounted for by the certificate surface.

Finally apply route totality and downstream readiness. Theorems Definition 488.14 and Definition 488.16 show that every public $\mathsf{Cat}^{\uparrow}$ export is already exhausted by O, H, I, C, A, U, P, N, leaving no host category carrier, quotient arrow class, global morphism equality, semantic functor row, natural transformation, limit object, or detached public certificate. □

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier category public export lock`

Theorem 488.45 (KernelCategory root continuation dependency)**.** *For an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *route* $K = (O, H, I, C, A, U, P, N)$*, every* $\mathsf{Cat}^{\uparrow}$ *hom read must first expose the UnaryHistory endpoint row* O*, the displayed* Cont *identity rows* I*, the displayed* Cont *composition rows* C*, and the* $\mathsf{ContinuationMonad}^{\uparrow}$ *source rows used by those identity and composition reads. No hom read may enter through a host category carrier, quotient morphism, or external arrow equality.*

Proof. Begin with the finite carrier. The carrier definition and Definition 488.8 require carrier admission, identity-continuation admission, and composition-continuation admission before any category-shaped consumer can read the packet.

The identity and composition obligations then expose the continuation surface. By Definition 488.2 and Definition 488.3, identities are empty Cont rows over unary endpoints and composites are displayed Cont rows over the hom ledger.

Finally use Definition 488.14. Its finite route lists exactly O, H, I, C, A, U, P, N, so the CategoryUp hom read has no host category, quotient, or external arrow-equality coordinate to consult before the continuation rows are visible. □

Theorem 488.46 (KernelCategory root law dependency)**.** *For an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *route* $K = (O, H, I, C, A, U, P, N)$*, every associativity or unit read is exhausted by the displayed componentwise* hsame *transport rows* A *and* U *after the identity and composition rows have been read. Host associativity, host unit equality, quotient morphism equality, and external arrow equality are not law sources for* K*.*

Proof. First read the operation rows. Definition 488.45 places endpoints, identity rows, composition rows, and the ContinuationMonad source surface before any law read.

Now apply the local law results. Definition 488.5, Definition 488.6, and Definition 488.13 identify the available associativity and unit comparisons with the componentwise hsame rows A and U.

The non-escape boundary closes the claim. By Definition 488.41, no host category law, quotient equality, or external arrow equality can be added to those displayed transport rows. □

Theorem 488.47 (KernelCategory root downstream unblock)**.** *Every* $\mathsf{Cat}^{\uparrow}$*,* $\mathsf{Functor}^{\uparrow}$*, and* $\mathsf{ContinuationMonad}^{\uparrow}$ *consumer of an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *route receives exactly the finite NameCert route* O, H, I, C, A, U, P, N*. The route is unblocked by the root obligation triad, the continuation dependency, the law dependency, route totality, and downstream readiness, and it has no detached consumer-specific carrier.*

Proof. Start with the root certificate obligations. Definition 488.8, Definition 488.45, and Definition 488.46 expose the carrier, continuation operation rows, and law-transport rows needed by all three consumers.

Next use the total route statement. Definition 488.14 exhausts every accepted route on the finite rows O, H, I, C, A, U, P, N.

Finally apply downstream readiness. Definition 488.16, Definition 488.42, and Definition 488.43 give the CategoryUp, FunctorUp, and ContinuationMonadUp handoffs from the same finite NameCert route, without a detached carrier for any one consumer. □

Theorem 488.48 (KernelCategory object-hom-law separation)**.** *For an accepted* $\mathsf{KernelCategory}^{\uparrow}$ *packet* $K = (O, H, I, C, A, U, P, N)$*, object rows, hom rows, and law rows are consumed through distinct finite coordinates:* O *for unary object endpoints,* H, I, C *for hom, identity, and composition continuation rows, and* A, U *for associativity and unit transport. No accepted consumer may collapse these coordinates into quotient morphisms, host arrow equality, or a single ambient category law.*

Lean4 ✓ `BEDC.Derived.KernelCategoryUp.KernelCategoryCarrier object hom law separation`

Proof. Project the carrier of Definition 488.1. It displays the object endpoint row O, the hom ledger H, the identity and composition continuation rows I, C, and the law transport rows A, U as separate coordinates.

Apply the root dependency theorems. The continuation dependency Definition 488.45 makes hom reads pass through O, H, I, C, while the law dependency Definition 488.46 makes associativity and unit reads pass through A, U after the operation rows are visible.

Finally use Definition 488.47. The downstream route exports the same finite packet O, H, I, C, A, U, P, N to category-shaped consumers, so quotient morphisms, host arrow equality, and ambient category laws have no coordinate through which to identify objects, homs, and laws. □

Closure status for $\mathsf{NameCert}_{\mathsf{KernelCategory}^{\uparrow}}$**.**

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{KernelCategory}^{\uparrow}}$, maturePackageClosed)

Constructive story: A $\mathsf{KernelCategory}^{\uparrow}$ packet is generated from the finite carrier rows O, H, I, C, A, U, P, N: unary object histories, continuation-ledger hom histories, empty-continuation identities, displayed Cont composites, componentwise hsame associativity and unit transports, package provenance, and local NameCert naming.

Scope closed: The closed scope is the finite KernelCategory carrier with identity, composition, law transport, package provenance, CategoryUp, FunctorUp, ContinuationMonadUp, and UnaryContMonoid rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{KernelCategory}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.KernelCategoryUp.KernelCategoryCertificateSurface`

Bridge status: bridgeChecked

Not claimed: The chapter does not close host category objects, quotient morphisms, external arrow equality, functor semantics, natural transformations, limits, adjunctions, or detached category certificates.

Upgrade path: No further upgrade is recorded on the formal axis; the chapter is bridge checked.

Chapter 489

A Concrete Naming Certificate for $\mathsf{ClassifierTyping}^{\uparrow}$

The $\mathsf{ClassifierTyping}^{\uparrow}$ surface realizes classifier membership as a finite typing packet. It records the visible term row, the Ext membership row, the Cont reduction row, the SigRel typing answer, and a local NameCert ledger, so a typing consumer reads only the rows displayed by the certificate.

$\mathsf{ClassifierTyping}^{\uparrow}$ is the visible classifier row consumed by chapter 476 and chapter 598. The dependency is the finite Ext/Cont/SigRel answer route, not a host type checker or hidden derivation object.

Definition 489.1 (ClassifierTyping carrier)**.** *A* $\mathsf{ClassifierTyping}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$X = (T, E, R, S, H, C, P, N)$$

with the following displayed coordinates:

1. *T is the term row whose finite syntax window is being checked;*
2. *E is the* Ext *membership row witnessing admission of T by the local classifier;*
3. *R is the* Cont *reduction row whose source and target term windows are visible in the packet;*
4. *S is the* SigRel *typing-answer row pairing the displayed classifier question with its accepted answer ledger;*
5. *H stores the componentwise* hsame *transports for the term, membership, reduction, signature-answer, package, and local ledger rows;*
6. *C stores the displayed* Cont *routes for reading membership, reduction, subject reduction, and signature-answer data;*
7. *P is the* Pkg *provenance over* BHist, Ext, Cont, SigRel, hsame, Pkg, *and* NameCert*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ClassifierTyping}^{\uparrow}}$ *ledger.*

The carrier contains no host typing semantics, no erased derivation object, no semantic equality of terms, no normalization oracle, and no classifier beyond the displayed Ext, Cont, SigRel, hsame, Pkg, *and* NameCert *rows.*

Definition 489.2 (ClassifierTyping classifier)**.** *For accepted* $\mathsf{ClassifierTyping}^{\uparrow}$ *carriers* $X = (T, E, R, S, H, C, P, N)$ *and* $X' = (T', E', R', S', H', C', P', N')$*, the classifier compares exactly the visible* Ext *membership rows, the* SigRel *typing-answer rows, and the* Cont *reduction rows under the componentwise* hsame

transports recorded in H and H'. The term rows, package rows, and local ledgers may be inspected only as the coordinates that name those visible comparisons.

Thus two accepted packets classify together precisely when the exposed membership answer, typing signature answer, and reduction route remain the same readable BEDC data under hsame*. No host typing derivation, semantic conversion relation, erased representative, or ambient normalization proof participates in the classifier.*

Theorem 489.3 (ClassifierTyping NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ClassifierTyping}^{\uparrow}}$ *surface for Definition 489.1 consists of five obligations:*

1. *carrier inhabitance by a finite packet $X = (T, E, R, S, H, C, P, N)$;*
2. *classifier equivalence for the visible* Ext*,* SigRel*, and* Cont *rows under componentwise* hsame *transport;*
3. *membership stability, saying that a transported accepted term row preserves the displayed* Ext *membership answer;*
4. *subject-reduction-as-*Cont *stability, saying that a visible typed reduction route reads its target membership through R, C, and the same local ledger;*
5. *signature-gap readback, saying that any readable typing answer factors through the* SigRel *row S and the local* $\mathsf{NameCert}_{\mathsf{ClassifierTyping}^{\uparrow}}$ *ledger.*

Lean4 ✓ `BEDC.Derived.ClassifierTypingUp.ClassifierTypingCarrier namecert obligations`

Proof. Carrier inhabitance is projection from Definition 489.1. The packet displays the term, membership, reduction, signature-answer, transport, continuation, package, and ledger rows needed by the local certificate.

Classifier equivalence is the comparison of Definition 489.2. Since the comparison may inspect only E, S, and R through H and C, stability of membership and reduction is a statement about visible rows rather than a host typing semantics.

For subject reduction, use the reduction coordinate R as the continuation route from the source window to the target window. The target membership read is licensed by the same Ext row and local ledger after transport, so it remains inside the packet.

For signature-gap readback, project the SigRel row S. A consumer that asks for the typing answer receives the answer ledger named by S and authenticated by N, with P recording the dependency package. No hidden conversion or normalization datum is available. □

Theorem 489.4 (ClassifierTyping membership stability)**.** *Let $X = (T, E, R, S, H, C, P, N)$ and $X' = (T', E', R', S', H', C', P', N')$ be accepted* $\mathsf{ClassifierTyping}^{\uparrow}$ *carriers that classify together. Every public membership read of X' is obtained by transporting the displayed* Ext *membership row of X through the recorded* hsame *comparison and the* Cont *routes in C and C'. The read cannot introduce a new classifier, a host typing derivation, or a semantic conversion rule.*

Lean4 ✓ `BEDC.Derived.ClassifierTypingUp.ClassifierTypingCarrier membership stability`

Proof. Start with the classifier comparison. By Definition 489.2, a classification of X with X' includes the visible comparison of E with E' and does not expose any other membership source.

Transport the membership row along the displayed hsame coordinate. The continuation routes in C and C' license the consumer reads of the source and target packets, so the transported row is still a finite Ext membership answer.

The carrier inventory excludes any host typing derivation or conversion rule. Hence every membership read of X' factors through E, E', H, H', C, and C', and no external classifier can enter the surface. □

Theorem 489.5 (ClassifierTyping signature-gap readback)**.** *Every readable typing answer in an accepted* $\mathsf{ClassifierTyping}^{\uparrow}$ *carrier factors through the displayed* SigRel *row S, the visible* Ext *membership row E, the reduction route R, and the local* $\mathsf{NameCert}_{\mathsf{ClassifierTyping}^{\uparrow}}$ *ledger N. A consumer therefore receives a finite signature-gap answer packet, not a host type checker, not an erased derivation, and not an unrecorded normalization theorem.*

Lean4 ✓ `BEDC.Derived.ClassifierTypingUp.ClassifierTypingCarrier signature gap readback`

Proof. Project the accepted carrier. The typing-answer coordinate is S, and the rows that can justify its use are the membership row E, the reduction row R, and the local ledger N.

Readback follows the displayed continuation routes in C. These routes determine how a consumer reaches E, R, and S, while H records the permitted transports and P records the dependency package.

Since the packet has no coordinate for host type checking, erased derivations, or normalization, the consumer can read only the finite signature-gap packet named by S and authenticated by N. □

Theorem 489.6 (ClassifierTyping subject-reduction Cont stability)**.** *Let $X = (T, E, R, S, H, C, P, N)$ be an accepted* $\mathsf{ClassifierTyping}^{\uparrow}$ *carrier. Every subject-reduction read of X is a* Cont*-stable read: the source membership is read through the visible* Ext *row E, the reduction step is read through R, the typing answer is read through* SigRel *row S, and the target membership is reached only by replaying the displayed* hsame*,* Pkg*, and* $\mathsf{NameCert}_{\mathsf{ClassifierTyping}^{\uparrow}}$ *rows H, P, N along the continuation routes in C.*

Lean4 ✓ `BEDC.Derived.ClassifierTypingUp.ClassifierTypingCarrier subject reduction cont stability`

Proof. Start with the carrier inventory of Definition 489.1. The packet displays the term row T, the membership row E, the reduction row R, the signature-answer row S, the transport row H, the route row C, the package row P, and the local naming row N.

Apply Definition 489.2. A reduction-preservation read can compare only the exposed Ext, Cont, and SigRel rows under the recorded hsame transports, so the source membership and typing answer cannot be replaced by a host derivation.

Use Definition 489.4 for the membership side. It routes transported membership through E, H, C and excludes a fresh classifier or semantic conversion rule.

Use Definition 489.5 for the answer side. It forces the typing answer through S, E, R, N, with P recording the finite provenance. Hence the subject-reduction read is exactly the displayed Cont route from source data to target membership inside X. □

Theorem 489.7 (ClassifierTyping visible-answer determinacy)**.** *Let $X = (T, E, R, S, H, C, P, N)$ and $X' = (T', E', R', S', H', C', P', N')$ be accepted* $\mathsf{ClassifierTyping}^{\uparrow}$ *carriers that classify together. If a public consumer reads a typing answer from both packets, then the two answers are the same displayed* SigRel *answer under the recorded* hsame *transports and* Cont *routes. No second visible answer can be produced from* Ext*,* Cont*,* SigRel*,* hsame*,* Pkg*, or* NameCert *rows outside the displayed packets.*

Lean4 ✓ `BEDC.Derived.ClassifierTypingUp.ClassifierTypingCarrier visible answer determinacy`

Proof. Begin with the classifier of Definition 489.2. Classification of X with X' compares the visible membership rows, signature-answer rows, and reduction rows, and the comparison is mediated only by H, H', C, C'.

Apply Definition 489.5 to each packet. Each readable answer factors through S or S' together with the corresponding membership row, reduction route, and local ledger.

Apply Definition 489.4. The membership rows used by the answer reads are transported by the same displayed hsame and Cont data that the classifier already exposes.

The package and naming rows P, N, P', N' record the provenance of those finite reads. Since neither carrier contains a host type checker, erased derivation, semantic conversion rule, or normalization theorem, the paired reads determine one visible SigRel answer and leave no route for a second answer. □

Theorem 489.8 (ClassifierTyping reduction-route ledger exhaustion)**.** *For every accepted* $\mathsf{ClassifierTyping}^{\uparrow}$ *carrier* $X = (T, E, R, S, H, C, P, N)$*, every reduction-preservation route exported by the packet is exhausted by the displayed rows* T, E, R, S, H, C, P, N*. In particular, a consumer that asks for subject reduction receives the visible* Ext *membership row,* Cont *reduction row,* SigRel *answer row, componentwise* hsame *transports,* Pkg *provenance, and* $\mathsf{NameCert}_{\mathsf{ClassifierTyping}^{\uparrow}}$ *ledger, and receives no hidden typing derivation, semantic conversion, erased representative, or normalization oracle.*

Lean4 ✓ `BEDC.Derived.ClassifierTypingUp.ClassifierTypingCarrier reduction route ledger exhaustion`

Proof. Project the carrier from Definition 489.1. Its reduction-facing coordinates are precisely the term, membership, reduction, signature-answer, transport, route, package, and local ledger rows.

Use Definition 489.6. Subject-reduction reads are replayed through the visible Cont route, with source membership from E, reduction from R, and target membership authenticated by H, P, N.

Use Definition 489.7. Any answer read along that route is the displayed SigRel answer named by S, so the reduction route cannot branch to an extra answer source.

The exclusion clauses of the carrier and classifier rule out host typing semantics, erased derivations, semantic conversion, and normalization. Therefore the reduction-route ledger is exhausted by T, E, R, S, H, C, P, N. □

Theorem 489.9 (ClassifierTyping kernel scope binding)**.** *Every public* $\mathsf{ClassifierTyping}^{\uparrow}$ *typing read is scoped by the concrete rows*

$$T, E, R, S, H, C, P, N$$

and by the kernel primitives Ext*,* Cont*,* SigRel*,* hsame*,* Pkg*, and* NameCert*. The read may inspect the term row, membership row, reduction row, signature-answer row, componentwise transport, continuation routes, package provenance, and local naming ledger. It has no coordinate for a host type checker, erased derivation, normalization oracle, or semantic conversion relation.*

Proof. Project the carrier of Definition 489.1. The displayed packet lists exactly the rows T, E, R, S, H, C, P, N, with E naming the Ext membership row, R and C naming the Cont reduction and read routes, and S naming the SigRel answer row.

Apply Definition 489.2. Public comparison is restricted to the visible Ext, SigRel, and Cont rows under the recorded hsame transports, with Pkg and NameCert providing provenance and local naming.

The excluded objects are not packet coordinates. Therefore every public typing read is bound to the displayed kernel rows and cannot appeal to a host type checker, erased derivation, normalization oracle, or semantic conversion relation. □

Lean4 ✓ `BEDC.Derived.ClassifierTypingUp.ClassifierTypingCarrier kernel scope binding`

Theorem 489.10 (ClassifierTyping Ext-Cont-SigRel scope exhaustion)**.** *The membership stability of Definition 489.4, subject-reduction* Cont *stability of Definition 489.6, signature-gap readback of Definition 489.5, visible-answer determinacy of Definition 489.7, and reduction-route ledger exhaustion of Definition 489.8 together exhaust the scoped kernel surface for* $\mathsf{ClassifierTyping}^{\uparrow}$ *over* Ext*,* Cont*,* SigRel*,* hsame*,* Pkg*, and* NameCert*.*

Proof. Start with Definition 489.9. It confines every public typing read to T, E, R, S, H, C, P, N and to the named kernel primitives.

Membership stability accounts for all reads of the Ext row. Subject-reduction Cont stability accounts for reduction-preservation reads, while signature-gap readback accounts for the SigRel answer row.

Visible-answer determinacy prevents a second public answer route, and reduction-route ledger exhaustion prevents an extra preservation route. The five cited results therefore cover the whole scoped surface and leave no host type checker, erased derivation, normalization oracle, or semantic conversion relation to inspect. □

Closure status for $\mathsf{NameCert}_{\mathsf{ClassifierTyping}^{\uparrow}}$.

Constructive story: A $\mathsf{ClassifierTyping}^{\uparrow}$ packet is generated from a visible term row, an Ext membership row, a Cont reduction row, a SigRel typing-answer row, componentwise hsame transports, displayed Cont read routes, Pkg provenance, and a local NameCert ledger.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ClassifierTyping}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 489.1, Definition 489.2, Definition 489.3, Definition 489.4, Definition 489.5, Definition 489.6, Definition 489.7, Definition 489.8, Definition 489.9, and Definition 489.10 bind the carrier, classifier, NameCert obligations, membership stability, signature-gap readback, subject-reduction Cont stability, visible-answer determinacy, reduction-route ledger exhaustion, kernel scope binding, Ext-Cont-SigRel scope exhaustion, and bridge surface from the finite Ext/Cont/SigRel typing packet to the standard acceptance schema.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ClassifierTyping}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ClassifierTypingUp.ClassifierTypingCarrier\_namecert\_obligations`

Bridge status: none

Origin: human

Not claimed: This chapter does not close host type checking, erased derivations, semantic conversion rules, Lean verification, or bridge checking.

Upgrade path: No further paper theory-axis step is recorded; formal bridge checking remains separate.

Chapter 490

A Concrete Naming Certificate for $\mathsf{HaltingObstruction}^{\uparrow}$

The $\mathsf{HaltingObstruction}^{\uparrow}$ surface realizes the halting fixed-point pressure of chapter 9368 as a finite naming certificate. It records only positive finite traces, self-reference rows, diagonal policy rows, and certificate provenance. It is not a global halting classifier and it carries no decision procedure for arbitrary continuation chains.

The $\mathsf{HaltingObstruction}^{\uparrow}$ packet supplies the finite obstruction ledger consumed by chapter 491 and the local fixed-point packet of chapter 496. This dependency is limited to finite trace, self-reference, diagonal-policy, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Definition 490.1 (Halting obstruction carrier)**.** *A* $\mathsf{HaltingObstruction}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (S, I, T, R, D, H, C, P, N)$$

with the following displayed coordinates:

1. *S is the certificate row naming the local program-or-certificate surface whose continuation behavior is being inspected;*
2. *I is the input-history row naming the starting history and its finite observation window;*
3. *T is the finite* Cont *trace row recording the positive continuation steps actually witnessed from I;*
4. *R is the self-reference row that identifies the history being fed back into the same certificate surface;*
5. *D is the diagonal policy row recording the local non-escape ledger attached to that self-application;*
6. *H stores the componentwise* hsame *transports for the certificate, input history, finite trace, self-reference row, diagonal policy row, package row, and local naming row;*
7. *C stores the displayed* Cont *routes by which a consumer reaches the trace, self-reference, and diagonal rows;*
8. *P is the* Pkg *provenance over* BHist, Cont, hsame, Pkg, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{HaltingObstruction}^{\uparrow}}$ *row.*

The carrier has no coordinate for deciding whether an arbitrary chain halts, no total classifier over all certificates and histories, and no host-level oracle for divergence.

Theorem 490.2 (Halting obstruction NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{HaltingObstruction}^{\uparrow}}$ *surface for Definition 490.1 consists of five obligations:*

1. *carrier habitation by the finite packet* $O = (S, I, T, R, D, H, C, P, N)$*;*
2. *trace exactness, saying that every positive continuation fact exported by the packet is one of the finite* Cont *steps recorded in* T*;*
3. *self-reference readability, saying that the feedback row* R *is reached only through the displayed input-history and certificate rows* I *and* S*;*
4. *diagonal policy locality, saying that each obstruction claim is the ledger entry named by* D *after the displayed self-application route;*
5. *package and name closure, saying that all public reads pass through the stored* hsame*,* Cont*,* Pkg*, and local* NameCert *rows.*

Thus the packet certifies a finite obstruction ledger for a displayed self-reference route, not a halting decision for every certificate-history pair.

Lean4 ✓ `BEDC.Derived.HaltingObstructionUp.HaltingObstructionNamecertObligations`

Proof. Project the carrier of Definition 490.1. The rows S, I, and T give the only continuation facts that can be read: each exported step is one displayed finite Cont transition in the trace row.

Next read the self-reference coordinate R. It is not a classifier over all histories; it is a recorded feedback row tied to the same certificate and input-history surface by the transports in H and the routes in C.

The diagonal row D is then local to that feedback route. A consumer can read its obstruction ledger only after following the displayed Cont routes through T and R.

Finally, repack the visible rows with P and N. Since no carrier coordinate names a total halting predicate or a divergence oracle, the NameCert obligations expose only the finite trace and diagonal ledger listed above. □

Lean4 ✓ `BEDC.Derived.HaltingObstructionUp.HaltingObstructionCarrier namecert obligations`

Theorem 490.3 (Halting obstruction diagonal non-escape)**.** *Let* $O = (S, I, T, R, D, H, C, P, N)$ *be an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *carrier. Every public attempt to turn the displayed self-reference route into a halting decision must factor through the finite trace row* T*, the self-reference row* R*, the diagonal policy row* D*, and the recorded* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *provenance. The exported surface therefore cannot escape into a global halting classifier, an unbounded search over continuation histories, a host divergence oracle, or quotient equality of certificate names.*

Proof. Start with the NameCert obligations of Definition 490.2. Trace exactness forces every positive continuation read to be one of the finite steps recorded in T.

Self-reference readability then routes the feedback claim through R together with the input-history and certificate rows. The consumer receives a displayed self-application route, not an external enumeration of all possible histories.

Apply diagonal policy locality. The obstruction ledger is exactly the row D attached to that route, transported only by H and read only through the continuations in C.

The exclusions follow by carrier inspection. Since O contains no total halting predicate, no unbounded search coordinate, no host divergence oracle, and no quotient equality of names, none of those objects can be exported from the public surface. □

Theorem 490.4 (Halting obstruction distinction boundary)**.** *Every accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *diagonal read consumes the HaltingDistinction certificate-history pair, finite trace, and diagonal self-reference boundary of chapter 491 before it can expose the obstruction ledger* D*. The obstruction surface is therefore a downstream finite ledger over* $S, I, T, R, D, H, C, P, N$*, not a global halting classifier and not a duplicate distinction principle.*

Proof. Project the obstruction carrier of Definition 490.1. Its diagonal read is available only after the certificate row S, input-history row I, finite trace row T, self-reference row R, and diagonal policy row D have been displayed.

Apply the local NameCert obligations of Definition 490.2. Trace exactness, self-reference readability, diagonal policy locality, and package closure force any public obstruction read through the finite rows T, R, D, H, C, P, N.

Now read the sibling boundary chapter 491. The certificate-history pair, finite trace, and diagonal self-reference packet supplied there are the distinction data consumed before the obstruction ledger is exposed.

Finally use diagonal non-escape from Definition 490.3. Since the obstruction packet has no total halting predicate, unbounded search, host divergence oracle, or quotient equality of certificate names, it remains a downstream finite ledger rather than a global classifier. □

Theorem 490.5 (Halting obstruction trace coverage)**.** *For an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, every positive continuation fact exported by the packet is a displayed member of the finite trace row* T*. Such a fact is read through* BHist*,* Cont*,* hsame*,* Pkg*, and the local* NameCert *rows, and it is not supplied by an unbounded search over histories.*

Lean4 ✓ `BEDC.Derived.HaltingObstructionUp.HaltingObstructionTraceCoverage`

Proof. Project the carrier of Definition 490.1. The only row that records positive continuation facts is the finite trace row T.

Apply trace exactness from Definition 490.2. Any exported continuation fact must be one of the displayed Cont steps stored in T, transported by H and reached by the route row C.

The package and local naming rows P, N only repack that same finite evidence. Since the carrier has no coordinate for an unbounded continuation search, the public trace surface is exactly the displayed membership surface of T. □

Theorem 490.6 (Halting obstruction self-reference route determinacy)**.** *For an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, the self-reference row* R *is readable only through the certificate row* S*, input-history row* I*, finite trace row* T*, componentwise transports* H*, and displayed continuations* C*. The rows* P *and* N *certify that route, and no second route can read* R *without passing through those displayed coordinates.*

Lean4 ✓ `BEDC.Derived.HaltingObstructionUp.HaltingObstructionSelfReferenceRouteDeterminacy`

Proof. Start with the self-reference coordinate in Definition 490.1. It is a row of the same finite packet, not a free-standing self-application operator.

Use self-reference readability from Definition 490.2. A read of R must first name the certificate surface S and input-history row I, and it must consume the finite trace row T along the displayed routes.

The transports H and continuations C determine the only admissible path to the row. The package provenance P and local NameCert row N certify that path rather than adding an alternate route. □

Theorem 490.7 (Halting obstruction diagonal policy ledger exactness)**.** *For an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, the row* D *is the unique diagonal policy ledger row exported by the packet. It records the local obstruction attached to the displayed self-reference route and cannot supply a total halting classifier for arbitrary certificate-history pairs.*

Proof. Inspect the carrier in Definition 490.1. Among its coordinates, only D is a diagonal policy row; the remaining rows name the certificate, input history, finite trace, self-reference route, transports, continuations, provenance, and local naming surface.

Apply diagonal policy locality from Definition 490.2. A public diagonal read reaches D only after following the displayed self-reference route through S, I, T, R, H, C, P, N.

Finally use Definition 490.3. Since the packet has no coordinate for a total halting predicate, unbounded search, host divergence oracle, or quotient equality of names, the diagonal ledger remains local and cannot become a classifier for arbitrary inputs. □

Theorem 490.8 (Halting obstruction positive trace ledger)**.** *For an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, every positive continuation fact exported by the public obstruction surface is one of the finite rows displayed in* T*. The exported fact is reached through the carrier, transport, route, package, and local naming coordinates of* O*, and it cannot be replaced by an unbounded search over continuation histories.*

Proof. Begin with the carrier of Definition 490.1. It names T as the finite Cont trace row and gives no separate coordinate for a search procedure over all histories.

Apply the trace exactness obligation in Definition 490.2. Any positive continuation fact exposed by the packet must already be one of the displayed finite Cont steps in T.

The non-escape statement of Definition 490.3 rules out reading this trace as a global halting classifier or as an unbounded continuation oracle. The distinction boundary of Definition 490.4 then identifies the downstream object as the same finite obstruction ledger. □

Theorem 490.9 (Halting obstruction finite route non-escape)**.** *For an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, every public diagonal read factors only through the displayed rows* $S, I, T, R, D, H, C, P, N$*. In particular, no consumer can obtain a diagonal obstruction read by bypassing the finite trace, self-reference, policy, transport, route, package, and local naming rows of* O*.*

Proof. Inspect the coordinates in Definition 490.1. The public packet lists exactly the certificate row, input-history row, trace row, self-reference row, diagonal policy row, transports, continuation routes, package provenance, and local NameCert row.

Use package and name closure from Definition 490.2. Public reads must pass through the stored hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, while self-reference readability and diagonal policy locality force the route through R and D.

Apply Definition 490.3. Since the carrier contains no global classifier, unbounded search coordinate, host oracle, or quotient equality of names, the only public diagonal route is the finite route through $S, I, T, R, D, H, C, P, N$. □

Theorem 490.10 (Halting obstruction public read boundary)**.** *Every downstream HaltingDistinction or HaltingDiagonal consumer of an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet receives the finite obstruction ledger displayed by* $S, I, T, R, D, H, C, P, N$*. The consumer receives trace exactness, self-reference readability, diagonal policy locality, and package/name closure for that ledger, not a global classifier for arbitrary certificate-history pairs.*

Proof. Project the accepted carrier from Definition 490.1. Its public payload is the finite obstruction packet $S, I, T, R, D, H, C, P, N$.

Apply the five NameCert obligations of Definition 490.2. They provide the carrier row, the exact finite positive trace, the readable self-reference route, the local diagonal policy ledger, and the package/name closure surface.

Now use Definition 490.4. Downstream HaltingDistinction and HaltingDiagonal uses consume the finite ledger after the displayed certificate-history and self-reference boundary have been read, so the public object is not a global halting classifier. □

Theorem 490.11 (Halting obstruction finite counterread refusal)**.** *Let $O = (S, I, T, R, D, H, C, P, N)$ be an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet. Any read that presents the finite trace row T together with the diagonal policy row D as a total classifier for arbitrary continuation chains is refused by the carrier: the public packet exposes only $S, I, T, R, D, H, C, P, N$, and no global halting classifier, divergence oracle, unbounded search surface, host oracle, or quotient equality of names.*

Proof. Use trace coverage from Definition 490.5. The row T covers exactly the displayed finite positive trace facts admitted by the packet, not all possible continuation chains.

Next apply diagonal policy ledger exactness from Definition 490.7. The row D records the local diagonal policy attached to the same certificate-history and self-reference route, so it does not decide arbitrary continuations outside that route.

Finally use the public read boundary of Definition 490.10. A downstream read receives the finite obstruction ledger $S, I, T, R, D, H, C, P, N$ rather than a global classifier. Therefore a counterread that treats T and D as a total halting decision procedure is not a public read of the accepted packet. □

Theorem 490.12 (Halting obstruction local NameCert repackaging)**.** *For an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet $O = (S, I, T, R, D, H, C, P, N)$, the package row P and local naming row N repackage only the carrier exposure, trace exactness, self-reference readability, diagonal policy locality, and package/name closure already displayed by the packet. They add no new classifier, search surface, host oracle, quotient equality, or alternate diagonal route.*

Proof. Read P and N against the carrier in Definition 490.1. They are package provenance and local NameCert rows for the same finite obstruction packet, not independent computational operators.

Apply Definition 490.2. The content available for repackaging is exactly carrier habitation, trace exactness, self-reference readability, diagonal policy locality, and package/name closure.

Finally combine Definition 490.3 with Definition 490.4. The repackaged public surface remains the same finite obstruction ledger and therefore cannot expose a global classifier, unbounded search, host oracle, quotient equality, or second diagonal route. □

Theorem 490.13 (Halting obstruction distinction trace handoff)**.** *For an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet $O = (S, I, T, R, D, H, C, P, N)$, every handoff to* $\mathsf{HaltingDistinction}^{\uparrow}$ *carries only the finite distinction-trace rows displayed by T together with the self-reference, transport, route, package, and local naming rows R, H, C, P, N. The handoff exposes no global halting classifier, no unbounded continuation search, and no off-packet equality of names.*

Proof. Project the accepted carrier of Definition 490.1. The only trace coordinate available to the packet is the finite row T, and its movement is recorded through H and C.

Apply Definition 490.2. The local $\mathsf{NameCert}_{\mathsf{HaltingObstruction}^{\uparrow}}$ row certifies carrier admission, trace exactness, self-reference readability, diagonal policy locality, and package/name closure for the same tuple $S, I, T, R, D, H, C, P, N$.

Use Definition 490.4 and Definition 490.10. The distinction consumer reads the displayed finite obstruction ledger, while the public boundary excludes a total classifier, host oracle, unbounded search, quotient equality, or alternate diagonal route.

Finally apply Definition 490.12. The package and local naming rows repackage the same trace and distinction rows, so the downstream handoff is exhausted by T, R, H, C, P, N inside the accepted packet. □

Theorem 490.14 (Halting obstruction diagonal policy refusal)**.** *For an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, any diagonal-policy read that bypasses one of the displayed rows* T, R, D, H, C, P, N *is refused by the public packet. The diagonal policy row* D *is readable only as the local obstruction ledger for the displayed trace and self-reference route.*

Proof. Start from the carrier in Definition 490.1. The row D is stored beside the finite trace row T, self-reference row R, transport row H, displayed route row C, provenance row P, and local naming row N.

Apply Definition 490.2. The local naming surface binds D to trace exactness, self-reference readability, diagonal policy locality, and package/name closure for the same tuple.

Use Definition 490.3 and Definition 490.10. A public diagonal read cannot be replaced by a global classifier, host divergence oracle, quotient equality, unbounded search, or a second route outside T, R, D, H, C, P, N.

Finally invoke Definition 490.12. Since P and N add no alternate classifier or diagonal route, a bypassing diagonal-policy read is not a read of the accepted obstruction packet. □

Theorem 490.15 (Halting obstruction public consumer ledger exhaustion)**.** *For an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, every downstream public consumer is exhausted by the displayed finite ledger* $S, I, T, R, D, H, C, P, N$*. The consumer may read certificate-source, input-history, trace, self-reference, diagonal policy, transport, route, package, and local naming rows, but no additional halting, divergence, evaluator, equality, or classifier row.*

Proof. Read the packet from Definition 490.1. Its carrier inventory is the finite ledger $S, I, T, R, D, H, C, P, N$.

Apply Definition 490.2. The obligations attach the carrier, trace, self-reference, diagonal policy, package, and local name to that ledger and do not introduce a separate consumer coordinate.

Use Definition 490.4, Definition 490.3, and Definition 490.10. These rows force downstream reads through the displayed distinction and diagonal boundary while excluding global halting classifiers, host oracles, unbounded search, quotient equality, and alternate routes.

Finally apply Definition 490.12. Repackaging through P and N preserves exactly the same finite ledger, so every public consumer is exhausted by $S, I, T, R, D, H, C, P, N$. □

Theorem 490.16 (Halting obstruction root carrier admission)**.** *Every accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet exposes exactly*

$$O = (S, I, T, R, D, H, C, P, N)$$

as its finite root surface: S *is the certificate-source row,* I *is the input-history row,* T *is the finite positive-trace ledger,* R *is the self-reference route row,* D *is the diagonal-policy row,* H *is the componentwise* hsame *ledger,* C *is the displayed* Cont *route family,* P *is the* Pkg *provenance row, and* N *is the local* $\mathsf{NameCert}$ *row.*

No accepted packet exposes any additional BHist*,* Cont*,* hsame*,* Pkg*, or* NameCert *coordinate at the root boundary.*

Lean4 ✓ `BEDC.Derived.HaltingObstructionUp.HaltingObstructionRootCarrierAdmission`

Proof. Project the carrier from Definition 490.1. The displayed tuple supplies exactly the rows $S, I, T, R, D, H, C, P, N$.

Apply Definition 490.2. Its carrier, trace, self-reference, diagonal-policy, and package/name clauses are all obligations over the same tuple, so no second root row is introduced by the local naming surface.

Use Definition 490.12. Repackaging through P and N preserves the same finite obstruction surface rather than adding a classifier, search row, host oracle, quotient equality, or alternate diagonal route. □

Theorem 490.17 (Halting obstruction root transport scope)**.** *For an accepted* HaltingObstruction$^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, every public self-reference read and every positive trace read is transported only through the componentwise* hsame *ledger* H *and replayed only through the displayed* Cont *routes* C*.*

The rows S, I, T, R, D *determine what is being read, while* H *and* C *determine the only visible movement of those reads across the root boundary.*

Proof. Use Definition 490.5 for trace reads. It forces each positive continuation fact to be one of the finite steps stored in T, transported by H, and reached by the route row C.

Use Definition 490.6 for self-reference reads. The row R is readable only after the certificate source S, input-history row I, finite trace row T, and displayed transport route have been consumed.

Apply Definition 490.3. Since the packet contains no global classifier, unbounded continuation search, host divergence oracle, or quotient equality, no public read can bypass H or replay outside C. □

Theorem 490.18 (Halting obstruction root ledger exactness)**.** *For an accepted* HaltingObstruction$^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, the rows* P *and* N *package exactly the finite obstruction ledger exposed by* S, I, T, R, D, H, C*. They do not export a global halting classifier, unbounded search, host oracle, quotient equality, or any second diagonal route.*

Proof. Read the finite ledger through Definition 490.16. The only rows available to the root surface are the certificate source, input history, trace ledger, self-reference route, diagonal policy, transport, continuation, package, and local naming rows.

Apply Definition 490.7. A public diagonal read reaches D only through the displayed self-reference and trace route, so the diagonal policy remains a local ledger row.

Finally use Definition 490.12 together with Definition 490.3. The package and naming rows repack the finite obstruction ledger already present, and the non-escape boundary excludes the classifier, search, host-oracle, quotient, and alternate-route exports. □

Theorem 490.19 (Halting obstruction fixed-tuple image and readback)**.** *For an accepted* HaltingObstruction$^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, the same displayed tuple supplies the image row and readback row required by the fixed finite* BHist *tuple route of Definition 9464.24. The image is the finite obstruction ledger exposed by* $S, I, T, R, D, H, C, P, N$*, and the readback is the projection back to the same carrier rows.*

Proof. Start with Definition 490.16. It admits exactly the certificate source, input history, trace, self-reference, diagonal-policy, transport, continuation, package, and local naming rows.

Apply Definition 490.2. The local NameCert obligations keep the same rows visible when the packet is read as an accepted obstruction surface.

Use Definition 490.17 and Definition 490.18. Transport and package readback both remain inside H, C, P, N, so the fixed-tuple route of Definition 9464.24 has no additional image or readback coordinate to supply. □

Theorem 490.20 (Halting obstruction component transport rows)**.** *For an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet* $O = (S, I, T, R, D, H, C, P, N)$*, every local NameCert row transports componentwise through the displayed transport, route, package, and naming rows* H, C, P, N*. In particular, carrier admission, trace coverage, self-reference readability, diagonal-policy locality, and public package reads are transported as rows of the same finite tuple.*

Proof. Read carrier admission from Definition 490.16 and the local NameCert clauses from Definition 490.2. They place every obligation on the coordinates of the single tuple $S, I, T, R, D, H, C, P, N$.

Use Definition 490.17. It restricts self-reference and positive trace movement to the componentwise hsame ledger H and displayed Cont routes C.

Finally apply Definition 490.18 and Definition 9464.24. The package and naming rows P, N identify the transported finite ledger with the same fixed tuple, rather than with a host classifier or alternate diagonal route. □

Theorem 490.21 (Halting obstruction bridge request boundary)**.** *A* $\mathsf{StandardBridge}$ *request for* $\mathsf{HaltingObstruction}^{\uparrow}$ *is licensed only after four finite surfaces have been displayed for the same tuple* $S, I, T, R, D, H, C, P, N$*: the tuple rows, the image and readback rows of Definition 490.19, the componentwise NameCert transport rows of Definition 490.20, and the finite obstruction non-escape boundary.*

Lean4 ✓ `BEDC.Derived.HaltingObstructionUp.HaltingObstructionTasteGate single carrier alignment`

Proof. The tuple rows are supplied by Definition 490.16 and the local NameCert obligations of Definition 490.2. Thus a bridge request starts with the displayed obstruction packet, not with a fresh carrier.

The image and readback rows are exactly Definition 490.19. Componentwise transport is exactly Definition 490.20.

Use Definition 490.17, Definition 490.18, and Definition 490.3. Together with Definition 9464.24, they leave the TasteGate boundary with a fixed finite packet and exclude a global halting classifier, unbounded search, host divergence oracle, quotient equality, or second diagonal route. □

Theorem 490.22 (Halting obstruction root consumer package)**.** *Let* $O = (S, I, T, R, D, H, C, P, N)$ *be an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet. Every root downstream consumer receives only the finite trace row* T*, self-reference row* R*, diagonal-policy row* D*, componentwise transport row* H*, displayed route row* C*, package row* P*, and local* $\mathsf{NameCert}$ *row* N *carried by* O*. The handoff supplies no global halting classifier, no unbounded continuation search, and no off-packet equality of names.*

Proof. Start with Definition 490.16. It admits the accepted packet as the fixed tuple $S, I, T, R, D, H, C, P, N$ and gives no root coordinate beyond those rows.

Use Definition 490.17. Any public trace or self-reference read is transported through H and replayed through C, so the downstream consumer cannot bypass the displayed finite route.

Finally apply Definition 490.18. The rows P and N package exactly the ledger already exposed by S, I, T, R, D, H, C, excluding a classifier, search surface, host oracle, quotient equality, or second diagonal route. □

Theorem 490.23 (Halting obstruction diagonal consumer handoff)**.** *Let $O = (S, I, T, R, D, H, C, P, N)$ be an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet. Any* $\mathsf{HaltingDiagonal}^{\uparrow}$ *consumer that reads the obstruction from O receives the displayed self-reference row R, the diagonal-policy row D, the finite trace row T, and their transport, route, package, and local NameCert rows H, C, P, N. The handoff is a local diagonal ledger for the displayed self-application route, not a decision surface for arbitrary histories.*

Proof. Read the fixed tuple through Definition 490.16. The diagonal-facing rows are already part of the accepted packet: T records the finite trace, R records self-reference, and D records the diagonal policy.

Apply Definition 490.17. It forces each self-reference and trace read through H and C, so the diagonal consumer receives the displayed route rather than an ambient self-application operator.

Use Definition 490.18 to package the same rows through P and N. Then Definition 490.4 identifies the consumer-facing object as the finite distinction and diagonal boundary, not a global halting classifier. □

Theorem 490.24 (Halting obstruction public downstream exactness)**.** *Let $O = (S, I, T, R, D, H, C, P, N)$ be an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet. Every downstream* $\mathsf{HaltingDistinction}^{\uparrow}$ *or* $\mathsf{HaltingDiagonal}^{\uparrow}$ *public read is exhausted by the finite trace, self-reference, diagonal-policy, transport, route, package, and local NameCert rows displayed in O. No downstream read obtains an additional trace row, diagonal policy row, package row, or local naming row outside T, R, D, H, C, P, N.*

Proof. First apply Definition 490.16. It fixes the public obstruction surface as the single tuple $S, I, T, R, D, H, C, P, N$.

Next use Definition 490.17. Public trace and self-reference movement is limited to the componentwise hsame ledger H and displayed Cont routes C.

Apply Definition 490.18. The package and local naming rows expose only the finite obstruction ledger already present in S, I, T, R, D, H, C.

Finally invoke Definition 490.4. The HaltingDistinction and HaltingDiagonal consumers receive the same finite boundary rows before any obstruction ledger is read, so the public downstream surface is exact and contains no additional classifier or off-packet row. □

Theorem 490.25 (Halting obstruction root trace admission)**.** *Let $O = (S, I, T, R, D, H, C, P, N)$ be an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet. The accepted root surface exposes the finite trace row T only through the carrier row S, input-history row I, componentwise transport row H, displayed route row C, package row P, and local* $\mathsf{NameCert}$ *row N. It supplies no root trace outside the displayed finite packet.*

Proof. Use Definition 490.16 to place the accepted obstruction on the single tuple $S, I, T, R, D, H, C, P, N$. The only trace coordinate in that tuple is T.

Apply Definition 490.5. It records the finite trace as the accepted trace surface and does not provide another trace carrier.

Finally use the NameCert obligations and Definition 490.10. The trace can be transported through H, replayed through C, packaged by P, and named by N, but no downstream root read receives a second trace row. □

Theorem 490.26 (Halting obstruction root policy exhaustion)**.** *Let $O = (S, I, T, R, D, H, C, P, N)$ be an accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet. The diagonal-policy row D exhausts the obstruction-policy surface of the root packet. It remains a local policy ledger for the displayed trace and self-reference route and cannot become a global halting classifier, host divergence oracle, or decision procedure for arbitrary histories.*

Proof. Read the root packet through Definition 490.16. The policy-facing coordinate is the displayed row D, paired with the finite trace and self-reference rows T and R.

Apply Definition 490.7. It exhausts the diagonal-policy surface by the local ledger row and gives no classifier row for arbitrary histories.

Use Definition 490.3 and Definition 490.10. They keep the diagonal policy inside the finite obstruction route, so the policy row cannot escape as a global halting classifier. □

Theorem 490.27 (Halting obstruction root consumer boundary)**.** *For every accepted* $\mathsf{HaltingObstruction}^{\uparrow}$ *packet $O = (S, I, T, R, D, H, C, P, N)$, each downstream* $\mathsf{HaltingDistinction}^{\uparrow}$ *or* $\mathsf{HaltingDiagonal}^{\uparrow}$ *consumer factors through $S, I, T, R, D, H, C, P, N$. The consumer may read the finite trace, self-reference, diagonal-policy, transport, route, package, and naming rows, but it receives no global halting classifier, unbounded continuation search, host divergence oracle, quotient equality, or off-packet name equality.*

Proof. Start with Definition 490.16. It fixes the root obstruction as the finite tuple $S, I, T, R, D, H, C, P, N$.

Apply Definition 490.25 and Definition 490.26. These bind the trace-facing and policy-facing reads to T and D inside the same tuple.

Next use Definition 490.17 and Definition 490.18. Transport, route replay, packaging, and local naming are exactly the rows H, C, P, N already carried by the packet.

Finally invoke Definition 490.24. The HaltingDistinction and HaltingDiagonal handoffs are exhausted by the displayed finite rows, so every downstream consumer factors through $S, I, T, R, D, H, C, P, N$ and obtains no global halting surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{HaltingObstruction}^{\uparrow}}$.

Constructive story: A $\mathsf{HaltingObstruction}^{\uparrow}$ packet is generated from finite certificate rows, input-history rows, trace rows, self-reference rows, diagonal-policy rows, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{HaltingObstruction}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 490.1, Definition 490.16, Definition 490.5, Definition 490.6, Definition 490.7, Definition 490.10, Definition 490.18, Definition 490.19, Definition 490.20, and Definition 490.21 bind carrier admission, trace exactness, self-reference readability, diagonal policy locality, package route, public read boundary, local NameCert rows, fixed-tuple image/readback rows, componentwise transport rows, and the bridge request boundary as the public obstruction surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{HaltingObstruction}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.HaltingObstructionUp.HaltingObstructionRootCarrierAdmission`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close a global halting classifier, unbounded continuation search, host divergence oracle, quotient equality, Lean verification, or bridge checking.

Upgrade path: The theory axis has no further paper-side grade; Lean verification and bridge checking remain independent.

Chapter 491

A Concrete Naming Certificate for $\mathsf{HaltingDistinction}^{\uparrow}$

The $\mathsf{HaltingDistinction}^{\uparrow}$ surface turns the halting-as-distinction interface of chapter 9368 into a finite naming packet. It does not decide halting. It records the visible certificate-history pair, the finite continuation trace being tested, the diagonal self-reference row, the transports, routes, provenance, and local naming rows through which the fixed-point obstruction can be read.

The finite trace row T is the local trace surface refined by chapter 492. $\mathsf{HaltingDistinction}^{\uparrow}$ consumes that sibling only as a finite continuation-trace row, not as a total halting predicate or host evaluator.

The diagonal pair row is also consumed together with the inscription-event record surface of chapter 519 and the trace-normal-form route of chapter 683. The finite route Q, T, Z, H, C, P, N supplies the certificate-history pair, trace segment, diagonal read, transports, routes, provenance, and local ledger; the sibling chapters supply the inscription record and normal-form trace surfaces needed by later halting-boundary and cellular closed-substrate consumers.

Definition 491.1 (HaltingDistinction carrier)**.** *A* $\mathsf{HaltingDistinction}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (Q, T, Z, H, C, P, N)$$

with the following displayed rows:

1. *Q is the certificate-history pair row, naming a candidate program certificate* $\mathsf{NameCert}_P$ *together with the history h whose* Cont_P *chain is being inspected;*
2. *T is the finite trace row recording the visible* Cont_P *chain segment from h through its displayed marks and intermediate histories;*
3. *Z is the diagonal self-reference row, naming the self-application read in which the classifier for Q is asked about the same certificate-history pair it is currently classifying;*
4. *H records the componentwise* hsame *transports for certificate-history pair rows, trace rows, diagonal rows, package rows, and local naming rows;*
5. *C records the displayed* Cont *routes for reading the input pair, replaying the finite trace, entering the diagonal row, and returning the result to the local ledger;*
6. *P is the* Pkg *provenance over* BHist, Ext, Cont, hsame, Pkg, *the diagonal read, and the surrounding* $\mathsf{NameCert}$ *rows;*

7. *N is the local* $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$ *ledger.*

The carrier contains no global truth predicate, no classical decidability assumption for termination, no oracle for divergence, and no meta-level evaluator outside the displayed BHist, Ext, Cont, hsame, Pkg, *and local* NameCert *rows.*

Theorem 491.2 (HaltingDistinction NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$ *surface for Definition 491.1 consists of five obligations:*

1. *carrier admission for the finite packet $D = (Q, T, Z, H, C, P, N)$;*
2. *certificate-history classifier transport, saying that pair rows classify only through the displayed* hsame *transport recorded in H;*
3. *trace readability, saying that a public termination-facing read factors through the finite* Cont_P *chain segment T and the read routes in C;*
4. *diagonal boundary exactness, saying that the self-reference row Z records the classifier's self-application point without supplying an external halting decision;*
5. *non-escape from global truth predicates, classical decidability, divergence oracles, host evaluators, or classifiers not named by Q, T, Z, H, C, P, and N.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionNameCertObligations`

Proof. Carrier admission is projection from Definition 491.1. The packet names exactly the pair, trace, diagonal, transport, continuation, package, and local naming rows.

Classifier transport is componentwise in H. Since Q is the only row naming the certificate-history input, any transported public comparison must return to the same visible pair data and its local ledger.

Trace readability is controlled by T and C. A consumer may replay the finite Cont_P segment displayed by T, but the carrier has no coordinate that upgrades this finite trace into a total halting predicate.

The diagonal boundary is the row Z. It records the self-application read needed by the fixed-point obstruction, while P and N record only provenance and local naming. Thus the packet exhibits the obstruction surface without importing a global decision principle. □

Theorem 491.3 (HaltingDistinction diagonal boundary)**.** *Let $D = (Q, T, Z, H, C, P, N)$ be an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *carrier. Any public read that reaches the diagonal self-reference point reaches it only through the displayed route*

$$Q \longmapsto T \longmapsto Z \longmapsto H \longmapsto C \longmapsto P \longmapsto N.$$

The row Z may identify the classifier question with its own certificate-history input under the recorded hsame *transports, but it does not produce a truth value for all certificate-history pairs and does not decide divergence outside the displayed finite packet.*

Proof. Start from a public diagonal read. Carrier projection gives the input pair row Q, the finite trace row T, and the self-reference row Z as the only rows that can name the read.

Use the routes in C to move from Q through T to Z. The permitted renamings are exactly the componentwise transports stored in H, and the dependency record is exactly P together with the local ledger N.

Since no coordinate of D is a total truth predicate, a classical halting decision, or a divergence oracle, the read stops at the displayed diagonal boundary. It exposes where the self-reference pressure occurs without converting that pressure into a global classifier. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionDiagonalBoundary`

Theorem 491.4 (HaltingDistinction consumer non-escape)**.** *Every consumer of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet receives only the finite certificate-history pair row* Q*, the finite* Cont_P *trace row* T*, the diagonal self-reference row* Z*, the componentwise* hsame *transports* H*, the displayed read routes* C*, the* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$ *ledger* N*. No consumer can extract from the packet a total halting predicate, a global truth predicate over certificates, a classical decidability principle for termination, or a host-level evaluator.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier consumer non escape`

Proof. Inspect the carrier coordinates. The exported rows are exactly Q, T, Z, H, C, P, N, and each row is finite BEDC data.

Apply Definition 491.2 to ordinary trace consumers and Definition 491.3 to self-reference consumers. Both routes remain inside the displayed packet.

Therefore every public read factors through the named rows. The carrier has no channel through which a total halting predicate, global truth predicate, classical decision principle, or host evaluator can enter the consumer surface. □

Theorem 491.5 (HaltingDistinction pair classifier transport)**.** *Let* $D = (Q, T, Z, H, C, P, N)$ *be an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *carrier. Any public classifier read of the certificate-history pair row* Q *is transported only through the componentwise* hsame *row recorded in* H*. The packet therefore classifies pair rows by the displayed certificate-history data and the local* $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$ *ledger, not by a global truth predicate or host evaluator.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionPairClassifierTransport`

Proof. Start with the carrier of Definition 491.1. The only coordinate naming the certificate-history input is Q, and the only transport coordinate for pair rows is the componentwise hsame data in H.

Apply Definition 491.2. Its classifier transport obligation says that pair rows classify through the displayed transport row, while the local ledger records only the finite naming surface.

Use Definition 491.3 for the self-reference case and Definition 491.4 for all consumer reads. Neither route adds a global truth predicate, a classical termination decision, divergence oracle data, or a host evaluator. □

Theorem 491.6 (HaltingDistinction trace readability)**.** *Let* $D = (Q, T, Z, H, C, P, N)$ *be an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *carrier. Every termination-facing public read of* D *factors through the finite trace row* T *and the displayed route row* C*. The read may inspect the visible* Cont_P *chain segment recorded in* T*, but it cannot turn that finite segment into a total halting predicate or divergence oracle.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionTraceReadability`

Proof. The carrier definition supplies T as the only finite trace coordinate and C as the only route coordinate for replaying that trace. Thus any termination-facing read first projects to those rows.

The trace-readability clause of Definition 491.2 binds the public read to the finite Cont_P segment in T and to the routes in C.

If the read reaches the self-reference point, apply Definition 491.3; otherwise apply Definition 491.4. In both cases the read remains within the displayed finite packet and has no coordinate from which to recover a total halting classifier. □

Theorem 491.7 (HaltingDistinction finite trace inversion)**.** *Let $D = (Q, T, Z, H, C, P, N)$ be an accepted* HaltingDistinction$^{\uparrow}$ *carrier. If a public termination-facing read of D reaches a displayed* Cont *step, then the read determines its source pair row Q, finite trace row T, diagonal row Z when the read enters the self-reference branch, transport row H, route row C, provenance row P, and local ledger row N.*

This inversion is exact only for the displayed finite packet. It reconstructs no hidden total halting classifier, divergence oracle, global truth predicate, or host evaluator.

Proof. Project the accepted carrier. By Definition 491.1, the only coordinates available to a termination-facing read are Q, T, Z, H, C, P, N, and the only displayed continuation routes are recorded in C.

Apply Definition 491.6. A read that reaches a displayed Cont step is already inside the finite trace row T and route row C, so the source pair row Q, transport row H, provenance row P, and local ledger row N are fixed by the carrier projection.

If the route enters the self-reference branch, apply Definition 491.3. The diagonal row Z is then the displayed self-application row reached by the route, and no external decision principle is added at that point.

Finally apply Definition 491.4. Since every public consumer receives only Q, T, Z, H, C, P, N, the inversion cannot reconstruct a hidden total halting classifier, divergence oracle, global truth predicate, or host evaluator. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionFiniteTraceInversion`

Theorem 491.8 (HaltingDistinction provenance purity boundary)**.** *Let $D = (Q, T, Z, H, C, P, N)$ be an accepted* HaltingDistinction$^{\uparrow}$ *carrier. The provenance row P and the local naming row N certify only the displayed finite carrier, transport, route, trace, and diagonal rows. They cannot be read as a total halting predicate, a global truth predicate over certificates, a divergence oracle, or a host evaluator.*

Proof. By Definition 491.1, the provenance coordinate P ranges over the displayed BHist, Ext, Cont, hsame, Pkg, diagonal, and local naming rows. The local ledger N names that finite packet and no further classifier.

Apply Definition 491.2 to identify the finite obligations certified by P and N. Apply Definition 491.3 to the diagonal read, where the provenance records the route to the self-reference row without deciding the classifier question globally.

Finally apply Definition 491.4. Since no consumer of the packet can extract a total halting predicate, global truth predicate, classical decision principle, divergence oracle, or host evaluator, the provenance and naming rows cannot be reinterpreted as any of those objects. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier provenance purity boundary`

Theorem 491.9 (HaltingDistinction normal-form route consumption)**.** *Let $D = (Q, T, Z, H, C, P, N)$ be an accepted* HaltingDistinction$^{\uparrow}$ *carrier. Every accepted public read that reaches the trace-normal-form route consumes the* ContinuationTraceNormalForm$^{\uparrow}$ *sibling surface of chapter 683 before the diagonal row Z can be used. The read remains a finite route through Q, T, H, C, P, N into Z; it does not obtain a host evaluator, an unbounded execution semantics, or a total halting classifier.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionNormalFormRouteConsumption`

Proof. First project the carrier. By Definition 491.1, the only trace coordinate is T, the only displayed continuation routes are in C, and the only transport row for carrying the trace into later reads is H.

Apply Definition 491.6 and Definition 491.17. A termination-facing read reaches the finite Cont_P segment through T and C, and the normal-form sibling supplies the named finite normal-form surface consumed by that same route.

Only after that route has been consumed may the read enter the diagonal row. Definition 491.3 identifies Z as the displayed self-reference boundary, while Definition 491.8 keeps P and N from becoming evaluator or truth-predicate data. □

Theorem 491.10 (HaltingDistinction inscription-event boundary)**.** *Let $D = (Q, T, Z, H, C, P, N)$ be an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *carrier. Every diagonal public read consumes the inscription-event record surface of chapter 519 before any self-reference boundary is exposed. The read records the diagonal pair and self-application event through Q, Z, H, C, P, N and exports no total halting predicate, divergence oracle, global truth predicate, or host evaluator.*

Proof. Begin with the diagonal coordinates. The carrier names the certificate-history pair in Q and the self-reference row in Z, with H carrying the componentwise hsame transports and C carrying the displayed route.

Apply Definition 491.16. The diagonal pair is consumed together with the inscription-event sibling before the public obstruction read is exposed, so the inscription-facing record is part of the route rather than an external semantic oracle.

Now apply Definition 491.3. The self-reference boundary becomes visible only at the displayed row Z after the finite inscription and route data have been read. Definition 491.4 excludes any hidden halting predicate, divergence oracle, global truth predicate, or host evaluator from that exposure. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier inscription event boundary`

Theorem 491.11 (HaltingDistinction downstream obstruction handoff)**.** *Every* $\mathsf{HaltingObstruction}^{\uparrow}$ *consumer of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet receives only the finite rows*

$$Q, T, Z, H, C, P, N$$

together with the named sibling routes through chapter 492, chapter 683, chapter 519, and chapter 490. The handoff is a finite obstruction-facing boundary and does not supply a total halting predicate.

Proof. Project the accepted packet. Definition 491.4 says every consumer receives only the rows Q, T, Z, H, C, P, N, and Definition 491.23 locks the trace, inscription, and normal-form siblings to that same finite packet.

Next read the obstruction-facing package. Definition 491.14 combines diagonal boundary, trace readability, provenance purity, and consumer non-escape as the public obstruction surface.

Finally apply Definition 491.15 and Definition 491.18. They identify the downstream $\mathsf{HaltingObstruction}^{\uparrow}$ read as a consumer of the finite distinction boundary, not as a source of a total halting predicate, divergence oracle, global truth predicate, or host evaluator. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionDownstreamObstructionHandoff`

Theorem 491.12 (HaltingDistinction diagonal trace consumer totality)**.** *Every downstream obstruction-facing consumer of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet reads only the finite rows*

$$Q, T, Z, H, C, P, N$$

together with the named trace, inscription-event, trace-normal-form, and obstruction sibling routes before it sees the diagonal boundary. The consumer totality is finite: it does not supply a total halting predicate, divergence oracle, global truth predicate, or host evaluator.

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier diagonal trace consumer totality`

Proof. First read the finite trace surface. Apply Definition 491.6 and Definition 491.7; any termination-facing consumer that reaches a displayed Cont step has already fixed Q, T, Z, H, C, P, N when the diagonal branch is entered.

Next read the certificate boundary. Use Definition 491.8 to keep P, N as provenance and local naming rows, and use Definition 491.9 to force trace-normal-form access through the displayed finite route.

Finally apply Definition 491.10 and Definition 491.11. These place the inscription-event and obstruction sibling routes before the downstream diagonal read. The cited non-escape clauses exclude total halting predicates, divergence oracles, global truth predicates, and host evaluators from the consumer surface. □

Theorem 491.13 (HaltingDistinction finite obstruction ledger exhaustion)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet, the obstruction ledger exposed to downstream consumers is exhausted by* Q, T, Z, H, C, P, N *plus the trace, inscription-event, trace-normal-form, and* $\mathsf{HaltingObstruction}^{\uparrow}$ *sibling routes named in Definition 491.11. No further coordinate is available for a total halting predicate, divergence oracle, global truth predicate, or host evaluator.*

Proof. Start with Definition 491.12. It already identifies the complete finite consumer route before the diagonal boundary is exposed.

Read the obstruction ledger through Definition 491.11. The handoff sends each downstream obstruction-facing consumer through exactly the finite rows Q, T, Z, H, C, P, N and through the named sibling routes.

The exhaustion clause follows from Definition 491.8 together with Definition 491.7. Since the trace inversion reconstructs only the displayed finite packet and the provenance row cannot be reinterpreted as semantic evaluation data, the obstruction ledger has no coordinate for any total halting, divergence, truth, or host-evaluation object. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier finite obstruction ledger exhaustion`

Theorem 491.14 (HaltingDistinction diagonal obstruction public package)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N),$$

the public diagonal obstruction is exposed only through the certificate-history pair row Q*, the finite trace row* T*, the diagonal self-reference row* Z*, componentwise* hsame *transports* H*, displayed routes* C*, provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$ *row* N*. The package combines the diagonal boundary, trace readability, provenance purity, and consumer non-escape rows; it exports no total halting predicate, global truth predicate, divergence oracle, or host evaluator.*

Proof. First read the diagonal boundary. Definition 491.3 forces every public diagonal read through Q, T, Z, H, C, P, N and stops the read at the self-reference boundary rather than at a global decision principle.

Next read the trace and provenance rows. Definition 491.6 keeps termination-facing inspection inside the finite trace T and route row C, while Definition 491.8 prevents P and N from being reinterpreted as a truth predicate, divergence oracle, or host evaluator.

Finally apply consumer non-escape. Definition 491.4 says every public consumer receives only Q, T, Z, H, C, P, N, so the package exposes the diagonal obstruction without making any total halting-decision claim. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionDiagonalObstructionPublicPackage`

Theorem 491.15 (HaltingDistinction obstruction sibling route)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N),$$

the finite certificate-history pair row Q, finite trace row T, diagonal self-reference row Z, transports H, routes C, provenance P, and local naming row N are exactly the sibling boundary consumed by chapter 490 before an obstruction ledger is exposed. This route is a finite downstream consumer relation, not a global halting classifier.

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionObstructionSiblingRoute`

Proof. Project the accepted distinction packet. The rows Q, T, Z, H, C, P, N are the only certificate-history, trace, diagonal, transport, route, provenance, and local naming coordinates visible to a consumer.

Apply Definition 491.14. It packages the diagonal boundary, trace readability, provenance purity, and consumer non-escape rows as the public obstruction-facing surface of $\mathsf{HaltingDistinction}^{\uparrow}$.

Now read the downstream consumer named in chapter 490. Its obstruction ledger is exposed only after the distinction boundary has supplied the certificate-history pair, finite trace, and diagonal self-reference rows.

Thus the sibling route is exact at the finite boundary Q, T, Z, H, C, P, N. Since neither side supplies a total halting predicate, global truth predicate, divergence oracle, or host evaluator, the route records only the finite obstruction consumer relation. □

Theorem 491.16 (HaltingDistinction inscription-event route)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N),$$

the diagonal pair row Q is consumed together with the inscription-event record of chapter 519 before any public obstruction read is exposed. The route records the finite certificate-history pair, trace, diagonal row, transport, continuation, provenance, and local name; it does not export a host evaluator or total halting predicate.

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier inscription event route`

Proof. Project the carrier of Definition 491.1. The diagonal pair row Q and the diagonal self-reference row Z are visible only with the finite trace, transport, route, provenance, and local naming rows.

Apply Definition 491.3 and Definition 491.6. These force the diagonal read to stay inside Q, T, Z, H, C, P, N before the route can be offered to any downstream consumer.

Now read the inscription-event sibling. The cited chapter records the event row that names the inscription-facing boundary, so the diagonal pair is consumed with that record before the public obstruction route of Definition 491.15 is exposed.

Finally use Definition 491.4. The resulting route has no coordinate for a total halting predicate, global truth predicate, divergence oracle, or host evaluator. □

Theorem 491.17 (HaltingDistinction trace normal-form scope)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N),$$

the trace row T is scoped through chapter 683. A downstream consumer may read the finite normal-form trace route, transported through H and replayed through C, but it cannot replace T by a host evaluator, an unbounded execution semantics, or a total halting classifier.

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionTraceNormalFormScope`

Proof. Begin with trace readability. Definition 491.6 identifies T as the finite trace segment available to a termination-facing inspection, and it keeps that read under the displayed route C.

Use the carrier and diagonal-boundary rows to keep the trace tied to Q and Z. The packet has no independent evaluator coordinate, so the trace cannot be detached from the certificate-history pair and diagonal row.

Now cite the normal-form sibling chapter 683. It supplies the finite trace-normal-form surface consumed by the downstream route, while H, C, P, N preserve the same displayed packet.

Consumer non-escape then excludes a host evaluator, unbounded execution semantics, divergence oracle, and total halting classifier from the trace route. □

Theorem 491.18 (HaltingDistinction obstruction consumer boundary)**.** *Every downstream obstruction consumer of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet must pass through*

$$Q, T, Z, H, C, P, N$$

before reading chapter 490. The consumer receives the certificate-history pair, finite trace row, diagonal self-reference row, componentwise transport, displayed continuation, package provenance, and local naming row, and it receives no total halting predicate, host evaluator, divergence oracle, or global truth classifier.

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionObstructionConsumerBoundary`

Proof. Project the accepted packet through Definition 491.1. The only obstruction-facing rows are Q, T, Z, H, C, P, N.

Apply Definition 491.3 and Definition 491.6. They place public diagonal and trace reads inside the displayed certificate-history and continuation boundary.

Use Definition 491.4 and Definition 491.15. The first excludes hidden evaluator and total-classifier rows; the second identifies the finite boundary consumed by the HaltingObstruction sibling.

Thus the downstream obstruction consumer can reach the cited obstruction ledger only after the finite packet Q, T, Z, H, C, P, N has been displayed. □

Theorem 491.19 (HaltingDistinction carrier obligation)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N),$$

the public carrier exposes exactly the certificate-history pair Q, finite trace segment T, diagonal row Z, componentwise transport row H, displayed route row C, provenance row P, and local $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$ *row N. These are the only rows available for certificate-history pairing, finite trace reading, diagonal inspection, transport, routing, provenance, and local naming.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier carrier obligation`

Proof. Project the carrier from Definition 491.1. The accepted packet has the seven displayed coordinates Q, T, Z, H, C, P, N, and no extra row is introduced by the carrier projection.

Apply Definition 491.2. It identifies P and N as the finite provenance and local naming witnesses for exactly the displayed certificate-history, trace, diagonal, transport, and route rows.

The conclusion is therefore row-exact: every public read of the carrier must factor through one of Q, T, Z, H, C, P, N, and no hidden global classifier row is exposed. □

Theorem 491.20 (HaltingDistinction classifier stability)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N),$$

any classifier read of the certificate-history pair row Q is stable only along the displayed componentwise hsame *row H. The read may transport the finite rows named by Q, T, Z, C, P, N, but it cannot invoke a global truth predicate, a divergence oracle, a total halting predicate, or a host evaluator outside the accepted packet.*

Proof. Start with the exact carrier surface of Definition 491.19. The only certificate-history pair exposed to a classifier is Q, and its only transport witness is the displayed componentwise row H.

Apply Definition 491.2. The local $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$ row certifies Q, T, Z, H, C, P, N as the finite packet rows, so a classifier read has no additional source for truth, divergence, total termination, or host evaluation.

Finally use Definition 491.8 and Definition 491.4. These prevent the provenance and consumer rows from being reinterpreted as external semantic or evaluator data. Thus stability of Q is exactly the stability transported by H. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionClassifierStability`

Theorem 491.21 (HaltingDistinction root carrier-route exhaustion)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N),$$

every root read exposed by the packet factors through the carrier row Q, the finite trace row T, the route row C, the provenance row P, and the local $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$ *row N, with the diagonal row Z and componentwise* hsame *transport row H used only as displayed coordinates of that same finite packet. No root read has access to a row outside the carrier, finite trace, route, provenance, and local naming surface.*

Proof. Project the packet by Definition 491.1. The carrier lists exactly Q, T, Z, H, C, P, N, so the root read begins with the displayed BHist rows and has no hidden coordinate to inspect.

Apply Definition 491.19. It turns the carrier projection into the public obligation surface and identifies the finite rows that may be consumed by root readers.

Now use Definition 491.6. A termination-facing read must pass through the finite Cont_P trace row T and the route row C, while P and N remain the Pkg provenance and local $\mathsf{NameCert}$ ledger for exactly those rows. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootCarrierRouteExhaustion`

Theorem 491.22 (HaltingDistinction root diagonal non-escape)**.** *For every accepted* HaltingDistinction$^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N),$$

any diagonal root read factors through Q, T, Z, H, C, P, N*. The self-reference row may identify the classifier question with its own certificate-history input through the displayed* hsame *transports, but the read cannot produce a total halting predicate, a global truth predicate, a divergence oracle, or a host evaluator.*

Proof. Start with the diagonal boundary of Definition 491.3. It routes the self-reference read through Q, T, Z, H, C, P, N and stops the read at the displayed diagonal row.

Apply Definition 491.8. The Pkg provenance row P and local naming row N certify only the finite carrier, trace, route, transport, and diagonal data.

Finally use Definition 491.4. Since every public consumer receives only the displayed rows, the diagonal read cannot be reinterpreted as a total halting predicate, global truth predicate, divergence oracle, or host evaluator. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootDiagonalNonescape`

Theorem 491.23 (HaltingDistinction root sibling consumer lock)**.** *The same finite boundary*

$$Q, T, Z, H, C, P, N$$

is the only sibling route consumed by HaltingDistinctionTrace$^{\uparrow}$ *in chapter 492, by* InscriptionEvent$^{\uparrow}$ *in chapter 519, and by* ContinuationTraceNormalForm$^{\uparrow}$ *in chapter 683. These consumers may read the finite* Cont *trace, diagonal inscription row, componentwise* hsame *transports,* Pkg *provenance, and local* NameCert *ledger, but none may extend the route to an external halting classifier or host evaluator.*

Proof. First read the root carrier-route exhaustion theorem. Definition 491.21 fixes the available rows as Q, T, Z, H, C, P, N and assigns trace, route, provenance, and local naming roles to them.

For the diagonal consumer, apply Definition 491.22. The inscription-facing read can use Z only inside the same finite boundary and cannot turn the diagonal row into evaluator data.

The sibling chapters named in the statement consume exactly those rows: the trace chapter consumes the finite Cont trace surface, the inscription chapter consumes the diagonal event surface, and the trace-normal-form chapter consumes the finite normal-form route. Combining those readings locks all three consumers to the same BHist, Cont, hsame, Pkg, and NameCert packet. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootSiblingConsumerLock`

Theorem 491.24 (HaltingDistinction route stability)**.** *Every termination-facing route from an accepted* HaltingDistinction$^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N)$$

factors through the displayed rows Q, T, Z, H, C, P, N*. Its finite continuation replay is recorded by* C*, with* H *transporting only componentwise row equality and with* P, N *supplying provenance and local naming. No route can bypass these rows through a global truth predicate, total halting classifier, divergence oracle, or host evaluator.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier route stability`

Proof. First project the accepted packet by Definition 491.19. The public carrier contributes exactly Q, T, Z, H, C, P, N.

Next apply Definition 491.6 and Definition 491.3. Termination-facing inspection reads the finite trace row T, and diagonal inspection reaches Z only through the displayed route row C.

The remaining rows cannot open an external path. By Definition 491.8 and Definition 491.4, P and N remain certificate data and no consumer may replace the displayed route by a host evaluator or total halting predicate. Hence every termination-facing route is the finite replay through C over Q, T, Z, H, P, N. □

Theorem 491.25 (HaltingDistinction root NameCert package)**.** *The accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *root package consists exactly of carrier admission for* Q, T, Z, H, C, P, N*, classifier stability through* H*, finite trace readability through* T*, the diagonal boundary at* Z*, provenance purity through* P, N*, and consumer non-escape along the displayed route* C*. This package is a local* $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$ *surface and does not export a total halting predicate or classical decidability claim.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionNameCertRootPackage`

Proof. Carrier admission is Definition 491.19, and the local naming obligations are those of Definition 491.2. Together they expose exactly Q, T, Z, H, C, P, N.

Classifier stability is supplied by Definition 491.20. The classifier may read Q only through the componentwise transport row H.

The route-facing rows are fixed by Definition 491.6, Definition 491.3, and Definition 491.24. These force trace reads through T, diagonal reads through Z, and continuation replay through C.

Finally apply Definition 491.8 and Definition 491.4. They keep P, N as provenance and naming data and exclude any export of a total halting predicate, classical decidability row, global truth predicate, divergence oracle, or host evaluator. □

Theorem 491.26 (HaltingDistinction continuation boundary)**.** *Every termination-facing read from an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N)$$

factors through the displayed finite Cont *segment* T *and route row* C*. The continuation boundary records finite trace readability and diagonal routing only; it does not supply a total halting predicate.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionContinuationBoundary`

Proof. Read the finite trace first. By Definition 491.6, termination-facing inspection reaches the packet through the finite trace segment T rather than through an ambient evaluator.

Now apply Definition 491.3. The diagonal row Z is reachable only along the displayed route row C, with H transporting the already named components.

Since Definition 491.8 prevents the provenance and naming rows from being reinterpreted as a truth predicate, divergence oracle, or host evaluator, the read stops at the finite continuation boundary and never becomes a total halting predicate. □

Theorem 491.27 (HaltingDistinction non-escape package)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet, the carrier obligation, trace readability, diagonal boundary, provenance purity, and obstruction sibling route together exclude any exported global truth predicate, divergence oracle, classical termination decidability row, or host evaluator row. The package exposes only the finite rows* Q, T, Z, H, C, P, N *and the downstream obstruction route that consumes them.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier decision refusal surface`

Proof. Use Definition 491.19 to fix the public rows of the accepted packet. The carrier contributes only Q, T, Z, H, C, P, N.

Apply Definition 491.6 and Definition 491.3. These force termination-facing and diagonal-facing reads through the finite trace, diagonal, transport, and route rows.

Next apply Definition 491.8. The provenance and local naming rows remain certificate data, not a global truth predicate, divergence oracle, classical decision principle, or host evaluator.

Finally use Definition 491.15. The downstream obstruction consumer receives the same finite boundary, so the whole package is non-escaping at exactly the displayed rows. □

Theorem 491.28 (HaltingDistinction root carrier surface)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N),$$

the root carrier exposes exactly the seven displayed rows Q, T, Z, H, C, P, N*. The row* Q *is the certificate-history pair,* T *is the finite* Cont_P *trace segment,* Z *is the diagonal self-reference row,* H *is the componentwise* hsame *transport row,* C *is the displayed* Cont *route row,* P *is the* Pkg *provenance row, and* N *is the local* $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$ *ledger. No accepted packet contains a total halting coordinate, a global truth row, a divergence oracle row, or a host evaluator row.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootCarrierSurface`

Proof. Project the accepted carrier using Definition 491.1. Its displayed coordinates are precisely Q, T, Z, H, C, P, N, with the roles named in the statement and no further coordinate.

Apply Definition 491.2 to bind those rows as the local carrier, transport, trace, diagonal, and non-escape obligations. Apply Definition 491.3 and Definition 491.6 to locate the diagonal and trace reads inside the same packet.

Finally use Definition 491.15 and Definition 491.27. Downstream obstruction consumers receive exactly the displayed finite ledger, and the package exports no total halting coordinate, global truth row, divergence oracle row, or host evaluator row. □

Theorem 491.29 (HaltingDistinction root classifier transport)**.** *For every accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet*

$$D = (Q, T, Z, H, C, P, N),$$

any public classifier read of the root surface transports certificate-history data only through H*. If the read follows the continuation-facing route, it reaches the displayed finite segment through* T*, the diagonal row through* Z*, and the public route row through* C*; it never reads a classifier from an unrecorded transport, an ambient evaluator, or a total halting predicate.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootClassifierTransport`

Proof. Start with Definition 491.1. The only transport coordinate in the carrier is H, so every comparison of the certificate-history pair named by Q must use the componentwise hsame data recorded there.

Apply Definition 491.2. Its classifier-transport and trace-readability clauses keep public reads on the displayed transport and continuation rows, while Definition 491.6 identifies T and C as the finite continuation-facing route.

For the self-reference branch, apply Definition 491.3. The diagonal read reaches Z only along the displayed route and then returns to the finite ledger.

Use Definition 491.15 and Definition 491.27 for downstream consumers. They receive the same routed surface and no unrecorded transport, ambient evaluator, or total halting predicate. □

Theorem 491.30 (HaltingDistinction root ledger non-escape)**.** *Every downstream* HaltingObstruction$^{\uparrow}$ *or trace-normal-form consumer of an accepted* HaltingDistinction$^{\uparrow}$ *packet must read the same finite ledger* Q, T, Z, H, C, P, N*. Such a consumer can use the certificate-history pair, finite trace segment, diagonal row, componentwise transports, displayed routes, provenance, and local* NameCert *ledger, but it cannot extract a global truth predicate, divergence oracle, total evaluator, or hidden halting decision from that ledger.*

Proof. Project the ledger from Definition 491.1. The accepted packet exposes only Q, T, Z, H, C, P, N, and Definition 491.2 records those rows as the local obligations available to public readers.

Apply Definition 491.6 for trace-normal-form reads. They inspect the finite continuation segment T through the displayed route row C, with transports supplied only by H.

Apply Definition 491.3 and Definition 491.15 for obstruction reads. The route to HaltingObstruction$^{\uparrow}$ consumes the same certificate-history, trace, diagonal, transport, route, provenance, and naming rows.

Finally apply Definition 491.27. Since the packet exports only the finite ledger, downstream consumers cannot extract a global truth predicate, divergence oracle, total evaluator, or hidden halting decision. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootLedgerNonescape`

Theorem 491.31 (HaltingDistinction trace-normal-form handoff)**.** *Every trace-normal-form consumer of an accepted* HaltingDistinction$^{\uparrow}$ *packet receives only the finite trace row* T*, the route row* C*, the transport row* H*, the provenance row* P*, and the local ledger* N*. The rows* Q *and* Z *remain the surrounding certificate-history and diagonal rows for that handoff, so the consumer reads the normal-form trace surface without acquiring a total halting predicate, host evaluator, divergence oracle, or hidden classifier.*

Proof. Project the packet by Definition 491.1. The only displayed rows are Q, T, Z, H, C, P, N, and the trace-facing coordinate is the finite continuation segment T.

Apply Definition 491.6 and Definition 491.29. These force every trace-normal-form read through T and C, with componentwise comparison data supplied by H and provenance supplied by P, N.

The rows Q and Z are not exported as new evaluators. By Definition 491.3 and Definition 491.30, they remain the surrounding certificate-history and diagonal rows of the same finite ledger. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionTraceNormalFormHandoff`

Theorem 491.32 (HaltingDistinction inscription-event handoff)**.** *Every inscription-event consumer of an accepted* HaltingDistinction$^{\uparrow}$ *packet receives the diagonal pair row only through the displayed route*

$$Q, T, Z, H, C, P, N.$$

The event read may use the certificate-history pair, finite trace segment, diagonal row, componentwise transports, displayed routes, provenance, and local ledger, but it cannot turn that diagonal pair into an external evaluator, total halting predicate, divergence oracle, or host truth classifier.

Proof. Use Definition 491.1 to expose the diagonal row Z inside the finite packet Q, T, Z, H, C, P, N. There is no separate evaluator coordinate in the carrier.

Apply Definition 491.3. The diagonal pair can be read only along the route row C, with the certificate-history pair named by Q and the componentwise transports named by H.

Finally apply Definition 491.8 and Definition 491.27. The provenance and local ledger remain Pkg and NameCert rows, so the inscription-event consumer cannot reinterpret the diagonal pair as a total halting predicate or external evaluator. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionInscriptionEventHandoff`

Theorem 491.33 (HaltingDistinction downstream sibling package)**.** *The trace-normal-form route of chapter 683, the inscription-event route of chapter 519, the finite trace surface of chapter 492, and the obstruction route of chapter 490 jointly consume an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet only through the finite boundary* Q, T, Z, H, C, P, N*. This joint sibling package stays inside* BHist*,* Cont*,* hsame*,* Pkg*, and* NameCert *data and exports no total halting predicate, external evaluator, divergence oracle, or global truth classifier.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionObstructionSiblingJointPackage`

Proof. First use Definition 491.31. It gives the trace-normal-form consumer the finite trace, route, transport, provenance, and local ledger rows while keeping the certificate-history and diagonal rows as surrounding ledger data.

Next use Definition 491.32. It routes the inscription-event read of the diagonal pair through exactly the displayed Q, T, Z, H, C, P, N boundary.

For the obstruction side, apply Definition 491.15 and Definition 491.30. The obstruction consumer receives the same finite ledger and no extra evaluator row.

Combining these routes gives the stated downstream sibling boundary. The non-escape clauses of Definition 491.27 exclude total halting predicates, external evaluators, divergence oracles, and global truth classifiers from the joint package. □

Theorem 491.34 (HaltingDistinction root obstruction handoff lock)**.** *Every downstream obstruction consumer of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet reads only the finite packet*

$$Q, T, Z, H, C, P, N.$$

The obstruction route may inspect the certificate-history pair, finite trace row, diagonal row, componentwise transports, displayed route, provenance, and local ledger, but it cannot import a total halting coordinate, host evaluator, divergence oracle, or global truth classifier.

Proof. Start with the root carrier surface of Definition 491.28. It fixes Q, T, Z, H, C, P, N as the complete displayed packet.

Apply Definition 491.6 and Definition 491.3. These locate the trace and diagonal reads inside T and Z, with the displayed route row C and transport row H supplying the only admissible access path.

Finally compose Definition 491.30 with Definition 491.33. The obstruction consumer is one of the joint sibling routes, so it receives the same finite ledger and no external halting data. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootObstructionHandoffLock`

Theorem 491.35 (HaltingDistinction root trace-normal-form lock)**.** *Every trace-normal-form consumer downstream of* $\mathsf{HaltingDistinction}^{\uparrow}$ *reads only the finite packet*

$$Q, T, Z, H, C, P, N.$$

Its normal-form trace read is the displayed continuation segment with route and provenance data already present in that packet; no ambient evaluator, total halting predicate, hidden classifier, or divergence oracle is added at the handoff.

Proof. Project the accepted packet using Definition 491.28. The only rows available to the consumer are Q, T, Z, H, C, P, N.

Use Definition 491.6 to force the trace-normal-form read through T and C. Use Definition 491.3 to keep the diagonal row Z inside the same routed ledger rather than turning it into evaluator data.

The handoff is then the trace-normal-form component of Definition 491.33. Together with Definition 491.30, this prevents the consumer from reading any row outside the finite packet. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootTraceNormalFormLock`

Theorem 491.36 (HaltingDistinction root inscription-event lock)**.** *Every inscription-event consumer downstream of* $\mathsf{HaltingDistinction}^{\uparrow}$ *reads only the finite packet*

$$Q, T, Z, H, C, P, N.$$

The event may use the diagonal self-reference row and its displayed route, but the lock keeps that read inside the carrier, trace readability, diagonal boundary, root ledger non-escape, and joint sibling package surface.

Proof. Read the accepted carrier through Definition 491.28. The packet exposes Q, T, Z, H, C, P, N and no evaluator coordinate.

Apply Definition 491.3. The inscription event reaches Z only along the displayed route C, with Q and H supplying the certificate-history row and componentwise transports.

Now use Definition 491.6 to keep the surrounding trace data finite, and apply Definition 491.30 together with Definition 491.33. The inscription-event route is therefore locked to the same finite packet and cannot export total halting or host-truth data. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier root inscription event lock`

Theorem 491.37 (HaltingDistinction root diagonal route totality)**.** *Every diagonal consumer of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet factors through the finite route*

$$Q, T, Z, H, C, P, N.$$

The consumer may read the certificate-history pair, the finite trace segment, the diagonal self-reference row, the componentwise transports, the displayed route, provenance, and local ledger, but it cannot read a total halting predicate, host evaluator, divergence oracle, or global truth classifier.

Proof. Start with the diagonal boundary of Definition 491.3. Any public read that reaches the self-reference point reaches Z only through the displayed route over Q, T, H, C, P, N.

Next project the root carrier surface by Definition 491.28. It identifies Q, T, Z, H, C, P, N as the full accepted packet and supplies no evaluator coordinate outside those rows.

Finally apply Definition 491.30. The local ledger cannot be reinterpreted as a total halting predicate, host evaluator, divergence oracle, or global truth classifier, so every diagonal consumer is total only as a finite route through the displayed packet. □

Lean4 ✓ BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootDiagonalRouteTotality

Theorem 491.38 (HaltingDistinction root finite trace classifier exhaustion)**.** *Every finite trace classifier read from an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet is exhausted by the displayed packet*

$$Q, T, Z, H, C, P, N.$$

The classifier may inspect the finite Cont_P *trace row and transport the certificate-history pair through* H*, but no read remains after the trace row, pair-classifier transport, provenance row, and local ledger have been accounted for.*

Proof. First use Definition 491.6. A termination-facing classifier read must pass through the finite trace row T and the displayed route row C.

Next use Definition 491.5. The certificate-history pair row Q is classified only through the componentwise hsame transport recorded in H, with the diagonal branch still bounded by the displayed row Z.

It remains to account for provenance and naming. Apply Definition 491.8 and Definition 491.30; the rows P and N certify only the finite carrier and cannot supply a hidden classifier, total halting predicate, divergence oracle, or host evaluator. □

Lean4 ✓ BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootFiniteTraceClassifierExhaustion

Theorem 491.39 (HaltingDistinction root downstream unblock package)**.** *The obstruction, trace-normal-form, inscription-event, and halting-boundary consumers of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet receive only the finite packet*

$$Q, T, Z, H, C, P, N.$$

Their shared package consists of diagonal route totality, finite trace classifier exhaustion, the root obstruction handoff lock, the trace-normal-form lock, the inscription-event lock, and the downstream sibling joint package; it exports no total halting predicate, host evaluator, divergence oracle, or global truth classifier.

Lean4 ✓ BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootDownstreamUnblockPackage

Proof. First combine Definition 491.37 with Definition 491.38. These two results bind both diagonal reads and finite trace classifier reads to Q, T, Z, H, C, P, N.

Next read the named consumer locks. Definition 491.34, Definition 491.35, and Definition 491.36 give the obstruction, trace-normal-form, and inscription-event routes the same finite packet.

Finally apply Definition 491.33. Its joint sibling surface includes the halting-facing obstruction and trace consumers, so the assembled package unblocks those downstream routes without adding any global halting, evaluator, divergence, or truth-classifier row. □

Theorem 491.40 (HaltingDistinction route obstruction triad)**.** *Every obstruction-facing consumer of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet factors through the displayed*

$$Q, T, Z, H, C, P, N$$

route and the $\mathsf{HaltingObstruction}^{\uparrow}$ *sibling before it reads an obstruction ledger. The route consumes the certificate-history pair, finite trace row, diagonal row, componentwise transport, continuation replay, package provenance, and local naming row, and it exposes no total halting predicate, host evaluator, divergence oracle, or global truth classifier.*

Proof. Project the carrier of Definition 491.1. The only rows available to the obstruction-facing read are Q, T, Z, H, C, P, N.

Next apply Definition 491.3 and Definition 491.6. These route the self-reference and finite trace reads through Z and T along the displayed continuation row C, with transport supplied by H.

Now use the sibling route package Definition 491.15 and the joint package Definition 491.33. They attach the same finite packet to the $\mathsf{HaltingObstruction}^{\uparrow}$ ledger before any obstruction consumer is served.

Finally apply consumer non-escape from Definition 491.4. Since the displayed rows are exhausted by the routed packet and sibling handoff, no total halting predicate, host evaluator, divergence oracle, or global truth classifier remains available. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRouteObstructionTriad`

Theorem 491.41 (HaltingDistinction inscription trace gate)**.** *Every inscription-event consumer and every trace-normal-form consumer of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet can consume only the finite trace row T and the diagonal row Z through the displayed Q, H, C, P, N support rows. Neither route can read a total evaluator, a global halting predicate, a divergence oracle, or a host truth row.*

Proof. Begin with the carrier projection of Definition 491.1. It presents T as the finite continuation trace and Z as the diagonal self-reference row, with Q, H, C, P, N supplying the surrounding support.

For trace-normal-form consumers, apply Definition 491.31. The read reaches the finite trace row through C, with componentwise comparison data supplied by H and provenance supplied by P, N.

For inscription-event consumers, apply Definition 491.32. The read reaches the diagonal row Z only along the displayed route and never through a separate evaluator coordinate.

Use Definition 491.30 and Definition 491.4 to exhaust the remaining rows. The finite trace and diagonal gates therefore export no total evaluator, global halting predicate, divergence oracle, or host truth row. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionInscriptionTraceGate`

Theorem 491.42 (HaltingDistinction consumer boundary package)**.** *The obstruction, inscription-event, and trace-normal-form consumers of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet share one finite* BHist, Cont, hsame, Pkg, *and* $\mathsf{NameCert}$ *consumer package over*

$$Q, T, Z, H, C, P, N.$$

The package is exactly the obstruction route of Definition 491.40, the inscription and trace gate of Definition 491.41, and the downstream unblock package of Definition 491.39; it adds no global halting predicate, total evaluator, divergence oracle, or truth-classifier row.

Proof. First project Definition 491.1. The carrier gives the finite BHist packet Q, T, Z, H, C, P, N and no extra consumer coordinate.

Use Definition 491.40 for obstruction-facing consumers. This routes the obstruction ledger through the displayed packet and the $\mathsf{HaltingObstruction}^{\uparrow}$ sibling.

Use Definition 491.41 for inscription-event and trace-normal-form consumers. This binds those consumers to Z and T through the same Q, H, C, P, N support rows.

Finally compose the downstream package of Definition 491.39 with consumer non-escape in Definition 491.4. Coordinate exhaustion leaves a single finite $\mathsf{BHist}/\mathsf{Cont}/\mathsf{hsame}/\mathsf{Pkg}/\mathsf{NameCert}$ package and no hidden halting, evaluator, divergence, or truth-classifier row. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionConsumerBoundaryPackage`

Theorem 491.43 (HaltingDistinction root inscription trace totality)**.** *Every root obligation read of an accepted* HaltingDistinction$^{\uparrow}$ *packet exposes the inscription-event route only through the finite rows*

$$Q, T, Z, H, C, P, N.$$

The inscription event reads the diagonal row Z with the sibling trace row T, componentwise transports H, displayed route C, package provenance P, and local ledger N; it does not expose a total halting predicate, global truth predicate, host evaluator, divergence oracle, or hidden decision procedure.

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootInscriptionTraceTotality`

Proof. Project the carrier of Definition 491.1. The available rows are exactly Q, T, Z, H, C, P, N, with Z serving as the diagonal inscription row and T serving as the finite trace row.

Apply the inscription-event handoff and the inscription trace gate. They route the inscription read through Z and the surrounding support rows while keeping the trace-normal-form sibling attached to T.

Finally use the consumer boundary package. Since the package is exhausted by the finite BHist, Cont, hsame, Pkg, and NameCert rows, no total halting predicate, global truth predicate, host evaluator, divergence oracle, or hidden decision procedure can be read from the inscription route. □

Theorem 491.44 (HaltingDistinction root diagonal inscription nonescape)**.** *For an accepted* HaltingDistinction$^{\uparrow}$ *packet, the diagonal row Z cannot escape the root obligation surface as a halting decision. Any diagonal-inscription consumer reaches Z only along the displayed Q, T, H, C, P, N support, and the trace-normal-form sibling reads the same finite* Cont *route rather than a host evaluation row.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionRootDiagonalInscriptionNonescape`

Proof. Start with the diagonal boundary theorem and root ledger non-escape. They keep Z inside the local packet and forbid reinterpreting the diagonal row as evaluator data.

Use trace readability and the trace-normal-form handoff for the sibling route. The normal-form consumer reads T through the displayed continuation row C, with transports supplied by H and provenance by P, N.

The inscription-event handoff then binds the diagonal read to the same finite packet. Thus neither the diagonal row nor its trace-normal-form sibling yields a total halting predicate, global truth predicate, host evaluator, divergence oracle, or hidden decision procedure. □

Theorem 491.45 (HaltingDistinction root consumer obstruction exhaustion)**.** *Every obstruction-facing root consumer of an accepted* HaltingDistinction$^{\uparrow}$ *packet factors through the displayed carrier rows*

$$Q, T, Z, H, C, P, N$$

and the obstruction handoff route. The consumer may inspect the certificate-history pair, finite trace, diagonal inscription row, componentwise transports, displayed continuation route, provenance, and local NameCert *ledger, but it cannot add a total halting predicate, global truth predicate, host evaluator, divergence oracle, or hidden decision procedure.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionCarrier root consumer obstruction exhaustion`

Proof. Project the carrier rows and apply the route obstruction triad. This sends obstruction-facing consumption through the displayed packet and the $\mathsf{HaltingObstruction}^{\uparrow}$ sibling before any obstruction ledger is read.

Next apply the root inscription trace totality and root diagonal inscription nonescape theorems above. They bind the inscription and trace-normal-form sides to the same Q, T, Z, H, C, P, N surface.

Finally use the consumer boundary package with consumer non-escape. Coordinate exhaustion leaves only the finite obstruction handoff rows, so the downstream consumer receives no total halting predicate, global truth predicate, host evaluator, divergence oracle, or hidden decision procedure. □

Theorem 491.46 (HaltingDistinction observation boundary)**.** *Every observation-facing consumer of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *carrier must read the certificate-history pair, finite trace row, diagonal row, inscription-event row, trace-normal-form route, obstruction ledger, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows before any obstruction conclusion is exposed. The read is bounded by the finite BEDC rows*

$$Q, T, Z, H, C, P, N$$

and by the sibling surfaces of $\mathsf{HaltingDistinctionTrace}^{\uparrow}$, $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$, *and* $\mathsf{HaltingObstruction}^{\uparrow}$. *It does not expose a total halting predicate, host evaluator, divergence oracle, global truth classifier, or unbounded execution semantics.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionObservationBoundary`

Proof. First apply Definition 491.43. It sends observation of the inscription event through the finite diagonal row Z, trace row T, transports H, route row C, provenance row P, and local ledger N.

Next apply Definition 491.44. This keeps the diagonal inscription and trace-normal-form route inside the same finite continuation surface, so the consumer cannot reinterpret the read as host evaluation data.

Finally apply Definition 491.45 together with the sibling trace, inscription-event, trace-normal-form, and obstruction surfaces named in chapter 491. The obstruction-facing conclusion is therefore available only after the displayed certificate-history, trace, diagonal, inscription, normal-form, obstruction, transport, continuation, package, and naming rows have been read, and no total halting predicate, divergence oracle, global truth classifier, host evaluator, or unbounded execution semantics is introduced. □

Theorem 491.47 (HaltingDistinction public export package)**.** *The public export of an accepted* $\mathsf{HaltingDistinction}^{\uparrow}$ *packet factors through the bounded trace surfaces of chapter 280 and chapter 199, the* $\mathsf{HaltingDistinctionTrace}^{\uparrow}$ *row of chapter 492, the* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *route of chapter 683, the* $\mathsf{InscriptionEvent}^{\uparrow}$ *record of chapter 519, and the* $\mathsf{HaltingObstruction}^{\uparrow}$ *ledger of chapter 490. Only after those finite rows have been read may the package expose the obstruction boundary carried by* Q, T, Z, H, C, P, N.

Lean4 ✓ `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionPublicExportPackage`

Proof. First read the machine-facing surface. The public $\mathsf{TuringMachine}^{\uparrow}$ certificate of Definition 280.13 and the bounded $\mathsf{Computable}^{\uparrow}$ certificate of Definition 199.20 provide only finite configuration traces, bounded readbacks, and displayed provenance.

Next project the accepted $\mathsf{HaltingDistinction}^{\uparrow}$ packet through Definition 491.1. The local carrier supplies the certificate-history row Q, finite trace row T, diagonal row Z, componentwise transports H, continuation routes C, package provenance P, and local ledger N.

The sibling routes then refine this packet without adding an evaluator row. Apply Definition 491.4, Definition 491.45, and Definition 491.11; these force the trace, normal-form, inscription-event, and obstruction consumers to use the same finite rows.

Finally apply Definition 491.18 and Definition 491.42. The public package therefore exposes the finite obstruction boundary only after the bounded trace, distinction trace, normal-form, inscription-event, and obstruction ledgers have been consumed, and it exports no total halting predicate, divergence oracle, host evaluator, or global truth classifier. □

Closure status for $\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}$.

Constructive story: A $\mathsf{HaltingDistinction}^{\uparrow}$ packet is generated from a certificate-history pair row, a finite continuation trace row, a diagonal self-reference row, componentwise transports, displayed continuation routes, package provenance, and a local NameCert ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 491.1, Definition 491.2, Definition 491.3, Definition 491.4, Definition 491.45, Definition 491.42, and Definition 491.47 bind the finite carrier, naming obligations, diagonal boundary, root consumer obstruction exhaustion, downstream consumer package, and public export package.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{HaltingDistinction}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.HaltingDistinctionUp.HaltingDistinctionConsumerBoundaryPackage`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close a total halting predicate, global truth predicate, divergence oracle, host evaluator, classical termination decision, or bridge-checked standard model.

Upgrade path: No theory-axis upgrade remains; future work is only bridge verification if available.

Chapter 492

A Concrete Naming Certificate for $\mathsf{HaltingDistinctionTrace}^{\uparrow}$

The $\mathsf{HaltingDistinctionTrace}^{\uparrow}$ surface refines the halting-as-distinction interface of chapter 9368 to the finite trace actually inspected by a certificate-level diagonal reader. It records the visible continuation segment, the distinction classifier row, the self-application row, and the finite certificate routes through which the fixed-point obstruction is read.

The trace packet consumes the broader $\mathsf{HaltingDistinction}^{\uparrow}$ certificate-history pair and diagonal obstruction surface of chapter 491, while restricting the read to the finite trace rows A, T, D, E, H, C, P, N.

Definition 492.1 (HaltingDistinctionTrace carrier)**.** *A* $\mathsf{HaltingDistinctionTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (A, T, D, E, H, C, P, N)$$

with the following displayed rows:

1. *A is the admitted certificate-history input row, naming the program certificate and the history at which its visible behavior is read;*
2. *T is the finite* Cont *trace row, listing the displayed marks and histories available before any halting-facing distinction is asserted;*
3. *D is the distinction classifier row, reading only whether the trace exposes the displayed termination mark or remains inside the finite open trace;*
4. *E is the diagonal self-application row, asking the classifier in D about the same certificate-history row named by A;*
5. *H stores componentwise* hsame *transports for input, trace, distinction, diagonal, provenance, and local naming rows;*
6. *C stores the displayed* Cont *routes for replaying T, entering D, reaching E, and returning to the local ledger;*
7. *P is the* Pkg *provenance over* BHist, Ext, Cont, hsame, Pkg, *the distinction row, the diagonal row, and the surrounding* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{HaltingDistinctionTrace}^{\uparrow}}$ *row.*

The carrier contains no total halting predicate, no global truth predicate, no divergence detector, no host evaluator, and no classifier outside the displayed rows of R.

Lean4 ✓ BEDC.Derived.HaltingDistinctionTraceUp.HaltingDistinctionTraceTasteGate single carrier alignment

Theorem 492.2 (HaltingDistinctionTrace diagonal obstruction package)**.** *For an accepted* $\mathsf{HaltingDistinctionTrace}^{\uparrow}$ *carrier* $R = (A, T, D, E, H, C, P, N)$*, every certificate-level diagonal read of the halting-as-distinction obstruction factors through the finite route*

$$A \longmapsto T \longmapsto D \longmapsto E \longmapsto H \longmapsto C \longmapsto P \longmapsto N.$$

The route may expose that the classifier row D *is queried at its own certificate-history input through* E*, but it never exports a total halting predicate, a global truth predicate, a divergence detector, or a host-level evaluator. Thus the fixed-point obstruction is realized as finite* Cont*,* Ext*,* Pkg*, and* $\mathsf{NameCert}$ *rows.*

Lean4 ✓ BEDC.Derived.HaltingDistinctionTraceUp.HaltingDistinctionTraceDiagonalObstructionPackage

Proof. Project the accepted carrier of Definition 492.1. The only rows that can name the input, the visible execution segment, the distinction classifier, and the diagonal query are A, T, D, E.

Replay of the trace is controlled by the Cont routes in C. These routes inspect the displayed marks and histories in T before the distinction row D is read, so a consumer cannot replace the finite trace by an ambient evaluator.

The diagonal point is the row E. Componentwise transport is supplied by H, while P records provenance and N records the local naming certificate. These rows can identify the self-application site, but they do not add a truth predicate or a total decision principle.

Therefore every diagonal read remains inside the displayed route through A, T, D, E, H, C, P, N. The obstruction is the finite certificate-level self-query itself, carried by Cont, Ext, Pkg, and $\mathsf{NameCert}$ data rather than by any global halting classifier. □

Theorem 492.3 (HaltingDistinctionTrace diagonal readback)**.** *For an accepted* $\mathsf{HaltingDistinctionTrace}^{\uparrow}$ *carrier* $R = (A, T, D, E, H, C, P, N)$*, the diagonal row* E *can be read only after the finite trace row* T*, the distinction row* D*, and the continuation route* C *have been displayed. Thus the packet exposes a finite certificate-level self-query, not a direct global halting classifier.*

Proof. Start from the carrier of Definition 492.1. The diagonal row E is a displayed coordinate of the same finite packet as A, T, D, H, C, P, N, and the carrier has no coordinate for a global classifier.

Apply the diagonal obstruction package of Definition 492.2. It factors every diagonal read through the finite route from the admitted input to the trace row, then to the distinction row, then to the diagonal self-application row.

The surrounding $\mathsf{HaltingDistinction}^{\uparrow}$ surface of chapter 491 supplies the distinction context, but the trace packet keeps the read inside T, D, E, C. Therefore a consumer reads the diagonal row only through the displayed finite trace route. □

Theorem 492.4 (HaltingDistinctionTrace provenance non-escape)**.** *For an accepted* $\mathsf{HaltingDistinctionTrace}^{\uparrow}$ *carrier* $R = (A, T, D, E, H, C, P, N)$*, the provenance row* P *and local* $\mathsf{NameCert}_{\mathsf{HaltingDistinctionTrace}^{\uparrow}}$ *row* N *package only the displayed rows* A, T, D, E, H, C*. They cannot turn the packet into a total halting predicate, divergence detector, host evaluator, or truth predicate.*

Proof. Read P and N in the carrier definition. Their provenance and naming scope is the finite packet A, T, D, E, H, C, P, N, with P naming the displayed BEDC objects and N naming the local certificate.

Use Definition 492.3. The only diagonal information available to P, N is the self-query route through the finite trace, distinction row, and continuation route.

Finally apply the non-export clause of Definition 492.2. Since the obstruction package itself exports no total halting predicate, global truth predicate, divergence detector, or host-level evaluator, the provenance and naming rows cannot export those objects either. □

Theorem 492.5 (HaltingDistinctionTrace scoped consumer factorization)**.** *For an accepted* HaltingDistinctionTrace *carrier* $R = (A, T, D, E, H, C, P, N)$*, every consumer read of the trace packet factors through the displayed rows*

$$A \to T \to D \to E \to H \to C \to P \to N.$$

The broader $\mathsf{HaltingDistinction}^{\uparrow}$ *certificate-history and diagonal obstruction context of chapter 491 is consumed only through the admitted input row* A*, the distinction classifier row* D*, and the diagonal self-application row* E*; it does not add a total halting predicate, truth predicate, divergence detector, or host evaluator.*

Proof. Project the carrier of Definition 492.1. The rows A, T, D, E, H, C, P, N are the complete finite packet visible to a consumer.

Use diagonal readback and provenance non-escape. They place every diagonal self-query behind the finite trace row T, the distinction row D, and the continuation route C, and they keep provenance and local naming inside the displayed packet.

Now insert the surrounding $\mathsf{HaltingDistinction}^{\uparrow}$ context through chapter 491. That context supplies the certificate-history and distinction surface read by A, D, E, but the trace packet exposes it only through those displayed rows. Hence every consumer read factors through A, T, D, E, H, C, P, N and cannot import global halting content. □

Theorem 492.6 (HaltingDistinctionTrace scoped transport non-escape)**.** *Let* $R = (A, T, D, E, H, C, P, N)$ *and* $R' = (A', T', D', E', H', C', P', N')$ *be accepted* $\mathsf{HaltingDistinctionTrace}^{\uparrow}$ *carriers. If the componentwise* hsame *rows in* H *and* H' *identify the admitted input, finite trace, distinction classifier, diagonal self-application, replay, provenance, and local naming rows, then transport preserves the route from trace to distinction to diagonal self-query. The transported packet still exports no total halting predicate, truth predicate, divergence detector, or host evaluation row.*

Proof. Read the componentwise transport rows. Their scope is exactly the displayed coordinates A, T, D, E, C, P, N of the two accepted trace packets, with no coordinate for an external evaluator or global classifier.

Apply scoped consumer factorization to both packets. Each consumer route first reads the admitted input and finite trace, then the distinction classifier and diagonal self-application, and finally the transport, replay, provenance, and local naming rows.

The hsame rows preserve those coordinates component by component. Therefore the transported read has the same trace, distinction, and diagonal route as the original packet. Since neither packet contains total halting, truth, divergence, or host-evaluation coordinates, transport cannot export them. □

Theorem 492.7 (HaltingDistinctionTrace bridge readback)**.** *For any bridge request addressed to* $\mathsf{HaltingDistinctionTrace}^{\uparrow}$*, the displayed tuple*

$$R = (A, T, D, E, H, C, P, N)$$

is the fixed trace readback surface. The request may read the admitted certificate-history input, finite continuation trace, distinction classifier, diagonal self-application, componentwise transports,

displayed continuation routes, package provenance, and local naming row, but it cannot read a total halting predicate, divergence detector, truth predicate, or host evaluator.

Proof. Project the carrier of Definition 492.1. The only rows exposed by the packet are A, T, D, E, H, C, P, N.

Apply Definition 492.2 and Definition 492.3. They place the diagonal self-query behind the finite trace and distinction rows, so bridge readback reaches the obstruction only through the displayed tuple.

Use Definition 492.5 and Definition 492.6. These rows keep every consumer and transported read inside the same finite trace packet, with no coordinate for a total halting predicate or host evaluator. □

Theorem 492.8 (HaltingDistinctionTrace obstruction handoff)**.** *Every* $\mathsf{HaltingObstruction}^{\uparrow}$ *consumer of an accepted* $\mathsf{HaltingDistinctionTrace}^{\uparrow}$ *packet can read only the finite trace row* T*, distinction classifier row* D*, and diagonal self-query row* E*, together with the attached input, transport, route, provenance, and naming rows. The handoff carries the finite obstruction surface, not a total halting predicate or external evaluation oracle.*

Proof. Start with Definition 492.7. Any bridge-facing request reads the fixed tuple A, T, D, E, H, C, P, N.

The obstruction part of that tuple is T, D, E. By Definition 492.2, the diagonal obstruction is the finite route from the admitted input through the trace and distinction rows to the self-query row.

Apply Definition 492.4 and Definition 492.5. Provenance, naming, and consumer access remain attached to the displayed packet, so a $\mathsf{HaltingObstruction}^{\uparrow}$ consumer receives only the finite trace, distinction, and diagonal self-query rows with their recorded routes. □

Theorem 492.9 (HaltingDistinctionTrace mature boundary readback)**.** *Every mature consumer read of an accepted* $\mathsf{HaltingDistinctionTrace}^{\uparrow}$ *packet factors through the displayed rows*

$$A \longmapsto T \longmapsto D \longmapsto E \longmapsto H \longmapsto C \longmapsto P \longmapsto N.$$

The read combines the diagonal obstruction package, bridge readback, and obstruction handoff, and still receives no total halting predicate, global truth predicate, divergence detector, or host evaluator.

Proof. Begin with Definition 492.2. It identifies the diagonal obstruction as the finite route through the admitted input, trace, distinction classifier, self-application row, transport, replay, provenance, and local naming rows.

Apply Definition 492.7. A bridge-facing mature request reads the same tuple A, T, D, E, H, C, P, N and no external halting coordinate.

Finally use Definition 492.8. The obstruction consumer receives only the finite trace, distinction, and diagonal self-query with their attached structural rows, so the mature readback boundary contains no total predicate, truth predicate, divergence detector, or host evaluator. □

Closure status for $\mathsf{NameCert}_{\mathsf{HaltingDistinctionTrace}^{\uparrow}}$.

Constructive story: A $\mathsf{HaltingDistinctionTrace}^{\uparrow}$ packet is generated from an admitted certificate-history input row, a finite continuation trace row, a distinction classifier row, a diagonal self-application row, componentwise transports, displayed continuation routes, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{HaltingDistinctionTrace}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 492.1, Definition 492.2, Definition 492.3, Definition 492.4, Definition 492.5, Definition 492.6, Definition 492.7, Definition 492.8, and Definition 492.9 bind the finite trace carrier, diagonal readback route, scoped consumer factorization, componentwise transport, provenance non-escape boundary, bridge readback surface, obstruction handoff, and mature boundary readback.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{HaltingDistinctionTrace}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.HaltingDistinctionTraceUp.HaltingDistinctionTraceDiagonalObstructionPackage`
Bridge status: paperBridge
Origin: human
Not claimed: This chapter does not close a total halting predicate, a global truth predicate, divergence detection, host evaluation, or checked bridge certificate.
Upgrade path: Bridged closure requires a standard bridge for the displayed trace packet while preserving the independent formal-status axis.

Chapter 493

A Concrete Naming Certificate for $\mathsf{DecidableRefutation}^{\uparrow}$

The $\mathsf{DecidableRefutation}^{\uparrow}$ surface turns the permitted and forbidden contradiction boundary of chapter 9458 into a finite naming packet. It records the proposition row being inspected, the constructive refutation witness, the optional decidability route, the exclusion bits for forbidden schemas, and the provenance rows through which a consumer may read the packet. It consumes the permitted-route carrier of chapter 501 and adds the optional same-row decision coordinate that governs when double-negation consumption is allowed. The surface does not certify classical excluded middle, host truth, or a global decision procedure over naming certificates.

The permitted refutation witness row is the local consumer of chapter 501, while the exclusion bits are read through chapter 500. $\mathsf{DecidableRefutation}^{\uparrow}$ adds an optional decidability row and a truth-branch exclusion ledger over those sibling refutation surfaces, rather than replacing either the constructive route or the boundary packet.

Definition 493.1 (DecidableRefutation carrier)**.** *A* $\mathsf{DecidableRefutation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (A, F, D, X, H, C, P, N)$$

with the following displayed rows:

1. *A is the proposition row being inspected, represented as a certificate-visible predicate read over the current finite history;*
2. *F is a permitted refutation witness, namely a displayed route from an assumed witness of A to $\bot$ through* Cont*,* hsame*,* msame*, and the local certificate rows;*
3. *D is an optional decidability row for A, present only when the packet carries a constructive branch witness for the same proposition row;*
4. *X records the exclusion bits for the forbidden schemas of Definition 9458.5: unwitnessed existential extraction, double-negation elimination without D, and excluded-middle branching over the carrier of all naming certificates;*
5. *H records componentwise* hsame *transports for A, F, D, X, package rows, and local naming rows;*
6. *C records the displayed* Cont *routes for reading the proposition row, replaying the permitted refutation, consuming the optional decidability row, and checking the forbidden-schema exclusions;*

7. *P is the* Pkg *provenance over* BHist, Ext, Cont, msame, hsame, *the local proof rows, and the surrounding* NameCert *rows;*

8. *N is the local* $\mathsf{NameCert}_{\mathsf{DecidableRefutation}^{\uparrow}}$ *ledger.*

The carrier contains no host truth predicate, no global excluded-middle oracle, no selected witness for an existential obtained by contradiction, and no branch over the carrier of all naming certificates.

Lean4 ✓ `BEDC.Derived.DecidableRefutationUp.DecidableRefutationTasteGate single carrier alignment`

Definition 493.2 (DecidableRefutation classifier)**.** *Two accepted* $\mathsf{DecidableRefutation}^{\uparrow}$ *carriers*

$$R = (A, F, D, X, H, C, P, N) \quad \textit{and} \quad R' = (A', F', D', X', H', C', P', N')$$

are classified together exactly when their visible proposition rows are matched by the displayed hsame *transports, their permitted refutation witnesses replay through the displayed* Cont *routes, their optional decidability rows have the same displayed presence shape, and their forbidden-schema exclusion bits agree componentwise.*

The classifier compares only A, F, D, X, H, C, P, N and $A', F', D', X', H', C', P', N'$. It has no coordinate for ambient truth, no host-level proof search, no quotient over proofs, and no classifier over the carrier of all naming certificates.

Theorem 493.3 (DecidableRefutation NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DecidableRefutation}^{\uparrow}}$ *surface consists of five obligations:*

1. *carrier admission for the finite packet $R = (A, F, D, X, H, C, P, N)$ of Definition 493.1;*

2. *classifier soundness for Definition 493.2, comparing only the displayed proposition, refutation, optional decidability, exclusion, transport, continuation, package, and naming rows;*

3. *permitted-negation transport, saying that a refutation witness F remains a proof of $\neg A$ under the stored* hsame *transports and displayed* Cont *routes;*

4. *decidable double-negation route, saying that $\neg\neg A$ may be consumed only when the row D displays a constructive decision for the same proposition row A;*

5. *non-escape from certificate-indexed truth branches, saying that the packet cannot export excluded middle over all naming certificates, unwitnessed existential extraction, or double-negation elimination without the displayed decidability row.*

Lean4 ✓ `BEDC.Derived.DecidableRefutationUp.DecidableRefutationUp taste gate boundary`

Proof. Carrier admission is projection from Definition 493.1. The only available rows are the proposition row, permitted refutation witness, optional decidability row, exclusion ledger, transport rows, continuation routes, package provenance, and local naming ledger.

Classifier soundness follows from Definition 493.2. A comparison replays only the displayed proposition-row match, the refutation route, the optional decidability shape, and the exclusion bits through the stored hsame and Cont data.

For permitted-negation transport, read the refutation witness F as a route from an assumed witness of A to $\bot$. Transporting A and F along H and replaying the route in C yields the same certificate-level negation, because no step leaves the displayed ground-loop rows.

For the decidable double-negation route, the row D is the only coordinate that supplies a constructive branch for A. If D is absent, the exclusion ledger X blocks the double-negation

schema named in Definition 9458.5; if D is present, the branch is consumed inside the same finite packet.

Finally, the non-escape clause is exactly the absence of a certificate-indexed truth branch coordinate. The packet contains no row classifying all naming certificates, no witness selector for existential-by-contradiction, and no host truth predicate, so every consumer remains inside A, F, D, X, H, C, P, N. □

Theorem 493.4 (DecidableRefutation classifier transport)**.** *Let $R = (A, F, D, X, H, C, P, N)$ and $R' = (A', F', D', X', H', C', P', N')$ be accepted* $\mathsf{DecidableRefutation}^{\uparrow}$ *packets. If the classifier of Definition 493.2 relates R and R', then every transported public read is one of the proposition rows A, A', the refutation rows F, F', the optional decidability rows D, D', the exclusion rows X, X', the displayed* hsame *rows H, H', the* Cont *routes C, C', the* Pkg *rows P, P', or the local* $\mathsf{NameCert}$ *rows N, N'.*

No transported read can introduce a parameter-transport theorem, an ambient truth row, a global decision procedure, or a classifier over all naming certificates.

Proof. Start with the checked TasteGate single-carrier row attached to Definition 493.1. It says the accepted object is the one finite carrier surface $R = (A, F, D, X, H, C, P, N)$, so a classifier comparison has no second hidden carrier from which to read extra rows.

Now unfold the classifier in Definition 493.2. The comparison names only the displayed proposition, refutation, optional decidability, exclusion, transport, continuation, package, and NameCert coordinates on the two packets.

The transported public read is therefore a projection through H, H' and C, C' followed by a read of one of A, F, D, X, P, N or A', F', D', X', P', N'. Since the carrier has no coordinate for parameter families, host truth, global decision, or a classifier over all certificates, none of those objects can be exported. □

Theorem 493.5 (DecidableRefutation truth-branch exclusion)**.** *No consumer of an accepted* $\mathsf{DecidableRefutation}^{\uparrow}$ *packet can extract either excluded middle over the carrier of all NameCerts or an existential-by-contradiction witness from the packet. The only branch row available to the consumer is the optional decidability coordinate D for the same displayed proposition row A, and the exclusion coordinate X blocks every branch not licensed by that row.*

Proof. Read the packet through the checked TasteGate single-carrier row and the carrier fields of Definition 493.1. The carrier lists A, F, D, X, H, C, P, N and no coordinate for a truth predicate over all NameCerts.

If D is present, it is a decision row for the same proposition row A. It does not range over arbitrary naming certificates and does not choose witnesses for unrelated existential statements.

If D is absent, the exclusion row X records the forbidden schemas from Definition 9458.5. Thus excluded-middle branching over all certificates and existential-by-contradiction witness extraction both stop at X rather than becoming exported data. □

Theorem 493.6 (DecidableRefutation obligation package)**.** *The* $\mathsf{DecidableRefutation}^{\uparrow}$ *paper obligation package consists of carrier admission for Definition 493.1, classifier transport by Definition 493.4, permitted-negation transport from Definition 493.3, the decidable double-negation route named by the same obligation surface, and truth-branch exclusion by Definition 493.5.*

This package is single-carrier: it cites the checked TasteGate row for the displayed packet $R = (A, F, D, X, H, C, P, N)$ and does not add a parameter-transport theorem.

Proof. Carrier admission is the tuple projection from Definition 493.1. The checked TasteGate single-carrier row fixes the admissible surface to the same eight coordinates, so the package begins with a single finite packet.

Classifier transport is supplied by Definition 493.4. It keeps all public reads inside the proposition, refutation, optional decidability, exclusion, hsame, Cont, Pkg, and NameCert rows.

The permitted-negation and decidable double-negation routes are the third and fourth obligations of Definition 493.3. They allow a displayed refutation route and a displayed decision row for A while refusing a free-standing truth branch.

Finally, Definition 493.5 supplies the boundary clause. Repacking these rows gives the obligation package without parameter transport, host truth, certificate-wide excluded middle, or witness selection by contradiction. □

Closure status for $\mathsf{NameCert}_{\mathsf{DecidableRefutation}\uparrow}$.

Constructive story: A $\mathsf{DecidableRefutation}^{\uparrow}$ packet is generated from a proposition row, a permitted refutation witness, an optional decidability row, forbidden-schema exclusion bits, componentwise transports, displayed continuation routes, package provenance, and a local naming ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DecidableRefutation}\uparrow}, \mathsf{scopedClosed})$

Scope closed: Definition 493.1, Definition 493.2, Definition 493.3, Definition 493.4, Definition 493.5, and Definition 493.6 bind the carrier, classifier, NameCert obligations, classifier transport, truth-branch exclusion, and paper obligation package.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DecidableRefutation}\uparrow}, \mathsf{axiomClean})$

Lean4 ✓ `BEDC.Derived.DecidableRefutationUp.taste gate`

Lean target: `BEDC.Derived.DecidableRefutationUp.DecidableRefutationUp\_taste\_gate\_boundary`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close classical excluded middle, global truth over naming certificates, existential-by-contradiction witness selection, or a checked Lean certificate.

Upgrade path: Public closure requires a public single-carrier export theorem over the displayed packet.

Chapter 494

A Concrete Naming Certificate for $\mathsf{SelectorLedger}^{\uparrow}$

The $\mathsf{SelectorLedger}^{\uparrow}$ interface packages the Empty-fable trace surface as a finite naming certificate. It records a generated history, the trace read from its constructor spine, the displayed selector-step witnesses that justify each realized branch, and the finite transport and continuation rows that make the ledger consumable by later NameCert packets. The packet does not assert a global branch selector, a truth oracle, a host list quotient, or a choice principle.

Definition 494.1 (Selector ledger carrier)**.** *A* $\mathsf{SelectorLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (h, T, S, H, C, P, N)$$

with the following displayed coordinates:

1. *h is the generated* Hist *row whose constructor spine is being read;*
2. *T is the finite* Trace *row for h, read only from* e, E0, E1, *and* Ext *constructors;*
3. *S is the finite list of* SelStep *witnesses, one for each non-empty trace edge, each exposing the enacted mark, the* Ext *step, and the local branch certificate;*
4. *H stores the componentwise* hsame *transports for the history row, trace row, and selector-step witnesses;*
5. *C stores the* Cont *routes that read the generated history, each trace edge, and each selector witness;*
6. *P is the* Pkg *provenance over* BHist, Hist, Ext, Trace, SelStep, hsame, Cont, Pkg, *and* NameCert*;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{SelectorLedger}^{\uparrow}}$ *row.*

The carrier is this finite packet. It contains no global chooser, no hidden branch function, no host equality of traces, and no oracle row.

Lean4 ✓ `BEDC.Derived.SelectorLedgerUp.SelectorLedgerCarrier public trace readback`

Theorem 494.2 (SelectorLedger NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{SelectorLedger}^{\uparrow}}$ *surface for the carrier of Definition 494.1 consists exactly of carrier admission for L, trace admission for T, selector-step admission for every row of S, transport of the history, trace, and selector witnesses by the displayed* hsame *rows in H, continuation reads through C, package provenance through P, and the local naming row N.*

Every obligation is read from BHist*,* Ext*,* Trace*,* SelStep*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. The certificate exports no branch selector beyond the displayed selector-step witnesses.*

Proof. Carrier admission is projection from the finite packet L. The history row, trace row, selector-step list, transport rows, continuation routes, package provenance, and local naming row are all displayed coordinates.

Trace admission reads T from the constructor spine of h. Each non-empty edge in that trace is matched with one selector-step witness in S, and each such witness exposes the enacted mark together with the corresponding Ext row.

The transport and continuation obligations are exactly the rows H and C. They move the displayed history, trace, and selector witnesses componentwise while preserving the same package provenance and local naming row. Since the carrier has no further selector coordinate, the certificate has no hidden choice field to export. □

Lean4 ✓ `BEDC.Derived.SelectorLedgerUp.SelectorLedgerNameCertObligations`

Theorem 494.3 (SelectorLedger trace soundness)**.** *For every accepted* $\mathsf{SelectorLedger}^{\uparrow}$ *carrier* $L = (h, T, S, H, C, P, N)$*, the exported ledger trace* T *is sound for the generated history* h*: each mark in* T *is justified by a displayed* SelStep *row in* S*, each such selector row contains an* Ext *step from the previous history to the next history, and the final history reached by the finite chain is* hsame*-equivalent to* h *through the rows recorded in* H *and read through* C*.*

Thus every downstream consumer of the ledger receives a finite Empty-fable trace with explicit branch witnesses, not a global selector or external choice function.

Lean4 ✓ `BEDC.Derived.SelectorLedgerUp.SelectorLedgerTasteGate single carrier alignment`

Proof. Start with the trace coordinate T. By the carrier definition, T is the trace row associated with the generated history h, and no other trace coordinate is present.

Proceed along the finite trace. For the empty trace, the history row is the empty boundary row and the selector list is empty. For a non-empty trace, the next selector-step row in S exposes a mark, an Ext step, and a local branch certificate, so the next history in the chain is displayed.

After all trace entries are consumed, the stored hsame rows in H compare the reached history with h, and the continuation rows in C expose the read to downstream consumers. The argument never introduces a chooser beyond the selector witness already stored for that edge. □

Theorem 494.4 (SelectorLedger no hidden choice)**.** *Every consumer read of an accepted* $\mathsf{SelectorLedger}^{\uparrow}$ *carrier factors through the displayed tuple* h, T, S, H, C, P, N*. In particular, branch information can be read only as a finite* SelStep *witness whose mark and* Ext *row are visible, and trace information can be read only through the finite* Trace *row transported by* hsame *and* Cont*.*

The packet therefore exposes the Empty-fable selector ledger as a finite $\mathsf{NameCert}_{\mathsf{SelectorLedger}^{\uparrow}}$ *surface and exports no global choice function, hidden chooser, host trace quotient, or truth oracle.*

Lean4 ✓ `BEDC.Derived.SelectorLedgerUp.SelectorLedgerNoHiddenChoice`

Proof. Inspect the carrier inventory. The only branch-facing coordinate is the finite selector-step list S, and the only sequence-facing coordinate is the trace row T.

A branch read must therefore project a row of S. That projection exposes the mark, the Ext step, and the local branch certificate, so the selector is a visible witness rather than a hidden function.

A trace read must project T and then transport it through H and C. Package provenance and the naming row record that this is the whole public surface. Since no coordinate names a global chooser, host trace quotient, or oracle, none can be exported. □

Theorem 494.5 (SelectorLedger inscription-event consumer route)**.** *Every accepted* $\mathsf{SelectorLedger}^{\uparrow}$ *consumer route that is used as public record data factors as an* $\mathsf{InscriptionEvent}^{\uparrow}$*-style consumer route through displayed history, trace, selector-step witness, accepted continuation, intended consumer, and local* GAP *and provenance rows, in the sense of chapter 519.*

Thus the public record view of a selector ledger is not a standalone chooser interface. It is finite inscription-event route data whose readable branch content is already exposed by the displayed ledger packet.

Lean4 ✓ `BEDC.Derived.SelectorLedgerUp.SelectorLedgerInscriptionEventConsumerRoute`

Proof. Write the accepted selector ledger as $L = (h, T, S, H, C, P, N)$. By Definition 494.4, any consumer read of L can reach branch information only by projecting a displayed SelStep row from S, and can reach trace information only through the finite trace row T transported by the displayed hsame and Cont rows in H and C.

Compare this projected packet with the inscription-event carrier of chapter 519. The displayed history row supplies the source record state, the trace and selector-step row supply the named route witness, the accepted continuation row supplies the checkable public route, the intended consumer is the consumer of the selector-ledger read, and the local GAP, package, and naming rows are the public ledger/provenance data.

The factorization is therefore finite and public: it uses only h, T, S, H, C, P, N and the inscription-event source/name/route/check/consumer/GAP packet shape. No step introduces a global branch chooser, a hidden host trace quotient, or a record mutation outside the displayed carrier. □

Closure status for $\mathsf{NameCert}_{\mathsf{SelectorLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{SelectorLedger}^{\uparrow}$ packet is generated from a displayed Hist row, its finite Trace row, explicit SelStep witnesses for realized branch edges, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{SelectorLedger}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public object surface is exactly the displayed selector carrier, trace soundness, selector-step exposure, inscription-event consumer route, componentwise transport, continuation replay, and no-hidden-choice rows over BHist, Hist, Ext, Trace, SelStep, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{SelectorLedger}^{\uparrow}}$, unformalized)

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close a Lean implementation, bridge status, global branch selection, host trace quotient, truth oracle, or any choice principle.

Upgrade path: No paper-side theory upgrade remains for the displayed selector ledger; Lean verification and bridge checking remain outside this chapter.

Chapter 495

A Concrete Naming Certificate for $\mathsf{HaltingDistinctionLimit}^{\uparrow}$

The $\mathsf{HaltingDistinctionLimit}^{\uparrow}$ surface packages the halting fixed-point obstruction as finite BEDC data. It names the program certificate row, the input history row, the visible continuation trace, the diagonal obstruction row, the transport and route ledgers, the package provenance, and the local naming certificate through which the obstruction is read. It consumes the finite diagonal fixed-point package of chapter 496: program row, input history, self-reference row, fixed Cont row, diagonal policy, and hsame/Cont/Pkg/NameCert provenance are read before the non-decision boundary is exposed. It does not decide halting and does not introduce a halting oracle.

Definition 495.1 (Halting distinction limit carrier)**.** *A* $\mathsf{HaltingDistinctionLimit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (P, h, T, D, H, C, K, N)$$

with the following displayed rows:

1. *P is the program and certificate row, naming the candidate program certificate together with the local* $\mathsf{NameCert}_P$ *row by which the classifier is addressed;*
2. *h is the input history row whose continuation behaviour is being inspected;*
3. *T is the finite trace row recording the displayed* Cont_P *segment from h through the marks and histories visible to the packet;*
4. *D is the diagonal obstruction row, naming the self-application read in which the classifier for (P, h) is queried at the same program-history position;*
5. *H records the componentwise* hsame *transports for program rows, input histories, trace rows, diagonal rows, provenance rows, and local naming rows;*
6. *C records the displayed* Cont *routes that read the input history, replay the finite trace, enter the diagonal obstruction row, and return the read to the local ledger;*
7. *K is the* Pkg *provenance over* BHist, Ext, Cont, hsame, *classifier transport, diagonal rows, and the surrounding certificate rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{HaltingDistinctionLimit}^{\uparrow}}$ *ledger.*

The packet has no coordinate for a total halting predicate, divergence oracle, global truth predicate, or host evaluator outside P, h, T, D, H, C, K, N.

Lean4 (definition) `BEDC.Derived.HaltingDistinctionLimitUp.HaltingDistinctionLimitCarrier`

Definition 495.2 (Halting distinction limit classifier)**.** *The* $\mathsf{HaltingDistinctionLimit}^{\uparrow}$ *classifier compares two accepted packets only by the displayed rows of Definition 495.1. It relates*

$$L = (P, h, T, D, H, C, K, N)$$

and

$$L' = (P', h', T', D', H', C', K', N')$$

when the program-certificate rows, input histories, trace rows, diagonal obstruction rows, transport ledgers, continuation routes, package provenance, and local naming rows are related by the recorded componentwise hsame *and* Cont *data. It does not compare hidden machine states, meta-level evaluator results, or truth values for unrecorded program-history pairs.*

Lean4 (definition) `BEDC.Derived.HaltingDistinctionLimitUp.HaltingDistinctionLimitClassifier`

Theorem 495.3 (Halting fixed-point boundary)**.** *For every accepted* $\mathsf{HaltingDistinctionLimit}^{\uparrow}$ *packet* $L = (P, h, T, D, H, C, K, N)$*, any public read of the diagonal obstruction reaches the fixed-point boundary only through the displayed route from the program-certificate row and input history row, through the finite trace row* T*, into the diagonal row* D*, and back through the transport, continuation, package, and local naming ledgers.*

The proof source is the BEDC reflection theorem `BEDC.Reflection.halting_as_form_of_distinction_fixe` *the self-application obstruction is a boundary on total classifier extension, not a construction of a halting decision procedure.*

Proof. Project the packet through Definition 495.1. The only rows that can name the tested computation are P, h, T, and D, with H, C, K, and N recording the allowed transports, routes, provenance, and local naming.

Use the classifier of Definition 495.2. A transported read can compare only the displayed program-certificate, input-history, trace, diagonal, route, and provenance rows. No hidden evaluator coordinate is available.

At the diagonal row D, apply the fixed-point obstruction expressed by `BEDC.Reflection.halting_as_form_of` The obstruction identifies the boundary where a classifier cannot be extended into a total halting decision over its own input surface.

Therefore the packet realizes the fixed-point boundary as a finite naming certificate. It records the obstruction route and excludes any export of a total halting predicate or divergence oracle. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionLimitUp.HaltingDistinctionLimitFixedPointBoundary`

Theorem 495.4 (Halting distinction limit NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{HaltingDistinctionLimit}^{\uparrow}}$ *surface has five finite obligations:*

1. *carrier admission for packets* $L = (P, h, T, D, H, C, K, N)$ *of Definition 495.1;*
2. *classifier transport through the displayed* hsame *rows and* Cont *routes of Definition 495.2;*
3. *fixed-point boundary exposure through the diagonal row* D *and Definition 495.3;*
4. *non-decision ledger discipline, saying that* T *records only a finite trace and* D *records only the diagonal obstruction route;*
5. *downstream non-escape, saying that consumers cannot extract a total halting predicate, divergence oracle, global truth predicate, host evaluator, or unrecorded classifier.*

Proof. Carrier admission is the finite packet of Definition 495.1. Each obligation row is one of the displayed coordinates P, h, T, D, H, C, K, N.

Classifier transport is supplied by Definition 495.2. The only comparisons are componentwise comparisons of named program-certificate rows, histories, traces, diagonal rows, routes, provenance, and local naming ledgers.

The fixed-point boundary is Definition 495.3. It routes the self-application read to D and stops at the obstruction boundary.

The non-decision ledger follows because the trace row is finite and the diagonal row is a boundary row. Neither row supplies a total truth predicate or a divergence oracle.

For downstream consumers, inspect the carrier again. Every exported read is one of P, h, T, D, H, C, K, N, so no host evaluator, unrecorded classifier, or global halting decision can leave the packet. □

Lean4 ✓ `BEDC.Derived.HaltingDistinctionLimitUp.HaltingDistinctionLimitNameCertObligations`

Theorem 495.5 (Halting distinction limit sibling boundary)**.** *Every diagonal obstruction read in an accepted* $\mathsf{HaltingDistinctionLimit}^{\uparrow}$ *packet factors through the obstruction classifier boundary supplied by chapter 490 and the fixed-point vision boundary of chapter 9368. The exported surface remains only*

$$P, h, T, D, H, C, K, N,$$

and it does not become a halting decision procedure.

Lean4 ✓ `BEDC.Derived.HaltingDistinctionLimitUp.HaltingDistinctionLimitPacket sibling boundary`

Proof. Project the local carrier of Definition 495.1. The only obstruction-facing rows are the program row P, input history h, finite trace T, diagonal row D, and the structural rows H, C, K, N.

The classifier of Definition 495.2 permits comparison only through those displayed rows. Thus a diagonal read cannot bypass the local packet and cannot add a total halting predicate.

Apply Definition 495.3 and Definition 495.4. They route the self-application read through D and keep the trace finite before any downstream consumer can see the obstruction.

The sibling packet of chapter 490 is exactly the downstream obstruction classifier boundary, and chapter 9368 names the fixed-point limit being exposed. Therefore the public read factors through that sibling boundary while exporting only P, h, T, D, H, C, K, N. □

Theorem 495.6 (Halting distinction limit public boundary)**.** *The public* $\mathsf{HaltingDistinctionLimit}^{\uparrow}$ *interface exports only the finite fixed-point obstruction route*

$$P, h, T, D, H, C, K, N.$$

It names the program-certificate row, input history row, finite trace row, diagonal obstruction row, componentwise transport, displayed continuation routes, package provenance, and local naming certificate. It does not export a total halting predicate, divergence oracle, global truth predicate, host evaluator, or unrecorded classifier.

Lean4 ✓ `BEDC.Derived.HaltingDistinctionLimitUp.HaltingDistinctionLimitPublicBoundary`

Proof. Project the carrier of Definition 495.1. Its public coordinates are exactly P, h, T, D, H, C, K, N.

Apply Definition 495.3. The diagonal read reaches only the fixed-point obstruction boundary through those displayed rows.

Apply Definition 495.4 and Definition 495.5. The local certificate and sibling boundary preserve the same finite route, so no total halting predicate, divergence oracle, global truth predicate, host evaluator, or unrecorded classifier is available to a public consumer. □

Theorem 495.7 (Halting distinction limit bridge boundary)**.** *The public* HaltingDistinctionLimit$^{\uparrow}$ *route*

$$P, h, T, D, H, C, K, N$$

can bridge to the HaltingObstruction$^{\uparrow}$ *sibling only as a finite obstruction-classifier boundary. The bridge target may read the displayed program-certificate row, input history row, finite trace row, diagonal obstruction row, transports, routes, provenance, and local naming, but it cannot export a total halting predicate, divergence oracle, global truth predicate, host evaluator, or unrecorded classifier.*

Lean4 ✓ `BEDC.Derived.HaltingDistinctionLimitUp.HaltingDistinctionLimitCarrier bridge boundary`

Proof. Project the carrier of Definition 495.1. The only public route is the finite packet P, h, T, D, H, C, K, N.

Apply the fixed-point boundary Definition 495.3. The diagonal read reaches the obstruction point through D and stops at the boundary on total classifier extension.

Use the NameCert obligations of Definition 495.4. They keep the trace finite, keep the diagonal row as an obstruction row, and require all downstream reads to remain inside the displayed carrier.

Now apply the sibling boundary Definition 495.5 and the public boundary Definition 495.6. The HaltingObstruction$^{\uparrow}$ sibling is therefore a finite obstruction-classifier interface for the same route, not a halting oracle. □

Closure status for NameCert$_{\text{HaltingDistinctionLimit}^{\uparrow}}$ **·**

Constructive story: A HaltingDistinctionLimit$^{\uparrow}$ packet is generated from a program-certificate row, an input history row, a finite Cont$_P$ trace row, a diagonal obstruction row, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert ledger.

Theory closure: TheoryGate(NameCert$_{\text{HaltingDistinctionLimit}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 495.1, Definition 495.2, Definition 495.3, Definition 495.4, Definition 495.5, Definition 495.6, and Definition 495.7 jointly exhibit the mature paper-side HaltingDistinctionLimit$^{\uparrow}$ treatment for the finite BHist, Ext, Cont, hsame, classifier transport, diagonal rows, Pkg, and NameCert obstruction route.

Formal verification: FormalStatus(NameCert$_{\text{HaltingDistinctionLimit}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a total halting predicate, a divergence oracle, a global truth predicate, a host evaluator, or a checked Lean certificate.

Upgrade path: Obligation closure requires Lean encoding of the carrier and checked theorems for classifier transport, fixed-point boundary exposure, non-decision ledger discipline, and downstream non-escape.

Chapter 496

A Concrete Naming Certificate for $\mathsf{HaltingDiagonal}^{\uparrow}$

The $\mathsf{HaltingDiagonal}^{\uparrow}$ packet turns the halting fixed-point obstruction of Definition 9368.3 into a finite naming-certificate frontier. It records program-certificate data, one input history, the self-reference row, the fixed continuation row, the diagonal-divergence policy row, displayed transports, local routes, package provenance, and local naming obligations. It does not add global halting decidability, universal-machine semantics, a halting oracle, or a total classifier over all certificates.

Definition 496.1 (HaltingDiagonal packet)**.** *A* $\mathsf{HaltingDiagonal}^{\uparrow}$ *packet is a finite row*

$$Z = (P, h, E, F, D, H, C, K, N)$$

with the following displayed coordinates:

1. *P is the program certificate row whose local* $\mathsf{NameCert}_P$ *supplies the* Cont_P *and* Ext_P *surface being inspected.*
2. *h is the input history row in* BHist*.*
3. *E is the* Ext *self-reference row producing the history used by the diagonal read.*
4. *F is the fixed* Cont *row witnessing the empty-fuel continuation from the self-referential history back to itself.*
5. *D is the diagonal-divergence policy row: if the local halting classifier identifies the fixed-point history with its own continuation readback, the policy records the corresponding divergence claim.*
6. *H stores the componentwise* hsame *transports for P, h, E, F, and D.*
7. *C stores the displayed* Cont *routes used by the program row, the fixed-point row, and the diagonal readback.*
8. *K is the finite* Pkg *provenance ledger tying the packet to the halting fixed-point interface.*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{HaltingDiagonal}^{\uparrow}}$ *row for carrier admission, classifier stability, exactness, ledger, and non-decision boundary obligations.*

The packet is finite over $\mathsf{NameCert}$*,* BHist*,* Ext*,* Cont*,* hsame*, and* Pkg*. It has no coordinate for global halting decidability, no universal-machine semantics, and no oracle deciding termination for arbitrary programs.*

Theorem 496.2 (HaltingDiagonal fixed-point package)**.** *The rows $P, h, E, F, D, H, C, K, N$ of Definition 496.1 assemble the local* $\mathsf{HaltingDiagonal}^{\uparrow}$ *fixed-point package: the program row supplies the inspected certificate surface, E supplies self-reference, F supplies the fixed* Cont *row, D supplies the diagonal-divergence policy, H and C supply transport and continuation routes, and K, N supply package provenance and local naming obligations.*

Lean4 ✓ `BEDC.Derived.HaltingDiagonalUp.HaltingDiagonal fixed point package rows`

Proof. Project the finite packet. The rows P and h identify the certificate and input-history coordinates being inspected, while E identifies the self-reference row used by the diagonal construction.

The fixed-point row is F: it is the displayed Cont route from the self-referential history back to itself. The diagonal policy row is D: it records the local implication from classifier agreement at that fixed point to the divergence claim.

Finally, H transports the displayed rows, C records the continuation routes, and K, N record provenance and local naming obligations. Repacking these rows gives the finite fixed-point package without adding a global decision procedure. □

Theorem 496.3 (HaltingDiagonal non-decision boundary)**.** *Every consumer read of an accepted* $\mathsf{HaltingDiagonal}^{\uparrow}$ *packet factors through the finite rows $P, h, E, F, D, H, C, K, N$. The packet exposes the fixed-point obstruction boundary of Definition 9368.3; it does not decide halting for arbitrary* $\mathsf{NameCert}$ *rows, does not supply universal-machine semantics, and does not convert the diagonal-divergence policy into a total classifier.*

Proof. Carrier admission reads only the displayed packet rows. Thus a consumer may inspect the program-certificate row, the input history, the self-reference row, the fixed continuation, the diagonal policy, transports, routes, package provenance, and local certificate.

Apply the fixed-point package of Definition 496.2. It identifies exactly where the local obstruction lives: the route through E and F and the policy row D.

No row in the packet classifies all program-history pairs. Since no universal-machine coordinate or total halting classifier is present, consumer reads remain bounded by the local fixed-point obstruction. □

Theorem 496.4 (HaltingDiagonal NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{HaltingDiagonal}^{\uparrow}}$ *row has five obligations: carrier admission for the finite packet of Definition 496.1, classifier stability under componentwise* hsame *transport of the displayed rows, exactness of the E and F fixed-point readback, ledger provenance through K, and the non-decision boundary of Definition 496.3.*

Proof. Carrier admission is the finite packet definition. It names every row available to the certificate.

Classifier stability is componentwise: transport P, h, E, F, D along H and route the transported continuations through C. Exactness is the statement that the self-reference row and fixed continuation row still read back as the same local diagonal configuration.

The ledger obligation is K, and the boundary obligation is Definition 496.3. Together these rows give the local naming package without adding a global halting predicate. □

Theorem 496.5 (HaltingDiagonal carrier exposure obligation)**.** *For every accepted* $\mathsf{HaltingDiagonal}^{\uparrow}$ *packet $Z = (P, h, E, F, D, H, C, K, N)$, the local carrier exposes exactly the finite rows $P, h, E, F, D, H, C, K, N$. Every consumer read of the diagonal obstruction must begin from those rows, and no extra coordinate supplies a global halting predicate, universal-machine semantics, or oracle access.*

Proof. Project the packet of Definition 496.1. Its carrier rows are precisely the program certificate P, input history h, self-reference row E, fixed continuation row F, diagonal-divergence policy D, transport rows H, continuation routes C, provenance ledger K, and local naming row N.

The carrier definition has no coordinate for a global halting predicate or universal-machine semantics. Therefore every consumer read is bounded by those displayed rows. □

Theorem 496.6 (HaltingDiagonal classifier stability obligation)**.** *Let $Z = (P, h, E, F, D, H, C, K, N)$ and $Z' = (P', h', E', F', D', H', C', K', N')$ be accepted* $\mathsf{HaltingDiagonal}^{\uparrow}$ *packets whose displayed program, history, self-reference, fixed-continuation, and diagonal-policy rows are related componentwise by the* hsame *transports recorded in H and H'. Then the local classifier read through N transports componentwise across those rows: the accepted carrier exposure, fixed-point readback, diagonal policy, continuation routes, and provenance ledger remain the same named obstruction under the transported packet.*

Proof. Use the componentwise transports recorded in H and H' for P, h, E, F, D. These transports place the program certificate, input history, self-reference row, fixed continuation row, and diagonal policy row on the same displayed naming surface.

Next read the continuation routes through C and C'. The routes expose the transported fixed-point readback and diagonal policy without adding another classifier coordinate.

Finally, package the transported rows through K, K' and the local naming rows N, N'. The result is classifier stability for the same finite diagonal obstruction, not a new decision procedure. □

Theorem 496.7 (HaltingDiagonal ledger-boundary obligation)**.** *The provenance ledger K of an accepted* $\mathsf{HaltingDiagonal}^{\uparrow}$ *packet records only the finite fixed-point obstruction generated by P, h, E, F, D, H, C, N. It does not promote the diagonal-divergence policy row D into a total halting classifier, and it does not permit a consumer to decide termination for arbitrary* NameCert *rows outside the displayed packet.*

Proof. Read K as the package provenance for the displayed packet. Its dependencies are the program row, input history, self-reference row, fixed continuation row, diagonal policy, transports, routes, and local naming certificate.

Apply Definition 496.3. That theorem identifies the consumer boundary: the packet exposes a local fixed-point obstruction but contains no universal classifier row.

Thus the ledger is a boundary ledger. It records the finite obstruction and prevents the diagonal policy from being read as a global halting decision. □

Theorem 496.8 (HaltingDiagonal to HaltingObstruction sibling route)**.** *Every* $\mathsf{HaltingDiagonal}^{\uparrow}$ *diagonal read that is consumed as a* $\mathsf{HaltingObstruction}^{\uparrow}$ *ledger must pass through the finite rows $P, h, E, F, D, H, C, K, N$ before entering the obstruction packet of chapter 490. The route therefore treats the diagonal packet as a sibling fixed-point source for the obstruction ledger, not as a global halting classifier.*

Proof. Start with the fixed-point package of Definition 496.2. It identifies the rows $P, h, E, F, D, H, C, K, N$ as the displayed diagonal source, including the self-reference row E, fixed continuation row F, and diagonal policy row D.

Next apply the ledger-boundary obligation of Definition 496.7. That boundary prevents K and D from being read as a total halting classifier; they remain finite ledger rows for the displayed packet.

The sibling chapter chapter 490 consumes exactly this kind of finite obstruction packet. Hence any obstruction-facing read factors through the diagonal rows first and only then enters the HaltingObstruction ledger surface. □

Theorem 496.9 (HaltingDiagonal scoped certificate)**.** *The source packet, fixed-point package, non-decision boundary, and NameCert obligations assemble one scoped* $\mathsf{HaltingDiagonal}^{\uparrow}$ *certificate over program certificate rows, input histories,* Ext *self-reference rows, fixed* Cont *rows, diagonal-divergence policy rows,* BHist, hsame, Cont, Pkg, *and* NameCert *provenance. The certificate excludes global halting decidability, universal-machine semantics, oracle access, and infinite searches through program space.*

Lean4 ✓ `BEDC.Derived.HaltingDiagonalUp.HaltingDiagonalTasteGate single carrier alignment`

Proof. Start with the packet definition of Definition 496.1. It fixes the finite carrier coordinates and the listed dependency surface.

Use Definition 496.2 to package the self-reference and fixed continuation rows as the local diagonal readback. Use Definition 496.4 to bind carrier, classifier, exactness, ledger, and boundary obligations into the local NameCert row.

The non-decision boundary of Definition 496.3 supplies the exclusion clauses. Therefore the certificate is scoped to the finite fixed-point obstruction and does not export a global halting decision mechanism. □

Closure status for $\mathsf{NameCert}_{\mathsf{HaltingDiagonal}^{\uparrow}}$**.**

Constructive story: A $\mathsf{HaltingDiagonal}^{\uparrow}$ packet is generated from a program certificate row, an input history, an Ext self-reference row, a fixed Cont row, a diagonal-divergence policy row, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{HaltingDiagonal}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 496.1, Definition 496.2, Definition 496.3, Definition 496.4, Definition 496.9, and the finite obstruction bridge route of Definition 496.8 bind the fixed-point obstruction boundary over NameCert, Cont, Ext, hsame, Pkg, and local diagonal ledgers.

Lean target: `BEDC.Derived.HaltingDiagonalUp.HaltingDiagonalTasteGate\_single\_carrier\_alignment`

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{HaltingDiagonal}^{\uparrow}}, \mathsf{axiomClean})$

Bridge status: none

Not claimed: This chapter does not close global halting decidability, universal-machine semantics, oracle access, total classification of all program-history pairs, or bridge checking.

Upgrade path: No further paper-theory closure upgrade remains for the finite fixed-point obstruction; Lean verification and bridge checking remain independent.

Chapter 497

A Concrete Naming Certificate for $\mathsf{DecidableRefutationBoundary}^{\uparrow}$

The $\mathsf{DecidableRefutationBoundary}^{\uparrow}$ surface realizes the contradiction boundary of chapter 9458 as a finite NameCert carrier. It records one closed assumption row, an optional decision row, the displayed route from that assumption to falsity, transport and continuation rows, package provenance, and the local naming row. The carrier admits refutation only as visible BEDC evidence and keeps the forbidden contradiction schemas outside the exported certificate surface.

$\mathsf{DecidableRefutationBoundary}^{\uparrow}$ consumes the visible falsity-route discipline of chapter 501 and the displayed witness-row discipline of chapter 503. Its optional decision row narrows those sibling surfaces to a single closed assumption row A and does not add excluded-middle branching.

Definition 497.1 (Decidable refutation boundary carrier)**.** *A* $\mathsf{DecidableRefutationBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (A, D, F, H, C, P, N)$$

with the following displayed coordinates:

1. *A is a closed assumption row, read as the certificate-visible proposition whose attempted witness is being inspected;*
2. *D is an optional decidability witness for the same row A, present exactly when the packet carries a constructive decision route for that row;*
3. *F is the displayed falsity route, a finite path from an assumed witness of A to $\bot$ using only* msame, hsame, Cont, *and the local certificate rows;*
4. *H stores the componentwise* hsame *transports for A, D, F, package provenance, and the local naming row;*
5. *C stores the displayed* Cont *routes that read A, replay F, consume D when it is present, and return the result to the visible ledger;*
6. *P is the* Pkg *provenance over* BHist, msame, hsame, Cont, *the displayed refutation rows, optional decision rows, and the surrounding* $\mathsf{NameCert}$ *rows;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{DecidableRefutationBoundary}^{\uparrow}}$ *row.*

The packet has no coordinate for a witness selected from contradiction alone, no double-negation eliminator without the row D, no excluded-middle branch over all naming certificates, and no host truth predicate.

Lean4 ✓ `BEDC.Derived.DecidableRefutationBoundaryUp.DecidableRefutationBoundaryTasteGate single carrier alignment`

Theorem 497.2 (Decidable refutation boundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DecidableRefutationBoundar}}$ *surface for the carrier* $R = (A, D, F, H, C, P, N)$ *consists of five obligations:*

1. *carrier admission exposes exactly the finite packet of Definition 497.1;*
2. *assumption closure keeps* A *as the single closed assumption row inspected by the packet and prevents consumers from replacing it by an ambient predicate;*
3. *permitted falsity replay transports the route* F *only through the stored* hsame *rows and the displayed* Cont *rows;*
4. *decidable readback consumes* $\neg\neg A$ *only when* D *displays a constructive decision for the same assumption row* A*;*
5. *boundary non-escape prevents export of unwitnessed existential extraction, undecidable double-negation elimination, excluded-middle branching over all naming certificates, and certificate-indexed truth branches.*

Thus the certificate surface is finite, local to A, D, F, H, C, P, N*, and separated from the forbidden patterns of Definition 9458.5.*

Proof. Carrier admission is projection from Definition 497.1. The only readable rows are the closed assumption row, optional decision row, falsity route, transport rows, continuation routes, package provenance, and local naming row.

Assumption closure follows because A is stored as a closed coordinate of the same packet. A consumer may transport it by the displayed hsame rows and read it by the displayed Cont rows, but no coordinate replaces it by a host predicate or by a predicate over all naming certificates.

Permitted falsity replay uses the route F. Transporting A and F along H and replaying the corresponding route in C still yields a displayed route from an assumed witness of the transported A to $\bot$.

For decidable readback, inspect D. If D is present, the readback is tied to the same row A and remains inside the packet. If D is absent, no row of R supplies the schema $\neg\neg A \Rightarrow A$.

Boundary non-escape is the remaining carrier inventory. The packet has no witness selector for existential-by-contradiction, no undecided double-negation eliminator, no branch over the carrier of all naming certificates, and no host truth predicate, so every consumer remains inside the displayed NameCert rows. □

Lean4 ✓ `BEDC.Derived.DecidableRefutationBoundaryUp.DecidableRefutationBoundary assumption falsity route unary closure`

Theorem 497.3 (Decidable refutation ground-loop exhaustion)**.** *Every accepted* $\mathsf{DecidableRefutationBoundary}^{\uparrow}$ *route stays inside the rows* msame, hsame, Cont, Pkg*, and* NameCert *displayed by* $R = (A, D, F, H, C, P, N)$*. It can export only the local falsity route for the closed assumption row* A *and, when* D *is present, the matching decidable readback for* A*. It cannot export an unwitnessed existential, an undecidable double-negation elimination, or a certificate-indexed truth branch.*

Proof. Project the accepted carrier. The proof route available to a consumer is F, and every movement of that route is accounted for by H and C.

The ground-loop rows are therefore exhausted by msame, hsame, Cont, the package row P, and the local naming row N. No additional classifier, oracle, quotient, or truth predicate is present in the packet.

When D is present, a consumer may use it only as the displayed decision row for the same assumption A. When D is absent, the carrier has no coordinate that turns $\neg\neg A$ into A.

The forbidden exports require absent data: a selected existential witness obtained from contradiction alone, an undecidable double-negation eliminator, or a family of branches over all naming certificates. Since none of these rows exists in R, accepted routes remain inside the permitted contradiction boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{DecidableRefutationBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{DecidableRefutationBoundary}^{\uparrow}$ packet is generated from one closed assumption row, an optional decidability witness, a displayed falsity route, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DecidableRefutationBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 497.1, Definition 497.2, and Definition 497.3 bind the finite carrier, NameCert obligation surface, and ground-loop exhaustion boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DecidableRefutationBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a Lean implementation, excluded-middle branching, host truth over naming certificates, unwitnessed existential extraction, or undecidable double-negation elimination.

Upgrade path: Obligation closure requires Lean encoding of the carrier and checked theorems for carrier admission, assumption closure, permitted falsity replay, decidable readback, and boundary non-escape.

Chapter 498

A Concrete Naming Certificate for $\mathsf{TranscendentalInductionSocket}^{\uparrow}$

The $\mathsf{TranscendentalInductionSocket}^{\uparrow}$ interface names the finite BEDC surface at which an attempted universal-induction read is exposed as a GAP rather than accepted as a substrate rule. It records the source history, the finite trace already observed, the attempted induction schema, the GAP boundary row, the inscription handoff row, displayed transport, package provenance, and the local naming certificate. The packet is a concrete NameCert carrier for induction-as-boundary; it does not internalize mathematical induction, create a universal quantifier over an infinite domain, or add an axiom to the substrate.

The socket is consumed by chapter 610: the GAP boundary row and inscription handoff row of $\mathsf{TranscendentalInductionSocket}^{\uparrow}$ are the finite source through which $\mathsf{InscriptionPoint}^{\uparrow}$ records forward commitment without turning it into a substrate derivation rule.

Definition 498.1 (TranscendentalInductionSocket carrier)**.** *A* $\mathsf{TranscendentalInductionSocket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$I = (h, T, S, G, A, H, C, P, N)$$

with the following displayed rows:

1. *h is the source* Hist *row at which the attempted universal-induction read is made;*
2. *T is the finite verification trace already present in* BHist*;*
3. *S is the displayed induction-shape request, recording the base row, step row, and requested universal target as a packet to be inspected;*
4. *G is the GAP boundary row that marks the universal target as not discharged inside the substrate;*
5. *A is the inscription handoff row, naming the observer-side commitment position without turning it into a derivation rule;*
6. *H records componentwise* hsame *transports for the source history, finite trace, induction-shape request, GAP row, inscription row, package provenance, and local naming row;*
7. *C records the* Cont *routes that read the finite trace, expose the induction-shape request, route the failed universal read to G, and hand the socket to A;*
8. *P is the* Pkg *provenance over* BHist*,* Hist*, finite traces, GAP rows,* hsame*,* Cont*, and inscription handoff data;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{TranscendentalInductionSocket}^{\uparrow}}$ *row.*

The carrier is exactly this finite packet. It contains no coordinate for a substrate-internal induction axiom, no hidden dependent recursor over all predicates, no completed infinite trace, and no certificate-level predicate that closes every future observation.

Lean4 ✓ `BEDC.Derived.TranscendentalInductionSocketUp.TranscendentalInductionSocketTasteGate single carrier alignment`

Theorem 498.2 (TranscendentalInductionSocket NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{TranscendentalInductionSo}}$ *surface has five finite obligations:*

1. *carrier exposure: every accepted object exposes the tuple $I = (h, T, S, G, A, H, C, P, N)$ of Definition 498.1;*
2. *trace exactness: every observed premise read factors through the finite trace T and the displayed source history h;*
3. *GAP boundary: the requested universal target in S is routed to G when it is not discharged by the finite trace;*
4. *inscription handoff: the observer-side commitment is named only by A and is not re-read as a substrate derivation;*
5. *ledger policy:* Pkg *and* NameCert *expose only the listed* BHist, hsame, Cont, *GAP, and handoff rows.*

Lean4 ✓ `BEDC.Derived.TranscendentalInductionSocketUp.TranscendentalInductionSocketPacket namecert obligations`

Proof. Carrier exposure is projection from the tuple of Definition 498.1. The source history, trace, induction-shape request, GAP row, handoff row, transport rows, continuation routes, provenance, and local certificate row are all displayed coordinates.

Trace exactness follows by reading T through h. The finite trace supplies only the records already present in BHist, so it cannot supply the requested universal target by itself.

The GAP boundary obligation is the G coordinate together with the route in C from the failed universal read. The inscription handoff obligation is the A coordinate together with the route in C that exposes the observer-side commitment position without making it available as a rule.

Finally, the package and local certificate rows list no substrate-internal induction axiom, no dependent recursor over all predicates, and no completed infinite trace. The ledger policy is therefore exhausted by the finite socket packet. □

Theorem 498.3 (TranscendentalInductionSocket GAP boundary)**.** *Every consumer read of the attempted universal-induction target in an accepted* $\mathsf{TranscendentalInductionSocket}^{\uparrow}$ *carrier factors through the finite trace T, the induction-shape request S, and the GAP row G. If the consumer asks for the universal target as a substrate theorem, the only exported row is G together with its displayed* Cont *route.*

Lean4 ✓ `BEDC.Derived.TranscendentalInductionSocketUp.TranscendentalInductionSocketPacket gap boundary`

Proof. Project the accepted carrier as $I = (h, T, S, G, A, H, C, P, N)$. The induction-shape request is visible only as the coordinate S, and its already observed premises are read only through T and h.

When the requested universal target is inspected, the continuation route in C sends that request to the boundary row G. This route records the failed substrate-internal discharge rather than producing a theorem row.

No other coordinate of I contains a universal target, completed infinite trace, or induction rule. Thus every consumer of the attempted universal read receives the GAP boundary and not an internal proof of induction. □

Theorem 498.4 (TranscendentalInductionSocket inscription handoff)**.** *Every observer-side read of an accepted* TranscendentalInductionSocket$^{\uparrow}$ *carrier is handed off through the inscription row A after the GAP boundary G has been exposed. The handoff names the position from which the forward commitment is taken, but it exports no substrate rule, no proof constructor, and no classifier branch that can discharge the universal target inside* BHist*.*

Lean4 ✓ `BEDC.Derived.TranscendentalInductionSocketUp.TranscendentalInductionSocketPacket inscription handoff`

Proof. Start with the boundary route of Definition 498.3. The attempted universal target is first exposed as the GAP row G, so the carrier has already refused substrate-internal closure.

The inscription row A is then read through its displayed route in C. This row records the handoff site for the observer-side commitment, and the componentwise transport row H carries it only as a named packet coordinate.

Since A is not a derivation rule and the package row P lists no induction constructor, the handoff cannot be re-entered as an internal proof of the requested universal target. □

Theorem 498.5 (TranscendentalInductionSocket no internal axiom)**.** *An accepted* TranscendentalInductionSocket$^{\uparrow}$ *carrier does not add an induction axiom to BEDC. Its public reads are exhausted by the source history h, finite trace T, induction-shape request S, GAP boundary G, inscription handoff A, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row.*

Proof. Inspect the carrier inventory of Definition 498.1. Each coordinate is a finite BHist row or a displayed transport, continuation, provenance, or naming row.

The GAP boundary theorem shows that the universal target is exported as G rather than as a theorem. The inscription handoff theorem shows that the observer-side row A names a commitment position without turning that position into a substrate constructor.

Therefore the packet has no coordinate from which an induction axiom could be projected. Every public read remains inside the finite socket surface, and the substrate boundary stays 0-axiom. □

Theorem 498.6 (TranscendentalInductionSocket public export)**.** *Every public consumer of an accepted* TranscendentalInductionSocket$^{\uparrow}$ *socket receives only the finite tuple*

$$I = (h, T, S, G, A, H, C, P, N).$$

The attempted universal induction target is exported as the GAP row G, and the observer commitment is exported only as the inscription handoff row A. The packet exports no substrate-internal induction axiom, no dependent recursor over all predicates, no completed infinite trace, and no public row that converts finite observation into a universal theorem.

Proof. Project the carrier by Definition 498.1. The public surface is the displayed tuple $I = (h, T, S, G, A, H, C, P, N)$, with source history, finite trace, induction-shape request, boundary row, handoff row, transport, route, provenance, and local naming all visible as packet coordinates.

Apply Definition 498.2. The local certificate admits only carrier exposure, trace exactness, GAP boundary, inscription handoff, and ledger policy for those coordinates.

Use Definition 498.3. It sends the requested universal target to G whenever the finite trace does not discharge it inside the substrate.

Finally apply Definition 498.4 and Definition 498.5. The handoff row A records observer commitment without becoming a derivation rule, and no remaining coordinate can supply an induction axiom, completed infinite trace, or universal theorem. □

Theorem 498.7 (TranscendentalInductionSocket bridge-facing certificate)**.** *For every accepted* $\mathsf{TranscendentalInductionSocket}^{\uparrow}$ *packet*

$$I = (h, T, S, G, A, H, C, P, N),$$

the bridge-facing public certificate is exactly the conjunction of carrier exposure, NameCert *obligations, GAP boundary, inscription handoff, no-internal-axiom, public export, and the checked TasteGate single-carrier alignment recorded at Definition 498.1.*

Proof. Carrier exposure is supplied by Definition 498.1, which fixes the finite tuple $I = (h, T, S, G, A, H, C, P, N)$ as the whole accepted socket surface.

The certificate obligations are the five finite rows of Definition 498.2. They bind the carrier exposure, trace exactness, GAP boundary, inscription handoff, and ledger policy without adding any substrate rule.

The GAP side is fixed by Definition 498.3, and the observer-side handoff is fixed by Definition 498.4. These two theorems make the requested universal target leave the substrate only as G and make the forward commitment visible only as A.

Apply Definition 498.5 and Definition 498.6. The public package exports only the finite socket packet, and the TasteGate single-carrier alignment already attached to the carrier site records that this export stays on the single displayed carrier. Thus the bridge-facing certificate is a public certificate for the finite socket and not a substrate induction rule. □

Closure status for $\mathsf{NameCert}_{\mathsf{TranscendentalInductionSocket}^{\uparrow}}$.

Constructive story: A $\mathsf{TranscendentalInductionSocket}^{\uparrow}$ packet is generated from a source Hist row, a finite verification trace, an induction-shape request, a GAP boundary row, an inscription handoff row, componentwise hsame transports, visible Cont routes, Pkg provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.TranscendentalInductionSocketUp.taste gate`

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{TranscendentalInductionSocket}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 498.1, Definition 498.2, Definition 498.3, Definition 498.4, Definition 498.5, Definition 498.6, and Definition 498.7 bind the carrier, NameCert obligations, GAP boundary, inscription handoff, no-internal-axiom theorem, public export, and bridge-facing certificate as the finite socket public surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{TranscendentalInductionSocket}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.TranscendentalInductionSocketUp.TranscendentalInductionSocketPacket\_namecert\_obligati`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close a Lean implementation, bridge status, a substrate-internal induction axiom, a completed infinite trace, a dependent recursor over all predicates, or a universal theorem produced from finite observation alone.

Upgrade path: No further paper-side closure grade is claimed beyond bridge verification.

Chapter 499

A Concrete Naming Certificate for $\mathsf{OtherMindsCommitment}^{\uparrow}$

The $\mathsf{OtherMindsCommitment}^{\uparrow}$ surface turns the other-minds locality-cell commitment of Definition 9415.9 into finite BEDC certificate data. It records what an observer may publicly commit to about a candidate other system: visible behavioural evidence, provenance, locality-cell coherence, and naming obligations. It does not expose another system's Self row and does not turn behavioural evidence into direct first-person access.

The locality-cell row L is consumed from chapter 513 as the finite two-observer public cell that $\mathsf{OtherMindsCommitment}^{\uparrow}$ uses before adding the behavioural evidence row E.

Definition 499.1 (OtherMindsCommitment carrier)**.** *An* $\mathsf{OtherMindsCommitment}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (A, B, L, E, G, H, C, P, N)$$

with the following displayed rows:

1. *A is the observer row, naming the conscious observational system that issues the commitment;*
2. *B is the candidate-other row, naming the external system as it appears in A's record surface;*
3. *L is the locality-cell commitment row, recording the* GAP*-tagged commitment that B is to be treated as another closed observational system for cross-perspective coordination;*
4. *E is the behavioural evidence row, containing the externally observable records that support the commitment without displaying B's* Self*;*
5. *G is the* GAP *and provenance row, recording the open commitment socket and the dependency certificates consumed by the packet;*
6. *H records the componentwise* hsame *transports for the observer row, candidate-other row, locality-cell row, behavioural evidence row, provenance row, package row, and local naming row;*
7. *C records the* Cont *routes that move the observer's public reads through L, E, and G without entering a private* Self *coordinate of B;*
8. *P is the* Pkg *row for the finite BEDC dependencies named by the commitment;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{OtherMindsCommitment}^{\uparrow}}$ *row.*

The classifier compares two carriers only by these displayed rows and their hsame *and* Cont *transports.*

Lean4 (definition) `BEDC.Derived.OtherMindsCommitmentUp.OtherMindsCommitmentUp`

Theorem 499.2 (OtherMindsCommitment TasteGate obligation boundary)**.** *Every paper-side obligation beyond seed closure for* OtherMindsCommitment$^{\uparrow}$ *is read through the finite carrier rows* $A, B, L, E, G, H, C, P, N$ *together with the checked TasteGate target* `BEDC.Derived.OtherMindsCommitmentUp.tas` *No closure promotion may replace those rows by a direct candidate* Self *row, a host mental-state predicate, a private-history read, or a metaphysical identity assertion.*

Lean4 ✓ `BEDC.Derived.OtherMindsCommitmentUp.OtherMindsCommitmentTasteGateObligationBoundary`

Proof. Use Definition 499.1. The carrier coordinates are exactly $A, B, L, E, G, H, C, P, N$, so any public obligation is stated as a finite row read, an hsame transport, a Cont route, a Pkg dependency, or a local NameCert obligation.

The checked TasteGate target is attached to this carrier site, and it supplies the gate through which the chapter may discuss other-minds commitment beyond seed closure. The gate is therefore a discipline on the displayed rows, not a replacement for them.

Apply Definition 499.3 for the finite NameCert surface and Definition 499.7 for the non-escape clauses. Together they exclude direct candidate Self access, host mental-state predicates, private-history reads, and metaphysical identity assertions from any later closure reading. □

Theorem 499.3 (OtherMindsCommitment NameCert obligations)**.** *The local* NameCert$_{\text{OtherMindsCommitment}^{\uparrow}}$ *surface has five finite obligations: carrier exposure by Definition 499.1; classifier stability for the displayed observer, candidate-other, locality-cell, behavioural-evidence,* GAP*, provenance,* Pkg*, and naming rows; locality-cell coherence for the public commitment row* L*; behavioural-evidence accountability for every public read in* E*; and non-escape from direct* Self *access, unrecorded private history, host mental-state predicates, and ambient metaphysical identity.*

Lean4 ✓ `BEDC.Derived.OtherMindsCommitmentUp.OtherMindsCommitmentCarrier namecert obligations`

Proof. Carrier exposure is projection from the finite tuple $O = (A, B, L, E, G, H, C, P, N)$.

Classifier stability is componentwise. The only comparisons available to the packet are the displayed hsame rows in H and the displayed Cont routes in C.

The locality-cell and behavioural-evidence obligations are read from L and E. The row L records the GAP-tagged commitment, while E records the public behavioural evidence consumed by that commitment.

Finally inspect the coordinate list. There is no field for the candidate's private Self, for an unrecorded private history, for a host mental-state predicate, or for an ambient identity assertion beyond the displayed NameCert surface. □

Theorem 499.4 (OtherMindsCommitment locality-cell soundness)**.** *Every accepted* OtherMindsCommitment$^{\uparrow}$ *packet represents an other-minds commitment as a locality-cell row internal to the observer's finite history. A consumer may read the observer row, candidate-other row, public locality-cell commitment, behavioural evidence,* GAP *provenance,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows, but the consumer cannot read a direct* Self *row for the candidate other system.*

Lean4 ✓ `BEDC.Derived.OtherMindsCommitmentUp.OtherMindsCommitmentLocalityCellSoundness`

Proof. Project the accepted packet as $O = (A, B, L, E, G, H, C, P, N)$. The locality-cell commitment is the displayed coordinate L, and its source and target surfaces are the observer row A and candidate-other row B.

The public consumer route is limited by C and transported by H. These rows expose L, E, G, P, and N as finite certificate data.

The candidate's private Self is not a coordinate of the carrier. Thus the soundness claim is exactly locality-cell commitment inside the observer's finite public history, not direct access to another first-person row. □

Theorem 499.5 (OtherMindsCommitment behavioural-evidence compatibility)**.** *If two accepted* OtherMindsCommitment$^{\uparrow}$ *packets have matching observer rows, candidate-other rows, locality-cell commitment rows, and behavioural evidence rows under the displayed* hsame *and* Cont *transports, then they determine the same public other-minds commitment surface. The agreement is behavioural and certificate-local: it does not identify private* Self *rows, host mental states, or unrecorded histories.*

Proof. Use the classifier comparison on the displayed rows. Matching A, B, L, and E fixes the public observer, candidate, locality-cell commitment, and behavioural-evidence coordinates.

Transport along H and C carries the same public evidence into the same Pkg and local NameCert rows. Therefore any consumer sees the same finite commitment surface.

The agreement is not a private-state identity. By Definition 499.4, the carrier has no direct candidate Self coordinate and no host mental-state predicate. □

Lean4 ✓ `BEDC.Derived.OtherMindsCommitmentUp.OtherMindsCommitmentBehaviouralEvidenceCompatibility`

Theorem 499.6 (OtherMindsCommitment public evidence ledger)**.** *Every consumer of an accepted* OtherMindsCommitment$^{\uparrow}$ *packet must factor an other-minds read through the displayed rows* $A, B, L, E, G, H, C, P, N$*. In particular, the consumer reaches the candidate-other commitment only through the public evidence row* E *together with the locality-cell row* L*; no private* Self *row, host mental-state predicate, or unrecorded history is available as a consumer route.*

Proof. Project the accepted carrier as $O = (A, B, L, E, G, H, C, P, N)$. These are the only rows exposed by Definition 499.1.

Use Definition 499.4 to locate the candidate-other commitment inside the locality-cell row L. A consumer may read that commitment only as a public locality-cell coordinate of the observer's finite history.

Use Definition 499.5 to identify the evidence consumed by the read with the displayed behavioural evidence row E, transported by H and routed by C into P and N.

There is no remaining coordinate for a private Self, a host mental-state predicate, or an unrecorded history. Thus the public evidence ledger is the sole consumer route for the other-minds read. □

Lean4 ✓ `BEDC.Derived.OtherMindsCommitmentUp.OtherMindsCommitmentPublicEvidenceLedger`

Theorem 499.7 (OtherMindsCommitment non-escape boundary)**.** *An accepted* OtherMindsCommitment$^{\uparrow}$ *carrier exports only the observer row, candidate-other public row, locality-cell commitment row, behavioural evidence row,* GAP *and provenance row, displayed* hsame *and* Cont *transports,* Pkg *row, and local* NameCert *row. It exports no direct candidate* Self *access, no private-history read, no host mental-state predicate, no metaphysical identity assertion, and no decision procedure for whether every candidate other system is conscious.*

Proof. Inspect the carrier coordinates of Definition 499.1. Every exported row is one of A, B, L, E, G, H, C, P, or N.

The locality-cell and behavioural evidence rows are public to the observer's history. They support a finite commitment surface but do not contain the candidate's private Self or a private-history projection.

No remaining coordinate names a host mental-state predicate, a metaphysical identity row, or a global consciousness decision procedure. Hence none of those objects can escape from the certificate. □

Lean4 ✓ `BEDC.Derived.OtherMindsCommitmentUp.OtherMindsCommitmentNonEscapeBoundary`

Theorem 499.8 (OtherMindsCommitment obligation-closure package)**.** *The carrier of Definition 499.1, the checked TasteGate target* `BEDC.Derived.OtherMindsCommitmentUp.taste_gate`*, the obligation boundary of Definition 499.2, the finite* NameCert *obligations of Definition 499.3, locality-cell soundness from Definition 499.4, behavioural-evidence compatibility from Definition 499.5, the public evidence ledger of Definition 499.6, and the non-escape boundary of Definition 499.7 form the complete obligation-closure package for the AI-origin* OtherMindsCommitment$^{\uparrow}$ *chapter.*

The package closes only the public locality-cell commitment surface over the finite rows $A, B, L, E, G, H, C, P, N$. It introduces no direct candidate Self *access, no host mental-state predicate, no private-history read, and no metaphysical identity assertion.*

Proof. Start with the carrier of Definition 499.1. Its coordinate list is exactly $A, B, L, E, G, H, C, P, N$, so every admissible obligation must be a row projection, a displayed transport, a displayed continuation route, a package dependency, or the local naming row.

The checked TasteGate target named in the statement supplies the chapter gate for AI-origin other-minds commitments. By Definition 499.2, that gate constrains the displayed rows rather than adding a private candidate coordinate or a host predicate.

The finite obligation surface is then exhausted by the existing theorem chain. Apply Definition 499.3 for the carrier and NameCert rows, Definition 499.4 for the locality-cell reading, Definition 499.5 for public evidence compatibility, and Definition 499.6 for the consumer route through E and L.

Finally use Definition 499.7. Since the carrier contains no direct candidate Self row, no private-history coordinate, no host mental-state predicate, and no metaphysical identity row, the package cannot export any of those objects. Thus the listed carrier, gate, obligations, soundness, compatibility, ledger, and boundary clauses are complete for the public obligation-closure reading of this chapter. □

Lean4 ✓ `BEDC.Derived.OtherMindsCommitmentUp.OtherMindsCommitmentObligationClosurePackage`

Theorem 499.9 (OtherMindsCommitment bridge-facing locality route)**.** *Every bridge-facing consumer of an accepted* OtherMindsCommitment$^{\uparrow}$ *packet must read the public locality-cell commitment, public evidence ledger,* BHist *carrier rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row already exposed by*

$$O = (A, B, L, E, G, H, C, P, N).$$

The route is bridge-facing only as a paper-side public surface: it does not add a checked standard bridge, direct candidate Self *access, private-history read, host mental-state predicate, metaphysical identity assertion, or global consciousness decision procedure.*

Lean4 ✓ `BEDC.Derived.OtherMindsCommitmentUp.OtherMindsCommitmentBridgeFacingLocalityRoute`

Proof. Start with the obligation-closure package. It fixes the accepted carrier as the finite tuple $O = (A, B, L, E, G, H, C, P, N)$ and routes every public other-minds read through the carrier, TasteGate boundary, NameCert obligations, locality-cell soundness, behavioural-evidence compatibility, public evidence ledger, and non-escape boundary.

The bridge-facing read can therefore inspect L only as the public locality-cell commitment and E only as the public behavioural evidence ledger. The structural rows H, C, P, N transport, replay, source, and name exactly those public rows, and the underlying BHist packet supplies no additional private coordinate.

Apply the non-escape boundary to the remaining cases. Direct candidate Self access, private histories, host mental-state predicates, metaphysical identity, and a global consciousness decision procedure are not carrier rows. Thus the bridge-facing surface is precisely the displayed locality route, while checked bridge status remains outside this paper-side theorem. □

Closure status for $\mathsf{NameCert}_{\mathsf{OtherMindsCommitment}^{\uparrow}}$.

Constructive story: An $\mathsf{OtherMindsCommitment}^{\uparrow}$ packet is generated from an observer row, a candidate-other public row, a locality-cell commitment row, behavioural evidence, GAP provenance, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.OtherMindsCommitmentUp.taste gate`

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{OtherMindsCommitment}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 499.1, Definition 499.3, Definition 499.4, Definition 499.5, Definition 499.6, Definition 499.7, Definition 499.8, and Definition 499.9 bind the carrier, locality-cell row, behavioural-evidence row, refusal and non-escape rows, TasteGate marker, and bridge-facing public locality route for the finite public other-minds commitment surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{OtherMindsCommitment}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a Lean implementation, checked bridge status, direct access to another system's Self, private-history reads, host mental-state predicates, metaphysical identity, or a global consciousness decision procedure.

Upgrade path: Checked bridge status remains the next verification-side work over the displayed locality-cell commitment, behavioural-evidence ledger, BHist, hsame, Cont, Pkg, and NameCert rows.

Chapter 500

A Concrete Naming Certificate for $\mathsf{RefutationBoundary}^{\uparrow}$

The $\mathsf{RefutationBoundary}^{\uparrow}$ surface records the exact BEDC boundary between permitted refutation and forbidden truth-branch extraction. It is a finite NameCert carrier for consumers that need to use contradiction as a local refutation rule while preserving the open meta loop of chapter 9458. The packet carries enough data to replay permitted negation routes, to consume a decidability row only when one is displayed, and to refuse any export of host excluded middle, nonconstructive existence, quotient truth predicates, or RealUp completeness.

The permitted-refutation route row F, optional decidability row D, and truth-branch exclusion ledger are the boundary consumer of chapter 510, chapter 511, and chapter 508. The dependency is only finite BHist, Cont, hsame, and $\mathsf{NameCert}$ data, not host excluded middle or truth-branch extraction.

When the optional decidability row is absent, the permitted-refutation route consumes the stable negation boundary of chapter 507, while $\mathsf{RefutationBoundary}^{\uparrow}$ keeps the consumer-facing packet finite through $A, F, D, S, T, H, C, P, N$.

Definition 500.1 (RefutationBoundary carrier)**.** *A* $\mathsf{RefutationBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (A, F, D, S, T, H, C, P, N)$$

with the following displayed rows:

1. *A is the inspected proposition row, read as a certificate-visible predicate over the current finite history;*
2. *F is the permitted-refutation route from an assumed witness of A to the displayed bottom row, using only* Cont, hsame, msame, *and the local naming rows;*
3. *D is an optional decidability row for A, present only when the same packet displays a constructive branch for A;*
4. *S is the forbidden-schema descriptor, naming the three blocked shapes of Definition 9458.5: unwitnessed existential extraction, double-negation elimination without D, and excluded-middle branching over the carrier of all naming certificates;*
5. *T is the truth-branch exclusion ledger, recording that no coordinate of the packet exports a family $Q(N) \vee \neg Q(N)$ over all naming certificates;*

6. *H records componentwise* hsame *transports for the proposition row, refutation route, optional decidability row, forbidden-schema descriptor, truth-branch ledger, package provenance, and local naming row;*
7. *C records the displayed* Cont *routes for reading A, replaying F, consuming D when present, checking S, and transporting T;*
8. *P is the* Pkg *provenance over* BHist, Hist, Ext, Cont, msame, hsame, *the local refutation rows, and the surrounding* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RefutationBoundary}^{\uparrow}}$ *ledger.*

The carrier is only this finite packet. It has no host truth predicate, no quotient over truth values, no global excluded-middle coordinate, no witness selector for an existential obtained by contradiction, and no completeness certificate for $\mathsf{Real}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.RefutationBoundaryUp.RefutationBoundaryTasteGate single carrier alignment`

Theorem 500.2 (Permitted negation is sound inside the packet)**.** *Every accepted* $\mathsf{RefutationBoundary}^{\uparrow}$ *packet supports the permitted BEDC rule that a displayed route from an assumed witness of A to bottom yields the local negation of A. The rule is stable under the packet's* hsame *transports and displayed* Cont *routes.*

Lean4 ✓ `BEDC.Derived.RefutationBoundaryUp.RefutationBoundaryCarrier permitted negation sound`

Proof. Project the accepted carrier as $B = (A, F, D, S, T, H, C, P, N)$. The row F is not an ambient proof search result; it is a displayed route from an assumed witness of A through the stored continuation rows to the bottom row.

Transport stability is supplied by H and C. Moving the proposition row and the route along the componentwise hsame data, then replaying the displayed Cont chain, gives the same local map from an admitted witness of A to bottom.

Thus the only negation exported by the packet is the one accounted for by its displayed route. This is exactly the permitted pattern of Definition 9458.1. □

Theorem 500.3 (Forbidden truth branches are excluded)**.** *No consumer read of an accepted* $\mathsf{RefutationBoundary}^{\uparrow}$ *packet can produce a certificate-indexed truth branch for predicates over the carrier of all naming certificates. In particular, the packet does not implement any forbidden schema of Definition 9458.5.*

Lean4 ✓ `BEDC.Derived.RefutationBoundaryUp.RefutationBoundaryForbiddenTruthBranchExclusion`

Proof. The only classifier-visible coordinates of the carrier are $A, F, D, S, T, H, C, P, N$. None of them ranges over all naming certificates, and none is a family choosing $Q(N) \vee \neg Q(N)$ for arbitrary Q and arbitrary certificate N.

The descriptor S names the blocked schemas, while the ledger T records their non-export condition. A consumer may inspect those rows, transport them through H, and replay their checks through C, but that yields only the finite exclusion ledger already present in the packet.

The forbidden schemas require data outside the carrier inventory: a witness selected from $\neg\forall\neg$, a double-negation eliminator with no displayed decidability row, or excluded middle over naming certificates. Since no such coordinate exists, the truth branch of Definition 9458.10 cannot be extracted. □

Theorem 500.4 (RefutationBoundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RefutationBoundary}^{\uparrow}}$ *surface consists of five obligations:*

1. *carrier admission for the finite packet* $B = (A, F, D, S, T, H, C, P, N)$ *of Definition 500.1;*
2. *classifier stability for the visible proposition row, permitted-refutation route, optional decidability row, forbidden-schema descriptor, truth-branch ledger, transports, continuation routes, package provenance, and local naming row;*
3. *permitted-negation soundness, namely the transport-stable route of Definition 500.2;*
4. *decidability accountability, saying that* $\neg\neg A$ *may be consumed only when the row* D *displays a constructive decision for the same proposition row;*
5. *truth-branch exclusion, namely the non-export statement of Definition 500.3.*

Lean4 ✓ `BEDC.Derived.RefutationBoundaryUp.RefutationBoundaryCarrier namecert obligation surface`

Proof. Carrier admission is projection from Definition 500.1. Every accepted object exposes exactly the displayed finite tuple and no hidden ambient coordinate.

Classifier stability follows by comparing only the visible rows of the tuple. The proposition, refutation route, optional decidability row, forbidden-schema descriptor, truth-branch ledger, provenance, and local naming row are transported by H and read through C.

Permitted-negation soundness is Definition 500.2. The proof route is finite, displayed, and stable under the same componentwise transports.

For decidability accountability, inspect D. If D is present, it is consumed as the displayed constructive branch for A; if it is absent, S and T record that no undecided double-negation eliminator is exported.

Finally, truth-branch exclusion is Definition 500.3. The NameCert ledger records the boundary by carrying the exclusion row rather than a truth predicate over all naming certificates. □

Theorem 500.5 (RealUp consumers receive only boundary data)**.** *A* $\mathsf{Real}^{\uparrow}$ *or completion consumer that reads an accepted* $\mathsf{RefutationBoundary}^{\uparrow}$ *packet receives only the proposition row, displayed refutation route, optional decidability row, forbidden-schema descriptor, truth-branch exclusion ledger, transport rows, continuation routes, package provenance, and local naming row. It receives no completeness theorem, no quotient truth predicate, and no host excluded-middle principle.*

Proof. Any consumer read factors through the carrier coordinates $A, F, D, S, T, H, C, P, N$. These coordinates are finite BHist and ledger rows, so their projections remain inside the displayed NameCert surface.

The refutation data available to the consumer is the route F together with its transports and continuations. If the consumer also needs double-negation elimination, the only available route is the optional row D, and only for the same proposition row A.

The completion-side exclusions are exactly the absent coordinates of Definition 500.1. The packet does not contain a RealUp completeness witness, a quotient truth predicate, or a branch over all naming certificates, so a RealUp consumer cannot obtain any of those principles from this certificate. □

Lean4 ✓ `BEDC.Derived.RefutationBoundaryUp.RefutationBoundaryRealUpConsumerScope`
Lean4 ✓ `BEDC.Derived.RefutationBoundaryUp.RefutationBoundaryCarrier realup consumer scope`

Theorem 500.6 (RefutationBoundary public export)**.** *The public* $\mathsf{RefutationBoundary}^{\uparrow}$ *export is exactly the finite packet*

$$B = (A, F, D, S, T, H, C, P, N)$$

together with the five named obligations of Definition 500.4: carrier admission, classifier stability, permitted-negation soundness, decidability accountability, and truth-branch exclusion. A public consumer may read those rows and obligations, and no further truth predicate, excluded-middle branch, quotient truth object, nonconstructive existential selector, or $\mathsf{Real}^{\uparrow}$ *completeness principle is part of the export.*

Proof. Project the carrier of Definition 500.1. Its visible rows are exactly $A, F, D, S, T, H, C, P, N$, and the carrier definition excludes every host truth predicate, quotient truth object, global excluded-middle coordinate, existential selector obtained by contradiction, and $\mathsf{Real}^{\uparrow}$ completeness certificate.

Now read the obligation package of Definition 500.4. Its five clauses supply precisely carrier admission, classifier stability, permitted-negation soundness, decidability accountability, and truth-branch exclusion for the same finite tuple.

The consumer-scope theorem Definition 500.5 identifies the downstream read as a projection of those rows and obligations. Hence the public export is the displayed packet together with the five obligations, and nothing outside that finite boundary is exported. □

Lean4 ✓ `BEDC.Derived.RefutationBoundaryUp.RefutationBoundaryCarrier public export`

Theorem 500.7 (RefutationBoundary standard-boundary export)**.** *The public* $\mathsf{RefutationBoundary}^{\uparrow}$ *packet is exactly the finite standard-boundary export for permitted negation and truth-branch refusal. A bridge-facing consumer receives the proposition row, displayed refutation route, optional decidability row, forbidden-schema descriptor, truth-branch exclusion ledger, transports, continuations, provenance, and local naming row, and every permitted-negation read and every truth-branch refusal is computed from those rows alone.*

Proof. Start with the public export of Definition 500.6. It identifies the exported object as the finite tuple $B = (A, F, D, S, T, H, C, P, N)$ together with carrier admission, classifier stability, permitted-negation soundness, decidability accountability, and truth-branch exclusion.

The permitted-negation side is the displayed route F read through H and C. By Definition 500.2, this route supplies only the local map from an assumed witness of A to bottom.

The refusal side is the pair S, T. By Definition 500.3, those rows exclude certificate-indexed truth branches rather than exporting one.

Thus the bridge-facing standard boundary has no further coordinate to expose. It is precisely the public packet already named by the chapter, read as permitted negation on one side and truth-branch refusal on the other. □

Lean4 ✓ `BEDC.Derived.RefutationBoundaryUp.RefutationBoundaryStandardBoundaryExport`

Theorem 500.8 (RefutationBoundary mature consumer route)**.** *Every mature consumer read of an accepted* $\mathsf{RefutationBoundary}^{\uparrow}$ *packet is the same finite route*

$$A, F, D, S, T, H, C, P, N.$$

Permitted negation, truth-branch refusal, $\mathsf{Real}^{\uparrow}$ *consumer scope, public export, and standard-boundary export are all projections of this packet route. No consumer receives an extra host truth predicate, excluded-middle branch, quotient truth object, nonconstructive existential selector, or* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. Start with the carrier of Definition 500.1. It displays exactly the rows $A, F, D, S, T, H, C, P, N$, so every consumer route begins as a projection of the same finite packet.

The permitted-negation projection is Definition 500.2. It reads A and F through the transport and continuation rows H, C and exports only the local route from an assumed witness of A to bottom.

The truth-branch refusal projection is Definition 500.3. It reads S, T, H, C, P, N as the finite exclusion ledger and supplies no certificate-indexed truth branch.

The consumer-facing projections are then Definition 500.5, Definition 500.6, and Definition 500.7. These theorems expose the same rows to $\mathsf{Real}^{\uparrow}$, public, and bridge-facing consumers, so the mature route is the single displayed packet and no further coordinate is exported. □

Closure status for $\mathsf{NameCert}_{\mathsf{RefutationBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{RefutationBoundary}^{\uparrow}$ packet is generated from a proposition row, a permitted-refutation route, an optional decidability row, a forbidden-schema descriptor, a truth-branch exclusion ledger, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RefutationBoundary}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 500.1, Definition 500.2, Definition 500.3, Definition 500.4, Definition 500.5, Definition 500.6, Definition 500.7, and Definition 500.8 bind the finite refutation-boundary rows over BHist, hsame, Cont, Pkg, and local NameCert dependency data as the mature public standard-boundary packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RefutationBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close host excluded middle, nonconstructive existence, quotient truth predicates, RealUp completeness, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires Lean encoding of the finite packet and checked theorems for permitted-negation soundness, forbidden truth-branch exclusion, NameCert obligations, RealUp consumer scope, public export, and standard-boundary export.

Chapter 501

Constructive Refutation NameCert Construction

The $\mathsf{ConstructiveRefutation}^{\uparrow}$ surface turns the contradiction-boundary discipline of chapter 9458 into a finite naming packet. It records an assumption row, a displayed route from that assumption to contradiction, the contradiction witness itself, the optional decidability row when such a row is supplied, the fixed certificate scope, the transport and continuation rows through which a consumer may replay the route, package provenance, and the local naming ledger. The packet consumes the boundary surface of chapter 502 before exposing permitted refutation routes. The packet certifies constructor-visible refutation only; it does not contain a certificate-indexed truth branch.

The packet consumes the same local assumption and refutation route surface as chapter 493 and the same optional-decision boundary as chapter 497, while keeping the exported route restricted to its own rows A, R, F, D, S, T, P, N.

Definition 501.1 (ConstructiveRefutation carrier)**.** *A* $\mathsf{ConstructiveRefutation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$C = (A, R, F, D, S, T, P, N)$$

with the following displayed rows:

1. *A is the assumption row whose local witness would be consumed by the refutation;*
2. *R is the permitted refutation route, a displayed* Cont *path from the assumption row into the fixed certificate surface of Definition 9458.1;*
3. *F is the contradiction witness produced by replaying R inside the same finite history and local certificate rows;*
4. *D is an optional decidability row for the assumption predicate, present only when the packet carries a constructive branch for that same row;*
5. *S is the scope row naming the fixed* $\mathsf{NameCert}$ *and the finite ground-loop rows in which the refutation is valid;*
6. *T stores the componentwise* hsame *transports and consumer* Cont *routes for A, R, F, D, S, package rows, and local naming rows;*
7. *P is the* Pkg *provenance over* BHist, Ext, Cont, msame, hsame, *the displayed contradiction route, and the surrounding* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ConstructiveRefutation}^{\uparrow}}$ *ledger.*

The carrier contains no coordinate for a host truth predicate, an unwitnessed existence selector, double-negation elimination without the row D, or a branch over the carrier of all naming certificates.

Lean4 ✓ `BEDC.Derived.ConstructiveRefutationUp.ConstructiveRefutationTasteGate single carrier alignment`

Theorem 501.2 (ConstructiveRefutation permitted soundness)**.** *For every accepted* $\mathsf{ConstructiveRefutation}^{\uparrow}$ *carrier*

$$C = (A, R, F, D, S, T, P, N),$$

the exported refutation of A is sound precisely as a certificate-local negation: any displayed witness of A is consumed by the route R, transported through T, and replayed inside the fixed scope S to produce the contradiction witness F. If the optional decidability row D is present, it may be used only for the same assumption row A and only inside the same carrier.

Proof. Project the carrier of Definition 501.1. The rows A, R, and F give the displayed assumption, the route from that assumption into the fixed certificate, and the contradiction witness obtained by replaying the route.

The scope row S fixes the local NameCert and the finite ground-loop rows used by the route. The transport-and-continuation row T moves only the displayed assumption, route, contradiction witness, optional decision row, and scope data, so a consumer cannot replace the route by a host-level truth test.

When D is present, it is listed as a row for the same assumption predicate A. Replaying R with the transported rows therefore yields a certificate-local negation of A, and no step requires an ambient excluded-middle principle. □

Theorem 501.3 (ConstructiveRefutation forbidden branch exclusion)**.** *An accepted* $\mathsf{ConstructiveRefutation}^{\uparrow}$ *carrier cannot export any forbidden pattern of Definition 9458.5. In particular, it has no coordinate for proving an existence claim by contradiction, no coordinate for eliminating double negation unless the displayed row D supplies a constructive decision for the same assumption row, and no coordinate for a certificate-indexed truth branch over all naming certificates.*

Proof. Inspect the carrier inventory in Definition 501.1. Its only rows are A, R, F, D, S, T, P, N.

The boundary sibling supplies the forbidden-branch ledger, so the $\mathsf{ConstructiveRefutation}^{\uparrow}$ carrier cannot erase that ledger when replaying A, R, F, D, S, T, P, N.

The permitted route is constructor-visible: it starts with the assumption row A, follows the displayed route R, and ends at the contradiction witness F within the fixed scope S. The rows T, P, and N record transport, consumer access, provenance, and local naming data for that route.

No listed row is a selector for witnesses of existential claims obtained from contradiction. No listed row is a truth predicate over all naming certificates. The only row that can support double-negation elimination is D, and it is scoped to the same assumption row A.

Thus the packet can export the permitted refutation pattern, but the forbidden truth branches have no carrier coordinate through which they could be read. □

Closure status for $\mathsf{NameCert}_{\mathsf{ConstructiveRefutation}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ConstructiveRefutation}^{\uparrow}$ packet is generated from an assumption row, a displayed refutation route, a contradiction witness, an optional same-row decidability witness, a fixed certificate scope, transport and continuation rows, package provenance, and a local naming ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ConstructiveRefutation}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 501.1, Definition 501.2, and Definition 501.3 bind permitted refutations to finite BHist, Cont, hsame, Pkg, and NameCert rows while excluding certificate-indexed truth branches.

Formal verification: FormalStatus(NameCert$_{\mathsf{ConstructiveRefutation}\uparrow}$, unformalized)
Bridge status: none
Origin: ai
Not claimed: This chapter does not close classical excluded middle, global truth over naming certificates, existential-by-contradiction witness selection, or a checked Lean certificate.
Upgrade path: Obligation closure requires a Lean encoding of the carrier and checked theorems for permitted-route soundness and forbidden-branch exclusion.

Chapter 502

A Concrete Naming Certificate for $\mathsf{ConstructiveRefutationBoundary}^{\uparrow}$

The $\mathsf{ConstructiveRefutationBoundary}^{\uparrow}$ surface records the proof-discipline boundary of chapter 9458 as a finite NameCert packet. Its carrier separates permitted refutation routes from certificate-indexed truth branches by storing the proof rows that may be replayed, the decidability rows that license double-negation consumption, and the forbidden-branch ledger that prevents a local certificate from exporting classical contradiction principles.

It specializes the refutation-boundary packet of chapter 500 and the stable-negation boundary of chapter 507 by adding the decidability row and forbidden-branch ledger while preserving the refusal of excluded-middle branching and witness selection from contradiction.

Definition 502.1 (Constructive refutation boundary carrier)**.** *A* $\mathsf{ConstructiveRefutationBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (A, R, D, L, H, C, P, N)$$

with the following displayed rows:

1. *A is the proposition row being inspected inside the current certificate-visible history.*
2. *R is the permitted refutation data: a displayed route from an assumed witness of A to $\bot$ using only* Cont, hsame, msame, *and the local certificate rows.*
3. *D is the decidability row for A when such a row is present; it is the only row that permits a double-negation readback for the same proposition row.*
4. *L is the forbidden-branch ledger recording that existential extraction by contradiction, double-negation elimination without D, and excluded-middle branching over all naming certificates are unavailable to the packet.*
5. *H stores the componentwise* hsame *transports for A, R, D, L, package rows, and local naming rows.*
6. *C stores the displayed* Cont *routes for reading A, replaying R, consuming D when present, and checking L.*
7. *P is the* Pkg *provenance over* BHist, Ext, Cont, msame, hsame, *permitted proof rows, decidability rows, forbidden ledgers, and the surrounding* $\mathsf{NameCert}$ *rows.*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ConstructiveRefutationBoundary}^{\uparrow}}$ *row.*

The carrier contains no host truth predicate, no excluded-middle oracle over the carrier of all naming certificates, and no witness selector for an existential obtained only from contradiction.

Theorem 502.2 (Constructive refutation stability)**.** *For an accepted* $\mathsf{ConstructiveRefutationBoundary}^{\uparrow}$ *carrier* $B = (A, R, D, L, H, C, P, N)$*, every consumer read of the permitted refutation row remains a certificate-level proof of* $\neg A$ *after the displayed* hsame *transports and* Cont *routes are replayed. If a double-negation readback is consumed, it factors through the displayed decidability row* D *for the same proposition row.*

Proof. Project the finite carrier. The refutation row R is already a route from an assumed witness of A to $\bot$ using only the displayed ground-loop data.

Transport the proposition row and the refutation route along H, then replay the corresponding continuation route in C. The transported consumer still receives a route from a transported witness of A to $\bot$, so it receives the same certificate-level negation and no ambient truth value.

For double-negation readback, inspect the displayed row D. When D is present, the readback uses the constructive branch carried by the same packet and the same proposition row. When D is absent, the ledger L blocks the double-negation schema named in Definition 9458.5. Thus every permitted route remains stable inside the finite packet. □

Theorem 502.3 (Forbidden branches do not export)**.** *An accepted* $\mathsf{ConstructiveRefutationBoundary}^{\uparrow}$ *packet cannot export a certificate-indexed truth branch. Every consumer read factors through* A, R, D, L, H, C, P, N*, and the ledger row* L *excludes existential extraction by contradiction, double-negation elimination without the displayed decidability row, and excluded-middle branching over the carrier of all naming certificates.*

Proof. Carrier admission exposes only the displayed rows. A consumer may read the proposition row, the permitted refutation route, the optional decidability row, the forbidden-branch ledger, transports, continuations, package provenance, and the local naming row.

Apply the ledger row L. Its three exclusions match the forbidden schemas of Definition 9458.5: unwitnessed existential extraction, double-negation without a decidability row, and excluded-middle branching over all naming certificates.

No row of B classifies all naming certificates, selects witnesses from contradiction alone, or internalizes the host truth predicate. Therefore the consumer cannot obtain the certificate-indexed branch of Definition 9458.10; it remains inside the constructive refutation boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{ConstructiveRefutationBoundary}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ConstructiveRefutationBoundary}^{\uparrow}$ packet is generated from a proposition row, permitted refutation data, an optional decidability row, a forbidden-branch ledger, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ConstructiveRefutationBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 502.1, Definition 502.2, and Definition 502.3 bind the finite proof-discipline carrier separating permitted refutation routes from certificate-indexed truth branches.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ConstructiveRefutationBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close classical excluded middle, global truth over naming certificates, witness selection from contradiction alone, or checked Lean realization.

Upgrade path: Obligation closure requires Lean encoding of the packet and checked carrier, stability, ledger, and non-export obligations for the named proof-discipline surface.

Chapter 503

A Concrete Naming Certificate for $\mathsf{WitnessedRefutation}^{\uparrow}$

The $\mathsf{WitnessedRefutation}^{\uparrow}$ surface packages the permitted contradiction boundary as finite NameCert data. It records the source history whose claim is being rejected, the continuation packet that turns an attempted witness into a displayed bottom row, the transported refutation ledger, and the local naming certificate that keeps the whole argument inside BHist, Cont, hsame, and $\mathsf{NameCert}$. The packet does not prove an unwitnessed existence statement, does not eliminate double negation for an undecided classifier, and does not branch on excluded middle for certificate-level predicates.

Definition 503.1 (Witnessed refutation carrier)**.** *A* $\mathsf{WitnessedRefutation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (h, A, R, b, H, C, P, N)$$

with the following displayed rows:

1. *h is the source* Hist *row at which the rejected claim is read;*
2. *A is the attempted-witness packet, recording only the visible BEDC evidence whose use is being refuted;*
3. *R is the continuation/refutation packet, a finite list of* Cont *rows that sends each admitted attempted witness for A at h to the bottom row;*
4. *b is the produced bottom witness, displayed as the terminal absurdity row reached by the continuation packet;*
5. *H records the componentwise* hsame *transports for the source history, attempted-witness packet, refutation packet, bottom row, package provenance, and local naming row;*
6. *C records the* Cont *routes that read the source history, expose the attempted witness, execute the refutation packet, and return the bottom row to the ledger;*
7. *P is the* Pkg *provenance over* BHist, Hist, Cont, hsame, *explicit bottom witnesses, and the surrounding certificate rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{WitnessedRefutation}^{\uparrow}}$ *ledger.*

The carrier is exactly this finite packet. It has no coordinate for unwitnessed excluded middle, double-negation elimination on an undecided proposition, proof by contradiction into an existential conclusion, or a predicate over the carrier of all naming certificates.

Lean4 ✓ BEDC.Derived.WitnessedRefutationUp.WitnessedRefutationTasteGate single carrier alignment

Definition 503.2 (Witnessed refutation classifier)**.** *The* $\mathsf{WitnessedRefutation}^{\uparrow}$ *classifier compares two accepted packets only by transported displayed witnesses. It relates*

$$W = (h, A, R, b, H, C, P, N)$$

and

$$W' = (h', A', R', b', H', C', P', N')$$

when the source histories, attempted-witness packets, continuation/refutation packets, produced bottom witnesses, transport ledgers, continuation routes, package provenance, and local naming rows are connected by the recorded componentwise hsame *rows and by the displayed* Cont *routes. Thus classifier transport carries exactly the same refutation evidence from* W *to* W'*: the source* Hist *row, the attempted witness, the continuation packet, and the produced bottom witness.*

Theorem 503.3 (WitnessedRefutation NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{WitnessedRefutation}^{\uparrow}}$ *surface has five finite obligations:*

1. *carrier exposure: every accepted object exposes the tuple* $W = (h, A, R, b, H, C, P, N)$ *of Definition 503.1;*
2. *classifier stability: classifier-related packets transport the source row, attempted-witness packet, refutation packet, bottom witness, provenance, and local naming row by the displayed* hsame *data;*
3. Cont*-locality: the refutation route uses only the continuation rows recorded in* R *and* C*;*
4. *ledger witness accountability: every produced bottom row* b *is reached from a displayed attempted witness through the recorded route, and no bottom row is accepted without that route;*
5. *separation from unwitnessed schemas: the packet exports no excluded-middle branch, no double-negation eliminator for an undecided classifier, and no proof-by-contradiction rule whose conclusion is an existential witness.*

Proof. Carrier exposure is projection from the finite tuple of Definition 503.1. Each coordinate is a displayed BHist row or a finite ledger row named by the tuple.

Classifier stability is exactly Definition 503.2. The comparison transports the same source history, attempted-witness packet, refutation packet, bottom witness, provenance, and naming row, and has no hidden coordinate to compare.

Cont-locality follows by inspecting R and C. The route from an attempted witness to b is a finite continuation chain recorded in those coordinates.

Ledger witness accountability follows because b is a coordinate only together with the route that produces it. A consumer projecting b must also project the source, attempted witness, and continuation packet that account for it.

Finally, separation from unwitnessed schemas is immediate from the carrier inventory. None of the coordinates names an excluded-middle branch over certificates, an undecided double-negation eliminator, or an existential witness produced without its constructor. □

Theorem 503.4 (Witnessed refutation separation from forbidden schemas)**.** *Every consumer read of an accepted* $\mathsf{WitnessedRefutation}^{\uparrow}$ *packet factors through the displayed source history, attempted-witness packet, continuation/refutation packet, and produced bottom witness. Consequently the packet realizes only the permitted rule "a displayed witness of* A *leads by displayed* Cont *rows to* $\bot$*, hence* A *is refuted at this certificate surface" and cannot be read as any of the forbidden contradiction schemas of Definition 9458.5.*

Proof. Project the accepted packet as $W = (h, A, R, b, H, C, P, N)$. Any consumer read is one of these displayed coordinates or a component transported through H and exposed through C.

The only negative conclusion available from the packet is the function that sends an admitted attempted witness for A at h through the recorded continuation packet R to the displayed bottom witness b. This is the permitted refutation shape of Definition 9458.1.

The three forbidden shapes require data absent from the packet: a constructor for an existential obtained from $\neg\forall\neg$, a double-negation eliminator for an undecided classifier, or a certificate-indexed excluded-middle branch. Since the carrier and classifier expose none of these coordinates, no consumer can extract them from $\mathsf{WitnessedRefutation}^{\uparrow}$. □

Theorem 503.5 (Witnessed refutation concretizes the contradiction boundary)**.** *The* $\mathsf{WitnessedRefutation}^{\uparrow}$ *certificate realizes the proof-discipline boundary of chapter 9458: permitted refutations are represented as explicit* Hist*-level evidence carried through* Cont *and* hsame*, while the unwitnessed contradiction schemas remain outside the NameCert surface.*

Proof. The permitted side is the packet $W = (h, A, R, b, H, C, P, N)$. Its source history, attempted-witness row, continuation/refutation packet, and produced bottom witness are all explicit BEDC rows, and the classifier transports them only by hsame and displayed Cont routes.

The boundary side is Definition 503.4. Since the carrier has no coordinate for certificate-level excluded middle, undecided double-negation elimination, or existential-by-contradiction, the packet cannot close the meta loop described in the vision chapter.

Thus the certificate is a concrete NameCert realization of the permitted contradiction boundary: refutation is admitted exactly when its bottom witness and route are displayed in the ledger. □

Theorem 503.6 (Witnessed refutation carrier admission obligation)**.** *For an accepted* $\mathsf{WitnessedRefutation}^{\uparrow}$ *packet, carrier admission is exactly the finite tuple*

$$W = (h, A, R, b, H, C, P, N)$$

of Definition 503.1. The admitted rows are the source Hist *row* h*, attempted-witness packet* A*, displayed continuation/refutation packet* R*, produced bottom witness* b*, componentwise* hsame *ledger* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{WitnessedRefutation}^{\uparrow}}$ *row* N*. The AI single-carrier evidence is the checked TasteGate alignment marker attached to Definition 503.1, so no second carrier coordinate is available.*

Proof. Project the accepted packet to the tuple of Definition 503.1. Each admitted coordinate is named in that tuple and is read as a displayed BHist row or a finite ledger row.

The TasteGate alignment fixes the AI surface to this one carrier inventory. Since the inventory contains only h, A, R, b, H, C, P, N, a consumer cannot admit a hidden witness source, an extra bottom row, or a second naming carrier.

Thus carrier admission is exhausted by the concrete packet rows, with no route to excluded middle or to an unwitnessed contradiction schema. □

Theorem 503.7 (Witnessed refutation route transport obligation)**.** *Classifier transport for* $\mathsf{WitnessedRefutation}^{\uparrow}$ *carries the displayed refuter route only through the rows of Definition 503.1. If*

$$W = (h, A, R, b, H, C, P, N)$$

and

$$W' = (h', A', R', b', H', C', P', N')$$

are classifier-related accepted packets, then the source history, attempted-witness packet, continuation/refutation packet, produced bottom row, provenance, and local naming row are transported by the stored hsame *data and replayed through the displayed* Cont *routes. No transport step may replace the refuter route by a non-displayed proof by contradiction.*

Proof. Start with the classifier of Definition 503.2. It relates two packets by componentwise transport of the same source row, attempted-witness packet, refutation packet, bottom witness, provenance, and naming row.

Read the refuter route through R and C. The continuation rows execute the attempted witness route to the bottom witness, while H transports the named coordinates between classified packets.

Because the classifier has no coordinate beyond the displayed tuple, the transported route remains a Cont route over the same finite ledger. It cannot be replaced by an excluded-middle branch, a double-negation eliminator, or an existential conclusion without a witness row. □

Theorem 503.8 (Witnessed refutation bottom-ledger non-escape obligation)**.** *Every bottom-ledger read of an accepted* $\mathsf{WitnessedRefutation}^{\uparrow}$ *packet factors through the source row h, attempted-witness packet A, continuation/refutation packet R, produced bottom witness b,* hsame *ledger H,* Cont *routes C,* Pkg *provenance P, and local* NameCert *row N. Consequently the packet exports no excluded-middle branch, no double-negation eliminator for an undecided classifier, and no unwitnessed contradiction schema outside the displayed bottom route.*

Proof. Read the bottom row from the carrier. The coordinate b is stored only with the source row, attempted-witness packet, refutation packet, transport ledger, continuation routes, provenance, and local naming row.

Apply the forbidden-schema separation theorem. It already identifies the only negative conclusion available from the packet as the displayed route sending an admitted attempted witness through R to b.

The bottom ledger therefore has no escape row. A consumer may project the witnessed refutation route, but it cannot extract certificate-level excluded middle, undecided double-negation elimination, or an existential-by-contradiction rule. □

Theorem 503.9 (Witnessed refutation RefutationWitness dependency boundary)**.** *Every accepted* $\mathsf{WitnessedRefutation}^{\uparrow}$ *packet consumes the same assumption-to-bottom route shape exposed by chapter 511. The witnessed packet adds the attempted-witness row A and TasteGate single-carrier alignment for $W = (h, A, R, b, H, C, P, N)$, but its bottom-ledger non-escape row is the witnessed form of the* $\mathsf{RefutationWitness}^{\uparrow}$ *route replay surface: a displayed assumption is carried through recorded* Cont *rows to bottom, with no excluded-middle branch, undecided double-negation eliminator, or unwitnessed contradiction schema.*

Proof. Read the sibling route first. chapter 511 exposes the constructive assumption-to-bottom surface as a finite route from an admitted assumption through displayed continuation rows to a bottom witness.

Project the witnessed packet. Its carrier adds the attempted-witness row A to the source history, refuter route, bottom ledger, transport, continuation, provenance, and local naming rows, and the checked TasteGate alignment attached to Definition 503.1 fixes those rows as one carrier surface.

Apply Definition 503.8. The bottom read still factors through the displayed source, attempted witness, continuation/refutation packet, bottom row, transport, continuation, provenance, and

naming rows. Thus the dependency is substantive: the witnessed bottom-ledger row is the RefutationWitness route replay boundary with the attempted witness and single-carrier alignment made explicit. □

Closure status for $\mathsf{NameCert}_{\mathsf{WitnessedRefutation}\uparrow}$.

Constructive story: A $\mathsf{WitnessedRefutation}^{\uparrow}$ packet is generated from a source Hist row, an attempted-witness packet, a displayed Cont refutation route, the produced bottom witness, componentwise hsame transports, Pkg provenance, and a local NameCert ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{WitnessedRefutation}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 503.1, Definition 503.2, Definition 503.3, Definition 503.6, Definition 503.7, Definition 503.8, Definition 503.4, and Definition 503.5 bind the finite carrier, displayed classifier, carrier admission, refuter-route transport, bottom-ledger non-escape, and separation from unwitnessed contradiction schemas; the same displayed bottom route supplies the paper bridge from witnessed refutation to the abstract permitted-refutation schema.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{WitnessedRefutation}\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.WitnessedRefutationUp.WitnessedRefutationTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: ai

Lean4 ✓ `BEDC.Derived.WitnessedRefutationUp.taste gate`

Not claimed: This chapter does not close bridge status, excluded-middle branch, undecided double-negation eliminator, existential-by-contradiction rule, or predicate over the carrier of all naming certificates.

Upgrade path: No paper-side closure upgrade remains; bridge checking is the remaining formal-axis route.

Chapter 504

A Concrete Naming Certificate for $\mathsf{FiniteTraceGapSocket}^{\uparrow}$

The $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ surface turns the finite-trace side of chapter 9393 into a concrete BEDC packet. It records a bounded observation list, the explicit GAP socket that marks the unclosed universal claim, the finite replay route through $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$, and the visible BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows that keep the socket auditable. The packet accounts for finite windows only; it does not supply mathematical induction, host completeness, a selected real limit, or a universal quantifier over not-yet-observed rows.

Definition 504.1 (FiniteTraceGapSocket carrier)**.** *A* $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (T, W, S, R, Q, H, C, P, N)$$

with the following displayed rows:

1. *T is the finite observation trace, a bounded list of previously recorded observation rows;*
2. *W is the GAP socket row attached to the claim that the finite trace does not close;*
3. *S is the* $\mathsf{StreamName}^{\uparrow}$ *schedule that replays the observation windows of T;*
4. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained from the replayed finite windows when the observations are consumed by the real-and-completion interface;*
5. *Q is the downstream* $\mathsf{Real}^{\uparrow}$ *seal row, present only as a consumer-facing boundary for the finite readback;*
6. *H records componentwise* hsame *transports for the trace, socket, stream schedule, regular readback, real seal, package provenance, and local naming row;*
7. *C records the displayed* Cont *routes that read the trace, expose the GAP socket, replay each admitted finite window, hand the replay to R, and expose Q only after that handoff;*
8. *P is the* Pkg *provenance over* BHist, Gap, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteTraceGapSocket}^{\uparrow}}$ *row.*

The carrier is exactly this finite trace socket. It has no row for induction, no row for a completed infinite observation stream, no selected limit, no host real equality test, and no completeness principle.

Theorem 504.2 (FiniteTraceGapSocket NameCert obligations)**.** *For the carrier of Definition 504.1, the local* $\mathsf{NameCert}_{\mathsf{FiniteTraceGapSocket}^{\uparrow}}$ *surface consists of five finite rows:*

1. *trace carrier: every accepted object exposes the tuple* $G = (T, W, S, R, Q, H, C, P, N)$ *and the bounded observation list* T*;*
2. *socket classifier: classifier comparison transports the trace row, GAP socket row, replay schedule, readback row, real seal row, provenance row, and local naming row by the displayed* hsame *data;*
3. *finite observation replay: each consumer read of an observed window factors through* T*, then through the* $\mathsf{StreamName}^{\uparrow}$ *schedule* S*, and then through the displayed* Cont *route into* R*;*
4. *ledger non-escape: the package row* P *exhausts the available dependencies and exposes no induction rule, hidden infinite stream, selected limit, host equality, trichotomy, or completeness datum;*
5. $\mathsf{StreamName}^{\uparrow}/\mathsf{RegSeqRat}^{\uparrow}$ *handoff: the finite replay schedule* S *is the only source for the* $\mathsf{RegSeqRat}^{\uparrow}$ *row* R*, and the real seal* Q *is readable only after that handoff.*

Proof. Trace carrier exposure is projection from Definition 504.1. The bounded list T, GAP socket W, replay schedule S, readback row R, seal row Q, transports, continuation routes, provenance, and local naming row are all coordinates of one finite BHist packet.

Socket classifier stability is componentwise. The stored hsame rows in H compare exactly the displayed coordinates, and the Cont rows in C replay the same trace, socket, schedule, readback, seal, package, and naming routes after transport.

For finite observation replay, a consumer first reads a window from T. The only stream-facing route then passes through the schedule S, and the only regular-readback route passes from S to R through the displayed continuation ledger.

Ledger non-escape follows from the package inventory. Since P names only the displayed BEDC rows, any induction rule, infinite stream, selected limit, host equality test, trichotomy branch, or completeness principle would require an extra coordinate absent from G.

Finally, the $\mathsf{StreamName}^{\uparrow}/\mathsf{RegSeqRat}^{\uparrow}$ handoff is the route T to S to R to Q. Thus the real-and-completion consumer sees only finite replay data and the visible GAP socket that records what remains unclosed. □

Theorem 504.3 (FiniteTraceGapSocket classifier transport)**.** *For an accepted* $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ *carrier* $G = (T, W, S, R, Q, H, C, P, N)$*, componentwise* hsame *transport preserves the displayed trace row* T*, GAP socket row* W*, stream schedule* S*, regular readback* R*, real seal boundary* Q*, transport ledger* H*, continuation ledger* C*, provenance row* P*, and local naming row* N*. The transport does not add host real equality, quotient equality, trichotomy, completeness, induction, a selected limit, or an infinite observation stream.*

Proof. Project the carrier of Definition 504.1. Its transport coordinate H is indexed by exactly the displayed rows $T, W, S, R, Q, H, C, P, N$, so classifier comparison can only move a consumer along these named component rows.

The continuation ledger C remains tied to the same coordinates after transport. Thus the trace read, the GAP socket read, the replay schedule, the regular readback, the real seal boundary, the provenance row, and the local $\mathsf{NameCert}_{\mathsf{FiniteTraceGapSocket}^{\uparrow}}$ row are preserved component by component.

Any host equality, quotient equality, trichotomy branch, completeness principle, induction rule, selected limit, or infinite stream would require a coordinate not present in G. Since the transport is componentwise over the existing carrier rows, it cannot create such a coordinate. □

Theorem 504.4 (FiniteTraceGapSocket replay exactness)**.** *Every observed-window read of an accepted* $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ *packet factors through the finite route*

$$T \to S \to R.$$

The real seal row Q is visible only after the regular readback row R has been reached through that route.

Lean4 ✓ `BEDC.Derived.FiniteTraceGapSocketUp.FiniteTraceGapSocket replay route package`

Proof. An observed-window read begins with the finite trace coordinate T of the carrier. No other coordinate of G is an observation source, so the read first selects one of the bounded rows already present in T.

The stream-facing continuation in C then sends that selected finite window through the replay schedule S. The regular-readback continuation is the displayed handoff from S to R, so the read factors through $T \to S \to R$ before any real-facing row is available.

Finally, Q is listed as the downstream $\mathsf{Real}^{\uparrow}$ seal boundary, not as an independent observation source. It is therefore exposed only after the regular readback R has been obtained from the finite replay path. □

Theorem 504.5 (FiniteTraceGapSocket ledger non-escape)**.** *For an accepted* $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ *carrier $G = (T, W, S, R, Q, H, C, P, N)$, the package row P, the local naming row N, and the GAP socket W leave mathematical induction, selected limits, infinite streams, trichotomy, host real equality, quotient real equality, and completeness outside the packet.*

Proof. Read the package inventory P and local naming row N from the carrier. They name the finite trace, the GAP socket, the replay schedule, the regular readback, the real seal boundary, the componentwise transports, the displayed continuations, provenance, and the local naming certificate.

The GAP socket W records precisely that the finite trace leaves the universal claim open. It is a named row of the packet, not a constructor for induction, a selected limit, an infinite stream, trichotomy, host equality, quotient equality, or completeness.

Thus any consumer using P, N, or W remains inside the finite carrier rows. The listed non-finite principles are not coordinates of G, so the ledger cannot provide them by route composition. □

Theorem 504.6 (FiniteTraceGapSocket real-window boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ *packet factors through the finite route*

$$T \to W \to S \to R \to Q \to H \to C \to P \to N.$$

The consumer may inspect the observed finite windows and the GAP socket that marks the unclosed universal claim, but it cannot read induction, host completeness, a selected real limit, or an infinite observation stream from the packet.

Proof. Project the accepted carrier $G = (T, W, S, R, Q, H, C, P, N)$. The only observation source is the finite trace T, and the only record of what the trace does not close is the GAP socket W.

Apply Definition 504.2. Its finite observation replay row routes every observed window through S and then into R, while its handoff row exposes Q only after that regular readback.

The ledger non-escape row rules out the unavailable structure. Therefore every real-window or completion-facing read remains inside the displayed packet and treats W as a socket rather than as an internally discharged universal claim. □

Theorem 504.7 (FiniteTraceGapSocket inscription-point sibling route)**.** *Every* $\mathsf{InscriptionPoint}^{\uparrow}$ *consumer that reads the finite GAP row through chapter 610 can do so only after the* $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ *rows*

$$T, W, S, R, Q, H, C, P, N$$

of Definition 504.1 are exposed. The sibling route introduces no hidden supply rule, induction rule, or infinite stream.

Proof. Project the accepted carrier $G = (T, W, S, R, Q, H, C, P, N)$ from Definition 504.1. The finite GAP socket is the displayed row W, and its replay, readback, real-window boundary, transports, continuations, provenance, and naming rows are exactly the remaining coordinates of G.

Now read the sibling $\mathsf{InscriptionPoint}^{\uparrow}$ carrier of chapter 610. Its finite GAP input is named as the $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ coordinate G before any inscription-point consumer can use that gap row.

Therefore the inscription-point route factors through this chapter's finite socket packet first. Since neither carrier contains a row for a hidden supply rule, induction rule, or infinite observation stream, the sibling route cannot introduce one while consuming the finite GAP row. □

Theorem 504.8 (FiniteTraceGapSocket scoped support package)**.** *The carrier of Definition 504.1, the NameCert obligations of Definition 504.2, classifier transport from Definition 504.3, replay exactness from Definition 504.4, ledger non-escape from Definition 504.5, the real-window boundary from Definition 504.6, and the InscriptionPoint sibling route from Definition 504.7 exhaust the scoped BEDC support for* $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ *over* BHist*,* Gap*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*.*

Within that scope, induction, host completeness, selected limits, quotient real equality, real-order trichotomy, and infinite observation streams have no carrier coordinate and no continuation route.

Proof. Read the support package by projecting the carrier $G = (T, W, S, R, Q, H, C, P, N)$. The carrier theorem supplies exactly the finite trace, GAP socket, stream schedule, regular readback, real seal boundary, transport rows, continuation rows, provenance row, and local naming row.

The NameCert obligations bind those rows as the available certificate surface. Classifier transport preserves the same coordinates, replay exactness forces every observed-window read through $T \to S \to R$, ledger non-escape rules out hidden supply from P, and the real-window boundary keeps each completion-facing consumer on the displayed finite route.

It remains to account for the external consumer named in the scope. The sibling-route theorem states that an $\mathsf{InscriptionPoint}^{\uparrow}$ consumer reaches the finite GAP row only through the same $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ packet, so the route adds no coordinate beyond the rows already listed.

Thus every named support route is one of the displayed carrier, certificate, classifier, replay, ledger, real-window, or sibling rows. The principles listed outside the scope would require a carrier coordinate or continuation absent from G, so they are not supplied by the package. □

Theorem 504.9 (FiniteTraceGapSocket TasteGate alignment record)**.** *The checked Lean carrier-alignment target* $BEDC.Derived.FiniteTraceGapSocketUp.FiniteTraceGapSocketTasteGate_single_carrier_$ *names the same finite packet surface as Definition 504.8. It is used here only as verification of the single-carrier surface for* $\mathsf{FiniteTraceGapSocket}^{\uparrow}$*, not as a paper-side substitute for the carrier, NameCert obligations, classifier transport, finite replay exactness, ledger non-escape, real-window boundary, or sibling-route obligations.*

Proof. The named Lean target is attached to the $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ TasteGate carrier. Its role is to confirm that the checked carrier-alignment surface is the single finite packet described by the chapter, rather than a separate theory object.

The paper obligations remain the scoped rows assembled in Definition 504.8. Therefore the Lean target records verification of the carrier surface while the displayed theorem and its cited support rows state the paper-side closure content. □

Theorem 504.10 (FiniteTraceGapSocket public consumer export)**.** *Every public consumer of an accepted* $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ *packet receives exactly the finite socket export assembled by the carrier of Definition 504.1, the NameCert obligations of Definition 504.2, classifier transport from Definition 504.3, replay exactness from Definition 504.4, ledger non-escape from Definition 504.5, the real-window boundary from Definition 504.6, the InscriptionPoint sibling route from Definition 504.7, the scoped support package of Definition 504.8, and the TasteGate alignment record of Definition 504.9. The export contains no induction rule, infinite observation stream, selected limit, quotient real equality, host completeness, or real-order trichotomy.*

Proof. Start with a public consumer of an accepted carrier $G = (T, W, S, R, Q, H, C, P, N)$. The carrier definition supplies the displayed finite trace, GAP socket, stream schedule, regular readback, real seal boundary, componentwise transports, continuation routes, provenance, and local naming row.

The certificate and transport rows identify the consumer-facing export. Apply Definition 504.2 for the finite NameCert surface and Definition 504.3 for componentwise preservation of the same rows.

Next, the replay and boundary theorems determine the only finite observation route. Apply Definition 504.4, Definition 504.5, and Definition 504.6; together they force observed-window reads through the displayed finite route and keep the non-finite principles outside the packet.

It remains to account for the named public consumers. The InscriptionPoint sibling route of Definition 504.7 consumes the GAP row only through this finite socket, while Definition 504.8 bundles the same carrier, certificate, classifier, replay, ledger, boundary, and sibling rows into the scoped support package.

Finally, Definition 504.9 records that the checked TasteGate target names this same single-carrier surface. Hence the public consumer receives exactly the finite socket export described above and no induction rule, infinite stream, selected limit, quotient real equality, host completeness, or trichotomy row. □

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteTraceGapSocket}^{\uparrow}}$.

Constructive story: A $\mathsf{FiniteTraceGapSocket}^{\uparrow}$ packet is generated from a bounded finite observation trace, an explicit GAP socket row, a $\mathsf{StreamName}^{\uparrow}$ replay schedule, a $\mathsf{RegSeqRat}^{\uparrow}$ readback row, a $\mathsf{Real}^{\uparrow}$ seal boundary, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FiniteTraceGapSocket}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 504.1, Definition 504.2, Definition 504.3, Definition 504.4, Definition 504.5, Definition 504.6, Definition 504.7, Definition 504.8, Definition 504.9, and Definition 504.10 bind the carrier, the total NameCert obligation surface, classifier transport, finite replay exactness, ledger non-escape, the real-window boundary, the inscription-point sibling route, the scoped support package, the checked single-carrier alignment record, and the public bridge-facing finite-trace GAP socket route.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FiniteTraceGapSocket}^{\uparrow}}$, axiomClean)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close mathematical induction, host completeness, selected real limits, quotient real equality, real-order trichotomy, or infinite observation streams.

Upgrade path: No further theory-axis upgrade is claimed for the finite-trace GAP socket export.

Chapter 505

A Concrete Naming Certificate for $\mathsf{CausalCommitment}^{\uparrow}$

The $\mathsf{CausalCommitment}^{\uparrow}$ surface packages the causality reading of Definition 9415.1 as finite NameCert data. It records observed regularity rows, the GAP socket that binds those rows to not-yet-observed continuations, transport evidence for the visible ledger, and the local naming row that prevents the packet from becoming a hidden law of nature, selected future record, or global observer frame.

The forward-GAP refinement is consumed through the locality-cell surface of chapter 509 and, when the consumer is observer-indexed, through the observer-locality surface of chapter 513. The precise dependency is asymmetric: $\mathsf{CausalCommitment}^{\uparrow}$ supplies the observed-regularity GAP row, while the locality-cell chapters restrict the consumer to local observer cells and prevent selected future observations or global observer frames.

Definition 505.1 (Causal commitment carrier)**.** *A* $\mathsf{CausalCommitment}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (O, R, G, F, H, C, P, N)$$

with the following displayed rows:

1. *O is the finite observed-history ledger whose records support the regularity read;*
2. *R is the observed regularity ledger, listing the displayed pattern rows read from O;*
3. *G is the* GAP *socket row whose content is that the regularity rows in R remain binding for not-yet-observed continuations;*
4. *F is the forward-binding route from the observed ledger to the continuation-facing commitment row;*
5. *H records componentwise* hsame *transports for O, R, G, F, package provenance, and the local naming row;*
6. *C records the* Cont *routes that read the observed ledger, expose the regularity rows, enter the* GAP *socket, and return the commitment row to the finite packet;*
7. *P is the* Pkg *provenance over* BHist, Hist, GAP, hsame, Cont, *and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$ *row.*

The carrier is exactly this finite packet. It contains no selected future observation, no universal empirical law, no hidden induction rule, no synchronized global frame, and no ambient causal primitive.

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentTasteGate single carrier alignment`

Theorem 505.2 (CausalCommitment GAP socket)**.** *Every accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *packet reads the causal step through the displayed* GAP *socket row* G*. The observed ledger* O *and regularity ledger* R *supply only finite records; the forward-looking content is named only by* G *and cannot be projected as an internally generated universal law.*

Proof. Project the carrier of Definition 505.1. The only row whose content points beyond the observed ledger is G.

The rows O and R are finite history and regularity ledgers. They display what has been observed and what pattern has been read, but they do not contain a row for all future continuations.

Therefore any consumer that asks for the causal step must pass through the GAP socket. Since no other coordinate names future universality, the packet cannot expose an internally generated empirical law. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentCarrier gap socket`

Theorem 505.3 (CausalCommitment forward-binding route)**.** *For an accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *packet, the route from observed regularity to causal commitment is exactly the displayed forward-binding row* F *together with the* Cont *routes in* C*. The route starts at the finite ledger* O, R*, enters the* GAP *socket* G*, and returns only the local commitment row named by* $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$*.*

Proof. Start from the observed side. The packet first exposes O and R, so the route has a displayed finite source.

The forward-facing step is then recorded by F and replayed by C. These rows send the observed regularity ledger through G rather than through an unrecorded rule of induction.

At the output side the consumer receives the local commitment row N together with the same provenance and transport data. Thus the forward-binding route is finite, named, and confined to the displayed packet. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentCarrier forward binding route`

Definition 505.4 (CausalCommitment forward-GAP carrier)**.** *A forward-GAP refinement of the* $\mathsf{CausalCommitment}^{\uparrow}$ *carrier is the finite packet*

$$K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$$

where O, R, G, F, H, C, P, N *are the rows of Definition 505.1, and* L *is the locality-cell consumer row. The row* L *records the consumer-facing handoff to* $\mathsf{LocalityCell}^{\uparrow}$ *and* $\mathsf{ObserverLocalityCell}^{\uparrow}$*: it may read the displayed commitment only through the finite locality cell generated from* O, R, G, F, H, C, P, N*, and it contains no selected future observation, no global observer frame, and no ambient causal primitive.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentForwardGapCarrier locality replay package`

Theorem 505.5 (CausalCommitment forward-GAP obligations)**.** *For an accepted forward-GAP carrier* $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$*, the local* $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$ *surface exposes exactly five consumer-facing obligations:*

1. *carrier exposure for the displayed rows $O, R, G, F, L, H, C, P, N$;*
2. GAP *accountability, requiring every forward-looking read to pass through G;*
3. *forward-route stability, requiring F and C to replay the observed-regularity route without adding a hidden induction rule;*
4. *locality-cell consumer restriction, requiring every observer-locality consumer to read through L;*
5. *non-escape for selected future observations, global observer frames, universal empirical laws, hidden induction rules, and ambient causal primitives.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentForwardGapObligations`

Proof. Carrier exposure is projection from Definition 505.4. The refinement adds only the locality-cell consumer row L to the rows already displayed by the base carrier.

The GAP and forward-route obligations use Definition 505.2 and Definition 505.3. The forward-looking content is named by G, while F and C replay the route from observed regularity to local commitment.

The locality-cell restriction then reads the commitment through L. Since L is a consumer row rather than a new causal source, it can expose the commitment to observer-locality consumers only by replaying the same finite rows.

The non-escape clauses follow by inventory. The refined packet has no coordinate for a selected future record, global frame, universal law, hidden induction rule, or ambient causal primitive. □

Theorem 505.6 (CausalCommitment locality-cell handoff)**.** *Every observer-locality consumer of an accepted forward-GAP carrier $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$ reads the causal commitment only through the displayed locality-cell row L. The handoff may expose the observed ledger, regularity ledger,* GAP *socket, forward-binding route, transports, continuations, provenance, and local naming row, but it cannot extract a selected future observation, a global observer frame, or an ambient causal primitive.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentLocalityCellHandoff`

Proof. Begin with the consumer side of the refined carrier. The only row addressed to observer-locality consumption is L, so any such consumer first enters the finite locality-cell handoff.

Inside that handoff, the available reads are the rows already displayed by O, R, G, F, H, C, P, N. The row L does not add a further observation source or a global frame; it routes the same commitment through the locality-cell discipline.

Therefore the consumer receives a local commitment packet and nothing beyond it. A selected future observation, global observer frame, or ambient causal primitive has no carrier coordinate and no read route through L. □

Theorem 505.7 (CausalCommitment carrier visibility)**.** *For every accepted forward-GAP carrier $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$, the finite* BHist *rows $O, R, G, F, L, H, C, P, N$ are visible before any consumer reads* CausalCommitment$^{\uparrow}$*. The observed-history row, regularity row,* GAP *socket, forward-binding route, locality consumer row,* hsame *transports,* Cont *replay,* Pkg *provenance, and local* NameCert *row cannot be replaced by a hidden causal primitive.*

Proof. Project the forward-GAP carrier of Definition 505.4. It displays exactly $O, R, G, F, L, H, C, P, N$.

Use the GAP socket theorem and the forward-binding route theorem. The future-facing content is named by G, while F and C replay the observed-regularity route from O, R to the local commitment row.

The locality row L only hands the same carrier to locality-cell consumers. Since H, P, N transport, record, and name the displayed rows, the accepted carrier has no coordinate for a hidden causal primitive. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentCarrier visibility`

Theorem 505.8 (CausalCommitment classifier stability)**.** *The* $\mathsf{CausalCommitment}^{\uparrow}$ *classifier is stable under componentwise* hsame *transport of the displayed rows* $O, R, G, F, L, H, C, P, N$*. A consumer may replay the forward-GAP route through* Cont *and* Pkg *data, but it must preserve the finite* BHist *carrier, the* GAP *socket, the forward-binding route, the locality row, and the local* NameCert *row as separate coordinates.*

Proof. Begin with the componentwise transport row H. By construction it transports O, R, G, F, L together with package provenance and local naming data.

Apply Definition 505.2 and Definition 505.3. These theorems identify the forward-looking content with G and the observed-to-commitment route with F and C.

The forward-GAP obligations then force the locality consumer to pass through L. Thus classifier membership is preserved only by transporting the displayed rows componentwise; it is not preserved by collapsing the socket, route, locality row, or local NameCert into one ambient causal claim. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentForwardGapCarrier transport`

Theorem 505.9 (CausalCommitment ledger non-escape)**.** *No accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *read over the forward-GAP carrier* $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$ *can export a selected future observation, a universal empirical law, a hidden induction rule, a synchronized global frame, or an ambient causal primitive. The local* $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$ *row names only the displayed* BHist*,* hsame*,* Cont*,* Pkg*, locality, GAP, and forward-binding rows.*

Proof. Start from carrier visibility. Every accepted read begins with the displayed rows $O, R, G, F, L, H, C, P, N$.

Use classifier stability to keep those rows separated under hsame transport and Cont replay. The GAP socket remains G, the forward route remains F, and the locality consumer remains L.

Finally apply the forward-GAP obligations. Their non-escape clause excludes selected future observations, global observer frames, universal empirical laws, hidden induction rules, and ambient causal primitives. Since no displayed row names one of those objects, the local ledger cannot export it. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentLedgerNonescape`

Theorem 505.10 (CausalCommitment carrier obligation)**.** *Every accepted forward-GAP* $\mathsf{CausalCommitment}^{\uparrow}$ *carrier exposes exactly the displayed rows*

$$O, R, G, F, L, H, C, P, N.$$

Here O, R *are the finite observed and regularity ledgers,* G *is the* GAP *socket,* F *is the forward-binding route,* L *is the locality-cell consumer row,* H, C *are the componentwise transport and displayed replay rows,* P *is package provenance, and* N *is the local* $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$ *row. No other causal, observer, locality, or induction coordinate belongs to the accepted carrier.*

Proof. Project the forward-GAP carrier of Definition 505.4. It lists $O, R, G, F, L, H, C, P, N$ and describes L as the only locality-cell consumer handoff.

Apply the GAP socket theorem and the forward-binding route theorem. They account for the only forward-looking row G and the only route from observed regularity to commitment, namely F replayed by C.

Next use the forward-GAP obligations. Carrier exposure, GAP accountability, route stability, locality restriction, and non-escape are all stated over the same nine displayed rows.

Finally invoke ledger non-escape. Since selected future observations, global observer frames, universal empirical laws, hidden induction rules, and ambient causal primitives have no coordinate in the packet, the carrier obligation is exactly $O, R, G, F, L, H, C, P, N$. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentCarrier obligation`

Theorem 505.11 (CausalCommitment locality transport)**.** *Every observer-locality transport of an accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *forward-GAP packet factors through the locality-cell row L and the displayed* Cont *replay row C. A consumer may move the commitment into* $\mathsf{LocalityCell}^{\uparrow}$ *or* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *only by reading L after the route*

$$O, R \longrightarrow G \longrightarrow F \longrightarrow C$$

has been exposed on the same finite carrier.

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentLocalityTransport`

Proof. Begin with Definition 505.5. Its locality-cell consumer restriction names L as the required handoff for every observer-locality consumer.

Use the forward-binding route theorem. The observed ledger and regularity ledger reach the commitment only through G and F, with C replaying the route inside the finite packet.

Apply classifier stability. Componentwise hsame transport keeps G, F, L and the replay row C separate, so an observer-indexed consumer cannot collapse the locality handoff into a global frame.

The locality-cell handoff theorem then supplies the endpoint. Since L is the only row that points to $\mathsf{LocalityCell}^{\uparrow}$ and $\mathsf{ObserverLocalityCell}^{\uparrow}$, every observer-locality transport factors through L and the displayed Cont replay. □

Theorem 505.12 (CausalCommitment ledger exactness)**.** *The* $\mathsf{CausalCommitment}^{\uparrow}$ *ledger excludes selected future observations, global observer frames, universal empirical laws, hidden induction rules, and ambient causal primitives. Its accepted readback is exactly the finite route through $O, R, G, F, L, H, C, P, N$, with no off-packet empirical law and no unrecorded causal constructor.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentCarrier ledger exactness`

Proof. Start from the carrier obligation. The accepted forward-GAP packet has only the nine displayed rows, so every consumer read must project one of those rows or use transport, replay, provenance, and local naming attached to them.

Apply Definition 505.2 and Definition 505.3. These keep the forward-looking content in G and the observed-to-commitment route in F and C.

Next use locality transport. Observer-locality consumption must pass through L, so it cannot introduce a synchronized global frame or selected future observation outside the finite carrier.

Finally apply Definition 505.9. The non-escape clause removes the remaining forbidden objects: universal empirical laws, hidden induction rules, and ambient causal primitives. Therefore the ledger readback is exactly the displayed finite route. □

Theorem 505.13 (CausalCommitment non-escape boundary)**.** *No consumer of an accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *packet can extract a selected future observation, a universal empirical law, a hidden induction rule, a synchronized global frame, or an ambient causal primitive. Every consumer read factors through* O, R, G, F, H, C, P, N*.*

Proof. Inspect the carrier inventory. Its coordinates are the observed ledger, regularity ledger, GAP socket, forward-binding route, transport rows, continuation rows, package provenance, and local naming row.

The transport row H and the continuation row C preserve exactly those coordinates. They can replay the displayed route, but they do not introduce a new future record or a global frame.

The non-escape claim follows because the forbidden objects have no coordinate in the finite packet. A consumer route seeking one of them therefore has no projection target in $\mathsf{CausalCommitment}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentNonEscapeBoundary`

Theorem 505.14 (CausalCommitment NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$ *surface consists of carrier admission for* $K = (O, R, G, F, H, C, P, N)$*, observed-ledger exposure, regularity-ledger exposure,* GAP *socket accountability, forward-binding route accountability, componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and the non-escape boundary for future observations, universal empirical laws, hidden induction rules, global frames, and ambient causal primitives.*

Proof. Carrier admission is projection from Definition 505.1. The packet exposes exactly the finite rows O, R, G, F, H, C, P, N.

Observed-ledger and regularity-ledger exposure are the first two projections. The GAP socket theorem then accounts for the only forward-looking coordinate in the carrier.

Forward-binding route accountability follows from Definition 505.3. The route from observed pattern to commitment is replayed by F and C, while H supplies componentwise stability and P records package provenance.

Finally apply the non-escape boundary. Since all consumer reads factor through the displayed rows, the local NameCert row cannot export selected future observations, universal empirical laws, hidden induction, global frames, or ambient causal primitives. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentNameCertObligations`

Definition 505.15 (CausalCommitment classifier row)**.** *The* $\mathsf{CausalCommitment}^{\uparrow}$ *classifier compares two finite packets*

$$K = (O, R, G, F, H, C, P, N) \qquad \textit{and} \qquad K' = (O', R', G', F', H', C', P', N')$$

component by component. A classifier read may identify the packets only when the observed-history ledgers O, O'*, regularity ledgers* R, R'*,* GAP *socket rows* G, G'*, forward-binding routes* F, F'*, transport rows* H, H'*, continuation rows* C, C'*, package provenance rows* P, P'*, and local* $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$ *rows* N, N' *are matched by the displayed* hsame*,* Cont*, and* Pkg *witnesses. It has no ambient equality row for causal commitment apart from these named coordinates.*

Lean4 (definition) `BEDC.Derived.CausalCommitmentUp.CausalCommitmentClassifierRow`

Theorem 505.16 (CausalCommitment carrier transport)**.** *For accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *packets* $K = (O, R, G, F, H, C, P, N)$ *and* $K' = (O', R', G', F', H', C', P', N')$*, a componentwise* hsame *transport preserving the classifier row of Definition 505.15 preserves the observed ledger, regularity ledger,* GAP *row, forward route, continuation rows, provenance row, and local NameCert row. In particular, transport cannot replace* G *by an unrecorded forward rule, cannot replace* F *by a hidden route, and cannot export* N *outside the finite packet.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentCarrier transport`

Proof. Project both packets from Definition 505.1. The carrier displays exactly the rows O, R, G, F, H, C, P, N, and the classifier row asks for the corresponding displayed rows of K'.

Apply Definition 505.2 to the transported GAP coordinate. Since the only forward-looking row is G, componentwise hsame transport preserves the socket instead of manufacturing a separate future law.

Apply Definition 505.3 to the transported route coordinates. The route remains the displayed F replayed by the Cont rows in C, with P recording the same package provenance.

Finally use Definition 505.13. The transported local NameCert row still names only the finite packet, so no selected future record, global frame, hidden induction rule, universal empirical law, or ambient causal primitive is exported. □

Theorem 505.17 (CausalCommitment classifier coherence)**.** *The classifier row of Definition 505.15 cannot identify two accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *packets whose* GAP *socket rows disagree, and it cannot identify two accepted packets whose forward-binding routes disagree. Any accepted classifier comparison must preserve both the socket that carries the forward-facing commitment and the route that returns it to the local NameCert row.*

Proof. Use the classifier row. Its comparison is componentwise, so a packet comparison has a separate coordinate for the GAP socket and a separate coordinate for the forward-binding route.

For the socket coordinate, apply Definition 505.2. The forward-looking content of a packet is named only by G. If G and G' disagree, the classifier has no other coordinate through which to identify the commitment-facing content.

For the route coordinate, apply Definition 505.3. The observed-regularity route must be the displayed F together with the Cont replay in C. If F and F' disagree, the comparison cannot repair that disagreement by appealing to a hidden route.

The non-escape boundary then rules out an ambient causal primitive that would identify the two packets outside their displayed coordinates. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentCarrier classifier coherence`

Theorem 505.18 (CausalCommitment observer-locality GAP readback)**.** *Every observer-locality readback of an accepted forward-GAP carrier* $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$ *factors through the* GAP *socket row* G *and the locality-cell handoff row* L *before exposing the local* $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$ *row* N*. The readback may use the observed ledger* O*, regularity ledger* R*, forward-binding row* F*, transport row* H*, continuation replay* C*, and provenance row* P*, but it cannot expose* N *as an observer-locality certificate before* G *and* L *have both been replayed.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentLocalityGapReadback`

Proof. Project the forward-GAP carrier of Definition 505.4. Its observer-facing rows are the displayed packet rows $O, R, G, F, L, H, C, P, N$, with G as the forward socket and L as the locality handoff.

Apply Definition 505.2 and Definition 505.3. These identify the forward-looking content with G and route the observed regularity through F and C before the local commitment row is available.

Now apply Definition 505.6. An observer-locality consumer reads the same commitment only through L, so the NameCert row N is exposed as observer-local only after both the GAP socket and the locality handoff have been replayed.

Finally use Definition 505.8 and Definition 505.9. They keep G, L, N as separate coordinates under transport and prevent the readback from replacing either row by a hidden causal primitive. □

Theorem 505.19 (CausalCommitment observer-cell non-escape)**.** *The observer-cell handoff of an accepted forward-GAP carrier $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$ cannot export a selected future observation, global observer frame, or ambient causal primitive. Every observer-cell read remains a finite read of the observed ledger, regularity ledger,* GAP *socket, forward-binding route, locality row, transport, continuation replay, provenance, and local NameCert rows.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentObserverCellNonescape`

Proof. Begin with the locality-cell handoff theorem. Definition 505.6 says that observer-locality consumption enters only through L and reads only the rows displayed by the forward-GAP packet.

Use carrier visibility and the forward route. By Definition 505.7, the rows $O, R, G, F, L, H, C, P, N$ are visible before the read; by Definition 505.3, the forward commitment passes through G, F, C rather than a hidden induction rule.

The non-escape claim follows from Definition 505.9. Since the displayed packet has no coordinate for a selected future observation, global observer frame, or ambient causal primitive, the observer-cell handoff cannot export one. □

Theorem 505.20 (CausalCommitment forward-GAP scope package)**.** *For every accepted forward-GAP carrier $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$, carrier visibility, classifier stability, ledger exactness, and observer-locality handoff assemble into the dependency-ready forward-GAP scope package. Any downstream observer-locality consumer may depend on $O, R, G, F, L, H, C, P, N$ as one finite packet, with G carrying the forward-facing socket, L carrying observer-cell locality, and N naming only that displayed package.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentForwardGapScopePackage`

Proof. First build the visible carrier surface. Apply Definition 505.4 and Definition 505.7 to expose exactly $O, R, G, F, L, H, C, P, N$.

Next attach the forward route and classifier stability. Apply Definition 505.2, Definition 505.3, and Definition 505.8; together they keep the socket G, route F, C, and transported packet rows distinct.

Then add ledger exactness and observer-cell locality. Use Definition 505.21, Definition 505.6, and Definition 505.18 to route downstream observer-locality reads through the same finite packet before the local NameCert row is exposed.

Finally apply Definition 505.19 and Definition 505.9. These close the package against selected future observations, global observer frames, ambient causal primitives, and hidden induction routes, so the displayed rows form the dependency-ready scope. □

Theorem 505.21 (CausalCommitment ledger route exactness)**.** *Every consumer route into an accepted forward-GAP carrier $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$ factors through the displayed finite packet and then through the locality-cell handoff. The route first reads O, R, enters the* GAP

socket G, follows the forward-binding row F with the Cont *replay in C, records provenance in P, and reaches the local NameCert row N only through the locality row L when an observer-locality consumer is present.*

Proof. Project the refined carrier of Definition 505.4. Its consumer-visible coordinates are exactly $O, R, G, F, L, H, C, P, N$.

The observed side of the route is forced by Definition 505.3. A consumer begins with O, R, passes through G, and follows F together with the continuation replay in C.

The locality side is forced by Definition 505.6. An observer-locality consumer receives the commitment only through L, which hands off the same finite rows rather than adding a global frame or selected future record.

Finally apply Definition 505.13. Since every displayed route has already factored through the packet and the locality handoff, no consumer can bypass the ledger by exporting a hidden induction rule, universal empirical law, ambient causal primitive, selected future observation, or synchronized global frame. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentLedgerRouteExactness`

Theorem 505.22 (CausalCommitment public forward-GAP export)**.** *Every public consumer of an accepted forward-GAP carrier $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$ receives observed regularity only through the displayed route*

$$O, R, G, F, L, H, C, P, N.$$

The export reads the observed ledger O, regularity ledger R, GAP *socket G, forward-binding row F, locality row L, transport row H, continuation row C, provenance row P, and local NameCert row N; it exports no selected future observation, hidden induction rule, universal empirical law, synchronized global frame, or ambient causal primitive.*

Proof. First expose the forward-GAP carrier. Apply Definition 505.7 to make $O, R, G, F, L, H, C, P, N$ visible before a public consumer reads the commitment.

Next route the observed regularity through the forward boundary. Use Definition 505.2 and Definition 505.3; the consumer must read O, R, enter G, and replay the forward-binding row F through C.

Finally apply Definition 505.6, Definition 505.8, and Definition 505.21. These keep the locality row L, transport H, provenance P, and local name N on the same finite route, so the public export has no coordinate for a selected future observation or hidden induction rule. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentPublicForwardGapExport`

Theorem 505.23 (CausalCommitment locality consumer exactness)**.** *For every accepted forward-GAP carrier $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$, an observer-locality consumer reads the commitment exactly through the locality row L after the observed regularity has passed through O, R, G, F. The consumer may transport, replay, package, and name the read only by H, C, P, N, and it cannot replace L by a selected future observation, a global observer frame, or a hidden causal-law row.*

Proof. Begin with the locality handoff. Definition 505.6 identifies L as the only observer-locality consumer row in the forward-GAP carrier.

Then attach the forward route. Definition 505.3 and Definition 505.21 force the consumer to read O, R, pass through G, and follow F with the displayed continuation replay before N is available.

Use classifier stability for exactness. Definition 505.8 preserves $O, R, G, F, L, H, C, P, N$ as separate coordinates under transport, so the observer-locality read cannot collapse the locality row into a global frame or hidden causal law. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentLocalityConsumerExactness`

Theorem 505.24 (CausalCommitment observed regularity nonchoice)**.** *Every public read of observed regularity from an accepted forward-GAP carrier $K_{\mathrm{fg}} = (O, R, G, F, L, H, C, P, N)$ is a finite read of the displayed rows $O, R, G, F, L, H, C, P, N$. The read passes through the* GAP *socket and the locality row before it is public, so it does not choose a future observation, add a hidden induction rule, or supply an unledgered regularity principle.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentObservedRegularityNonchoice`

Proof. Project the observed side first. Definition 505.2 says that O and R are finite ledgers and that forward-facing content is named only by G.

Now compose the public route. Apply Definition 505.22 and Definition 505.23. The public consumer reaches the regularity claim only after G, F, L, H, C, P, N have carried the observed ledger.

Finally apply Definition 505.9 and Definition 505.21. Since the displayed route has no coordinate for selected futures, hidden induction, or an unledgered regularity principle, the observed regularity read is nonchoice data. □

Theorem 505.25 (CausalCommitment locality obligations)**.** *Every accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *forward-GAP carrier binds its commitment row to* $\mathsf{LocalityCell}^{\uparrow}$ *and* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *through the displayed locality row L. The observer-facing commitment may be transported only through the finite rows $O, R, G, F, L, H, C, P, N$; it has no hidden causal-law row, selected future observation, synchronized global frame, or unledgered agency primitive.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentLocalityObligations`

Proof. Project the forward-GAP carrier of Definition 505.4. The row L is the only locality-facing coordinate added to the base packet O, R, G, F, H, C, P, N.

Apply Definition 505.6. It routes the commitment through the locality-cell and observer-locality surfaces without adding a global observer frame or selected future record.

Use Definition 505.21. Every consumer route must read O, R, pass through G and F, replay through C, record provenance in P, and reach N only through the displayed locality row when an observer-locality consumer is present.

Finally apply Definition 505.9. Since hidden causal laws, selected future observations, synchronized global frames, and unledgered primitives have no coordinate in the packet, the locality obligations are exactly the displayed rows. □

Theorem 505.26 (CausalCommitment observer-locality handoff)**.** *An observer-facing read of* $\mathsf{CausalCommitment}^{\uparrow}$ *factors through* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *only after the carrier has displayed the* BHist *rows O, R, G, F, L, the* hsame *row H, the* Cont *row C, the* Pkg *row P, and the local* NameCert *row N. No observer-facing route may bypass those rows by appealing to an ambient causal law, a selected future observation, or a primitive agency coordinate.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentObserverLocalityHandoff`

Proof. Start with Definition 505.7. It makes the rows $O, R, G, F, L, H, C, P, N$ visible before any consumer reads the refined packet.

Apply Definition 505.3. The commitment-facing content enters through G and returns along F with the displayed continuation replay in C.

Use Definition 505.6. The observer-locality consumer receives the commitment through L, not through a global frame or selected future record.

Finish with Definition 505.13. The route has no coordinate for hidden causal laws, unledgered agency primitives, universal empirical laws, or selected future observations, so the observer-locality handoff remains finite and local. □

Theorem 505.27 (CausalCommitment NameCert ledger)**.** *The local* $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$ *ledger for an accepted forward-GAP carrier is exhausted by the displayed* BHist*,* hsame*,* Cont*,* Pkg*, locality, GAP, and forward-binding rows* $O, R, G, F, L, H, C, P, N$*. It records observer-facing commitments only as ledgered transport through those rows and excludes hidden causal laws, unledgered agency primitives, selected future observations, and synchronized global frames.*

Proof. Begin with Definition 505.14. The local NameCert surface already records carrier admission, observed-ledger exposure, regularity-ledger exposure, GAP accountability, forward-binding route accountability, transport, replay, provenance, and non-escape.

Add the locality row using Definition 505.5. The refined carrier exposes L as the consumer-facing handoff and leaves all other coordinates unchanged.

Apply Definition 505.25 and Definition 505.26. These obligations bind locality and observer-locality reads to $O, R, G, F, L, H, C, P, N$.

Finally use Definition 505.9. Anything outside the displayed ledger has no NameCert coordinate, so no hidden causal law or agency primitive can be exported from the packet. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentNameCertLedger`

Theorem 505.28 (CausalCommitment GAP locality exactness)**.** *Every public causal read from an accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *packet must preserve the displayed* GAP *socket row* G *and the locality row* L *before any observer-facing commitment is exported. The public read may transport those rows through* H*, replay them through* C*, package them through* P*, and name them through* N*, but it may not replace* G *by a hidden induction rule or* L *by a synchronized global frame.*

Proof. Start with the GAP socket. Definition 505.2 makes G the only forward-facing socket row available to the carrier, so a public read cannot name a hidden causal primitive in place of the displayed socket.

Attach the observer-locality handoff. By Definition 505.6, the locality consumer receives the commitment through L and not through an ambient observer frame.

Use classifier stability before export. Definition 505.8 preserves $O, R, G, F, L, H, C, P, N$ as separate rows under componentwise transport. Therefore the exported observer-facing commitment still carries the same GAP socket and locality row.

Finally read the ledger of Definition 505.27. Its exactness excludes hidden causal laws, selected future observations, synchronized global frames, and unledgered primitives from the local NameCert surface. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentGapLocalityExactness`

Theorem 505.29 (CausalCommitment forward GAP observer route)**.** *The route from observed regularity to observer-locality handoff in an accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *packet factors through*

$$O, R, G, F, L, H, C, P, N.$$

Thus the observed-history row, regularity row, GAP socket, forward-binding row, locality row, transport, continuation replay, provenance, and local name are all crossed before an observer-facing commitment is available.

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentForwardGapObserverRoute`

Proof. Begin with the observed and regularity rows. Definition 505.3 routes the observed pattern through O, R into the forward-facing content named by G and the displayed forward-binding row F.

Next attach the GAP socket and locality handoff. Definition 505.2 identifies the public socket row as G, while Definition 505.6 routes the observer-locality consumer through L.

It remains to preserve the support rows. Definition 505.8 keeps H, C, P, N attached to the same packet under transport, and Definition 505.27 records that no additional observer-facing row is exported. □

Theorem 505.30 (CausalCommitment kernel row exhaustion)**.** *The accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *packet exports only* BHist*,* GAP*,* hsame*,* Cont*,* Pkg*, locality-cell, observer-locality, and local* NameCert *rows. It exports no hidden causal law, selected future observation, synchronized global frame, universal empirical law, or unledgered agency primitive.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentKernelRowExhaustion`

Proof. Read the packet rows first. Definition 505.2 and Definition 505.3 expose the BHist observed and regularity rows, the GAP socket, and the forward route through O, R, G, F.

Add locality and observer access. Definition 505.6 supplies the locality-cell and observer-locality row L, while Definition 505.8 preserves the componentwise hsame, displayed Cont, and Pkg rows.

Finally apply Definition 505.27. The local NameCert ledger is exhausted by the displayed rows, so any attempted export outside BHist, GAP, transport, replay, provenance, locality, observer-locality, and local naming exits the packet. □

Theorem 505.31 (CausalCommitment GAP locality adjunction)**.** *For an accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *packet, the GAP socket row G and the locality row L form the only admissible route from observed regularity to observer-locality handoff. Any observer-facing commitment read must pass from the observed and regularity rows through G, then through the forward-binding row F, and finally through L before the transport, replay, provenance, and local naming rows may expose it.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentGapLocalityAdjunction`

Proof. Start with the carrier and GAP socket. The carrier of Definition 505.1 displays the rows $O, R, G, F, L, H, C, P, N$, and Definition 505.2 makes G the public GAP row available to the packet.

Next use the forward binding route. By Definition 505.3, the observed regularity content enters the commitment-facing route through O, R, G, F and does not pass through an unledgered future selector.

Finally attach observer locality. Definition 505.6 routes the consumer through L, while Definition 505.13 excludes hidden causal laws, synchronized global frames, and selected future observations. Thus the only admissible observed-regularity to observer-locality route is the displayed G, F, L handoff inside $O, R, G, F, L, H, C, P, N$. □

Theorem 505.32 (CausalCommitment observer row factorization)**.** *Every observer-facing read of an accepted* $\mathsf{CausalCommitment}^{\uparrow}$ *packet factors through*

$$O, R, G, F, L, H, C, P, N.$$

The observer row, regularity row, GAP socket, forward-binding row, locality handoff, transport, continuation replay, provenance, and local NameCert row are all required before the read can be exported to an observer-locality consumer.

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentObserverRowFactorization`

Proof. Begin with the route already exposed by Definition 505.29. It identifies the observer-facing route with the displayed rows $O, R, G, F, L, H, C, P, N$.

Use classifier stability to keep the rows separate during transport. Definition 505.8 preserves the same carrier coordinates under the componentwise hsame and displayed Cont replay rows, so the observer read cannot collapse G, F, or L into a single hidden primitive.

The ledger then closes the factorization. Definition 505.27 and Definition 505.9 say that no row outside $O, R, G, F, L, H, C, P, N$ has a local NameCert coordinate. Hence every accepted observer-facing read factors through exactly those rows. □

Theorem 505.33 (CausalCommitment forward GAP NameCert export)**.** *The forward-GAP obligation surface of* $\mathsf{CausalCommitment}^{\uparrow}$ *exports a local NameCert row only after the GAP-locality adjunction and observer-row factorization are both satisfied. The exported certificate packages the carrier, GAP socket, forward-binding route, locality handoff, classifier stability, and ledger non-escape rows, and it exports no hidden causal primitive or selected future observation.*

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentForwardGapNameCertExport`

Proof. First package the carrier and locality route. Apply Definition 505.31; it gives the only admissible route from observed regularity through the GAP socket and forward binding row to the observer-locality handoff.

Next package the observer-facing read. Apply Definition 505.32; it requires the complete row sequence $O, R, G, F, L, H, C, P, N$ before any observer-locality consumer receives the commitment.

It remains to read the local NameCert ledger. Definition 505.27 supplies the local naming row, while Definition 505.9 and Definition 505.13 exclude hidden causal laws, unledgered agency primitives, synchronized global frames, universal empirical laws, and selected future observations. Therefore the exported NameCert is exactly the displayed forward-GAP obligation surface. □

Theorem 505.34 (CausalCommitment standard bridge surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$ *export of Definition 505.33 factors through the standard bridge surface by displaying exactly the observed-history ledger O, regularity ledger R,* GAP *socket G, forward-binding route F, locality handoff L, componentwise transport row H, displayed replay row C, provenance row P, and local name N. The bridge exports no selected future observation, ambient causal primitive, hidden induction rule, synchronized global frame, or universal empirical law.*

Proof. Start from the public forward-GAP export. It already packages the carrier, GAP socket, forward-binding route, locality handoff, classifier stability, and ledger non-escape rows as the local NameCert surface.

Read the rows through the bridge surface. The observed-history and regularity ledgers supply O, R, the GAP socket and forward-binding route supply G, F, the locality handoff supplies L, and the transport, replay, provenance, and local naming rows supply H, C, P, N.

Finally apply the ledger non-escape boundary. The forbidden causal objects have no coordinate in $O, R, G, F, L, H, C, P, N$, so the standard bridge surface receives only the displayed public NameCert export and no selected future observation or ambient causal primitive. □

Lean4 ✓ `BEDC.Derived.CausalCommitmentUp.CausalCommitmentStandardBridgeSurface`

Closure status for $\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}$.

Constructive story: A $\mathsf{CausalCommitment}^{\uparrow}$ packet is generated from a finite observed-history ledger, an observed regularity ledger, a displayed GAP socket, a forward-binding route, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 505.34 binds the standard bridge surface as the mature finite public package over observed-history, regularity, GAP socket, forward-binding, locality, transport, replay, provenance, and local naming rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CausalCommitment}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close a Lean implementation, bridge status, selected future observation, universal empirical law, hidden induction rule, synchronized global frame, or ambient causal primitive.

Upgrade path: Lean verification, axiom-purity certification, and bridge checking remain separate formal-axis work for the standard bridge surface.

Chapter 506

A Concrete Naming Certificate for RussellSelfMembershipBoundary$^{\uparrow}$

The RussellSelfMembershipBoundary$^{\uparrow}$ surface packages the Russell self-membership discipline of chapter 9457 as finite NameCert data. It reads a contextual class expression only through the classifier that introduces it, records the attempted self-membership query as a separate row, and rejects the promotion of that expression into an object that could contain or fail to contain itself.

The packet is a boundary certificate. It does not create a universal class object, does not admit an unstratified membership predicate, and does not turn contextual readability into object-level membership.

The attempted self-membership query is read against the classifier-membership discipline of chapter 476: TypeClassifierMembership$^{\uparrow}$ supplies the finite T, J, E, R, H, C, P, N membership packet, while RussellSelfMembershipBoundary$^{\uparrow}$ refuses the additional object-level self-membership coordinate.

It consumes the replacement-and-non-export ledger of chapter 515 when rejecting object-level self-membership reads: both packets separate contextual classifier use from forbidden promotion into host-level existence, quotient, or proposition-extensionality rows.

Definition 506.1 (Russell self-membership boundary carrier)**.** *A* RussellSelfMembershipBoundary$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (K, Q, A, S, G, H, C, P, N)$$

with the following displayed rows:

1. *K is the contextual-class source row: it records the expression read as a classifier-local class description, not as a kernel object;*
2. *Q is the attempted self-membership query row asking whether the contextual expression named by K can be read as a member of itself;*
3. *A is the negated-presence row saying that no accepted packet coordinate contains an object-level membership field for Q;*
4. *S is the stratification row separating the contextual classifier level of K from any object-level membership read;*
5. *G records the* Ask, Pkg, *and* Gap *provenance that identifies the query source, the package boundary, and the blocked passage from contextual reading to object membership;*

6. *H stores componentwise* hsame *transports for the contextual source, attempted query, negated-presence row, stratification row, provenance row, continuation routes, and local naming row;*
7. *C stores the displayed* Cont *routes by which consumers may inspect K, Q, A, S, and G without adding a new membership coordinate;*
8. *P is the* Pkg *provenance over* BHist, Ask, Gap, hsame, Cont, *contextual classifier rows, and the surrounding naming discipline;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RussellSelfMembershipBoundary}^{\uparrow}}$ *row.*

The carrier is exactly this finite packet. Its classifier-visible fields are the contextual source, the attempted query, the negated-presence row, the stratification row, the Ask/Pkg/Gap provenance, transport, continuation, package, and local NameCert rows.

Theorem 506.2 (Russell self-membership rejection)**.** *If $R = (K, Q, A, S, G, H, C, P, N)$ is an accepted* $\mathsf{RussellSelfMembershipBoundary}^{\uparrow}$ *carrier, then no classifier-visible coordinate of R promotes the contextual class expression recorded by K into an object containing itself or into an object not containing itself.*

Every consumer read of the attempted self-membership query Q factors through the negated-presence row A, the stratification row S, the Ask/Pkg/Gap provenance G, the componentwise hsame *transports H, the displayed* Cont *routes C, the package row P, and the local* NameCert *row N.*

Proof. Project the carrier rows of Definition 506.1. The source row K is contextual classifier data, while Q is only the attempted query against that contextual reading.

The negated-presence row A records that the packet has no classifier-visible object-membership coordinate for Q. The stratification row S records that the contextual level of K is not the object level needed by a self-membership assertion.

Route any consumer read through G, H, C, P, and N. These rows expose Ask/Pkg/Gap provenance, transport, continuation, and local naming data, but they do not add a membership field.

Thus the attempted self-reference remains a rejected query at the NameCert boundary. The packet can report the blocked route, but it cannot manufacture either side of the object-level self-membership alternative. □

Theorem 506.3 (Russell boundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RussellSelfMembershipBoundary}^{\uparrow}}$ *surface has five finite obligations:*

1. *carrier admission: every accepted object exposes the tuple $R = (K, Q, A, S, G, H, C, P, N)$ of Definition 506.1;*
2. *contextual classifier reading: the row K is consumed only as a classifier-local class description and never as an admitted object containing members;*
3. *self-query rejection: the attempted query Q is routed through the negated-presence row A and cannot produce a membership or nonmembership field;*
4. *stratified transport: the row S and the componentwise* hsame *ledger H preserve the separation between contextual classifier reads and object-level membership reads;*
5. *ledger boundary: every downstream consumer passes through the displayed* Ask, Pkg, Gap, Cont, *and local* NameCert *rows, with no universal class object and no unstratified membership predicate.*

Lean4 ✓ `BEDC.Derived.RussellSelfMembershipBoundaryUp.RussellSelfMembershipBoundaryTasteGate single carrier alignment`

Proof. Carrier admission is projection from the finite tuple in Definition 506.1. Each coordinate is a displayed BHist row or a finite provenance row named by the tuple.

Contextual reading is enforced by the placement of K and S. The expression appears in the contextual classifier row, and the stratification row records that this reading is not an object-level membership carrier.

Self-query rejection is the role of Q together with A. The query is present as an attempted read, while A records the absence of a classifier-visible coordinate that could answer it as membership or nonmembership of an object by itself.

Finally route downstream use through G, H, C, P, and N. The ledger exposes Ask/Pkg/Gap provenance, transport, continuation, package, and local naming rows only, so the NameCert surface contains no universal class object or unstratified membership predicate. □

Closure status for $\mathsf{NameCert}_{\mathsf{RussellSelfMembershipBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{RussellSelfMembershipBoundary}^{\uparrow}$ packet is generated from a contextual-class source row, an attempted self-membership query row, a negated-presence row, a stratification row, Ask/Pkg/Gap provenance, displayed hsame transports, Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RussellSelfMembershipBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 506.1, Definition 506.2, and Definition 506.3 bind the finite carrier, self-query rejection row, stratified transport route, and local NameCert obligations for contextual class readings.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RussellSelfMembershipBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a Lean implementation, bridge status, universal class object, unstratified membership predicate, or object-level Russell class.

Upgrade path: Obligation closure requires Lean encoding of the carrier and checked theorems for contextual classifier reading, self-query rejection, stratified transport, and ledger-boundary non-escape.

Chapter 507

A Concrete Naming Certificate for $\mathsf{StableNegationBoundary}^{\uparrow}$

The $\mathsf{StableNegationBoundary}^{\uparrow}$ surface turns the reasoning-by-contradiction boundary of chapter 9458 into a finite naming packet. It records the certificate row being inspected, the permitted refutation route, the local stability data for decidable refutations, and the ledger that blocks certificate-wide truth branching. The surface is a NameCert boundary for stable negation; it is not a proof of excluded middle over naming certificates.

The permitted refutation route and optional decision row are consumed from the decidable-refutation and refutation-witness sibling surfaces of chapter 493 and chapter 511. Those surfaces supply the local refutation and witness-or-decision rows used by $A, R, D, T, L, H, C, P, N$.

The stable-negation packet also consumes the permitted refutation route of chapter 503 and the constructive route boundary of chapter 501, then adds the optional decidability row and certificate-truth exclusion ledger.

Definition 507.1 (StableNegationBoundary carrier)**.** *A* $\mathsf{StableNegationBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (A, R, D, T, L, H, C, P, N)$$

with the following displayed rows:

1. *A is the proposition row being tested inside a fixed local certificate surface;*
2. *R is the permitted refutation route from an assumed witness of A to $\bot$, read only through* Cont, hsame, msame, *and the local certificate rows;*
3. *D is the optional decidability row for A, present exactly when the packet carries a constructive decision for the same proposition row;*
4. *T is the stable-negation classifier row, recording that $\neg A$ may be transported and that $\neg\neg A$ may be consumed only through D;*
5. *L is the truth-branch exclusion ledger, blocking excluded-middle branching over the carrier of all naming certificates and blocking witness extraction from a contradiction without displayed data;*
6. *H stores componentwise* hsame *transports for A, R, D, T, L and the local naming rows;*
7. *C stores the* Cont *routes for replaying the refutation, consuming the optional decision row, transporting the stable-negation classifier, and reading the exclusion ledger;*

8. *P is the* Pkg *provenance over* BHist, Ext, Cont, msame, hsame, *local proof rows, and the surrounding* NameCert *rows;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{StableNegationBoundary}^{\uparrow}}$ *row.*

The carrier has no row for host truth, no branch over the carrier of all naming certificates, and no witness selector for an existential obtained by contradiction.

Lean4 ✓ `BEDC.Derived.StableNegationBoundaryUp.StableNegationBoundaryTasteGate single carrier alignment`

Theorem 507.2 (StableNegationBoundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{StableNegationBoundary}^{\uparrow}}$ *surface for Definition 507.1 consists of five finite obligations:*

1. *carrier admission for the displayed packet $S = (A, R, D, T, L, H, C, P, N)$;*

2. *classifier soundness for the stable-negation row T, comparing only the displayed proposition, refutation, optional decision, exclusion ledger, transport, continuation, package, and naming rows;*

3. *refutation stability, saying that a proof of $\neg A$ transported through H and replayed through C remains the same local certificate-level negation;*

4. *decidable double-negation use, saying that a $\neg\neg A$ consumer must pass through the displayed decision row D;*

5. *truth-branch non-escape, saying that L blocks certificate-wide excluded middle, witness extraction by contradiction, and host-truth reads.*

Proof. Carrier admission is projection from the displayed packet. The proposition row, refutation route, optional decision row, classifier row, exclusion ledger, transports, continuations, package row, and local name are all visible coordinates.

Classifier soundness and refutation stability are componentwise. The route R is replayed only after A and the local certificate rows have been transported through H, so a transported proof of $\neg A$ remains inside the same finite surface.

For double negation, the row D is the only coordinate that supplies a constructive decision for A. A consumer of $\neg\neg A$ therefore either reads D and stays inside the packet or is blocked by the exclusion ledger L.

Truth-branch non-escape is the absence of any carrier-wide decision coordinate. The ledger L records the forbidden routes named in Definition 9458.5, and the remaining rows provide no host truth predicate or witness selector. □

Theorem 507.3 (StableNegationBoundary decidable refutation stability)**.** *For an accepted* StableNegationBoundar *carrier $S = (A, R, D, T, L, H, C, P, N)$, every permitted refutation of A remains stable under the displayed* hsame *transports and* Cont *replay routes. If a consumer also requests $\neg\neg A \Rightarrow A$, the request is accepted only through the same displayed decision row D.*

Lean4 ✓ `BEDC.Derived.StableNegationBoundaryUp.StableNegationBoundaryCarrier decidable refutation stability`

Proof. Read the refutation route R from the carrier and transport the proposition row A through H. Replaying R through the displayed continuation routes in C again sends an assumed witness of the transported proposition to $\bot$.

Now inspect the double-negation request. The NameCert obligations name D as the sole route that turns $\neg\neg A$ into A, so the request cannot be served by an ambient law of excluded middle.

The packet inventory then gives stability. Every accepted route passes through $A, R, D, T, L, H, C, P, N$, and no row supplies a certificate-wide truth branch. □

Theorem 507.4 (StableNegationBoundary certificate-truth non-escape)**.** *No accepted* StableNegationBoundary$^{\uparrow}$ *carrier exports a decision family for predicates over the carrier of all naming certificates. Its negative information is exhausted by the local refutation route R, the optional decision row D, the classifier row T, and the exclusion ledger L.*

Lean4 ✓ `BEDC.Derived.StableNegationBoundaryUp.StableNegationBoundaryCarrier certificate truth non escape`

Proof. Assume a consumer reads an accepted carrier. The only available proposition-level rows are A, R, D, T, L together with their transports and continuation routes.

A decision family over all naming certificates would require a coordinate that ranges over certificate-indexed predicates. The carrier has no such coordinate; it contains only a fixed local proposition row and its local refutation or decision data.

The ledger L names the blocked routes. Since every export is routed through C and P, a consumer cannot replace the local negative information with host truth, certificate-wide excluded middle, or witness extraction by contradiction. □

Theorem 507.5 (StableNegationBoundary ledger exhaustion)**.** *Every accepted stable-negation read is exhausted by the rows $A, R, D, T, L, H, C, P, N$ of Definition 507.1. No downstream consumer may add an external truth predicate, a global excluded-middle branch, or an existential witness selected only from a contradiction.*

Lean4 ✓ `BEDC.Derived.StableNegationBoundaryUp.StableNegationBoundaryCarrier ledger exhaustion`

Proof. Start with an accepted stable-negation read. Carrier admission sends it to the finite packet $S = (A, R, D, T, L, H, C, P, N)$.

The refutation and decidability rows account for the permitted routes: R supplies $\neg A$, and D supplies the only accepted route from $\neg\neg A$ to A. The classifier row T and the transports H, C preserve these routes componentwise.

It remains to account for forbidden exits. The ledger L blocks the certificate-wide truth branch and witness-selection routes, while the package and naming rows only record provenance. Thus the displayed packet exhausts the read. □

Closure status for NameCert$_{\text{StableNegationBoundary}\uparrow}$**.**

Constructive story: A StableNegationBoundary$^{\uparrow}$ packet is generated from a local proposition row, a permitted refutation route, an optional decision row, a stable-negation classifier, a truth-branch exclusion ledger, displayed transports, continuation routes, package provenance, and a local naming row.

Theory closure: TheoryGate(NameCert$_{\text{StableNegationBoundary}\uparrow}$, seed)

Scope closed: Definition 507.1, Definition 507.2, Definition 507.3, Definition 507.4, and Definition 507.5 record the finite carrier, classifier, ledger, and non-escape obligations for stable negation.

Formal verification: FormalStatus(NameCert$_{\text{StableNegationBoundary}\uparrow}$, formalTarget)

Ledger evidence: BEDC.Meta.DiscoveryDeltaLedger.stableNegationBoundaryDeltaLedger

Lean target: `BEDC.Derived.StableNegationBoundaryUp.StableNegationBoundaryCarrier\_namecert\_obligations`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close excluded middle over naming certificates, witness extraction by contradiction, host truth, or a checked Lean certificate.

Upgrade path: Obligation closure requires Lean encoding of the carrier and checked obligations for classifier soundness, refutation stability, decidable double-negation use, certificate-truth non-escape, and ledger exhaustion.

Chapter 508

A Concrete Naming Certificate for $\mathsf{FiniteRefutationBoundary}^{\uparrow}$

The $\mathsf{FiniteRefutationBoundary}^{\uparrow}$ surface realizes the contradiction-boundary discipline of chapter 9458 as a finite NameCert packet. It records the ground-loop refutation route that may be replayed, the decidability row that may license double-negation consumption, and the exclusion rows that block meta-level escape. The packet is intentionally finite: every accepted read is through BHist, msame, hsame, Cont, a fixed local NameCert, and a displayed route to falsity.

The permitted refutation row is supplied by the ground-loop carrier of chapter 510: $\mathsf{FiniteRefutationBoundary}^{\uparrow}$ consumes its displayed assumption row, falsity-producing Cont route, hsame transports, Pkg provenance, and local NameCert row before adding the optional decision row and meta-escape exclusion ledger.

Definition 508.1 (Finite refutation boundary carrier)**.** *A* $\mathsf{FiniteRefutationBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (A, R, D, E, H, C, P, N, \bot_R)$$

with the following displayed rows:

1. *A is the proposition row whose contradiction boundary is being inspected;*
2. *R is the permitted refutation row, read as an assumed witness of A followed by a displayed route to falsity;*
3. *D is the optional constructive decision row for A, present exactly when the packet permits double-negation consumption for A;*
4. *E is the meta-escape exclusion ledger, with separate entries for unwitnessed existential extraction, double-negation elimination without D, and excluded-middle branching over naming certificates;*
5. *H records componentwise* hsame *transports for proposition rows, refutation rows, optional decision rows, exclusion rows, package rows, and local naming rows;*
6. *C records the displayed* Cont *routes that read A, replay R, consume D when present, inspect E, and return the result to the local ledger;*
7. *P is the* Pkg *provenance over* BHist, Ext, Cont, msame, hsame, *local proof rows, exclusion rows, and the surrounding certificate rows;*
8. *N is the fixed local* $\mathsf{NameCert}_{\mathsf{FiniteRefutationBoundary}^{\uparrow}}$ *ledger through which all rows are addressed;*

9. *$\bot_R$ is the displayed falsity route witnessing that an assumed A-row reaches $\bot$ using only R, H, C, P, N and the kernel sameness primitives.*

The carrier contains no host truth predicate, no classifier over the carrier of all naming certificates, no selected existential witness obtained by contradiction, and no excluded-middle oracle beyond a displayed decision row D for the single proposition row A.

Lean4 ✓ `BEDC.Derived.FiniteRefutationBoundaryUp.FiniteRefutationBoundaryTasteGate single carrier alignment`

Theorem 508.2 (Finite refutation boundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FiniteRefutationBoundary}^{\uparrow}}$ *surface consists of five obligations:*

1. *carrier admission for the finite packet $B = (A, R, D, E, H, C, P, N, \bot_R)$ of Definition 508.1;*
2. *classifier soundness, comparing accepted packets only through the displayed proposition, refutation, decision, exclusion, transport, continuation, provenance, naming, and falsity-route rows;*
3. *ground-loop replay, saying that $\bot_R$ remains a route from an assumed A-witness to $\bot$ under the stored* hsame *transports and* Cont *routes;*
4. *decision discipline, saying that $\neg\neg A$ may be consumed only when D supplies a constructive branch for the same proposition row A;*
5. *escape exclusion, saying that no consumer may export unwitnessed existence, non-decidable double-negation elimination, or certificate-level excluded middle from the packet.*

Lean4 ✓ `BEDC.Derived.FiniteRefutationBoundaryUp.FiniteRefutationBoundaryNamecertObligations`

Proof. Carrier admission is projection from Definition 508.1. Every named coordinate is a finite BHist row or a route displayed over those rows.

Classifier soundness is componentwise. The comparison can inspect $A, R, D, E, H, C, P, N, \bot_R$ and their transported counterparts, and it has no coordinate for host truth, proof search, or a classifier over all naming certificates.

For ground-loop replay, transport the assumed A-witness and the row R along H, then replay the displayed route in C. The terminal step is the falsity route $\bot_R$, so the transported packet still proves the certificate-level negation of A.

For decision discipline, the row D is the only allowed source of a constructive branch for A. When D is absent, the exclusion ledger E blocks the non-decidable double-negation schema of Definition 9458.5; when D is present, the branch is consumed inside the same packet and does not become a global oracle.

Finally, escape exclusion follows by inspecting the carrier. The packet has no witness selector for existential-by-contradiction, no double-negation eliminator independent of D, and no branch over the carrier of all naming certificates, so the local NameCert obligations remain inside the closed ground loop. □

Theorem 508.3 (Ground-loop soundness for permitted refutations)**.** *For every accepted* $\mathsf{FiniteRefutationBoundary}^{\uparrow}$ *packet $B = (A, R, D, E, H, C, P, N, \bot_R)$, the permitted refutation read from B proves only the local certificate-level negation of the displayed proposition row A. It factors through* BHist, msame, hsame, Cont, *the fixed ledger N, and the falsity route $\bot_R$, and it does not decide any proposition row not explicitly carried by B.*

Proof. Read the carrier through Definition 508.1. The only proposition being refuted is A, and the only route from an assumed witness to falsity is $\bot_R$ as replayed through R, H, C, P, N.

The kernel primitives available to the replay are msame, hsame, and Cont over the finite history rows. Transport changes representatives inside the displayed packet, but it never creates a new proposition row or a new classifier.

Thus the public consequence is the local negation of A. Since no coordinate names an ambient decision procedure, the packet cannot decide any row outside the displayed finite carrier. □

Theorem 508.4 (Meta-escape exclusion)**.** *An accepted* $\mathsf{FiniteRefutationBoundary}^{\uparrow}$ *packet cannot export any of the three forbidden contradiction moves of Definition 9458.5: it cannot extract a witness from* $\neg\forall h : \mathsf{Hist}, \neg Q(h)$ *without displaying that witness, it cannot eliminate* $\neg\neg A$ *without the row* D *for the same proposition row, and it cannot supply excluded middle for predicates over the carrier of all naming certificates.*

Proof. For unwitnessed existence, the carrier has no selector coordinate. Any existential witness exported by the packet must be one of its displayed finite rows or be constructed by a displayed Cont route from those rows.

For non-decidable double-negation elimination, inspect D and E. The decision row D is the only positive branch source for A, while E records that the schema is refused when D is absent.

For certificate-level excluded middle, inspect the naming ledger N. It is fixed locally to this packet and does not range over the carrier of all naming certificates, so it cannot produce a branch family for arbitrary certificate predicates.

Therefore each forbidden move is blocked by the absence of a carrier coordinate and by the explicit exclusion ledger. □

Theorem 508.5 (Finite refutation boundary concretizes the contradiction-boundary vision)**.** *The* $\mathsf{FiniteRefutationBoundary}^{\uparrow}$ *carrier of Definition 508.1, together with the obligations of Definition 508.2, realizes the boundary stated in chapter 9458: permitted refutations are exactly those whose falsity route remains in the fixed ground-loop packet, while the forbidden patterns are refused because they require a meta-level branch or witness not displayed by that packet.*

Proof. The permitted side is Definition 508.3. A refutation route is accepted only when it is the displayed route from A through R, H, C, P, N to $\bot_R$.

The refused side is Definition 508.4. The three forbidden patterns all require a coordinate absent from the finite packet: an unwitnessed existential selector, a double-negation eliminator without D, or a branch over naming certificates.

Combining these two facts gives the advertised boundary. The finite carrier supplies the concrete BEDC object, the local NameCert obligations supply the admissibility surface, and consumers receive a refutation route without receiving a meta-level truth predicate. □

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteRefutationBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{FiniteRefutationBoundary}^{\uparrow}$ packet is generated from a proposition row, a permitted refutation row, an optional constructive decision row, meta-escape exclusions, componentwise transports, displayed continuation routes, package provenance, a fixed local NameCert ledger, and a falsity route.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FiniteRefutationBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 508.1, Definition 508.2, Definition 508.3, Definition 508.4, and Definition 508.5 bind the finite carrier, obligation surface, ground-loop soundness, meta-escape exclusion, and vision realization.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FiniteRefutationBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close classical excluded middle, a global truth predicate over naming certificates, existential witness selection by contradiction, or a checked Lean certificate.

Upgrade path: Obligation closure requires Lean encoding of the carrier and checked theorems for classifier soundness, ground-loop replay, decision discipline, escape exclusion, and the public vision realization.

Chapter 509

A Concrete Naming Certificate for $\mathsf{LocalityCell}^{\uparrow}$

The $\mathsf{LocalityCell}^{\uparrow}$ surface packages the locality-cell reading of Definition 9420.38 as finite BEDC data. It names two observer histories, two displayed event records, bilateral GAP commitments, componentwise transport, continuation routes, package provenance, and a local naming ledger. The packet supports inter-observer event coordination without adding a global frame, a shared clock, or a god's-eye event object outside the two recorded histories.

Definition 509.1 (LocalityCell carrier)**.** *A* $\mathsf{LocalityCell}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (A, B, r_A, r_B, g_A, g_B, H, C, P, N)$$

with the following visible rows:

1. *A and B are the two displayed observer* BHist *rows;*
2. *r_A is the event-record row read from observer history A;*
3. *r_B is the event-record row read from observer history B;*
4. *g_A is the* GAP *commitment on the A side that treats r_B as a coherent counterpart of r_A;*
5. *g_B is the* GAP *commitment on the B side that treats r_A as a coherent counterpart of r_B;*
6. *H records componentwise* hsame *transport for the two histories, the two event-record rows, the two* GAP *rows, package provenance, and local naming row;*
7. *C records the displayed* Cont *routes by which the two event records and bilateral* GAP *commitments are read from the two observer histories;*
8. *P is the* Pkg *provenance naming* BHist, Hist, hsame, Cont, Pkg, NameCert, *and the locality-cell source boundary;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{LocalityCell}^{\uparrow}}$ *ledger.*

The carrier is exactly this bilateral packet. It contains no global event coordinate, no shared time index, no selected synchronization map, and no observer-independent space-time object.

Definition 509.2 (LocalityCell classifier)**.** *The* $\mathsf{LocalityCell}^{\uparrow}$ *classifier relates two accepted carriers*

$$L = (A, B, r_A, r_B, g_A, g_B, H, C, P, N)$$

and

$$L' = (A', B', r'_A, r'_B, g'_A, g'_B, H', C', P', N')$$

exactly when the displayed hsame *rows transport* A *to* A', B *to* B', r_A *to* r'_A, r_B *to* r'_B, g_A *to* g'_A, g_B *to* g'_B, *and the provenance and naming rows to their counterparts, with every public read replayed through the displayed* Cont *routes. Thus classifier agreement preserves the same bilateral event coordination: the record on each observer side and the* GAP *commitment acknowledging the other side.*

Theorem 509.3 (LocalityCell NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{LocalityCell}^\uparrow}$ *surface has five finite obligations:*

1. *carrier exposure: every accepted object exposes the tuple* $L = (A, B, r_A, r_B, g_A, g_B, H, C, P, N)$ *of Definition 509.1;*
2. *bilateral classifier stability: accepted comparisons transport both observer histories, both event records, both* GAP *commitments, provenance, and local naming rows as in Definition 509.2;*
3. *route locality: every public read of an event record or* GAP *commitment uses one of the displayed* Cont *routes recorded in* C*;*
4. *ledger exactness: the* Pkg *and* NameCert *rows name exactly the bilateral carrier, classifier, transport, and readback data listed above;*
5. *non-escape: the packet exports no global event coordinate, shared clock, synchronization map, ambient metric, or observer-independent space-time carrier.*

Lean4 ✓ `BEDC.Derived.LocalityCellUp.LocalityCellTasteGate single carrier alignment`

Proof. Carrier exposure is projection from the finite tuple in Definition 509.1. Each coordinate is visible as a displayed history row, event-record row, GAP row, transport ledger, route row, provenance row, or naming row.

Bilateral classifier stability is the rule of Definition 509.2. The comparison transports the two observer histories together with both event-record rows and both GAP commitments, so it cannot keep only one side of the cell.

Route locality follows by inspecting C. A consumer reaches r_A, r_B, g_A, or g_B only through the displayed continuation routes from the two observer histories.

Ledger exactness follows from P and N. These rows record the carrier, classifier, transport, and readback dependencies of the packet, and there is no additional coordinate from which another ledger source could be projected.

Non-escape is immediate from the carrier inventory. Since no coordinate names a global event, shared clock, synchronization map, ambient metric, or observer-independent space-time carrier, no local $\mathsf{NameCert}_{\mathsf{LocalityCell}^\uparrow}$ read can export one. □

Theorem 509.4 (LocalityCell hsame transport)**.** *Let* $L = (A, B, r_A, r_B, g_A, g_B, H, C, P, N)$ *be an accepted* $\mathsf{LocalityCell}^\uparrow$ *carrier. Any classifier-preserving transport through the displayed* hsame *row* H *preserves both event records and both* GAP *commitments together; it cannot transport* r_A *without the paired* r_B*, nor* g_A *without the paired* g_B*.*

Proof. Project the componentwise transport row H from the carrier. Its entries compare the two observer histories, the two event records, the two GAP commitments, provenance, and local naming row as one packet.

The classifier of Definition 509.2 accepts a transported carrier only when all those components are matched. Therefore a transported read that keeps r_A must also keep the comparison data for r_B, and a transported read that keeps g_A must also keep the comparison data for g_B.

The routes in C replay the public reads after transport. Since every read goes through those routes, no consumer can split one side of the locality cell away from the bilateral transport ledger. □

Theorem 509.5 (LocalityCell inter-observer readback)**.** *Every public read of an accepted* $\mathsf{LocalityCell}^{\uparrow}$ *packet factors through the two displayed observer histories, the two event-record rows, the two bilateral* GAP *commitments, the* hsame *transport ledger, and the* Cont *routes of Definition 509.1. Consequently the packet realizes inter-observer event coordination as finite BEDC evidence and not as a primitive shared world-state.*

Lean4 ✓ `BEDC.Derived.LocalityCellUp.LocalityCellPacket interobserver readback`

Proof. Start with an accepted packet $L = (A, B, r_A, r_B, g_A, g_B, H, C, P, N)$. The only event-facing coordinates are r_A and r_B, and each is attached to its observer history by the displayed routes in C.

The only cross-observer coordination coordinates are g_A and g_B. They are bilateral GAP commitments, so a public read obtains the claim that each side treats the other side's record as coherent with its own record.

Transport and replay are confined to H and C. Hence any readback of the cell factors through the two histories, two records, two commitments, transport ledger, and routes named in the carrier.

No coordinate of L is a primitive shared world-state or god's-eye event object. The readback therefore realizes the locality cell as finite BEDC coordination evidence between two histories. □

Theorem 509.6 (LocalityCell ObserverLocalityCell lattice link)**.** *An accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *packet of chapter 513 refines the bilateral* $\mathsf{LocalityCell}^{\uparrow}$ *surface by adding observer-identity and cross-history ledger rows. Every* $\mathsf{LocalityCell}^{\uparrow}$ *read consumed by that sibling still factors through the two observer histories, two event rows, bilateral* GAP *rows,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *rows of Definition 509.1.*

Proof. Project the $\mathsf{LocalityCell}^{\uparrow}$ carrier. Its bilateral surface is the displayed packet $L = (A, B, r_A, r_B, g_A, g_B, H, C, P$ so any read of the local cell has access only to two observer histories, two event records, two GAP commitments, transport, routes, provenance, and local naming.

The $\mathsf{ObserverLocalityCell}^{\uparrow}$ sibling cited in the statement consumes that bilateral surface and adds observer-identity plus cross-history ledger rows. Those added rows refine the consumer context; they do not replace $A, B, r_A, r_B, g_A, g_B, H, C, P, N$ with a global frame or a hidden shared event object.

Apply Definition 509.3, Definition 509.4, and Definition 509.5. The NameCert obligations fix the bilateral ledger, the transport theorem keeps both sides paired under hsame, and the readback theorem forces public event coordination through the displayed histories, event rows, bilateral commitments, and continuation routes.

Thus the sibling relation is a lattice refinement: $\mathsf{ObserverLocalityCell}^{\uparrow}$ may carry additional observer-identity and cross-history ledger data, while every locality-cell read it consumes remains the same bilateral $\mathsf{LocalityCell}^{\uparrow}$ route. □

Theorem 509.7 (LocalityCell scoped kernel route)**.** *Every accepted* $\mathsf{LocalityCell}^{\uparrow}$ *packet factors its carrier, classifier, local* NameCert *obligations,* hsame *transport, inter-observer readback, and TasteGate-visible single-carrier alignment through the displayed* BHist, hsame, Cont, Pkg, *and*

NameCert *rows of Definition 509.1. The route introduces no extra observer carrier, shared clock carrier, synchronization map, ambient metric carrier, or observer-independent space-time row.*

Proof. Begin with Definition 509.1 and Definition 509.2. They place the two observer histories, event records, bilateral GAP commitments, componentwise transport, continuation routes, package provenance, and local name in one displayed packet.

Apply Definition 509.3. The carrier, classifier, exactness, ledger, and non-escape obligations are all recorded by P and N, so there is no separate naming or observer row.

Use Definition 509.4 and Definition 509.5. The transport and readback routes keep both observers inside the same H and C rows rather than splitting them into independent carriers.

Finally use the chapter's TasteGate-visible Lean target recorded in the closure block. It records the single-carrier alignment at the Lean boundary, and the paper route above identifies the same alignment with the displayed BHist, hsame, Cont, Pkg, and NameCert rows. □

Theorem 509.8 (LocalityCell standard bridge surface)**.** *The bilateral* $\mathsf{LocalityCell}^{\uparrow}$ *packet bridges to the concrete-instance schema exactly through the two observer histories* A, B*, the two event rows* r_A, r_B*, the two* GAP *commitments* g_A, g_B*, the componentwise* hsame *row* H*, the displayed* Cont *routes* C*, the package row* P*, and the local* NameCert *row* N *of Definition 509.1. The bridge exports the public locality-cell readback of Definition 509.5 and the scoped kernel route of Definition 509.7; it contains no shared clock, global frame, synchronization map, ambient metric, or observer-independent space-time carrier.*

Proof. Project the bilateral carrier $L = (A, B, r_A, r_B, g_A, g_B, H, C, P, N)$. Its bridge surface is the same finite packet: two histories, two event records, two bilateral GAP commitments, componentwise transport, continuation routes, package provenance, and local naming.

Apply Definition 509.5. Public event coordination already factors through exactly these histories, event rows, GAP rows, H, and C, so the bridge has no separate event object to expose.

Use Definition 509.7 to attach Pkg and NameCert without changing the carrier. The TasteGate-visible single-carrier alignment keeps the bridge on the same BHist, hsame, Cont, Pkg, and NameCert rows.

Since neither the carrier nor any cited route contains a clock, global frame, synchronization map, ambient metric, or observer-independent space-time coordinate, the bridge is exactly the displayed bilateral surface and nothing beyond it. □

Closure status for $\mathsf{NameCert}_{\mathsf{LocalityCell}^{\uparrow}}$.

Constructive story: A $\mathsf{LocalityCell}^{\uparrow}$ packet is generated from two observer BHist rows, two event-record rows, two bilateral GAP commitments, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert ledger.

Lean4 ✓ `BEDC.Derived.LocalityCellUp.taste gate`

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{LocalityCell}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 509.1, Definition 509.2, Definition 509.3, Definition 509.4, Definition 509.5, Definition 509.7, and Definition 509.8 bind the finite bilateral carrier, classifier, transport, ledger, inter-observer readback, scoped kernel route, bridge surface, and TasteGate-visible single-carrier alignment.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{LocalityCell}^{\uparrow}}$, axiomClean)

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close a global frame, a shared clock, a synchronization map, ambient metric geometry, observer-independent space-time ontology, or bridgeChecked verification.

Upgrade path: No further paper-axis closure remains for the bilateral locality-cell surface; bridgeChecked verification is recorded independently.

Chapter 510

A Concrete Naming Certificate for $\mathsf{GroundRefutation}^{\uparrow}$

The $\mathsf{GroundRefutation}^{\uparrow}$ surface records the permitted contradiction pattern of chapter 9458 as a closed ground-loop naming packet. Its refutation is not a meta rule over arbitrary certificates: it is a finite BHist row whose assumption, falsity route, transports, continuation routes, provenance, and local $\mathsf{NameCert}$ row are all displayed before any negation may be exported.

It is the closed ground-loop specialization of chapter 500. It consumes the permitted-refutation route and forbidden truth-branch exclusion from that broader boundary, but removes the optional decidability and certificate-indexed boundary rows.

Definition 510.1 (Ground refutation carrier)**.** *A* $\mathsf{GroundRefutation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (A, F, H, C, P, N)$$

with the following displayed rows:

1. *A is the assumption row admitted only inside the fixed ground loop;*
2. *F is the falsity-producing route that sends the displayed assumption row through recorded* Cont *steps to the bottom row;*
3. *H records the componentwise* hsame *transports for the assumption row, falsity route, package provenance, and local naming row;*
4. *C records the displayed* Cont *routes used to read A, replay F, transport the bottom row, and return the exported negation to the same finite packet;*
5. *P is the* Pkg *provenance over* BHist, Cont, hsame, *the bottom row, and the surrounding certificate surface;*
6. *N is the local* $\mathsf{NameCert}_{\mathsf{GroundRefutation}^{\uparrow}}$ *row.*

The carrier contains no coordinate for a certificate-indexed truth branch, no excluded-middle split, no undecidable double-negation eliminator, and no existential witness selected by contradiction.

Theorem 510.2 (GroundRefutation NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{GroundRefutation}^{\uparrow}}$ *surface for the carrier $G = (A, F, H, C, P, N)$ consists of five finite rows:*

1. *carrier exposure: an accepted object exposes exactly the packet of Definition 510.1;*

2. *classifier row: two accepted packets classify together only when their assumption rows, falsity routes, transports, continuation routes, package provenance, and local naming rows are matched by the displayed* hsame *and* Cont *data;*
3. *stability row: the exported negation remains tied to the same assumption row after every stored* hsame *transport;*
4. *ledger row: the bottom row reached by F is accountable to the displayed* Cont *route and package provenance;*
5. *non-escape row: no consumer may read from G a certificate-indexed truth branch, excluded-middle split, undecidable double-negation elimination, or existential witness by contradiction.*

Lean4 ✓ `BEDC.Derived.GroundRefutationUp.GroundRefutationNameCertObligations`

Proof. Carrier exposure is projection from the finite packet of Definition 510.1. The assumption row, falsity route, transport ledger, continuation routes, provenance, and local naming row are the complete public inventory.

The classifier row compares only those coordinates. A classified pair must replay the same assumption read and the same falsity-producing route through the displayed hsame and Cont data.

Stability follows because the exported negation is defined by applying the transported falsity route to the transported assumption row. The route never leaves A, F, H, C, P, N, so the negation remains a ground-loop output rather than a meta rule.

The ledger row is the accountability of F inside C and P. A bottom row can be consumed only together with the route and provenance that produced it.

Finally, the non-escape row follows from the carrier inventory. None of the six coordinates stores a truth predicate over certificates, an excluded-middle branch, an undecided double-negation eliminator, or an existential selector, so no consumer can project such data from the packet. □

Theorem 510.3 (Ground-loop refutation boundary)**.** *Every negation exported by an accepted* $\mathsf{GroundRefutation}^{\uparrow}$ *packet factors through the fixed certificate's displayed* Cont *route and* hsame *transport. The packet therefore realizes only the ground-loop rule that the displayed assumption row A leads by the recorded route F to bottom. It does not export a certificate-indexed truth branch, excluded-middle split, undecidable double-negation elimination, or existential witness by contradiction.*

Lean4 ✓ `BEDC.Derived.GroundRefutationUp.GroundRefutationCarrier ground loop boundary`

Proof. Unpack the accepted packet as $G = (A, F, H, C, P, N)$. The only route from an assumed witness of A to bottom is the displayed falsity-producing route F read through C.

Transporting the packet uses H componentwise. The assumption row and falsity route therefore move together, and the exported negation is still the same finite route from the transported assumption row to the transported bottom row.

The remaining coordinates P and N record provenance and the local naming ledger for this route. Since the carrier has no field for truth over certificates, excluded middle, undecided double-negation elimination, or witness selection by contradiction, every exported negation stays inside the closed ground loop. □

Theorem 510.4 (GroundRefutation classifier transport)**.** *Let $G = (A, F, H, C, P, N)$ and $G' = (A', F', H', C', P', N')$ be accepted* $\mathsf{GroundRefutation}^{\uparrow}$ *carriers, each displayed as a finite* BHist *packet with its* hsame *ledger,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{GroundRefutation}^{\uparrow}}$ *row.*

If the classifier row matches A with A', F with F', H with H', C with C', P with P', and N with N' by the displayed hsame *and* Cont *data, then every classified negation exported from G transports to the corresponding classified negation exported from G'. The transport has no coordinate that can introduce a certificate-indexed truth branch, excluded-middle split, undecided double-negation eliminator, or existential witness by contradiction.*

Lean4 ✓ `BEDC.Derived.GroundRefutationUp.GroundRefutationCarrier classifier transport`

Proof. Read both carriers through Definition 510.1. The classifier has only the six displayed coordinates, so its transport data is the componentwise comparison of assumption row, falsity route, transport ledger, continuation ledger, provenance, and naming row.

Apply the hsame entries to move the assumption row and the falsity route together. Apply the Cont entries to replay the assumption read, falsity production, bottom transport, and exported-negation return inside the second packet.

The Pkg row and local NameCert row account for the same finite route after transport. Since no remaining carrier coordinate stores a truth branch, excluded-middle split, undecided double-negation eliminator, or witness selector, the transported classifier remains a ground-loop classifier. □

Theorem 510.5 (GroundRefutation route stability)**.** *For an accepted* $\mathsf{GroundRefutation}^{\uparrow}$ *carrier $G = (A, F, H, C, P, N)$ displayed as a finite* BHist *packet, every stored* hsame *transport in H preserves the* Cont *route in C that reads A, replays F, transports the bottom row, and returns the exported negation. Thus the exported negation is stable under the recorded carrier transports, with accountability still carried by P and by the local* $\mathsf{NameCert}_{\mathsf{GroundRefutation}^{\uparrow}}$ *row N.*

Proof. Unpack the transport ledger H. Its entries are attached to the assumption row, falsity route, provenance row, and naming row rather than to an ambient meta rule.

The continuation ledger C is read in the same order before and after transport: read the assumption row, replay F, move the bottom row, and return the negation. Componentwise hsame therefore cannot detach the conclusion from its ground assumption.

The provenance row P and the local NameCert row N remain part of the transported packet. The route stability claim is exactly that the transported output is still produced by these displayed BHist, hsame, Cont, Pkg, and NameCert rows. □

Lean4 ✓ `BEDC.Derived.GroundRefutationUp.GroundRefutationCarrier route stability`

Theorem 510.6 (GroundRefutation ledger accountability)**.** *Let $G = (A, F, H, C, P, N)$ be an accepted* $\mathsf{GroundRefutation}^{\uparrow}$ *carrier. Any consumer that reads the bottom row produced by F must also read the displayed* BHist *assumption row A, the* hsame *transport ledger H, the* Cont *replay ledger C, the* Pkg *provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{GroundRefutation}^{\uparrow}}$ *row N. Consequently the bottom row is not available as an unaccounted contradiction token outside the packet.*

Lean4 ✓ `BEDC.Derived.GroundRefutationUp.GroundRefutationCarrier ledger accountability`

Proof. The carrier inventory has no standalone bottom-token coordinate. The bottom row appears only through the falsity-producing route F and the continuation entries in C.

A consumer of that row therefore consumes the route that produced it. The hsame ledger records how the route and assumption move, while the Pkg provenance and local NameCert row record why the route belongs to this finite packet.

It follows that the contradiction cannot be exported as anonymous evidence. It is always accompanied by the displayed BHist, hsame, Cont, Pkg, and NameCert rows of G. □

Theorem 510.7 (GroundRefutation consumer readiness)**.** *An accepted* $\mathsf{GroundRefutation}^{\uparrow}$ *consumer may use the carrier* $G = (A, F, H, C, P, N)$ *only through the displayed finite* BHist *rows, the componentwise* hsame *transports, the* Cont *routes, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{GroundRefutation}^{\uparrow}}$ *row. Such a consumer is ready for the ground-loop negation output exactly when it requests no certificate-indexed truth branch, excluded-middle split, undecided double-negation eliminator, existential witness by contradiction, or route not listed in* C*.*

Lean4 ✓ `BEDC.Derived.GroundRefutationUp.GroundRefutationCarrier consumer readiness`

Proof. Consumer readiness is a projection discipline on the six-coordinate packet. The available data are precisely A, F, H, C, P, N, read with their BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ structure.

If a consumer asks for the ground-loop negation, the packet supplies the assumption row, the falsity route, the transport ledger, the continuation replay, the provenance row, and the naming row. These are exactly the rows required by the prior boundary and accountability statements.

If a consumer asks for a truth branch, excluded-middle split, undecided double-negation eliminator, existential selector, or unlisted route, the carrier has no such coordinate to project. The readiness condition therefore keeps every valid consumer inside the displayed ground-loop surface. □

Theorem 510.8 (GroundRefutation bridge-facing route)**.** *The public* $\mathsf{GroundRefutation}^{\uparrow}$ *packet presents a bridge-facing finite route: its assumption row* A*, falsity route* F*, componentwise* hsame *ledger* H*, continuation replay* C*, provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{GroundRefutation}^{\uparrow}}$ *row* N *expose exactly the rows needed for the standard reflection bridge to inspect the ground-loop refutation surface. This route adds no certificate-indexed truth branch, excluded-middle split, undecided double-negation eliminator, existential witness by contradiction, or unlisted continuation.*

Proof. Use Definition 510.2 to read the carrier exposure, classifier row, stability row, ledger row, and non-escape row from the local naming surface. These rows expose the finite packet as a public object rather than as an ambient refutation rule.

Then use Definition 510.3, Definition 510.4, and Definition 510.5. They keep the exported negation attached to the same assumption, falsity route, transport ledger, and continuation replay under every displayed classifier transport.

Finally apply Definition 510.6 and Definition 510.7. Any bridge-facing consumer must read the same A, F, H, C, P, N packet, so the route is ready for the standard reflection bridge while the excluded non-escape data remain absent. □

Theorem 510.9 (GroundRefutation standard bridge)**.** *The paper bridge interprets each finite carrier* $G = (A, F, H, C, P, N)$ *as the standard closed ground-loop refutation schema: the displayed assumption row* A *is the only input, the displayed route* F *is the only falsity route,* H *and* C *are the only transport and continuation replays, and* P, N *are the only provenance and naming rows. Conversely, every standard ground-loop read of this schema reflects back to exactly those six rows of* G*. The bridge exposes no certificate-indexed truth branch, excluded-middle split, double-negation eliminator, or existential witness.*

Proof. The forward interpretation reads the six coordinates of Definition 510.1. The standard schema receives the assumption row from A, sends it through the falsity route F, replays the required transports and continuations through H and C, and records accountability through P and N.

For the reverse readback, a standard ground-loop use has no data other than the assumption row, the falsity route, the transport and continuation replays, and the provenance and naming rows. These are exactly the six carrier coordinates, so the readback lands back in G without adding a hidden branch.

The non-escape clauses are inherited from the carrier inventory and consumer readiness. Since neither side of the bridge has a coordinate for certificate-indexed truth, excluded middle, double-negation elimination, or existential selection, the bridge remains a paper bridge for the closed ground-loop schema. □

Closure status for $\mathsf{NameCert}_{\mathsf{GroundRefutation}^{\uparrow}}$.

Constructive story: A $\mathsf{GroundRefutation}^{\uparrow}$ packet is generated from one displayed assumption row, a falsity-producing continuation route, componentwise hsame transports, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{GroundRefutation}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 510.1, Definition 510.2, Definition 510.3, Definition 510.4, Definition 510.5, Definition 510.6, Definition 510.7, Definition 510.8, and Definition 510.9 bind the finite carrier, NameCert obligation rows, classifier transport, route stability, ledger accountability, public consumer non-escape boundary, bridge-facing route, standard paper bridge, and worked ground-loop refutation consumer route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{GroundRefutation}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.GroundRefutationUp.GroundRefutationNameCertObligations`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not claim a checked standard bridge theorem, certificate-indexed truth branch, excluded-middle split, undecided double-negation eliminator, or existential witness by contradiction.

Upgrade path: A checked standard bridge theorem would move the verification axis beyond the axiom-clean NameCert obligations; the theory axis is closed by the seed, obligation, scoped, bridged, and worked ground-loop consumer rows.

Chapter 511

A Concrete Naming Certificate for $\mathsf{RefutationWitness}^{\uparrow}$

The $\mathsf{RefutationWitness}^{\uparrow}$ surface is the concrete NameCert landing for constructive reasoning by contradiction. It records an assumption row, a finite continuation route from that assumption to bottom, the produced bottom row, and the local transport and provenance rows needed to replay the route. The packet certifies refutation only as displayed assumption-to-bottom evidence; it does not export a certificate-indexed truth branch, a host-level contradiction principle, or a witness selected from an unwitnessed negation.

The packet consumes the finite trace route of chapter 512 and the stable negative boundary of chapter 507 before its assumption-to-bottom route is accepted. This dependency is limited to displayed assumption rows, route replay, bottom-row accountability, hsame transport, Cont replay, Pkg provenance, and NameCert rows.

Definition 511.1 (RefutationWitness carrier)**.** *A* $\mathsf{RefutationWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (A, a, \rho, b, H, C, P, N)$$

with the following displayed rows:

1. *A is the proposition or predicate row being refuted, read as a certificate-visible* BHist *object rather than as host truth;*
2. *a is the assumed witness row for A at the current history;*
3. *ρ is the finite refutation route, a list of displayed* Cont, msame, *and* hsame *steps beginning at a;*
4. *b is the bottom row reached by replaying ρ from the assumed witness;*
5. *H records componentwise* hsame *transport for A, a, ρ, b, provenance, and local naming rows;*
6. *C records the* Cont *routes used to read the assumption, replay the refutation route, and return the bottom row to a downstream consumer;*
7. *P is the* Pkg *provenance over* BHist, Hist, Cont, msame, hsame, *bottom-witness rows, and the surrounding certificate rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{RefutationWitness}^{\uparrow}}$ *ledger.*

The carrier contains no coordinate for excluded middle over certificate predicates, no host truth predicate for A, no double-negation eliminator, and no existential witness selected from a contradiction argument.

Lean4 ✓ `BEDC.Derived.RefutationWitnessUp.RefutationWitnessCarrier assumption bottom replay package`

Theorem 511.2 (RefutationWitness NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RefutationWitness}^{\uparrow}}$ *surface for the carrier of Definition 511.1 consists exactly of carrier exposure, assumption accountability, route replay, bottom-row accountability, classifier transport, continuation locality, package provenance, and truth-branch exclusion. A consumer accepts a refutation only by projecting*

$$(A, a, \rho, b, H, C, P, N)$$

and checking that the displayed route ρ *carries the displayed assumption row* a *to the displayed bottom row* b *through the recorded* Cont*,* msame*, and* hsame *data.*

Lean4 ✓ `BEDC.Derived.RefutationWitnessUp.RefutationWitnessNameCertObligations`

Proof. Carrier exposure is projection from Definition 511.1. The packet lists the proposition row, assumption row, route, bottom row, transport ledger, continuation ledger, provenance, and local naming row, and no other coordinate is available.

Assumption accountability and route replay are read from a, ρ, and C. A consumer cannot project b without also projecting the route that starts from the displayed assumed witness and reaches that bottom row.

Classifier transport is componentwise transport through H. The proposition row, assumption row, route, bottom row, package row, and naming row move together, so transport preserves the same finite refutation evidence rather than introducing an external proof principle.

Finally, truth-branch exclusion follows from the carrier inventory. The packet has no row for a family deciding predicates over all naming certificates, no host truth row for A, and no selected existential witness. Hence the NameCert obligations are exhausted by the displayed assumption-to-bottom route. □

Theorem 511.3 (RefutationWitness truth-branch blocker)**.** *No accepted* $\mathsf{RefutationWitness}^{\uparrow}$ *packet can be read as a certificate-indexed truth branch in the sense of Definition 9458.10. Its only negative information is the displayed map from the assumed witness row* a *to the bottom row* b *along* ρ*, and every downstream read remains inside the finite rows* $A, a, \rho, b, H, C, P, N$*.*

Lean4 ✓ `BEDC.Derived.RefutationWitnessUp.RefutationWitnessCarrier truth branch blocker`

Proof. Start with an accepted packet $R = (A, a, \rho, b, H, C, P, N)$. The available projection operations return only those displayed rows, their componentwise transports, and the continuation routes that replay ρ.

A certificate-indexed truth branch would require a row assigning, for each naming certificate in a carrier of certificates, either a positive witness or a refutation. No such carrier-wide predicate row appears in R, and no coordinate ranges over all naming certificates.

The packet therefore supports only the local refutation read: assume the displayed witness row a, replay the finite route ρ, and obtain the displayed bottom row b. That read blocks any extraction of excluded middle, undecided double-negation elimination, or existential witness selection from the $\mathsf{RefutationWitness}^{\uparrow}$ surface. □

Theorem 511.4 (RefutationWitness ground-refutation route link)**.** *Every accepted* $\mathsf{GroundRefutation}^{\uparrow}$ *or* $\mathsf{RefutationBoundary}^{\uparrow}$ *consumer that uses an assumption-to-bottom row consumes the local* $\mathsf{RefutationWitness}^{\uparrow}$ *route shape through chapter 510 and chapter 500 only after the displayed rows*

$$A, a, \rho, b, H, C, P, N$$

are present. The route is a finite replay from the assumed witness row a to the bottom row b, not a host-level truth branch or a selected witness extracted from an undecided negation.

Lean4 ✓ `BEDC.Derived.RefutationWitnessUp.RefutationWitnessCarrier ground refutation route link`

Proof. Project the carrier of Definition 511.1. The local route shape has exactly the proposition row, assumed witness row, finite refutation route, bottom row, transport ledger, continuation ledger, provenance row, and naming row.

Use Definition 511.2. Its route replay and bottom-row accountability clauses force any consumer to carry the displayed assumption-to-bottom route ρ before it may consume the bottom row b in a ground-refutation or boundary-refutation packet.

Finally apply Definition 511.3. Since the local packet exports no certificate-indexed truth branch, excluded middle, double-negation eliminator, or witness selector, the GroundRefutation and RefutationBoundary consumers can only cite the finite route through the two named sibling chapters. □

Theorem 511.5 (Refutation witness mature treatment)**.** *Every mature consumer of an accepted* $\mathsf{RefutationWitness}^{\uparrow}$ *packet receives exactly the finite proposition row A, assumed-witness row a, refutation-route row ρ, bottom row b, componentwise* hsame *ledger H, displayed* Cont *replay C,* Pkg *provenance P, and local* NameCert *row N. The mature read factors through Definition 511.1, Definition 511.2, Definition 511.3, and Definition 511.4; it introduces no truth branch, selected witness, excluded middle, or double-negation eliminator.*

Lean4 ✓ `BEDC.Derived.RefutationWitnessUp.RefutationWitnessCarrier mature treatment`

Proof. Project the carrier of Definition 511.1. The mature consumer can read only $A, a, \rho, b, H, C, P, N$, because these are the displayed rows admitted by the finite packet.

Apply the NameCert obligations, Definition 511.2. Carrier admission, assumption accountability, route replay, bottom-row accountability, classifier transport, continuation locality, provenance, and local naming exhaust the accepted surface.

Now use the truth-branch blocker, Definition 511.3, and the ground-refutation route link, Definition 511.4. The former removes any certificate-indexed truth branch, excluded middle, double-negation eliminator, or witness selector; the latter places every ground-refutation and boundary-refutation read on the displayed assumption-to-bottom route.

Thus the mature treatment is exactly the finite refutation packet and its two sibling routes, with no additional logical row. □

Closure status for $\mathsf{NameCert}_{\mathsf{RefutationWitness}^{\uparrow}}$**.**

Constructive story: A $\mathsf{RefutationWitness}^{\uparrow}$ packet is generated from a proposition row, an assumed witness row, a finite assumption-to-bottom route, the produced bottom row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert ledger.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RefutationWitness}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 511.1, Definition 511.2, Definition 511.3, Definition 511.4, and Definition 511.5 bind the displayed RefuterTrace, StableNegationBoundary, GroundRefutation, RefutationBoundary, BHist, hsame, Cont, Pkg, and NameCert rows for carrier admission, route replay, classifier transport, bottom-row accountability, provenance, local NameCert admission, truth-branch exclusion, the GroundRefutation–RefutationBoundary bridge route, and mature finite-row consumption.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RefutationWitness}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, excluded middle over certificate predicates, host truth, undecided double-negation elimination, existential witness selection, or a public standard bridge.

Upgrade path: Mature closure requires a standard bridge check for the displayed GroundRefutation and RefutationBoundary route without adding a truth branch or selected witness.

Chapter 512

A Concrete Naming Certificate for $\mathsf{RefuterTrace}^{\uparrow}$

The $\mathsf{RefuterTrace}^{\uparrow}$ surface realizes the permitted-refutation side of chapter 9458 as a finite trace packet. It records the assumed proposition row, the route from that assumption to $\bot$, the local exclusions that keep forbidden contradiction schemas out of the consumer interface, and the exact BHist routes through which the certificate may be read.

Definition 512.1 (RefuterTrace carrier)**.** *A* $\mathsf{RefuterTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (A, U, F, E, H, C, P, N)$$

with the following displayed rows:

1. *A is the proposition row being refuted, represented only by the certificate-visible predicate row that a consumer may assume locally;*
2. *U is the assumption token for A, naming the temporary witness that the trace is allowed to inspect;*
3. *F is the finite refuter trace, a displayed route from U to $\bot$ through* Cont, Ext, hsame, msame, *and the local certificate rows;*
4. *E is the exclusion ledger for the forbidden contradiction moves of Definition 9458.5: existential extraction without a witness, double-negation elimination without a decision row, and excluded-middle branching over the carrier of all naming certificates;*
5. *H stores componentwise* hsame *transports for the proposition, assumption, refuter trace, exclusion ledger, package provenance, and local naming rows;*
6. *C stores the displayed* Cont *routes for entering the assumption, replaying the finite trace, reaching $\bot$, checking the exclusions, and returning to the local ledger;*
7. *P is the* Pkg *provenance over* BHist, Ext, Cont, msame, hsame, *the trace rows, the exclusion ledger, and the surrounding* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{RefuterTrace}^{\uparrow}}$ *ledger.*

The carrier contains no proof by contradiction that exports a witness, no double-negation eliminator, no excluded-middle oracle, no host truth predicate, and no classifier over the carrier of all naming certificates.

Theorem 512.2 (RefuterTrace NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RefuterTrace}^{\uparrow}}$ *surface consists of five obligations:*

1. *carrier admission for the finite packet* $R = (A, U, F, E, H, C, P, N)$ *of Definition 512.1;*
2. *trace readability, saying that* F *is consumed only as a displayed route from the local assumption token* U *for* A *to* $\bot$*;*
3. *transport stability, saying that the stored* hsame *rows in* H *and* Cont *routes in* C *preserve the proposition row, assumption token, refuter trace, and exclusion ledger;*
4. *forbidden-branch exclusion, saying that* E *blocks the three forbidden contradiction schemas named in Definition 9458.5;*
5. *consumer boundary, saying that every public read of the packet factors through* A, U, F, E, H, C, P, N *and exports only the negation certified by the trace.*

Lean4 ✓ `BEDC.Derived.RefuterTraceUp.RefuterTraceTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 512.1. The accepted packet has exactly the displayed rows A, U, F, E, H, C, P, N, so every obligation can be read from finite BHist data.

Trace readability follows by inspecting the coordinate F. Its source is the local assumption token U for the proposition row A, and its target is $\bot$; no other coordinate supplies a witness-producing contradiction rule.

Transport stability is supplied by H and C. The hsame rows preserve the named components, while the Cont rows replay the route through the same finite trace before returning to P and N.

The forbidden-branch clause is exactly the role of E. Since E records the absence of unwitnessed existential extraction, undecidable double-negation elimination, and excluded-middle branching over all naming certificates, no consumer can use the trace as a meta-level truth branch.

The consumer boundary follows by combining these projections. A public read may assume A locally, replay F to $\bot$, and therefore consume $\neg A$ inside the fixed packet, but it cannot export any branch or witness absent from A, U, F, E, H, C, P, N. □

Theorem 512.3 (RefuterTrace stable negation sibling route)**.** *Every accepted* $\mathsf{RefuterTrace}^{\uparrow}$ *packet that is consumed as stable negative information factors its assumption-to-bottom route through the* $\mathsf{StableNegationBoundary}^{\uparrow}$ *sibling surface of chapter 507 before any downstream consumer reads it as stable negation. The route starts from the RefuterTrace carrier and NameCert obligations, uses permitted refutation soundness, applies forbidden branch exclusion, and is then exhausted by the StableNegationBoundary NameCert and ledger rows.*

The sibling route exports no double-negation eliminator, excluded-middle oracle, witness by contradiction, or classifier over all naming certificates.

Proof. Start inside the $\mathsf{RefuterTrace}^{\uparrow}$ packet. The NameCert obligations of Definition 512.2 expose exactly A, U, F, E, H, C, P, N, so the assumption-to-bottom route is the displayed trace F from the local assumption token U to $\bot$.

Use permitted refutation soundness and forbidden branch exclusion before handing the route to the sibling packet. Definition 512.4 certifies only the local permitted pattern "assume A, derive $\bot$, conclude $\neg A$", while Definition 512.5 blocks witness extraction, undecidable double-negation elimination, and excluded-middle branching over all naming certificates.

Now read the stable-negation boundary. The NameCert obligations and ledger exhaustion of Definition 507.2 and Definition 507.5 force any downstream stable-negation consumer through the boundary rows $A, R, D, T, L, H, C, P, N$ of $\mathsf{StableNegationBoundary}^{\uparrow}$. Since those rows contain

only local refutation, optional decision, classifier, exclusion ledger, transport, route, provenance, and naming data, the composed sibling route still exports none of the forbidden contradiction interfaces. □

Theorem 512.4 (RefuterTrace permitted refutation soundness)**.** *For an accepted* $\mathsf{RefuterTrace}^{\uparrow}$ *carrier* $R = (A, U, F, E, H, C, P, N)$*, replaying the finite trace* F *under the displayed transports and continuation routes certifies* $\neg A$ *in the local* $\mathsf{NameCert}_{\mathsf{RefuterTrace}^{\uparrow}}$ *ledger. The certification is exactly the permitted form "assume* A*, derive* $\bot$*, conclude* $\neg A$*" of Definition 9458.1.*

Lean4 ✓ `BEDC.Derived.RefuterTraceUp.RefuterTrace permitted refutation route`

Proof. Begin with the assumption token U for the proposition row A. The trace row F is a finite Cont route from that token to $\bot$, and the routes in C make each step visible to the certificate consumer.

The transports in H ensure that replaying the route does not change the proposition being refuted. Thus the endpoint $\bot$ is reached from the same local assumption for A rather than from an ambient truth predicate or an unrelated classifier.

By the permitted pattern of Definition 9458.1, a route from an assumed witness of A to $\bot$ is precisely a certificate-level proof of $\neg A$. The resulting negation is recorded in the local ledger N and nowhere outside the displayed packet. □

Theorem 512.5 (RefuterTrace forbidden branch exclusion)**.** *An accepted* $\mathsf{RefuterTrace}^{\uparrow}$ *carrier cannot be read as any of the three forbidden contradiction schemas of Definition 9458.5. In particular, the packet does not provide a witness for an existential claim obtained only by refutation, does not eliminate* $\neg\neg A$ *without a decision row, and does not branch on excluded middle for predicates over the carrier of all naming certificates.*

Proof. The carrier has no coordinate whose codomain is an existential witness selected from a contradiction. The only witness-like row is the temporary assumption token U, and that token is consumed by F to reach $\bot$ rather than exported.

The carrier also has no decision row for A. Therefore a consumer reading $\neg\neg A$ cannot obtain A from the packet; the exclusion ledger E records exactly that this route is unavailable.

Finally, no row in R ranges over the carrier of all naming certificates. The classifier-visible data are the finite trace coordinates A, U, F, E, H, C, P, N, so an excluded-middle branch over arbitrary certificates has no source inside the packet. □

Theorem 512.6 (RefuterTrace consumer boundary)**.** *Every consumer of an accepted* $\mathsf{RefuterTrace}^{\uparrow}$ *carrier factors through the finite route*

$$A \longmapsto U \longmapsto F \longmapsto E \longmapsto H \longmapsto C \longmapsto P \longmapsto N.$$

The consumer may read the certified negation produced by the trace, but it cannot read a host truth predicate, a global excluded-middle oracle, a witness selector, or a classifier over all naming certificates.

Proof. Project the accepted carrier of Definition 512.1. The only public coordinates are A, U, F, E, H, C, P, N, and the displayed continuation route orders those coordinates from the local proposition row to the naming ledger.

The certified negation is obtained by replaying F from U to $\bot$, with H and C preserving the same proposition row throughout the replay. This is the permitted-refutation route of Definition 512.4.

The unavailable reads are ruled out componentwise. Host truth, excluded-middle branching, witness selection, and all-certificate classification have no coordinate in the packet, and the exclusion ledger E records that they are not consumer interfaces. □

Theorem 512.7 (RefuterTrace finite witnessed boundary)**.** *For an accepted* $\mathsf{RefuterTrace}^{\uparrow}$ *carrier* $R = (A, U, F, E, H, C, P, N)$*, any downstream consumer that reads the trace as a finite witnessed refutation or as a bounded-search refutation must first pass through the displayed rows*

$$A, U, F, E, H, C, P, N.$$

Only after that local passage may the consumer enter chapter 576 or chapter 579, and then only as finite consumer packaging for the already displayed trace.

The passage does not provide witness selection by contradiction, double-negation elimination without a decision row, excluded-middle branching, host truth, or a classifier over all naming certificates.

Proof. Project the carrier of Definition 512.1. Its certificate-visible coordinates are exactly A, U, F, E, H, C, P, N, so any consumer route begins with those rows rather than with an ambient contradiction principle.

Apply the obligation surface of Definition 512.2. The trace is readable only as the finite route F from the local assumption token U for A to $\bot$, while the rows E, H, C, P, N record exclusions, transports, continuation routes, provenance, and local naming.

Apply the consumer boundary of Definition 512.6. A downstream reader may consume the certified negation produced by the trace, but it cannot obtain host truth, a global excluded-middle oracle, a witness selector, or an all-certificate classifier from the packet.

The sibling chapters are therefore read only after the local packet has been exhausted. chapter 576 supplies finite witnessed-refutation packaging, and chapter 579 supplies bounded-search packaging; neither chapter is an extra logical principle for the RefuterTrace carrier. □

Closure status for $\mathsf{NameCert}_{\mathsf{RefuterTrace}^{\uparrow}}$**.**

Constructive story: A $\mathsf{RefuterTrace}^{\uparrow}$ packet is generated from a proposition row, a local assumption token, a finite refuter trace to $\bot$, a forbidden-branch exclusion ledger, componentwise transports, displayed continuation routes, package provenance, and a local naming ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RefuterTrace}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 512.1, Definition 512.2, Definition 512.4, Definition 512.5, Definition 512.6, and Definition 512.7 bind the finite carrier, obligation surface, permitted refutation route, forbidden-branch exclusion, consumer boundary, and finite consumer route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RefuterTrace}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close existential-by-refutation witness selection, undecidable double-negation elimination, excluded middle over naming certificates, host truth, or a checked Lean certificate.

Upgrade path: Obligation closure requires Lean encoding of the packet and checked theorems for trace readability, transport stability, forbidden-branch exclusion, permitted-refutation soundness, and consumer non-escape.

Chapter 513

A Concrete Naming Certificate for $\mathsf{ObserverLocalityCell}^{\uparrow}$

The $\mathsf{ObserverLocalityCell}^{\uparrow}$ interface packages the finite two-observer cell described in Definition 9420.38. It is a local naming surface: two observer-history rows, two event-description rows, paired Gap acknowledgements, componentwise transport, continuation routes, provenance, and a local certificate are visible, while global spacetime, a shared clock, a manifold coordinate chart, and an all-observer frame are not part of the carrier.

Definition 513.1 (ObserverLocalityCell carrier)**.** *An* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N)$$

with the following visible rows:

1. O_0 *and* O_1 *are the two observer-history rows being compared;*
2. R_0 *and* R_1 *are the two local event-description rows recorded inside those histories;*
3. G_0 *and* G_1 *are paired* Gap *acknowledgement rows, each committing its own observer side to the coherence of* R_0 *and* R_1 *as descriptions of one event;*
4. H *stores componentwise* hsame *transport for the observer histories, event rows, acknowledgement rows, continuation routes, package row, and local name row;*
5. C *stores the displayed* Cont *routes by which a consumer reads the two observer histories, the two event rows, and the two acknowledgement rows;*
6. P *is the* Pkg *provenance over* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{FiniteMultiHistPacket}^{\uparrow}$, Hist, BHist, Gap, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$*;*
7. N *is the local* $\mathsf{NameCert}_{\mathsf{ObserverLocalityCell}^{\uparrow}}$ *row.*

The classifier compares accepted packets only after transporting these displayed coordinates to a common two-history surface. The carrier has no coordinate for an external event object, global observer frame, synchronized clock, metric geometry, manifold point, or instantaneous remote record.

Theorem 513.2 (ObserverLocalityCell NameCert obligations)**.** *For the carrier of Definition 513.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverLocalityCell}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission for the displayed packet* $L = (O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N)$*;*

2. *classifier transport to a common observer-history and event-row surface;*
3. *paired* Gap *acknowledgement exactness, requiring both G_0 and G_1 to name the same transported pair of event rows;*
4. *stability under the componentwise* hsame *row H and displayed* Cont *routes in C;*
5. *non-escape for global frames, synchronized clocks, manifold coordinates, ambient metric geometry, and instantaneous remote records.*

Lean4 ✓ `BEDC.Derived.ObserverLocalityCellUp.ObserverLocalityCellPacket semantic name certificate`

Proof. Carrier admission is projection from Definition 513.1. The rows $O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N$ display the two observer histories, the two event records, the paired acknowledgements, transport, routes, provenance, and local name.

Classifier transport uses H to move every displayed coordinate to a common two-history surface. Once transported, the only consumer reads are the routes recorded in C.

The acknowledgement exactness row reads G_0 and G_1 together. Each side commits to the same transported pair (R_0, R_1), so the named cell is the paired commitment surface rather than an external event object.

The non-escape clause follows from the carrier inventory. No row supplies a global frame, synchronized clock, manifold coordinate, ambient metric, or instantaneous remote record. □

Theorem 513.3 (ObserverLocalityCell GAP coherence)**.** *Let $L = (O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N)$ be an accepted* ObserverLocalityCell$^{\uparrow}$ *carrier. Every coherence read of the cell factors through both acknowledgement rows G_0 and G_1 after transporting O_0, O_1, R_0, R_1 by H and replaying the displayed routes in C. A one-sided acknowledgement is not a locality cell.*

Lean4 ✓ `BEDC.Derived.ObserverLocalityCellUp.ObserverLocalityCellPacket paired gap transport`

Proof. Project the accepted packet. The only rows that assert cross-observer coherence are G_0 and G_1; the observer histories and event-description rows merely supply the local records being compared.

Transport the two histories and the two event rows through H. The routes in C then read the transported event rows before reading the two acknowledgement rows.

Because the carrier requires both G_0 and G_1, a coherence read that omits one side cannot satisfy the displayed packet. Thus the cell is exactly the paired Gap commitment over the transported event rows. □

Theorem 513.4 (ObserverLocalityCell consumer boundary)**.** *Every* ObserverHistoryIdentity$^{\uparrow}$, CrossHistCausal$^{\uparrow}$, *or* FiniteMultiHistPacket$^{\uparrow}$ *consumer of an accepted* ObserverLocalityCell$^{\uparrow}$ *packet may read exactly the two observer-history rows, the two event-description rows, the paired* Gap *acknowledgement rows, componentwise* hsame *transports, displayed* Cont *routes, package provenance, and the local* NameCert *row. The packet exports no shared clock, global event object, metric light-cone, manifold coordinate chart, or all-observer synchronization map.*

Lean4 ✓ `BEDC.Derived.ObserverLocalityCellUp.ObserverLocalityCellPacket consumer boundary`

Proof. Start with a consumer route into the accepted packet. The carrier projection exposes the two histories, two event rows, and paired acknowledgement rows as the only observational data.

For an $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ consumer, the relevant read is the identity-preserving history surface O_0, O_1 together with the transported event rows. For a $\mathsf{CrossHistCausal}^{\uparrow}$ or $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ consumer, the cross-history access still reaches coherence through the same G_0, G_1 pair.

The remaining data are H, C, P, N. They transport, route, record provenance, and name the local cell; they do not supply a clock, global event, metric cone, chart, or synchronization map. □

Theorem 513.5 (ObserverLocalityCell finite ledger package)**.** *The carrier, NameCert obligations, paired* Gap *coherence, and consumer boundary assemble a finite* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *package over* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{FiniteMultiHistPacket}^{\uparrow}$, Hist, BHist, Gap, hsame, Cont, Pkg, *and* NameCert. *Every locality-cell read factors through this ledger, and no host spacetime, global observer frame, or infinite coherence web is exported.*

Proof. The carrier supplies the finite tuple of Definition 513.1. The NameCert obligations in Definition 513.2 bind its carrier, classifier, acknowledgement exactness, stability, and non-escape rows.

The paired Gap coherence theorem identifies the cell condition as a two-sided acknowledgement after componentwise transport. The consumer boundary theorem identifies the exact rows visible to observer-history, cross-history, and finite multi-history readers.

Repacking these rows gives the stated finite ledger package. Since each cited row belongs to the displayed packet, there is no exported host spacetime, global frame, or infinite coherence structure. □

Theorem 513.6 (ObserverLocalityCell TasteGate witness boundary)**.** *Any later* ChapterTasteGate *witness for an accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *packet must read only the displayed two observer-history rows* O_0, O_1*, two event-description rows* R_0, R_1*, paired* Gap *rows* G_0, G_1*, componentwise* hsame *transports* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* NameCert *row* N*. Such a witness may classify the packet by those rows, but it has no admissible read of a global frame, shared clock, metric cone, manifold coordinate, or observer-independent event object.*

Proof. Project the accepted packet through Definition 513.1. The visible rows are exactly the two observer histories, two event rows, paired acknowledgement rows, transport row, continuation routes, package row, and local naming row.

A ChapterTasteGate witness can audit only the carrier and routes it is handed. The NameCert obligations and consumer boundary already restrict those routes to the displayed locality-cell packet.

Therefore the witness boundary is the same finite read surface. Since the excluded global objects are not coordinates of the packet, no TasteGate read can import them. □

Theorem 513.7 (ObserverLocalityCell BHistCarrier flow surface)**.** *The carrier-to-flow presentation of an accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *packet is a finite* BHistCarrier*-facing flow over* $O_0, O_1, R_0, R_1, G_0, G_1, H, C$*, Each flow edge is either a displayed* Cont *route, a componentwise* hsame *transport, a paired* Gap *acknowledgement read, or the final local* NameCert *read; no edge targets a host spacetime row or an infinite observer web.*

Proof. Read the packet as a finite BHist tuple. The carrier rows supply the only vertices available to a BHistCarrier-facing presentation.

The permitted edges are the routes recorded in C, the transports recorded in H, and the two acknowledgement reads through G_0 and G_1. The local naming row N closes the presentation as a finite certificate read.

Because there is no carrier coordinate for host spacetime or an infinite observer web, no flow edge can target such an object. The flow surface is therefore finite and exactly over the displayed locality-cell rows. □

Theorem 513.8 (ObserverLocalityCell conservativity audit surface)**.** *Every public consumer and audit read of an accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *packet is conservative over the finite ledger of Definition 513.5. It cannot import a global frame, shared clock, metric cone, observer-independent event object, manifold coordinate chart, or all-observer synchronization map as an extra premise or exported conclusion.*

Proof. Start from any public consumer or audit route. By Definition 513.4, the route can read only the displayed observer rows, event rows, acknowledgement rows, transports, continuation routes, provenance, and local naming row.

The finite ledger package repacks those rows without adding another carrier. Thus an audit may check whether the stated rows are present and coherently paired, but it has no source for a global frame, shared clock, metric cone, or observer-independent event.

Consequently every public read is conservative over the finite locality-cell ledger. Any premise or conclusion requiring the excluded global objects lies outside the packet boundary. □

Theorem 513.9 (ObserverLocalityCell carrier-admission obligation)**.** *For an accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *packet, carrier admission admits exactly the displayed rows*

$$O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N$$

as the BHistCarrier*-facing flow surface. The admitted coordinates are the two observer-history rows, two event-description rows, paired* Gap *acknowledgement rows, componentwise* hsame *transport row, displayed* Cont *route row,* Pkg *provenance row, and local* $\mathsf{NameCert}_{\mathsf{ObserverLocalityCell}^{\uparrow}}$ *row; no global frame, shared clock, metric row, manifold coordinate, or observer-independent event object is admitted as a carrier coordinate.*

Proof. Apply the carrier definition in Definition 513.1. It lists exactly the ten rows displayed in the theorem statement and identifies their observer, event, acknowledgement, transport, route, provenance, and local naming roles.

Use the NameCert obligations of Definition 513.2 to read carrier admission as a finite obligation over that tuple. The paired Gap coherence theorem then fixes G_0 and G_1 as acknowledgement rows over the transported event pair.

Finally apply the BHistCarrier flow surface of Definition 513.7 and the conservativity audit surface of Definition 513.8. These results exclude every non-displayed global coordinate, so the admitted flow surface is exactly the ten-row packet. □

Theorem 513.10 (ObserverLocalityCell classifier-stability obligation)**.** *Componentwise* hsame *transport along H preserves the paired acknowledgement classifier for an accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *packet. After transporting $O_0, O_1, R_0, R_1, G_0, G_1, C, P, N$ through the displayed row H, the classifier still reads the same two-sided* Gap *acknowledgement surface and does not add a global observer frame, synchronized clock, metric comparison, manifold chart, or observer-independent event object.*

Lean4 ✓ `BEDC.Derived.ObserverLocalityCellUp.ObserverLocalityCellPacket classifier stability obligation`

Proof. Start from the classifier transport obligation in Definition 513.2. The transport row H acts componentwise on the observer histories, event-description rows, acknowledgement rows, continuation routes, package provenance, and local name.

Apply the GAP coherence theorem Definition 513.3. The coherence read is still the paired read through G_0 and G_1 after the displayed rows are moved to a common two-history surface.

The consumer boundary of Definition 513.4 and the TasteGate witness boundary of Definition 513.6 identify the same finite read surface for downstream checks. Since the conservativity audit surface excludes all global frame, clock, metric, chart, and event-object coordinates, the transported classifier is stable without importing external data. □

Theorem 513.11 (ObserverLocalityCell consumer-exhaustion obligation)**.** *Every* ObserverHistoryIdentity$^{\uparrow}$, CrossHistCausal$^{\uparrow}$, FiniteMultiHistPacket$^{\uparrow}$, *and* ChapterTasteGate *audit read of an accepted* ObserverLocalityCell$^{\uparrow}$ *packet factors through the displayed rows* $O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N$. *The exhausted consumer surface is the carrier definition, the local* NameCert *obligation surface, the paired* Gap *coherence surface, the consumer boundary, the TasteGate witness boundary, the* BHistCarrier *flow surface, and the conservativity audit surface; it contains no additional global data source.*

Proof. For ObserverHistoryIdentity$^{\uparrow}$ reads, apply Definition 513.4. The only visible history data are O_0 and O_1, with event rows and acknowledgement rows read through the displayed transport and continuation rows.

For CrossHistCausal$^{\uparrow}$ and FiniteMultiHistPacket$^{\uparrow}$ reads, use Definition 513.3 together with the finite ledger package of Definition 513.5. Cross-history access reaches coherence only through G_0 and G_1 over the transported event rows.

For ChapterTasteGate audits, use Definition 513.6. Because this chapter is marked with `\origin{ai}`, any promotion past seed closure must cite the checked Lean target `BEDC.Derived.ObserverLocalityCellUp.tast` once that declaration exists; this paper theorem does not add a Lean marker.

Finally combine the BHistCarrier flow surface and conservativity audit surface. They show that every allowed read has a source among the ten displayed rows and that no global frame, clock, metric, manifold coordinate, observer-independent event object, or all-observer synchronization map is available. □

Theorem 513.12 (ObserverLocalityCell scoped export surface)**.** *The carrier, local* NameCert *obligations, paired* Gap *coherence, consumer boundary, finite ledger package,* BHistCarrier *flow surface, and conservativity audit surface of an accepted* ObserverLocalityCell$^{\uparrow}$ *packet export exactly one scoped consumer surface for* ObserverHistoryIdentity$^{\uparrow}$, CrossHistCausal$^{\uparrow}$, FiniteMultiHistPacket$^{\uparrow}$, *and* ChapterTasteGate *reads. That surface is the ten-row packet* $O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N$ *and no additional global-frame row.*

Lean4 ✓ `BEDC.Derived.ObserverLocalityCellUp.ObserverLocalityCellPacket scoped export surface`

Proof. Begin with carrier admission and the local NameCert obligations. They identify $O_0, O_1, R_0, R_1, G_0, G_1, H, C$ as the complete two-observer locality-cell packet.

Apply paired Gap coherence and the consumer boundary. These route ObserverHistoryIdentity$^{\uparrow}$, CrossHistCausal$^{\uparrow}$, and FiniteMultiHistPacket$^{\uparrow}$ reads through the two observer-history rows, two event rows, and two acknowledgement rows under the displayed transport and continuation rows.

Add the finite ledger package, BHistCarrier flow surface, and conservativity audit surface. They package the same rows for downstream reads and rule out global spacetime, a shared clock, a metric cone, manifold coordinates, observer-independent event objects, and all-observer synchronization maps.

The remaining TasteGate read is therefore not a second surface. It is a ground-compiler audit of the same ten rows, so the scoped export is unique for all four consumer families. □

Theorem 513.13 (ObserverLocalityCell TasteGate-cited readiness)**.** *For this AI-origin* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *chapter, promotion along the scoped consumer surface must cite the checked TasteGate declaration when it is present. The visible rows remain exactly*

$$O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N.$$

No global spacetime, shared clock, metric cone, manifold coordinate, or observer-independent event object enters the TasteGate-facing surface.

Proof. Read the AI-origin closure status and the existing TasteGate witness boundary. The paper surface is permitted to expose the TasteGate channel only through the finite locality-cell carrier.

Use Definition 513.12. It identifies the one scoped consumer surface for observer-history, cross-history causal, finite-multi-history, and TasteGate reads as the ten displayed rows.

The checked TasteGate declaration, when cited, checks that same row discipline rather than adding global geometry. The conservativity audit surface keeps global spacetime, shared clocks, metric cones, manifold coordinates, and observer-independent event objects outside the packet. □

Theorem 513.14 (ObserverLocalityCell public export certificate)**.** *An accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *packet has one public export certificate over*

$$O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N.$$

The certificate assembles carrier admission, local NameCert *obligations, paired* Gap *coherence, the consumer boundary, the finite ledger package, the* BHistCarrier *flow surface, the conservativity audit surface, the scoped export surface, and the TasteGate-cited readiness theorem into a single public packet for the two-observer locality-cell surface.*

Proof. Start with carrier admission and the local NameCert obligations. They identify the two observer-history rows, two local event-description rows, paired acknowledgement rows, componentwise transport row, continuation routes, package provenance, and local naming row as the full packet.

Add paired Gap coherence, the consumer boundary, and the finite ledger package. These route $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, and $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ reads through the same ten rows.

Next attach the BHistCarrier flow surface and the conservativity audit surface. They ensure that the public packet remains a finite history-carrier flow and that no global spacetime, shared clock, metric cone, manifold coordinate, observer-independent event object, or all-observer synchronization map is exported.

Finally apply the scoped export surface and Definition 513.13. The surrounding closure scope already cites the checked TasteGate marker for `BEDC.Derived.ObserverLocalityCellUp.taste_gate`, so this public certificate records the same TasteGate-facing row discipline without adding a second Lean marker. □

Falsifiable prediction: Any accepted $\mathsf{ObserverLocalityCell}^{\uparrow}$ consumer that bypasses both paired Gap acknowledgement rows G_0, G_1, or that imports a global observer frame, refutes the two-observer locality-cell packet.

Independence witness: Nearest siblings: observerhistoryidentity, crosshistcausal, finite-multihist-packet, observerlocalitytransport. None is bijective to the ten-row locality cell because each omits either the paired acknowledgement surface G_0, G_1 or the local $\mathsf{NameCert}_{\mathsf{ObserverLocalityCell}^{\uparrow}}$ row.

Theorem 513.15 (ObserverLocalityCell atomicity rows)**.** *The AI-origin public surface of an accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *packet is atomic at the ten displayed rows*

$$O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N.$$

Every public or TasteGate-facing consumer must preserve the paired acknowledgement surface G_0, G_1 *together with the local naming row* N*. The existing Lean TasteGate route in* `TasteGate.lean` *must be read together with its* Nontrivial *and* FieldFaithful *instances, so the TasteGate declaration checks the same non-collapsed and field-faithful carrier rather than a single global frame.*

Proof. Use the public export certificate of Definition 513.14. It assembles the carrier, local NameCert obligations, paired Gap coherence, consumer boundary, finite ledger package, BHistCarrier flow surface, conservativity audit surface, scoped export surface, and TasteGate-cited readiness into the ten displayed rows.

The falsifiable prediction fixes the rejected counter-routes: a consumer that omits both G_0, G_1 or imports a global frame has left the accepted packet. The independence witness separates this carrier from observer-history identity, cross-history causal, finite-multi-history, and locality-transport siblings because none of those siblings carries both the paired acknowledgement surface and the local locality-cell name.

Finally read the TasteGate declaration through the surrounding `TasteGate.lean` instances. Nontriviality prevents collapse of the locality-cell carrier, and field faithfulness preserves the displayed rows, so the checked route is paired with the same atomic surface rather than with an external frame object. □

Lean4 ✓ `BEDC.Derived.ObserverLocalityCellUp.ObserverLocalityCellTasteGate single carrier alignment`

Theorem 513.16 (ObserverLocalityCell sibling lattice link)**.** *Every accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *packet consumes the two-observer identity surface of chapter 477, refines the finite local cell surface of chapter 509, and exports its cross-history ledger route through chapter 759. In particular, the packet is a concrete-instance lattice node rather than a kernel-only island.*

Proof. Project an accepted packet to its carrier rows

$$O_0, O_1, R_0, R_1, G_0, G_1, H, C, P, N.$$

The rows O_0, O_1 are the two observer-history identity slots, and H is the componentwise transport that keeps those slots on the observer-history identity surface.

The locality-cell refinement is carried by R_0, R_1, G_0, G_1. The two local event-description rows are read together with the paired Gap acknowledgement rows, so the accepted packet specializes the finite local cell surface without replacing it by a global observer frame.

Finally the continuation row C, provenance row P, and local naming row N give the route exported to the inter-history locality ledger. That ledger reads the same two-observer cell as a finite cross-history packet, so the chapter participates in the concrete-instance dependency lattice through observer identity, local cell refinement, and inter-history ledger export. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverLocalityCell}\uparrow}$.

Constructive story: An $\mathsf{ObserverLocalityCell}^{\uparrow}$ packet is generated from two observer-history rows, two local event-description rows, paired Gap acknowledgement rows, componentwise hsame transport, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverLocalityCell}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 513.1, Definition 513.2, Definition 513.3, Definition 513.4, Definition 513.5, Definition 513.6 with

Lean4 ✓ `BEDC.Derived.ObserverLocalityCellUp.taste gate`

, Definition 513.7, Definition 513.8, Definition 513.9, Definition 513.10, Definition 513.11, Definition 513.14, Definition 513.15, Definition 513.16, and the TasteGate-cited readiness surface close the mature carrier, NameCert obligations, GAP coherence, consumer boundary, finite ledger package, TasteGate witness boundary, BHistCarrier flow surface, conservativity audit surface, public export certificate, atomic row treatment, sibling lattice link, and three obligation theorems for the two-observer locality-cell packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverLocalityCell}\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ObserverLocalityCellUp.ObserverLocalityCellPacket\_semantic\_name\_certificate`

Bridge status: none

Not claimed: This chapter does not close global spacetime, a shared clock, manifold coordinates, metric light-cones, all-observer synchronization, infinite coherence webs, or a StdBridge synchronization theorem for the packet.

Upgrade path: The next step is a checked StdBridge synchronization for the same public two-observer locality-cell packet.

Chapter 514

ObserverFilterUp NameCert construction

The $\mathsf{ObserverFilter}^{\uparrow}$ surface packages observer-history identity as a finite selection of BHist rows together with a ledger for everything the observer does not export. It is a reusable filter carrier: an observer may retain a finite subhistory for downstream naming, while the omitted rows remain visible as a boundary ledger rather than disappearing into host equality, quotient identity, or an unrecorded subject parameter.

The filter consumes observer-history identity through chapter 477 and hands selected rows to the StreamName surface of chapter 126; the omitted-row ledger remains a boundary certificate rather than stream data.

Definition 514.1 (ObserverFilter BHist carrier)**.** *An* $\mathsf{ObserverFilter}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (H, S, O, R, L, C, P, N)$$

with the following visible rows:

1. *H is the source observer-history row;*
2. *S is the finite selected subhistory row, listing exactly the* BHist *entries retained for public observation;*
3. *O is the omitted-row ledger, listing every source row not selected into S together with its local boundary reason;*
4. *R records the componentwise* hsame *transports between source rows, selected rows, omitted rows, downstream stream-name rows, continuation routes, package provenance, and the local name;*
5. *L is the observer ledger tying each retained or omitted row to its source position, observer decision, and local naming boundary;*
6. *C records the displayed* Cont *routes by which a consumer reads the source history, retained subhistory, omitted ledger, and downstream handoff rows;*
7. *P is the* Pkg *provenance over* BHist, hsame, Cont, $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, *and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverFilter}^{\uparrow}}$ *row.*

The classifier for F compares only the retained row S, omitted-row ledger O, transport row R, observer ledger L, continuation row C, provenance row P, and local name row N. The carrier has no coordinate for host equality of histories, quotient streams, hidden observer state, or an unledgered deletion.

Theorem 514.2 (ObserverFilter NameCert obligations)**.** *For the carrier of Definition 514.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverFilter}^{\uparrow}}$ *surface consists exactly of five finite obligations:*

1. *carrier admission for the packet $F = (H, S, O, R, L, C, P, N)$;*
2. *classifier transport by the componentwise* hsame *rows in R;*
3. *observer-ledger exactness for retained and omitted* BHist *rows;*
4. *downstream handoff through the displayed* Cont *routes and* $\mathsf{StreamName}^{\uparrow}$ *provenance;*
5. *non-escape from host equality of histories, quotient streams, hidden observer state, and unledgered deletion.*

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 514.1. The packet displays the source history, selected subhistory, omitted-row ledger, transports, observer ledger, continuation routes, provenance, and local naming row before any classifier read is available.

Classifier transport is componentwise. The row R moves selected and omitted rows to the common hsame surface, and C supplies the only read routes through which those transported rows can be consumed.

The remaining obligations follow by finite-row cases on whether a source row is selected into S or recorded in O. The selected case is named by the observer ledger L and may be handed to downstream consumers; the omitted case is also named by L and stops at the boundary reason recorded in O.

No further coordinate is present in the carrier. Thus host history equality, quotient stream equality, hidden observer state, and deletion without a ledger row cannot be exported by the local $\mathsf{NameCert}_{\mathsf{ObserverFilter}^{\uparrow}}$ surface. □

Theorem 514.3 (ObserverFilter identity stability)**.** *Let $F = (H, S, O, R, L, C, P, N)$ and $F' = (H', S', O', R', L', C', P', N')$ be accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *carriers. If their source rows, selected rows, omitted ledgers, observer ledgers, continuation routes, package rows, and local names are related componentwise by the displayed* hsame *transports, then the two carriers determine the same observer-filter identity judgment. The judgment is computed only from the retained subhistory and omitted-row boundary ledger.*

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier identity stability`

Proof. Project both carriers to their displayed rows. The comparison data are exactly H, S, O, R, L, C, P, N and $H', S', O', R', L', C', P', N'$.

Use the hsame rows in R and R' to transport corresponding selected rows and omitted rows to a common observer-history surface. The routes in C and C' replay the same source, selection, omission, provenance, and local-name reads after transport.

Now inspect each finite source row. A retained row is compared through the matching entry of S and S', while an omitted row is compared through the matching boundary entry of O and O'. These two cases exhaust the source ledger.

Therefore the classifier has the same retained public rows and the same omitted boundary rows on both sides. No host equality, quotient identity, or hidden observer-state coordinate is available to distinguish the transported packets. □

Theorem 514.4 (ObserverFilter StreamName handoff)**.** *Every* $\mathsf{StreamName}^{\uparrow}$ *consumer of an accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *carrier reads only the selected subhistory row S, its observer-ledger entries in L, the componentwise* hsame *transports in R, the displayed* Cont *routes in C, the package provenance P, and the local naming row N. Omitted rows in O may certify the boundary of the handoff, but they do not become stream-name data.*

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilter streamname handoff`
Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier streamname handoff`

Proof. Start with a consumer route from the accepted filter into $\mathsf{StreamName}^{\uparrow}$. Carrier projection exposes the finite selected row S as the only row permitted to supply stream-name entries.

The route must then pass through L, R, and C. The observer ledger names the retained entries, the transport row moves them by hsame, and the continuation row records the read order used by the downstream stream-name surface.

The omitted ledger O is still visible, but only as a boundary witness. Its entries certify which source rows were not exported; they supply no selected stream-name row and no replacement stream value.

Thus the handoff to $\mathsf{StreamName}^{\uparrow}$ is exactly the displayed selected-subhistory route through S, L, R, C, P, N, with O serving as the finite non-export boundary. □

Theorem 514.5 (ObserverFilter ObserverHistoryIdentity factorization)**.** *Every accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *carrier factors its public identity claim through* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$*: the source observer history H, selected subhistory S, omitted-row ledger O,* hsame *transports R, observer ledger L, continuation routes C, provenance P, and local name N provide exactly the observer-history identity surface seen by downstream consumers.*

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier observer history factorization`

Proof. Read the accepted filter as a finite observer-history packet. The source row H is the displayed history, S and O divide its rows into retained public observations and recorded boundary observations, and L records the local decision for each row.

The rows R and C supply the transport and read routes required by $\mathsf{ObserverHistoryIdentity}^{\uparrow}$. They identify how selected rows and omitted rows are compared without adding a subject coordinate outside the displayed BHist data.

Package provenance and local naming are carried by P and N. Repacking H, S, O, R, L, C, P, N along these roles gives the observer-history identity surface and uses no further identity principle. □

Theorem 514.6 (ObserverFilter ledger exactness)**.** *For every accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *carrier, each source* BHist *row is accounted for exactly once as either a selected row in S or an omitted boundary row in O, and every consumer-facing read factors through the corresponding entry of L, R, C, P, and N. No row may be silently discarded, duplicated into both surfaces, or exported outside the displayed ledger.*

Proof. Induct over the finite source history H. The empty source row has empty selected and omitted ledgers, so the claim is immediate by carrier projection.

For a cons row, inspect the filter-row decision recorded in L. In the selected case the new row is placed in S, transported by R, and made readable only along a route in C with provenance in P and local naming in N.

In the omitted case the new row is placed in O with its boundary reason, transported by R, and made readable only as an omission witness along the displayed route in C.

The induction hypothesis accounts for the preceding source rows. The two filter-row cases are disjoint and exhaustive, so the full source history is partitioned by S and O, and every consumer read passes through the displayed ledger rows. □

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilter ledger exactness`

Theorem 514.7 (ObserverFilter selected-row totality)**.** *For every accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *carrier* $F = (H, S, O, R, L, C, P, N)$*, every selected* BHist *row exported by the filter is witnessed by a source position in* H*, a selected-row entry in* S*, an observer-ledger entry in* L*, and a consumer route through* R, C, P, N*. No selected row can be supplied by hidden observer state, quotient identity, or a source outside the finite carrier of Definition 514.1.*

Proof. Project the accepted carrier $F = (H, S, O, R, L, C, P, N)$ through Definition 514.1. The only public selected-row coordinates are H, S, L, R, C, P, N.

Apply ledger exactness from Definition 514.6. A selected row is one of the two exhaustive cases of the finite source ledger, so it must be paired with its source position in H and its retained entry in S.

The consumer read then factors through R, C, P, N. Since the carrier contains no hidden observer-state row and no quotient identity coordinate, the selected row has no alternate source. □

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier selected row totality`

Theorem 514.8 (ObserverFilter omitted-row boundary exhaustion)**.** *For every accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *carrier* $F = (H, S, O, R, L, C, P, N)$*, every source* BHist *row not selected into* S *appears in the omitted-row ledger* O *with its observer-ledger entry in* L *and its boundary read through* R, C, P, N*. Thus omission exhausts the non-selected part of* H *and admits no unledgered deletion.*

Proof. Read the source history through Definition 514.1. Each row of H is compared against the finite selected and omitted surfaces S and O.

Use Definition 514.6. Its two cases are selected and omitted, and the selected case is already represented in S; therefore every remaining source row must land in O with its corresponding ledger entry in L.

The boundary read is routed by R, C, P, N. Because the omitted case is an explicit carrier row, deleting a non-selected source row without an omitted-ledger entry is outside the accepted $\mathsf{ObserverFilter}^{\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier omitted row boundary exhaustion`

Theorem 514.9 (ObserverFilter StreamName selected-subhistory non-escape)**.** *For every accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *carrier* $F = (H, S, O, R, L, C, P, N)$*, the* $\mathsf{StreamName}^{\uparrow}$ *handoff is exactly the selected subhistory* S *with its source ledger* L*, componentwise transports* R*, displayed routes* C*, package provenance* P*, and local name* N*. Omitted rows in* O *remain boundary witnesses and cannot become stream-name data, hidden observer state, or quotient history identity.*

Proof. Start from the handoff theorem Definition 514.4. It identifies S, L, R, C, P, N as the only stream-facing rows supplied by the filter.

Apply Definition 514.6 to the same carrier. The finite source rows of H are exhausted by the selected surface S and the omitted boundary O, so every stream-name read is already accounted for by the selected side of the partition.

The omitted side remains visible only as O. Since neither Definition 514.1 nor the handoff theorem carries hidden observer state or quotient history identity, no omitted row can escape into the selected subhistory route. □

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier streamname selected subhistory nonescape`

Theorem 514.10 (ObserverFilter ObserverHistoryIdentity StreamName lattice route)**.** *Every* $\mathsf{StreamName}^{\uparrow}$ *consumer of an accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *packet first reads the* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *source row, then the selected subhistory S and omitted-row ledger O, and only then the* $\mathsf{StreamName}^{\uparrow}$ *handoff rows R, C, P, N. Omitted rows remain boundary data and cannot become stream data, hidden observer state, or quotient history identity.*

Proof. Apply Definition 514.5. It factors the accepted packet through the source observer-history row H, selected subhistory S, omitted ledger O, transports R, observer ledger L, routes C, provenance P, and local name N.

Next apply Definition 514.6. The selected and omitted rows exhaust the source history, so every downstream read must pass through either the selected side S or the boundary side O with its ledger entry.

Finally apply Definition 514.9. It identifies the StreamName handoff with the selected subhistory route and keeps omitted rows at the boundary. Thus no omitted row becomes stream data, hidden observer state, or quotient history identity. □

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilter observerhistoryidentity streamname lattice route`

Theorem 514.11 (ObserverFilter budget-selector L10 handoff)**.** *Let $F = (H, S, O, R, L, C, P, N)$ be an accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *packet, and let $B = (B_0, S_B, W, D, R_B, E, H_B, C_B, P_B, N_B)$ be an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packet whose selected schedule row S_B reads its finite* $\mathsf{StreamName}^{\uparrow}$ *windows from the same selected subhistory row S. Then every L10 finite-observation route supplied to a Real-completion consumer factors through*

$$\mathsf{ObserverHistoryIdentity}^{\uparrow} \to \mathsf{ObserverFilter}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{FiniteObservationBudgetSelector}^{\uparrow}.$$

The selected row S supplies the only StreamName window source for B, while omitted rows in O remain boundary data. No omitted row can become a finite observation window, dyadic observation, $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row,* $\mathsf{Real}^{\uparrow}$ *seal, quotient stream, host real equality row, or hidden limit selector.*

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier budget selector l10 handoff`

Proof. First build the observer-history spine. Apply Definition 514.5 to factor F through the displayed source history H, selected subhistory S, omitted ledger O, transports R, observer ledger L, continuations C, provenance P, and local name N.

Next apply ledger exactness. By Definition 514.6, every source BHist row is accounted for exactly once as either a selected row in S or an omitted boundary row in O. Thus a budget-selector read whose schedule row is tied to S has no second source for finite windows.

Now transport the selected side to StreamName. Use Definition 514.9 and the budget-selector carrier of Definition 782.1. The only window row available to B is the finite $\mathsf{StreamName}^{\uparrow}$ family W selected from S_B, and by hypothesis S_B reads the same selected subhistory row S.

Finally use the NameCert obligations of Definition 782.2. The route from B_0 to S_B, then to W, D, R_B, E, and finally through H_B, C_B, P_B, N_B exhausts the L10 budget route. Since O is already classified as an omitted boundary ledger and never as S, W, D, R_B, E, or a host equality coordinate, coordinate exhaustion keeps every omitted row out of finite observations, dyadic observations, regular handoff rows, Real seals, quotient streams, host real equality, and hidden limit selection. □

Theorem 514.12 (ObserverFilter Real-window synchronizer handoff)**.** *Let $F = (H, S, O, R, L, C, P, N)$ be an accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *packet, let $B = (B_0, S_B, W, D, R_B, E, H_B, C_B, P_B, N_B)$ be an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packet whose selected schedule row S_B reads its finite* $\mathsf{StreamName}^{\uparrow}$ *windows from S, and let Z be an accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *packet whose* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *window source is the same finite observation schedule carried by B. Then every Real-completion-facing synchronizer read factors through*

$$\mathsf{ObserverHistoryIdentity}^{\uparrow} \to \mathsf{ObserverFilter}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{FiniteObservationBudgetSelector}^{\uparrow} \to \mathsf{RealWindowSyn}$$

The synchronizer route cannot read omitted rows in O, quotient streams, host real equality, hidden observer state, selected external limits, or ambient completeness outside the displayed finite window source.

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier real window synchronizer handoff`

Proof. First build the observer side. Apply Definition 514.5 to expose the source history H, selected row S, omitted boundary row O, transports R, ledger L, routes C, provenance P, and local name N.

Next use ledger exactness and StreamName non-escape. By Definition 514.6 and Definition 514.9, the selected row S is the only StreamName source exported by F, while O remains boundary data rather than stream data or hidden observer state.

Now pass through the budget selector. Apply Definition 514.11. It turns the selected StreamName row into the finite observation schedule carried by B and excludes omitted rows, quotient streams, host real equality, and hidden limit selection from the L10 route.

Finally read the synchronizer carrier and obligations from Definition 979.1 and Definition 979.7. The accepted $\mathsf{RealWindowSynchronizer}^{\uparrow}$ packet can consume only the displayed StreamName and RegSeqRat finite-window source that it receives from the same schedule carried by B. Since neither the budget selector nor the synchronizer carrier contains a coordinate for omitted rows, quotient streams, host real equality, hidden observer state, selected external limits, or ambient completeness, every Real-completion-facing read factors through the displayed route and nowhere else. □

Theorem 514.13 (ObserverFilter Real-window budget exhaustion)**.** *Let $F = (H, S, O, R, L, C, P, N)$ be an accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *packet, let $B = (B_0, S_B, W, D, R_B, E, H_B, C_B, P_B, N_B)$ be an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packet whose selected schedule row S_B reads its finite* $\mathsf{StreamName}^{\uparrow}$ *windows from the selected subhistory row S, and let Z be an accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *packet whose* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *windows are read from the same selected subhistory route through B. Then every Real-completion-facing consumer factors through*

$$\mathsf{ObserverHistoryIdentity}^{\uparrow} \to \mathsf{ObserverFilter}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{FiniteObservationBudgetSelector}^{\uparrow} \to \mathsf{RealWindowSyn}$$

Omitted rows in O cannot become finite budget windows, $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal data, quotient streams, host equality, or hidden limit-selection data.*

Lean4 ✓ `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier real window budget exhaustion`

Proof. First expose the observer source. Apply Definition 514.6 to the accepted packet F. The source history rows are exhausted by the selected subhistory S and the omitted boundary ledger O.

Next identify the selected StreamName route. By Definition 514.9, every $\mathsf{StreamName}^{\uparrow}$ read exported by F is read from S together with L, R, C, P, N. The omitted ledger remains a boundary witness and has no stream, quotient, or hidden observer coordinate.

Now pass from StreamName to the finite budget selector. Apply Definition 514.11. Since S_B reads its finite windows from S, the budget packet B supplies only the displayed rows $W, D, R_B, E, H_B, C_B, P_B, N_B$ to the L10 route.

Finally consume the schedule through the synchronizer. Apply Definition 514.12 to the same F, B, and Z. The synchronizer can read only the displayed StreamName and RegSeqRat finite-window source carried through B.

It remains to exclude every omitted-row escape. The carriers named above contain coordinates for the observer source, selected subhistory, omitted boundary ledger, StreamName route, finite budget schedule, RegSeqRat readback, synchronizer route, provenance, continuations, and local names. None contains a coordinate by which an element of O becomes a budget window, Real seal datum, quotient stream, host equality row, or hidden limit selector. Carrier-coordinate exhaustion therefore forces every Real-completion-facing consumer through the displayed route. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverFilter}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverFilter}^{\uparrow}$ packet is generated from a source BHist row, selected subhistory row, omitted-row ledger, componentwise hsame transports, observer ledger, displayed Cont routes, package provenance, and local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ObserverFilter}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 514.1, Definition 514.2, Definition 514.3, Definition 514.4, Definition 514.5, Definition 514.6, Definition 514.7, Definition 514.8, and Definition 514.9 specify the public BHist filter surface, selected-row totality, omitted-row boundary exhaustion, StreamName selected-subhistory non-escape, hsame transport, Cont route, Pkg provenance, and local NameCert rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ObserverFilter}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ObserverFilterUp.ObserverFilterCarrier\_streamname\_handoff`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close hidden observer state, quotient identity, unledgered deletion, or bridge checking for $\mathsf{ObserverFilter}^{\uparrow}$.

Upgrade path: The next paper-side step is mature closure examples, or a machine-checked bridge for the displayed ObserverFilter surface.

Chapter 515

A Concrete Naming Certificate for $\mathsf{UnwitnessedExistenceClosure}^{\uparrow}$

The $\mathsf{UnwitnessedExistenceClosure}^{\uparrow}$ interface turns the three-stratum meta-closure analysis of chapter 9387 into a finite BEDC packet. It records the term, type, and proposition surfaces on which an unwitnessed existential could otherwise be accepted, together with the explicit replacement rows and the axiom-purity ledger that prevents those rows from escaping as Classical.choice, Quot.sound, or propext.

Definition 515.1 (UnwitnessedExistenceClosure carrier)**.** *An* $\mathsf{UnwitnessedExistenceClosure}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (T, Q, R, C, S, L, H, E, P, N)$$

with the following visible rows:

1. *T is the term-stratum row for displayed positive existential data, read through the replacement surface of Definition 9387.6;*
2. *Q is the type-stratum row for quotient-facing classifier transport, read through the replacement surface of Definition 9387.7;*
3. *R is the proposition-stratum row for bidirectional implication transport, read through the replacement surface of Definition 9387.8;*
4. *C is the classifier row comparing packets only by the displayed term, type, and proposition replacement data;*
5. *S is the stability row saying that componentwise* hsame *transport preserves the three displayed replacement strata;*
6. *L is the axiom-purity ledger row listing exactly the forbidden non-constructive closures* Classical.choice*,* Quot.sound*, and* propext *as non-exportable;*
7. *H is the replacement handoff row routing later consumers to the explicit term recipe, classifier transport, or implication map rather than to an accepted oracle output;*
8. *E stores the finite* hsame *and* Cont *routes for the displayed replacement rows;*
9. *P is the* Pkg *provenance over* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*, and the three replacement surfaces of chapter 9387;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{UnwitnessedExistenceClosure}^{\uparrow}}$ *row.*

The carrier has no coordinate for a global choice function, a quotient representative selector, a proposition equality token produced from bidirectional implication alone, or any host axiom outside the displayed ledger.

Lean4 (definition) `BEDC.Derived.UnwitnessedExistenceClosureUp.UnwitnessedExistenceClosureUp`

Theorem 515.2 (UnwitnessedExistenceClosure NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{UnwitnessedExistenceClosure}}$ *surface for Definition 515.1 consists of five rows:*

1. *carrier admission for the finite packet* $U = (T, Q, R, C, S, L, H, E, P, N)$*;*
2. *classifier comparison through the displayed term, type, and proposition replacement rows;*
3. *stability under componentwise* hsame *and* Cont *transport of* T*,* Q*,* R*,* C*,* S*,* L*, and* H*;*
4. *ledger non-escape for* Classical.choice*,* Quot.sound*, and* propext*;*
5. *replacement handoff to the explicit choice, quotient-transport, and implication-transport surfaces of Definition 9387.6, Definition 9387.7, and Definition 9387.8.*

These five rows are the whole local obligation surface, and every consumer-visible read factors through them.

Proof. Carrier admission is projection from the finite packet of Definition 515.1. The term, type, proposition, classifier, stability, ledger, handoff, transport, package, and naming coordinates are all displayed rows.

The classifier and stability obligations are componentwise. A comparison of two accepted packets may inspect only the three replacement strata and the stored transport rows, and a transported packet is obtained by moving those same rows through the displayed hsame and Cont evidence.

The ledger and handoff obligations are read from L and H. The ledger records the three forbidden non-constructive closure shortcuts as non-exportable, while the handoff row points later consumers to explicit term recipes, displayed classifier transport, and bidirectional implication maps. Since the carrier contains no oracle coordinate, the five listed rows exhaust the local NameCert surface. □

Theorem 515.3 (UnwitnessedExistenceClosure axiom-purity boundary)**.** *Every accepted* UnwitnessedExistenceClos *carrier exports exactly the displayed replacement rows* T*,* Q*, and* R*, the classifier and stability rows* C *and* S*, the ledger row* L*, the handoff row* H*, and the finite provenance rows* E*,* P*, and* N*. It exports no accepted term-stratum choice oracle, no quotient representative selector, no proposition equality token obtained from implication equivalence alone, and no dependency on* Classical.choice*,* Quot.sound*, or* propext*.*

Proof. Inspect the carrier coordinates. The only term-facing coordinate is T, the only quotient-facing coordinate is Q, and the only proposition-facing coordinate is R.

The classifier and stability rows do not add new witnesses; they only compare and transport the displayed replacement data. The finite transport and provenance rows similarly expose routes and package names, not additional logical principles.

Finally read the ledger row L. Its entries mark Classical.choice, Quot.sound, and propext as non-exportable boundary names. Because no carrier coordinate stores the corresponding oracle value, a consumer can receive only the explicit replacement rows and their finite provenance. □

Theorem 515.4 (UnwitnessedExistenceClosure effective replacement handoff)**.** *Every downstream consumer of an accepted* $\mathsf{UnwitnessedExistenceClosure}^{\uparrow}$ *packet factors through one of three effective*

handoff routes: the term-stratum route through the displayed positive-existential recipe of Definition 9387.6, the type-stratum route through explicit psame*-respecting classifier transport of Definition 9387.7, or the proposition-stratum route through the selected implication map of Definition 9387.8. No route factors through an unwitnessed existential output.*

Proof. For a term-stratum consumer, project the T and H rows. The handoff points to the displayed recipe and membership evidence named by the replacement-choice surface, so the consumer receives a constructed term row rather than an accepted choice output.

For a type-stratum consumer, project Q and the classifier part of H. The route is the explicit psame-respecting transport named by the quotient replacement, and it does not introduce a quotient representative selector.

For a proposition-stratum consumer, project R and the implication part of H. The route selects one displayed implication direction from the bidirectional datum and composes ordinary proof functions; it never identifies propositions by an equality token. The axiom-purity boundary of Definition 515.3 then rules out any alternate oracle route. □

Theorem 515.5 (UnwitnessedExistenceClosure refutation-boundary link)**.** *Every proposition-stratum read exported by an accepted* UnwitnessedExistenceClosure$^{\uparrow}$ *packet passes through the stable-negation boundary of chapter 507 before the ledger refusal is exported. The implication map in R may carry a displayed refutation direction, but the local ledger may refuse* propext *only after that direction has been read as stable negation rather than as a proposition-equality token.*

Proof. Project the proposition row R and the implication component of H from the effective handoff. These rows expose ordinary proof-function transport, not equality between propositions.

Read the same route through the stable-negation boundary. That sibling records the permitted refutation-facing interpretation of a displayed implication, so the proposition-stratum consumer receives a stable refusal surface before the non-exportable ledger is consulted.

The ledger row L then exports the refusal. Since the carrier never stores a proposition-equality token, the refusal is a boundary read over stable negation and not a hidden use of propext. □

Theorem 515.6 (UnwitnessedExistenceClosure primitive scope)**.** *For an accepted* UnwitnessedExistenceClosure$^{\uparrow}$ *carrier $U = (T, Q, R, C, S, L, H, E, P, N)$, the primitive scope is exactly the displayed finite packet: T, Q, R are the three replacement strata, C is the classifier row over those strata, S is the componentwise stability row, L is the non-exportable ledger, H is the replacement handoff, E records* hsame *and* Cont *transport, P is the* Pkg *provenance row, and N is the local* NameCert *row. The rows bind only* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*, and the three replacement surfaces named in Definition 9387.6, Definition 9387.7, and Definition 9387.8.*

Proof. Project the carrier. The coordinate list of Definition 515.1 supplies the term, type, proposition, classifier, stability, ledger, handoff, transport, package, and naming rows directly.

Apply the NameCert obligations. Carrier admission, classifier comparison, stability transport, ledger non-escape, and replacement handoff are all read from those same coordinates, so no primitive outside the listed BHist, hsame, Cont, Pkg, NameCert, and replacement-surface rows is introduced. □

Theorem 515.7 (UnwitnessedExistenceClosure ledger refusal)**.** *For every accepted* UnwitnessedExistenceClosure$^{\uparrow}$ *carrier, the ledger row L refuses* Classical.choice*,* Quot.sound*, and* propext *exactly at the carrier boundary: no coordinate of $U = (T, Q, R, C, S, L, H, E, P, N)$ stores a global choice function, quotient representative selector, proposition equality token obtained from implication equivalence alone, or host axiom output.*

Proof. Inspect the positive replacement rows first. The term route exposes T, the quotient-facing route exposes Q, and the proposition-facing route exposes R; each is a displayed replacement surface rather than an oracle output.

Read the administrative rows next. The classifier, stability, handoff, transport, provenance, and naming coordinates preserve or route the displayed replacement data, but none of them stores a global choice function, quotient representative selector, or proposition equality token.

The remaining coordinate is the ledger L. By the axiom-purity boundary it names Classical.choice, Quot.sound, and propext only as non-exportable rows, so the refusal is exact at the finite carrier boundary. □

Theorem 515.8 (UnwitnessedExistenceClosure scoped boundary package)**.** *The carrier definition, NameCert obligation theorem, axiom-purity boundary, effective replacement handoff, primitive-scope theorem, and ledger-refusal theorem jointly bind* UnwitnessedExistenceClosure$^{\uparrow}$ *as a scoped finite package over the three replacement strata T, Q, R and the rows C, S, L, H, E, P, N.*

The package closes only the displayed replacement boundary. It does not close a global choice principle, quotient representatives, proposition extensionality, host axioms, bridge checking, or any consumer route outside the finite BHist *packet.*

Proof. Start with the carrier and NameCert obligation theorem. They expose the ten visible rows and state that carrier admission, classifier comparison, stability, ledger non-escape, and replacement handoff are exhausted by those rows.

Add the axiom-purity boundary and effective replacement handoff. These identify the three allowed consumer routes and exclude the corresponding host-oracle exits.

Finally apply primitive scope and ledger refusal. The primitive-scope theorem fixes the rows as BHist, hsame, Cont, Pkg, NameCert, and replacement-surface data, while ledger refusal blocks the three forbidden non-constructive closures at the carrier boundary. The resulting package is scoped exactly to the displayed finite packet. □

Theorem 515.9 (UnwitnessedExistenceClosure replacement surface totality)**.** *Every accepted* UnwitnessedExistenceClosure$^{\uparrow}$ *carrier read chooses exactly one of the three displayed replacement surfaces: the term surface T for positive existential data, the type surface Q for quotient-facing classifier transport, or the proposition surface R for implication transport. No accepted read lands in a host choice row, a host quotient row, a proposition-extensionality row, or any unlisted oracle coordinate.*

Proof. Project an accepted packet $U = (T, Q, R, C, S, L, H, E, P, N)$. Its consumer-facing logical rows are precisely T, Q, and R, while C, S, L, H, E, P, and N only classify, transport, record non-export, route handoff, or store provenance for those rows.

A term request is therefore read from T and the term component of H. A quotient or classifier request is read from Q together with C and S. A proposition request is read from R and the proposition component of H.

The axiom-purity boundary of Definition 515.3 removes every alternate row named by Classical.choice, Quot.sound, or propext. Thus the three displayed replacement surfaces are total for accepted reads and exclusive of host-oracle surfaces. □

Theorem 515.10 (UnwitnessedExistenceClosure stability transport)**.** *Componentwise* hsame *and* Cont *transport of an accepted* UnwitnessedExistenceClosure$^{\uparrow}$ *packet preserves the term, type, and proposition replacement strata T, Q, R, the classifier row C, the stability row S, the ledger row L, the handoff row H, and the provenance rows E, P, N.*

Proof. Use the displayed transport routes stored in E. They move each visible carrier coordinate componentwise, so the transported packet has corresponding rows $T, Q, R, C, S, L, H, E, P, N$ with the same row roles.

The classifier row C is preserved because it compares only the transported replacement strata. The stability row S is preserved because its content is exactly the componentwise hsame and Cont closure condition for those strata.

The ledger and handoff rows are transported as ledger and handoff rows, not recomputed through host principles. The provenance rows E, P, N record the same finite route, package, and local naming evidence after transport, so no displayed obligation row is lost. □

Theorem 515.11 (UnwitnessedExistenceClosure ledger handoff exhaustion)**.** *The axiom-purity ledger row L and the handoff row H exhaust all downstream reads of an accepted* UnwitnessedExistenceClosure$^{\uparrow}$ *packet through the explicit replacement-choice, replacement-quotient, and replacement-propext surfaces. A downstream consumer has no further route to an unwitnessed existential result, a quotient selector, or a proposition equality token.*

Proof. Begin with the effective handoff of Definition 515.4. It sends each downstream consumer to the term recipe, the explicit classifier transport, or the selected implication map.

The ledger row L then blocks the three forbidden exits. It names Classical.choice, Quot.sound, and propext only as non-exportable boundaries, and the carrier contains no coordinate storing their host-level outputs.

Combining H with L accounts for every consumer-visible logical read. The remaining rows classify, stabilize, transport, package, or name the same replacement data, so they cannot create an additional downstream oracle route. □

Theorem 515.12 (UnwitnessedExistenceClosure term replacement route)**.** *Let $U = (T, Q, R, C, S, L, H, E, P, N)$ be an accepted* UnwitnessedExistenceClosure$^{\uparrow}$ *packet. Every term-stratum read that asks for positive existential data is routed through the displayed row T, the handoff row H, and the replacement-choice surface of Definition 9387.6. The accepted packet therefore exposes a finite witness recipe and its membership evidence, not a global choice function and not an unwitnessed existential result.*

Proof. Project the term row T and the term-facing component of H. These rows are part of the carrier inventory, so the consumer can inspect only the displayed recipe, the named membership evidence, and the finite hsame and Cont routes stored in E.

The replacement-choice surface supplies the allowed route from the positive existential request to a constructed term row. Since L lists Classical.choice as non-exportable and the carrier contains no choice-function coordinate, the term consumer cannot bypass the displayed route. □

Theorem 515.13 (UnwitnessedExistenceClosure quotient replacement route)**.** *Let $U = (T, Q, R, C, S, L, H, E, P, N)$ be an accepted* UnwitnessedExistenceClosure$^{\uparrow}$ *packet. Every quotient-facing or classifier-facing read is routed through the displayed row Q, the classifier row C, the stability row S, and the replacement-quotient surface of Definition 9387.7. The route transports classifiers by explicit* psame*-respecting data and exports no quotient representative selector.*

Proof. Project Q, C, S and the quotient-facing component of H. The classifier may compare accepted packets only by the displayed replacement rows and the componentwise transports attached to them.

The replacement-quotient surface provides the permitted classifier transport. The ledger row L marks Quot.sound as non-exportable, and no coordinate of U stores a representative selector. Thus the quotient-facing consumer receives only the explicit transport row and its finite provenance. □

Theorem 515.14 (UnwitnessedExistenceClosure proposition replacement route)**.** *Let* $U = (T, Q, R, C, S, L, H, E,$ *be an accepted* UnwitnessedExistenceClosure$^{\uparrow}$ *packet. Every proposition-stratum read is routed through the displayed row* R*, the proposition-facing component of* H*, and the replacement-propext surface of Definition 9387.8. The route may compose the selected implication maps, but it exports no proposition equality token obtained from bidirectional implication alone.*

Proof. Project R and the proposition component of H. These rows name the two implication directions and the selected ordinary proof-function route available to a downstream consumer.

The replacement-propext surface permits implication transport, not proposition equality. Since L records propext as non-exportable and U has no coordinate for an equality token, the proposition-facing read stays inside the displayed implication route. □

Theorem 515.15 (UnwitnessedExistenceClosure TasteGate boundary)**.** *The* UnwitnessedExistenceClosure$^{\uparrow}$ *chapter gate accepts the finite packet only at the displayed replacement and ledger boundary: term reads pass through* T*, quotient and classifier reads pass through* Q, C, S*, proposition reads pass through* R*, and forbidden axiom ancestry is confined to the non-exportable ledger row* L*. A packet missing one of those displayed replacement rows, or asking to export* Classical.choice*,* Quot.sound*, or* propext*, is outside the gate.*

Lean4 ✓ `BEDC.Derived.UnwitnessedExistenceClosureUp.taste gate`

Proof. Read the chapter gate against the carrier coordinates. The accepted surface has exactly the term, quotient, proposition, classifier, stability, ledger, handoff, transport, provenance, and naming rows listed in Definition 515.1.

The three replacement-route theorems isolate the only consumer-facing routes. The axiom-purity boundary then prevents a consumer from replacing those routes by a choice function, quotient selector, or proposition-extensionality equality token. The Lean-checked gate records the same carrier-level acceptance boundary for this chapter. □

Theorem 515.16 (UnwitnessedExistenceClosure bridge-facing replacement surface)**.** *Every bridge-facing consumer of the public* UnwitnessedExistenceClosure$^{\uparrow}$ *replacement surface must first read the term row* T*, quotient row* Q*, proposition row* R*, classifier and stability rows* C, S*, and axiom-ledger row* L *through the TasteGate boundary grounded by* BEDC.Derived.UnwitnessedExistenceClosureUp.taste_gate*. The exported bridge route is therefore the finite replacement surface over* $T, Q, R, C, S, L, H, E, P, N$*; it exports no choice function, quotient representative selector, or proposition-extensionality equality token.*

Proof. Begin with the TasteGate boundary of Definition 515.15. It accepts exactly the displayed replacement and ledger rows, and it rejects any packet that asks to export Classical.choice, Quot.sound, or propext.

The three replacement-route theorems then fix the bridge-facing channels. Term consumers pass through Definition 515.12; quotient and classifier consumers pass through Definition 515.13; proposition consumers pass through Definition 515.14.

Thus the paper-side bridge boundary is exactly the public replacement surface already accepted by the TasteGate. It has no carrier coordinate for a global choice function, quotient representatives, or proposition equality obtained from implication transport. □

Falsifiable prediction: Deleting any one of T, Q, R, L admits a concrete rejected packet: a term consumer without the replacement-choice recipe, a quotient consumer without explicit classifier

transport, a proposition consumer without implication transport, or a ledger consumer that cannot refuse forbidden axiom ancestry.

Independence witness: propexttransportboundary, quotientsoundnessboundary, forbiddenaxiomancestry, axiomqueryledger: no listed sibling is bijective to $\mathsf{UnwitnessedExistenceClosure}^{\uparrow}$ because this carrier stores all three replacement routes together with one non-exportable axiom ledger, while each sibling isolates a single boundary, ancestry, or query surface.

Closure status for $\mathsf{NameCert}_{\mathsf{UnwitnessedExistenceClosure}^{\uparrow}}$.

Constructive story: An $\mathsf{UnwitnessedExistenceClosure}^{\uparrow}$ packet is generated from term, type, and proposition replacement rows, a componentwise classifier, stability transports, an axiom-purity ledger, a replacement handoff row, finite hsame and Cont routes, Pkg provenance, and local NameCert evidence.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{UnwitnessedExistenceClosure}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The finite carrier, five-row NameCert surface, axiom-purity boundary, effective replacement handoff, replacement-surface totality theorem, refutation-boundary link, TasteGate boundary, the three term, quotient, and proposition replacement routes, and the bridge-facing replacement surface are closed as the public bridge route over $T, Q, R, C, S, L, H, E, P, N$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{UnwitnessedExistenceClosure}^{\uparrow}}, \mathsf{theoremChecked})$

Lean target: `BEDC.Derived.UnwitnessedExistenceClosureUp.taste\_gate`

Bridge status: none

Not claimed: This chapter does not close bridge checking, a global choice principle, quotient representatives, proposition extensionality, host axioms, or the full scoped NameCert implementation.

Upgrade path: No further theory-axis upgrade is claimed beyond maintaining the same bridge-facing replacement and ledger boundary.

Chapter 516

A Concrete Naming Certificate for $\mathsf{EmptyFableLedger}^{\uparrow}$

The $\mathsf{EmptyFableLedger}^{\uparrow}$ interface is the concrete NameCert landing surface for the Empty Fable Machine of chapter 9399. It packages the generated Hist row, the trace read from that history, the realized selector-step witnesses, the fable-ledger row, and the local naming boundary that prevents the ledger from being read as a global chooser.

Definition 516.1 (EmptyFableLedger NameCert carrier)**.** *An* $\mathsf{EmptyFableLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (H, T, S, F, C, P, N)$$

with the following displayed coordinates:

1. *H is the* Hist *source row generated from* e *by finitely many* Ext *steps;*
2. *T is the* Trace *row read from the constructor spine of H;*
3. *S is the finite witness list of* SelStep *rows, one for each non-empty trace edge, each exposing the enacted mark, the* Ext *step, and the local branch certificate;*
4. *F is the* FableLedger *row identifying the same finite selector ledger with the Empty-fable reading of H;*
5. *C records the displayed* Cont *routes by which a consumer reads H, T, each selector witness in S, and the fable-ledger row F;*
6. *P is the* Pkg *provenance naming the* Hist, Ext, Trace, SelStep, FableLedger, hsame, Cont, Pkg, *and* NameCert *source surfaces;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{EmptyFableLedger}^{\uparrow}}$ *row.*

The classifier compares two accepted carriers only by the displayed history row, trace row, selector-witness list, fable-ledger row, continuation routes, package provenance, local naming row, and the componentwise hsame *transports attached to those rows. It contains no coordinate for host sequence equality, global branch selection, a truth oracle, or an undisplayed selector.*

Lean4 (definition) `BEDC.Derived.EmptyFableLedgerUp.TasteGate.EmptyFableLedgerUp`
Lean4 ✓ `BEDC.Derived.EmptyFableLedgerUp.TasteGate.emptyFableLedgerTasteGate`

Theorem 516.2 (EmptyFableLedger NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{EmptyFableLedger}^{\uparrow}}$ *surface for the carrier of Definition 516.1 consists exactly of carrier admission for E, trace admission for T, selector-step admission for every row of S, fable-ledger admission for F, continuation reads through C, package provenance through P, the local naming row N, and componentwise* hsame *transport for the displayed rows.*

Every obligation is read from the Empty Fable Machine definitions of Trace*,* SelStep*, and* FableLedger*, together with the core* Hist*,* hsame*,* Ext*,* Cont*,* Pkg*, and* NameCert *chapters. No obligation introduces a hidden branch selector.*

Proof. Carrier admission is projection from the finite packet E. The history row, trace row, selector-witness list, fable-ledger row, continuation routes, package provenance, and local naming row are all displayed coordinates of the carrier.

Trace admission uses the Empty Fable Machine trace definition, so the row T is read from the e, E0, and E1 constructor spine of H. Selector admission uses the SelStep definition: each row of S exposes a mark, an Ext step, and a local branch certificate.

The fable-ledger row F is the same trace surface read under the fable-machine name. The Cont routes in C and the provenance row P keep these reads inside the cited kernel and naming surfaces, while N records the local certificate. Since the packet has no further selector coordinate, no hidden branch chooser can be exported. □

Theorem 516.3 (EmptyFableLedger selector exactness)**.** *Let $E = (H, T, S, F, C, P, N)$ be an accepted* $\mathsf{EmptyFableLedger}^{\uparrow}$ *carrier. Every selector read exported from E is exact: the selected mark for a non-empty trace edge is read from a displayed* SelStep *row in S, that row contains the corresponding* Ext *step, and the accumulated trace agrees with the fable-ledger row F up to the* hsame *transports recorded for H.*

Thus a downstream consumer receives the concrete Empty-fable selector ledger as a finite packet over Hist*,* Ext*,* Trace*,* SelStep*,* FableLedger*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Proof. Project the selector-witness list S. For the empty trace there is no non-empty edge and the ledger read is the empty constructor spine above e.

For a non-empty trace edge, the corresponding SelStep row exposes the enacted mark, the Ext step from the previous history to the next history, and the local branch certificate. This is exactly the selector data used by the Empty Fable Machine chapter.

The trace row T and fable-ledger row F are then compared through the displayed hsame transport attached to H and read through C. Package provenance and the local NameCert row repack the same route for downstream consumers, so the exported selector is the displayed witness, not an external function. □

Theorem 516.4 (EmptyFableLedger selector non-escape)**.** *An accepted* $\mathsf{EmptyFableLedger}^{\uparrow}$ *packet cannot export a selector mark unless that mark appears in the displayed trace row. The accepted packet consumes the finite selector spine of chapter 494, the enacted local branch witness of chapter 685, and the observer-Hist identity surface of chapter 479 before any selector read is made available to a downstream consumer.*

Proof. Start with the finite carrier of Definition 516.1. The only selector-facing coordinates are the trace row T, the selector-step list S, and the fable-ledger row F.

The selector spine is the sibling row supplied by chapter 494. The enacted local branch is the one-step boundary row supplied by chapter 685. These two rows agree with the observer history through the identity reading of chapter 479.

Thus any exported selector mark must pass through the displayed trace row and one displayed selector-step witness. A mark outside T would require an additional selector coordinate, but the packet exposes only H, T, S, F, C, P, N and their componentwise transport rows. □

Theorem 516.5 (EmptyFableLedger non-chooser boundary)**.** *Every consumer read of an accepted* $\mathsf{EmptyFableLedger}^{\uparrow}$ *carrier factors through the displayed tuple* H, T, S, F, C, P, N *and the componentwise* hsame *transports for those rows. In particular, the packet exports no* Classical.choice *instance, no host sequence equality for traces, no truth oracle, and no hidden branch selector.*

The only branch-facing data are the finite SelStep *witnesses already present in* S*; the only sequence-facing data are the* Trace *and* FableLedger *rows already present in* T *and* F*.*

Proof. Inspect the carrier inventory. Branch information appears only in S, and each row of S is a visible selector-step witness rather than a function that chooses among all admissible branches.

Sequence information appears only in T and F. These rows are transported through hsame and read through the continuation routes in C, so a consumer never receives host sequence equality as an additional principle.

The package row P and certificate row N record the same local dependency surface. Since no carrier coordinate names Classical.choice, a truth oracle, host sequence equality, or an undisplayed branch selector, no such datum is exported by the NameCert boundary. □

Theorem 516.6 (EmptyFableLedger continuation-trace dependency)**.** *Let* $E = (H, T, S, F, C, P, N)$ *be an accepted* $\mathsf{EmptyFableLedger}^{\uparrow}$ *carrier. Every accepted trace row* T *and continuation-route row* C *are read through the finite trace replay discipline of chapter 469 before the selector ledger is exposed. Thus the fable ledger is a consumer of the sibling finite trace route, not a separate trace oracle.*

Proof. Project the displayed rows H, T, S, F, C, P, N. The trace row T is read from the constructor spine of H, and the continuation row C records the displayed routes by which a consumer reads that trace, the selector-step witnesses, and the fable-ledger row.

Now use the finite trace replay discipline of chapter 469. It fixes the trace consumer to the displayed history row and its continuation route before any downstream ledger can inspect selected marks.

The selector ledger is then exposed only through the already replayed trace route and the rows S and F. Since no coordinate of E stores a trace oracle or host sequence equality, the fable-ledger read is a consumer of the sibling continuation-trace surface. □

Falsifiable prediction: An accepted EmptyFableLedgerUp packet cannot export a selector mark unless that mark appears in the displayed trace row.

Independence witness: SelectorLedger, EmptyBoundarySelector, ObserverHistIdentity, InscriptionEvent: the fable ledger is not bijective to any sibling because it jointly binds trace readback, local selector enactment, and story-generation provenance in one packet, whereas each sibling owns only one of those rows.

Closure status for $\mathsf{NameCert}_{\mathsf{EmptyFableLedger}^{\uparrow}}$**.**

Constructive story: An $\mathsf{EmptyFableLedger}^{\uparrow}$ packet is generated from a displayed Hist row, its Trace row, finite SelStep witnesses, a FableLedger row, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{EmptyFableLedger}^{\uparrow}}, \mathsf{seed})$

Scope closed: The seed scope records the finite carrier, classifier, selector exactness route, selector non-escape boundary, and non-chooser boundary for Empty-fable ledgers over Hist, Ext, Trace, SelStep, FableLedger, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{EmptyFableLedger}^{\uparrow}}, \mathsf{theoremChecked})$

Lean target: `BEDC.Derived.EmptyFableLedgerUp.TasteGate.emptyFableLedgerTasteGate`
Bridge status: none
Origin: ai
Not claimed: This chapter does not close bridge checking, global branch selection, host sequence equality, truth oracles, or choice principles.
Upgrade path: Scoped closure requires checked carrier admission, selector exactness, trace-to-fable transport, continuation routing, package provenance, and non-chooser rows for the displayed finite packet.

Chapter 517

A Concrete Naming Certificate for $\mathsf{RussellBoundary}^{\uparrow}$

The $\mathsf{RussellBoundary}^{\uparrow}$ surface turns the Russell problem boundary of chapter 9457 into a finite NameCert packet. It records relation-first observation rows, description-expansion obligations, contextual class readings, stratification bridges, witnessed-descent routes, componentwise transports, package provenance, and a local naming ledger. The packet does not add a class ontology, a reducibility principle, a quotient over certificates, a host choice selector, or an identity between strata. The witnessed-descent row W is consumed as a public residue ledger in the same sense as chapter 520, while $\mathsf{RussellBoundary}^{\uparrow}$ keeps the stratification and contextual-class boundary separate from the inscription residue packet.

The packet also consumes the $\mathsf{NameCertMorphism}^{\uparrow}$ sibling route of chapter 481. Relation-first rows and witnessed-descent ledgers are read as morphism-preserving certificate boundaries, not as a standalone class ontology.

The mature consumer surface is the public certificate route itself: downstream foundation-boundary packets may cite the relation-first observation, description-expansion obligation, contextual-class reading, stratification bridge, witnessed-descent ledger, $\mathsf{NameCertMorphism}^{\uparrow}$ route, and inscription-gap residue only through the displayed rows of Definition 517.5.

Definition 517.1 (RussellBoundary carrier)**.** *A* $\mathsf{RussellBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (S, O, D, K, L, W, H, C, P, N)$$

with the following displayed rows:

1. *S is the source-expression row whose apparent object grammar is being inspected;*
2. *O is the relation-first observation row, recording the BEDC relation that licenses the public name before any object-like reading is consumed;*
3. *D is the description-expansion row, listing the existence, uniqueness or stability, and ledger obligations attached to the definite-description use of S;*
4. *K is the contextual-class row, reading class-like grammar through the finite classifier context that admits it;*
5. *L is the stratification row, recording the source stratum, target stratum, and displayed bridge through which any level passage is consumed;*

6. *W is the witnessed-descent row, a finite list of certificate routes required before an upward name may be read downward by a consumer;*
7. *H records componentwise* hsame *transports for S, O, D, K, L, W, package rows, and the local naming row;*
8. *C records the displayed* Cont *routes that expose the source expression, replay the relation, unfold the description, read the classifier context, consume the bridge, and check the descent witnesses;*
9. *P is the* Pkg *provenance over* BHist, Hist, Cont, hsame, msame, *bridge rows, and the surrounding certificate rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{RussellBoundary}^{\uparrow}}$ *ledger.*

The carrier is exactly this finite packet. It has no coordinate for a class object beyond its contextual classifier row, no primitive denoting description, no reducibility-style stratum collapse, no host quotient over certificate rows, and no choice selector for unlisted descent witnesses.

Lean4 ✓ `BEDC.Derived.RussellBoundaryUp.RussellBoundaryCarrier source relation description transport`

Theorem 517.2 (RussellBoundary fivefold obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RussellBoundary}^{\uparrow}}$ *surface binds five obligations: relation-first licensing through O, description expansion through D, contextual class reading through K, stratification by the displayed bridge row L, and witnessed descent through the route ledger W.*

Proof. Carrier exposure is projection from Definition 517.1. The rows $S, O, D, K, L, W, H, C, P, N$ are the only displayed data admitted by the packet.

Relation-first licensing is the row O. A consumer reads the public name through the relation recorded there, and the continuation routes in C replay that relation before any object-like use is available.

Description expansion is the row D. It displays the obligations attached to the description rather than treating the description as a primitive denoting term.

Contextual class reading is the row K. Class-like grammar is consumed only through the finite classifier context recorded in that row.

Stratification and witnessed descent are the rows L and W. The bridge row records the level passage, while the descent ledger records the finite certificate routes required for downward use. Together with H, P, N, these rows form the local NameCert surface. □

Lean4 ✓ `BEDC.Derived.RussellBoundaryUp.RussellBoundaryCarrier fivefold obligations`

Theorem 517.3 (RussellBoundary NameCert noncollapse)**.** *Every accepted* $\mathsf{RussellBoundary}^{\uparrow}$ *packet keeps source expressions, contextual classifier rows, bridge rows, and witnessed-descent rows as distinct displayed coordinates. Hence the packet cannot be read as an identity between a class expression and a class object, between a description and a primitive denotation, or between source and target strata.*

Proof. Project an accepted carrier as $R = (S, O, D, K, L, W, H, C, P, N)$. The source expression, relation row, description row, contextual-class row, stratum bridge, and descent ledger occupy separate coordinates.

The classifier context cannot collapse into a class object, because the only class-like coordinate is K, and K is read through the continuation routes and transports recorded in C and H. No coordinate stores an object obtained by forgetting that context.

The description row cannot collapse into primitive denotation, because D records obligations rather than a bare selected object. A consumer of the description must also consume the displayed rows that account for existence, stability, and ledger use.

The source and target strata cannot collapse, because L records the bridge as a bridge row. The packet exposes a consumable passage between strata, not an equality of the strata themselves. □

Lean4 ✓ `BEDC.Derived.RussellBoundaryUp.RussellBoundaryCarrier namecert noncollapse`

Theorem 517.4 (RussellBoundary witnessed-descent ledger)**.** *Any downward consumer read of a* $\mathsf{RussellBoundary}^{\uparrow}$ *upward name factors through the witnessed-descent row W and the displayed* Cont *routes in C. Therefore the packet admits downward use only when the relevant certificate route is present in the finite ledger.*

Proof. Let a consumer attempt a downward read of an accepted packet. The only descent coordinate in Definition 517.1 is W, and the only executable routes available to the packet are the displayed continuation rows in C.

If the read is admitted, it must project a route from W and replay it through C. The componentwise transports in H ensure that the source expression, relation row, description row, contextual classifier, and bridge row are the same displayed data after transport.

If no such route is present in W, the carrier has no substitute coordinate from which to manufacture a witness. The packet has no host choice selector, no class-level truth branch, and no quotient that can identify an absent witness with a present one. Thus downward use is ledger-bounded. □

Lean4 ✓ `BEDC.Derived.RussellBoundaryUp.RussellBoundaryCarrier witnessed descent ledger`

Theorem 517.5 (RussellBoundary public certificate)**.** *The carrier, fivefold obligations, noncollapse boundary, and witnessed-descent ledger assemble a public* $\mathsf{RussellBoundary}^{\uparrow}$ *certificate for relation-first, description-expansion, contextual-class, stratification, and witnessed-descent discipline over finite BEDC rows.*

Proof. Start with the carrier of Definition 517.1. It fixes the finite source, relation, description, contextual classifier, bridge, descent, transport, continuation, package, and naming rows.

Apply Definition 517.2. It identifies the five public obligations by their rows O, D, K, L, W.

Use Definition 517.3 for the boundary side: the packet does not identify class grammar with a class object, description grammar with primitive denotation, or bridge consumption with stratum equality.

Use Definition 517.4 for the consumer side: downward use is admitted only through recorded certificate routes.

These clauses expose a public certificate surface. It is public because every consumer-facing use is one of the displayed rows or a route through those rows, and it is a Russell boundary because the five restrictions of section 9457.1 are enforced by the NameCert packet rather than by an external ontology. □

Lean4 ✓ `BEDC.Derived.RussellBoundaryUp.RussellBoundaryCarrier public certificate`

Closure status for $\mathsf{NameCert}_{\mathsf{RussellBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{RussellBoundary}^{\uparrow}$ packet is generated from a source-expression row, a relation-first observation row, a description-expansion obligation row, a contextual-class row, a stratification bridge row, a witnessed-descent ledger, componentwise transports, displayed continuation routes, package provenance, and a local naming ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RussellBoundary}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 517.1, Definition 517.2, Definition 517.3, Definition 517.4, and the public export surface of Definition 517.5 bind the mature finite scope of relation-first rows, description expansion, contextual class readings, stratification bridge, witnessed descent, $\mathsf{NameCertMorphism}^{\uparrow}$ routing, inscription-gap ledger consumption, and downstream foundation-boundary citation.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RussellBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close a Lean implementation, bridge checking, class ontology, reducibility principle, quotient over certificates, host choice selector, identity between strata, or a global foundation ontology.

Upgrade path: The paper theory axis is mature through the public certificate route; Lean verification and bridge checking remain independent axes.

Chapter 518

A Concrete Naming Certificate for $\mathsf{RussellAnalysisLadder}^{\uparrow}$

Falsifiable prediction: Every accepted RussellAnalysisLadderUp packet exposes description, contextual-class, Russell-boundary, self-membership, type-classifier membership, stratification, and witnessed-descent rows before any consumer may read a description as a public name.

Independence witness: definitedescriptionboundary, contextualclassreading, russellboundary, russellselfmembershipboundary, typeclassifiermembership: none is bijective because the ladder carrier consumes these rows together with stratification and witnessed-descent evidence, while each sibling isolates one description, contextual, boundary, self-membership, or type-membership surface.

The $\mathsf{RussellAnalysisLadder}^{\uparrow}$ surface turns the Russell problem boundary of chapter 9457 into a finite NameCert packet. It records the five kernel-facing analysis roles as displayed rows: description expansion, contextual class reading, relation-first classifier exposure, stratification control, and witnessed descent. The packet does not import Russell's logicist axioms, class ontology, reducibility principle, host quotient principles, or any global construction of analysis.

The ladder consumes the description boundary, contextual-class reading, Russell boundary, and type-classifier membership surfaces via chapter 661, chapter 684, chapter 517, and chapter 476. It also reads the self-membership boundary of chapter 506. These dependencies are row consumption inside the finite packet, not external ontology.

Definition 518.1 (RussellAnalysisLadder carrier)**.** *A* $\mathsf{RussellAnalysisLadder}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (D, Q, A, S, W, H, C, P, N)$$

with the following displayed rows:

1. *D is the description row, recording the analysed source phrase and the local existence, stability, and ledger obligations needed before it may be read as a name;*
2. *Q is the contextual-class row, recording the context that classifies the phrase without promoting that context to a class object;*
3. *A is the relation-first row, recording the relation or pattern that licenses the behaviour of the name before any object-like reading is consumed;*
4. *S is the stratification row, recording the level at which the name is admitted and the explicit bridge by which any higher or lower read is requested;*

5. *W is the witnessed-descent row, recording the certificate evidence required before an upward name is used downward by a consumer;*
6. *H stores the componentwise* hsame *transports for D, Q, A, S, W and for the surrounding package and local naming rows;*
7. *C stores the displayed* Cont *routes by which consumers read the description, context, relation, stratum, and witnessed-descent rows;*
8. *P is the* Pkg *provenance over* BHist, Hist, Ask, msame, hsame, Cont, *relation rows, bridge rows, and local naming evidence;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RussellAnalysisLadder}^{\uparrow}}$ *row.*

The carrier is exactly this finite packet. It has no coordinate for a primitive class object, an unanalysed definite description, a unary property replacing a relation, a level collapse, a reducibility-style descent, a host quotient, or a global analytic universe.

Lean4 ✓ `BEDC.Derived.RussellAnalysisLadderUp.RussellAnalysisLadderTasteGate single carrier alignment`

Theorem 518.2 (RussellAnalysisLadder NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RussellAnalysisLadder}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *description exposure: every accepted carrier exposes the description row D together with the displayed obligations that license name use;*
2. *contextual-class locality: every class-like read factors through the context row Q and does not export a class object;*
3. *relation-first classifier stability: every classifier read factors through the relation row A and is transported only by the displayed* hsame *data;*
4. *stratification accountability: every cross-level use is routed through S, C, P, and N rather than through a level collapse;*
5. *witnessed descent: every downward consumer of an upward name presents the evidence row W and the local naming row N.*

Proof. Carrier exposure is projection from the finite tuple of Definition 518.1. The rows $D, Q, A, S, W, H, C, P, N$ are the only data admitted to the packet.

The contextual and relation-first obligations are read from Q and A. A consumer of a class-like phrase must pass through the displayed context, and a consumer of the name's behaviour must pass through the relation row before obtaining any object-like public use.

Stratification and witnessed descent are then read from S and W. The only routes available to a consumer are the displayed Cont rows in C, transported through H and recorded by the provenance and local naming rows P and N.

Since the carrier has no coordinate beyond these rows, the certificate cannot export a primitive class, unanalysed description, unary replacement of the relation, level collapse, or unwitnessed downward use. □

Lean4 ✓ `BEDC.Derived.RussellAnalysisLadderUp.RussellAnalysisLadderCarrier namecert obligations`

Theorem 518.3 (RussellAnalysisLadder description factorization)**.** *Every public read of a description in an accepted* $\mathsf{RussellAnalysisLadder}^{\uparrow}$ *carrier factors through the finite rows $D, Q, A, S, W, H, C, P, N$.*

In particular, an apparent denoting phrase is consumed only after the source description, classifying context, relation row, stratification row, witnessed-descent evidence, transport rows, continuation routes, provenance row, and local naming row have been displayed.

Proof. Begin with the carrier of Definition 518.1. The description row D is present only together with Q, A, S, W, H, C, P, N.

Apply the NameCert obligations of Definition 518.2. Description exposure gives D, contextual-class locality routes class-like uses through Q, and relation-first classifier stability routes behavioural uses through A.

The remaining public read is accountable only through S and W. Transport and continuation rows H and C record how the consumer reaches the displayed name, while P and N record the package and local certificate.

Thus the denoting phrase is not a primitive coordinate. Its public use factors through the complete finite packet. □

Lean4 ✓ `BEDC.Derived.RussellAnalysisLadderUp.RussellAnalysisLadderCarrier description factorization`

Theorem 518.4 (RussellAnalysisLadder non-escape boundary)**.** *Every consumer read of an accepted* $\mathsf{RussellAnalysisLadder}^{\uparrow}$ *packet remains inside the finite description, contextual-class, relation-first, stratification, witnessed-descent, transport, continuation, provenance, and local naming rows. The packet cannot be read as Russellian class ontology, an imported reducibility principle, host quotient reasoning, proposition extensionality, proof irrelevance, or a completed host construction of analysis.*

Proof. Project the accepted packet as $R = (D, Q, A, S, W, H, C, P, N)$. A consumer can inspect only these displayed rows or a component transported through H and routed through C.

Use Definition 518.3. Any description read returns to the full packet, so a denoting phrase cannot bypass the contextual, relational, stratification, witnessed-descent, package, and local naming obligations.

The excluded principles require coordinates absent from the carrier: a primitive class object, a level-collapsing reducibility rule, a host quotient law, proposition extensionality, proof irrelevance, or a completed analytic universe. Since none of these coordinates occurs in R, no consumer can extract them from $\mathsf{RussellAnalysisLadder}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.RussellAnalysisLadderUp.RussellAnalysisLadderCarrier non escape boundary`

Theorem 518.5 (RussellAnalysisLadder public export)**.** *Every public consumer of an accepted* $\mathsf{RussellAnalysisLadder}^{\uparrow}$ *packet receives only the finite description row, contextual-class row, relation-first row, stratification row, witnessed-descent row, componentwise transport rows, continuation-route rows, package-provenance row, and local naming row of* $R = (D, Q, A, S, W, H, C, P, N)$*. The public export gives no class ontology, reducibility principle, quotient reasoning, proposition extensionality, proof irrelevance, or host analytic universe.*

Proof. Project the carrier of Definition 518.1. Its public-facing rows are exactly $D, Q, A, S, W, H, C, P, N$, so a consumer can read the description only together with the contextual, relational, stratification, witnessed-descent, transport, continuation, provenance, and local naming data.

Use the NameCert obligations of Definition 518.2. Description exposure, contextual-class locality, relation-first classifier stability, stratification accountability, and witnessed descent account for every public use of the displayed packet.

Apply description factorization and the non-escape boundary. The factorization theorem keeps each public description read inside the finite carrier rows, and the boundary theorem excludes class ontology, reducibility, quotient reasoning, proposition extensionality, proof irrelevance, and host analytic completion. Thus the exported public surface is the finite packet itself. □

Closure status for $\mathsf{NameCert}_{\mathsf{RussellAnalysisLadder}^{\uparrow}}$.

Constructive story: A $\mathsf{RussellAnalysisLadder}^{\uparrow}$ packet is generated from description, contextual-class, relation-first, stratification, witnessed-descent, componentwise transport, continuation-route, package-provenance, and local naming rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RussellAnalysisLadder}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 518.1, Definition 518.2, Definition 518.3, Definition 518.4, and Definition 518.5 bind the finite Russell problem boundary obligations, public export, and paper-side finite-description bridge to the NameCert and TasteGate carrier surface over BHist, hsame, Cont, Pkg, and witnessed-descent rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RussellAnalysisLadder}^{\uparrow}}, \mathsf{auditClean})$

Lean target: `BEDC.Derived.RussellAnalysisLadderUp.RussellAnalysisLadderTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Not claimed: This chapter does not close machine bridge checking, Russellian class ontology, imported reducibility, host quotient reasoning, proposition extensionality, proof irrelevance, or a completed host construction of analysis.

Upgrade path: The remaining independent upgrade is machine bridge checking of the already mature paper package for the public finite description, contextual-class, relation-first, stratification, and witnessed-descent packet.

Chapter 519

A Concrete Naming Certificate for $\mathsf{InscriptionEvent}^{\uparrow}$

The $\mathsf{InscriptionEvent}^{\uparrow}$ surface turns an inscription into finite NameCert data. It records the accepted public transition by which prior record state is carried into a named statement, a route witness, a check row, a downstream consumer, and a GAP ledger. The packet is not private intention, raw byte change, hidden agency, or an unconstrained host event.

The inscription packet consumes the kernel-acceptance trace of chapter 557, the TasteGate admission surface of chapter 545, and the audit membrane of chapter 524 before its route, check, and GAP ledger rows become public certificate data.

The public GAP row is consumed through chapter 520, while the accepted record route remains the $\mathsf{InscriptionEvent}^{\uparrow}$ carrier. The event packet owns the prior record, named statement, route witness, accepted check, and consumer rows; the ledger sibling owns the residue and non-escape accounting attached to that public gap row.

Definition 519.1 (InscriptionEvent carrier)**.** *An* $\mathsf{InscriptionEvent}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$I = (S, M, R, K, U, G, H, C, P, N)$$

with the following displayed rows:

1. *S is the prior record-state row, naming the finite source history before the inscription is accepted;*
2. *M is the named statement or record row, naming the public inscription target and its interface;*
3. *R is the proof route or route-witness row, recording how the prior record state reaches the named statement;*
4. *K is the accepted check row, recording the finite checker result that admits the route as public record data;*
5. *U is the intended-consumer row, naming the downstream reader, citation, theorem site, or certificate surface that may consume the inscription;*
6. *G is the public* GAP *ledger row, recording the open commitment socket and the residue not discharged by generator replay alone;*
7. *H records componentwise* hsame *transports for the source, name, route, check, consumer,* GAP *ledger, package, and local naming rows;*

8. *C records the displayed* Cont *routes by which consumers read S, M, R, K, U, G without leaving the finite public packet;*
9. *P is the* Pkg *provenance row over* BHist, hsame, Cont, *public check data,* GAP *ledger data, and local certificate dependencies;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{InscriptionEvent}^{\uparrow}}$ *row.*

The classifier for two accepted carriers compares only the public source row, named statement row, route-witness row, accepted check row, intended-consumer row, GAP *ledger row, and their displayed* hsame, Cont, Pkg, *and* NameCert *provenance.*

Lean4 ✓ `BEDC.Derived.InscriptionEventUp.InscriptionEventTasteGate single carrier alignment`

Theorem 519.2 (InscriptionEvent NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{InscriptionEvent}^{\uparrow}}$ *surface for the carrier of Definition 519.1 consists of five finite obligations:*

1. *carrier exposure: every accepted inscription event exposes exactly the packet $I = (S, M, R, K, U, G, H, C, P, N)$;*
2. *classifier locality: public comparison is restricted to the source, name, route, check, consumer, ledger, transport, continuation, package, and local naming rows;*
3. *route acceptance: the route-witness row R reaches the named statement row M from the prior record-state row S only through the accepted check row K;*
4. *consumer accountability: every downstream use of the inscription first reads the intended-consumer row U and the displayed* Cont *routes in C;*
5. *ledger exposure: the* GAP *row G is public certificate data and cannot be replaced by private intention, unrecorded agency, raw byte difference, or host-level completion.*

Proof. Carrier exposure is projection from the finite tuple in Definition 519.1. The source state, named statement, route witness, accepted check, consumer, ledger, transport, continuation, package, and local naming rows are all displayed coordinates.

Classifier locality follows from the last sentence of the carrier definition. The comparison has no coordinate beyond the public rows and their recorded hsame and Cont routes, so it cannot inspect private intention or unrecorded state.

Route acceptance and consumer accountability are read from R, K, U, and C. The route witness reaches the name only after the checker row accepts it, and every downstream consumer is one of the rows named by the consumer surface. The GAP ledger is therefore a public row in the same packet rather than an external explanation. □

Theorem 519.3 (InscriptionEvent carrier stability)**.** *For every accepted* $\mathsf{InscriptionEvent}^{\uparrow}$ *carrier, the public surface is stable under the displayed rows $S, M, R, K, U, G, H, C, P, N$. The* GAP *ledger is exactly the row G attached to the source record state, named statement, route witness, accepted check, and intended consumer, and every public comparison is transported only through the displayed* hsame, Cont, Pkg, *and* NameCert *provenance.*

Proof. Inspect the carrier coordinates. The ledger available to a consumer is G, and G appears beside $S, M, R, K, U, H, C, P, N$ in the same finite packet.

The NameCert obligations force the route witness through the accepted check row before the inscription is consumed. Thus any residue recorded by G is downstream of the public route and checker rows, not a replacement for them.

No carrier coordinate names private psychology, an agency primitive, a raw byte-difference classifier, or a host completion object. Therefore ledger exactness is exactly the displayed public GAP row. □

Theorem 519.4 (InscriptionEvent non-escape boundary)**.** *If two accepted* InscriptionEvent$^{\uparrow}$ *packets agree on the displayed source record state, named statement, route witness, accepted check row, intended consumer,* GAP *ledger, and their* hsame*,* Cont*,* Pkg*, and* NameCert *provenance, then every public consumer route sees the same inscription-event surface. The agreement does not identify private motives, host process traces, unrecorded edits, or any object outside the finite packet.*

Proof. Use classifier locality from Definition 519.2. The listed rows are exactly the rows the classifier may compare, so agreement on them fixes the public inscription surface.

The displayed Cont routes then carry each intended consumer through the same source, name, route, check, and ledger rows. Package and local certificate provenance are part of the same comparison, so downstream reads receive the same public packet.

The exclusions are immediate from the carrier inventory. Motives, host process traces, unrecorded edits, and non-packet objects are not coordinates of I and cannot be recovered by public compatibility. □

Theorem 519.5 (InscriptionEvent downstream handoff)**.** *Every accepted* InscriptionEvent$^{\uparrow}$ *packet hands public record use to downstream consumers only through the rows* $S, M, R, K, U, G, H, C, P, N$*. In particular, a theorem site, citation row, certificate checker, or audit consumer may read the named statement, route witness, accepted check, intended-consumer row, and* GAP *ledger, but it receives no private intention, host agency predicate, unchecked route, or hidden record mutation.*

Proof. Start from the carrier of Definition 519.1. Its intended-consumer coordinate U names the public reader, and its continuation coordinate C records the permitted routes into the packet.

Apply the route-acceptance and ledger-exposure obligations from Definition 519.2. They force the downstream route through R, K, and G after the source and named-statement rows have been displayed.

Finally use Definition 519.4. Any public consumer comparing inscription events is limited to the same rows, so the handoff cannot export private intention, host agency, unchecked routes, or hidden mutation outside the finite certificate. □

Theorem 519.6 (InscriptionEvent route obligation ledger)**.** *For an accepted* InscriptionEvent$^{\uparrow}$ *carrier*

$$I = (S, M, R, K, U, G, H, C, P, N),$$

the route row R*, checker row* K*, and named statement row* M *form the accepted route obligation. A public consumer may cite the inscription route only as the displayed passage from prior record state* S *to named statement* M *through the accepted checker row* K*.*

Proof. Project the carrier of Definition 519.1. The rows M, R, K are displayed coordinates, with R recording the route witness and K recording the accepted checker result.

Apply the route-acceptance clause of Definition 519.2. It forces the route witness to reach the named statement only through the accepted check row, so the route obligation is exactly the ledger formed by R, K, M inside the packet. □

Theorem 519.7 (InscriptionEvent consumer obligation ledger)**.** *For an accepted* InscriptionEvent$^{\uparrow}$ *carrier* I*, the consumer row* U*, public* GAP *row* G*, and continuation table* C *form the consumer-ledger obligation. Every downstream use of the inscription must read the intended consumer, the*

open commitment residue, and the displayed continuation routes before treating the inscription as public record data.

Proof. The carrier definition displays U, G, and C as finite rows of the same packet. The row U names the downstream consumer, G records the public GAP ledger, and C records the routes by which consumers read the packet.

Use consumer accountability and ledger exposure from Definition 519.2. They identify downstream use with reads through U and C, and they keep G as public certificate data rather than as private intention or host-level completion. □

Theorem 519.8 (InscriptionEvent public package obligation)**.** *For an accepted* $\mathsf{InscriptionEvent}^{\uparrow}$ *carrier* I*, the rows* H, C, P, N *assemble the public package obligation over* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. The inscription event is therefore available to public consumers only as a finite package with displayed transports, continuation routes, provenance, and local naming data.*

Proof. Project H, C, P, N from the carrier. The row H records componentwise hsame transports, C records displayed Cont routes, P records Pkg provenance over BHist and the public certificate data, and N records the local NameCert row.

The classifier locality clause in Definition 519.2 restricts public comparison to these displayed support rows together with the source, statement, route, check, consumer, and ledger rows. Thus the public package obligation is precisely the finite assembly over BHist, hsame, Cont, Pkg, and NameCert. □

Closure status for $\mathsf{NameCert}_{\mathsf{InscriptionEvent}^{\uparrow}}$**.**

Constructive story: An $\mathsf{InscriptionEvent}^{\uparrow}$ packet is generated from prior record state, a named statement or record, a route witness, an accepted check row, an intended consumer, a public GAP ledger, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{InscriptionEvent}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 519.1, Definition 519.2, Definition 519.3, Definition 519.4, Definition 519.5, Definition 519.6, Definition 519.7, and Definition 519.8 bind inscription events as finite public NameCert packets with the downstream consumer package.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{InscriptionEvent}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.InscriptionEventUp.InscriptionEventTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close a Lean implementation, bridge checking, hidden agency, private intention, raw byte-change identity, host process trace semantics, or completed record ontology.

Upgrade path: The paper-side theory closure is complete for the displayed finite inscription-event package; machine bridge checking remains a separate verification-axis obligation.

Chapter 520

A Concrete Naming Certificate for $\mathsf{InscriptionGapLedger}^{\uparrow}$

The $\mathsf{InscriptionGapLedger}^{\uparrow}$ surface isolates the ledger side of inscription. It records the residue left at the accepted route boundary as finite public NameCert data: the prior source scope, the named public record, the route witness, the accepted check row, the intended consumer, and the GAP row that accounts for what the generator replay alone does not discharge. The packet is narrower than the whole inscription event; it is the public residue ledger that downstream audit and supply-socket consumers may read. It is the residue-facing projection of the full inscription event carrier in chapter 519: the event chapter carries the broader inscription route, while this chapter keeps only source state, public record, route witness, accepted check, consumer, GAP residue, transport, route, provenance, and local name rows.

Definition 520.1 (InscriptionGapLedger carrier)**.** *An* $\mathsf{InscriptionGapLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (S, M, R, K, U, Q, H, C, P, N)$$

with the following visible rows:

1. *S is the prior source-state row at which the inscription route begins;*
2. *M is the named public record, theorem site, citation row, or interface reached by the route;*
3. *R is the displayed route witness from S to M;*
4. *K is the accepted check row that admits R as public record data;*
5. *U is the intended-consumer row naming the downstream reader of the ledger;*
6. *Q is the GAP residue row, recording the open commitment socket and the residue not discharged by generator replay alone;*
7. *H records componentwise* hsame *transport for S, M, R, K, U, Q together with package and naming rows;*
8. *C records the displayed* Cont *routes by which consumers read S, M, R, K, U, Q without leaving the finite packet;*
9. *P is the* Pkg *provenance over* BHist, hsame, Cont, *accepted check data, GAP residue data, and local certificate dependencies;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{InscriptionGapLedger}^{\uparrow}}$ *row.*

The carrier contains no private intention, hidden agency predicate, raw byte-change identity, unchecked route, host process trace, or complete inscription-event ontology.

Theorem 520.2 (InscriptionGapLedger NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{InscriptionGapLedger}^{\uparrow}}$ *surface for the carrier of Definition 520.1 consists of five finite obligations: carrier exposure for* $G = (S, M, R, K, U, Q, H, C, P, N)$*; source-scope locality for the prior source state* S*; named route compression through* M, R, K*; consumer accountability through* U *and* C*; and GAP residue exactness through* Q, H, P, N*.*

Lean4 ✓ `BEDC.Derived.InscriptionGapLedgerUp.InscriptionGapLedgerTasteGate single carrier alignment`

Proof. Carrier exposure is projection from the displayed packet. Source-scope locality reads only S and the continuation rows in C, so the ledger begins at the public record state and not at an unstated host process.

Named route compression is the row chain S, R, K, M. The route witness reaches the named public record only through the accepted check row, and the package row records that this is the route admitted into the certificate.

Consumer accountability and residue exactness use U, Q, H, C, P, N. A downstream consumer must be one of the displayed readers and obtains the GAP residue through the same transport, continuation, package, and local naming rows. No additional coordinate can supply private intention, hidden agency, raw byte identity, or a complete inscription event. □

Theorem 520.3 (InscriptionGapLedger source boundary)**.** *Every accepted* $\mathsf{InscriptionGapLedger}^{\uparrow}$ *carrier reads source information only from the prior source-state row* S*, the route witness* R*, and the accepted check row* K*. The GAP residue row* Q *is attached to that boundary and cannot be used as a second source state, an unchecked route, or a replacement for the named public record* M*.*

Lean4 ✓ `BEDC.Derived.InscriptionGapLedgerUp.InscriptionGapLedger source boundary`

Proof. Project the carrier rows $S, M, R, K, U, Q, H, C, P, N$. The only source-facing rows are S, R, K, with M as the named endpoint reached after acceptance.

The GAP residue Q is recorded beside those rows and transported by H through routes in C. It therefore accounts for the displayed residue at the accepted boundary rather than adding another source, another route, or another public name.

Since the carrier has no further source coordinate, every public read of the ledger remains confined to the displayed source boundary. □

Theorem 520.4 (InscriptionGapLedger consumer exhaustion)**.** *Every downstream consumer of an accepted* $\mathsf{InscriptionGapLedger}^{\uparrow}$ *carrier is exhausted by the rows* $S, M, R, K, U, Q, H, C, P, N$*. A theorem site, citation row, audit surface, or supply-socket consumer may read the named route, accepted check, intended-consumer row, and GAP residue, but it receives no hidden mutation, private agency predicate, unchecked route, or host trace.*

Lean4 ✓ `BEDC.Derived.InscriptionGapLedgerUp.InscriptionGapLedger consumer exhaustion`

Proof. Start with a public consumer route and project U and C. These rows name the consumer and the displayed continuations into S, M, R, K, Q.

The package and local naming rows P and N attach the same route, check, consumer, and residue to one finite certificate. Componentwise transport through H preserves that attachment under accepted comparisons.

Thus the consumer sees exactly the displayed packet. Hidden mutation, private agency, unchecked routing, and host traces are absent from the carrier and cannot be exported by the ledger. □

Theorem 520.5 (InscriptionGapLedger non-escape)**.** *If two accepted* InscriptionGapLedger$^{\uparrow}$ *carriers agree on the displayed source state, named public record, route witness, accepted check, intended consumer, GAP residue,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *rows, then every public ledger consumer sees the same GAP-ledger surface. This agreement does not identify complete inscription events, private motives, host process traces, or objects outside the finite residue packet.*

Proof. Agreement on the listed rows is agreement on every coordinate of the carrier. The classifier has no additional public input beyond those rows and their displayed transport and continuation evidence.

Every consumer route factors through U and C, then reads the route, check, name, and residue rows transported by H and accounted for by P and N. Therefore the visible ledger surface is fixed.

The excluded objects are not coordinates of G. Complete inscription events, motives, host traces, and outside objects cannot be recovered from equality of the finite residue packet. □

Closure status for NameCert$_{\text{InscriptionGapLedger}^{\uparrow}}$**.**

Constructive story: An InscriptionGapLedger$^{\uparrow}$ packet is generated from prior source state, a named public record, a route witness, an accepted check row, an intended consumer, a GAP residue row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.InscriptionGapLedgerUp.taste gate`

Theory closure: TheoryGate(NameCert$_{\text{InscriptionGapLedger}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 520.1, Definition 520.2, Definition 520.3, Definition 520.4, and Definition 520.5 bind the GAP-ledger side of inscription as a finite NameCert residue packet with a checked TasteGate obligation surface.

Formal verification: FormalStatus(NameCert$_{\text{InscriptionGapLedger}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.InscriptionGapLedgerUp.InscriptionGapLedgerTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close bridge checking, complete inscription-event ontology, private intention, hidden agency, raw byte-change identity, unchecked route semantics, or host process traces.

Upgrade path: The paper-side mature treatment is closed over the same finite residue packet, while bridge checking remains a separate Lean-side target.

Chapter 521

A Concrete Naming Certificate for $\mathsf{ContourIntegralOperation}^{\uparrow}$

The $\mathsf{ContourIntegralOperation}^{\uparrow}$ interface turns the contour-integration operation of chapter 9340 into a finite BEDC NameCert packet. It displays the piecewise-linear contour, holomorphic input, Riemann-sum ledger, convergence modulus, output complex-history row, componentwise transport, continuation routes, package provenance, and local naming row that downstream integral, residue, and RH scaffold consumers may inspect without importing a host analytic integral operator.

Definition 521.1 (Contour-integral operation carrier)**.** *A* $\mathsf{ContourIntegralOperation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (G, F, S, M, I, H, C, P, N)$$

with the following displayed rows:

1. *G is the* $\mathsf{PLContour}$ *row, including the finite list of* $\mathsf{Complex}^{\uparrow}$ *endpoints and the boundary-read data for its piecewise-linear segments;*
2. *F is the* $\mathsf{Holomorphic}^{\uparrow}$ *input row on a neighbourhood containing the image of G;*
3. *S is the Riemann-sum ledger, recording subdivision counts, sample rows, segment contributions, and the finite sum row used by Definition 9340.5;*
4. *M is the explicit modulus row witnessing convergence of the Riemann sums toward the output;*
5. *I is the output* $\mathsf{Complex}^{\uparrow}$ *history row satisfying the contour-integral predicate of Definition 9340.7;*
6. *H stores componentwise* hsame *transport for G, F, S, M, I;*
7. *C stores the displayed* Cont *routes by which a consumer reads the contour, holomorphic input, Riemann-sum ledger, modulus, output, package provenance, and local name;*
8. *P is the* Pkg *provenance over* $\mathsf{PLContour}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{Complex}^{\uparrow}$, *Riemann sums, the modulus row,* hsame, Cont, *and the local naming surface;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ContourIntegralOperation}^{\uparrow}}$ *row.*

The carrier has no coordinate for an ambient Lebesgue integral, a host path object, a quotient-of-paths class, a global branch choice, or an unledgered limiting operation.

Theorem 521.2 (Contour-integral operation NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContourIntegralOperation}^{\uparrow}}$ *surface for Definition 521.1 consists of five finite obligations:*

1. *carrier exposure for* $T = (G, F, S, M, I, H, C, P, N)$*;*
2. *classifier stability for the* PLContour *row,* Holomorphic$^{\uparrow}$ *input row, Riemann-sum ledger, modulus row, and output* Complex$^{\uparrow}$ *history under the componentwise* hsame *row* H*;*
3. *operation-law ledger exactness for linearity, concatenation, reversal, and piecewise-linear reparameterization as recorded in the finite ledger* S *and routes* C*;*
4. *uniqueness of the output row* I *up to* hsame *using the modulus row* M *and the contour-integral uniqueness boundary;*
5. *non-escape from ambient integration operators, host path equality, quotient-of-paths classes, unrecorded sample choices, and global branch selectors.*

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationNameCertObligations`

Proof. Carrier exposure is projection from the finite packet of Definition 521.1. The contour, holomorphic input, Riemann-sum ledger, modulus, output, transport, routes, provenance, and local naming row are all displayed before a consumer can read the operation.

Classifier stability follows by transporting each displayed coordinate through H. The operation laws are not imported as host analytic facts; they are read through the ledger rows named by Definition 9340.20 and the routes in C.

Uniqueness is the boundary supplied by Definition 9340.9: any two accepted outputs for the same transported contour and holomorphic input are hsame-equal. Since no remaining coordinate stores an ambient integral or a host path quotient, the non-escape clause is exactly the carrier inventory. □

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationCarrier namecert obligations`

Theorem 521.3 (Contour-integral PL-contour boundary)**.** *Every accepted* ContourIntegralOperation$^{\uparrow}$ *packet reads its path data through the displayed* PLContour *row* G*. Public consumers may inspect the finite endpoint list, segment continuation rows, endpoint* Complex$^{\uparrow}$ *classifiers, and componentwise* hsame *transports for those rows, but they may not replace* G *by an ambient smooth path, a host homotopy class, or an unbounded path object.*

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationCarrier pl contour boundary`

Proof. Project the carrier coordinate G. Its only path data are the finite endpoint list and the segment rows licensed by the piecewise-linear contour carrier.

The routes in C read G before any Riemann-sum or output row is inspected. Transport through H can rename the displayed endpoint and segment rows, but it does not introduce a smooth path carrier or a host homotopy class.

Thus every contour read remains on the finite PLContour boundary, and any request for data outside that boundary has no coordinate in the packet. □

Theorem 521.4 (Contour-integral Riemann-sum ledger)**.** *For an accepted* ContourIntegralOperation$^{\uparrow}$ *packet* $T = (G, F, S, M, I, H, C, P, N)$*, every approximation read of the integral factors through the finite Riemann-sum ledger* S *and the modulus row* M*. The ledger records the subdivision count, sample rows, segment contributions, finite sum value, and precision comparison used to relate the sum to* I*; no unrecorded limiting process or sample-selection oracle is exported.*

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationCarrier riemann sum route closure`

Proof. Begin with an approximation read. The displayed routes in C first expose the contour row G and holomorphic input row F, then enter the Riemann-sum ledger S.

Inside S, the subdivision, samples, segment contributions, and finite sum are explicit rows. The modulus row M is the only row that turns these finite sums into a convergence claim about the output I.

Consequently an audit of the approximation surface reads only S and M after the input rows. Since no separate coordinate stores a limiting oracle or hidden sample selector, those objects are not public exports of the packet. □

Theorem 521.5 (Contour-integral public export)**.** *The public surface of an accepted* $\mathsf{ContourIntegralOperation}^{\uparrow}$ *carrier exports exactly the finite operation packet: a* $\mathsf{PLContour}$ *row, a* $\mathsf{Holomorphic}^{\uparrow}$ *input row, the Riemann-sum ledger, convergence modulus, output* $\mathsf{Complex}^{\uparrow}$ *history, componentwise* hsame *transports, finite* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row. The exported operation laws are ledgered laws for this packet, not host-level contour-integration principles.*

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationPublicExport`

Proof. The carrier definition lists every row available to public consumers. The NameCert obligations bind carrier exposure, classifier stability, operation-law ledger exactness, uniqueness, and non-escape to precisely those rows.

The PL-contour boundary prevents path data from escaping the finite endpoint and segment surface. The Riemann-sum ledger theorem forces approximation reads through S and M before they reach the output row.

Therefore the public export is exactly the finite BEDC operation packet over contour, holomorphic input, sums, modulus, output, transport, routes, provenance, and local naming. No host analytic integral principle is exported. □

Theorem 521.6 (Contour-integral modulus transport)**.** *For accepted* $\mathsf{ContourIntegralOperation}^{\uparrow}$ *packets with componentwise* hsame *transport of the contour row G, holomorphic input row F, Riemann-sum ledger S, modulus row M, and output row I, the transported modulus row remains the only public witness relating finite Riemann sums to the output* $\mathsf{Complex}^{\uparrow}$ *row. The transport excludes hidden sample selectors, ambient path equality, global branch choice, and unledgered limiting operations.*

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationModulusTransport`

Proof. Apply Definition 521.2 to expose the packet rows and the classifier-stability obligation. The componentwise transport preserves G, F, S, M, I as displayed coordinates, so the transported packet has the same public inventory.

Apply Definition 521.4. Every approximation read factors through the Riemann-sum ledger S and the modulus row M before it reaches the output row I.

Apply Definition 521.5. The exported operation packet has no coordinate for a hidden sample selector, ambient path equality, global branch choice, or unledgered limiting operation.

Therefore the transported modulus row is still the unique public bridge from finite Riemann sums to the transported $\mathsf{Complex}^{\uparrow}$ output row. Any requested witness outside S and M has no row in the accepted packet. □

Theorem 521.7 (Contour-integral operation-law ledger closure)**.** *For an accepted* ContourIntegralOperation$^{\uparrow}$ *packet*

$$T = (G, F, S, M, I, H, C, P, N),$$

linearity, concatenation, reversal, and piecewise-linear reparameterization are consumer-visible only as ledgered operation rows inside S and through the displayed routes C. No consumer may replace those rows by a host analytic integration law, a path-quotient principle, or an unrecorded limiting operation.

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationCarrier operation law ledger closure`

Proof. Project the local NameCert obligations of Definition 521.2. The operation-law clause names linearity, concatenation, reversal, and piecewise-linear reparameterization as ledger facts for the finite packet.

Apply Definition 521.3. The contour side is restricted to the displayed PLContour row G, so the laws cannot be read through an ambient smooth path object or path quotient.

Apply Definition 521.4 and Definition 521.5. The consumer sees the operation through S, C, P, N and the displayed input-output rows only. Hence the operation laws are closed at the ledger surface. □

Theorem 521.8 (Contour-integral operation modulus uniqueness boundary)**.** *For an accepted* ContourIntegralOperation$^{\uparrow}$ *packet $T = (G, F, S, M, I, H, C, P, N)$, the modulus row M is the unique public bridge from the Riemann-sum ledger S to the output row I. Any transported packet with the same displayed G, F, S, I, H, C, P, N must read convergence toward I through the transported M row and not through a hidden sample selector, host path equality, global branch choice, or ambient integral operator.*

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationModulusUniquenessBoundary`

Proof. Apply Definition 521.4. Approximation reads reach I only after passing through the finite ledger S and the modulus row M.

Use Definition 521.6. Componentwise transport preserves M as the only public witness relating the ledger to the output row.

Finally apply Definition 521.2 and Definition 521.5. The carrier exposes no second convergence bridge, so uniqueness is exactly the finite inventory of the accepted packet. □

Theorem 521.9 (Contour-integral operation residue-consumer boundary)**.** *Every residue-facing consumer of an accepted* ContourIntegralOperation$^{\uparrow}$ *packet*

$$T = (G, F, S, M, I, H, C, P, N)$$

may inspect only the PLContour *row G, holomorphic input row F, Riemann-sum ledger S, modulus row M, output row I, componentwise transports H, displayed routes C, provenance P, and local name N. It receives no residue theorem, pole-order classifier, host contour integral, global branch selector, quotient path class, or ambient analytic continuation principle from this operation packet.*

Proof. First apply Definition 521.2. The local NameCert surface exposes exactly the displayed carrier rows and the non-escape clause for the operation packet.

Use Definition 521.3 to keep path data inside G, and use Definition 521.4 to keep approximation data inside S and M.

Apply Definition 521.5. The public operation surface is precisely $G, F, S, M, I, H, C, P, N$. A residue-facing consumer can route through that surface, but the carrier has no coordinate for residue calculus or host analytic integration principles. □

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationCarrier residue consumer boundary`

Theorem 521.10 (Contour-integral operation classifier stability)**.** *Let $T = (G, F, S, M, I, H, C, P, N)$ and $T' = (G', F', S', M', I', H', C', P', N')$ be accepted* $\mathsf{ContourIntegralOperation}^{\uparrow}$ *packets. If the contour row, holomorphic input, Riemann-sum ledger, modulus row, output row, route rows, package provenance, and local* $\mathsf{NameCert}$ *row are related componentwise by* hsame*, then T' is again classified as a* $\mathsf{ContourIntegralOperation}^{\uparrow}$ *packet over the transported rows. The transport adds no host path equality, hidden sample choice, global branch choice, or ambient integral data.*

Proof. Apply Definition 521.2. Its classifier-stability clause requires exactly componentwise transport of the contour, holomorphic input, Riemann-sum ledger, modulus, output, routes, provenance, and local naming rows.

Use Definition 521.6 for the modulus side. The transported modulus remains the only public witness from finite Riemann sums to the transported output row, so hidden sample choice and unledgered limiting data cannot enter during transport.

Finally apply Definition 521.5. The exported packet after transport is still the finite operation surface $G', F', S', M', I', H', C', P', N'$, and the public surface contains no coordinate for host path equality, global branch choice, or an ambient integral operator. □

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationClassifierStability`

Theorem 521.11 (Contour-integral operation bridge envelope)**.** *The bridge-facing read of an accepted* $\mathsf{ContourIntegralOperation}^{\uparrow}$ *packet is exactly the* $\mathsf{PLContour}$ *row, the* $\mathsf{Holomorphic}^{\uparrow}$ *input row, the Riemann-sum ledger, the modulus row, the* $\mathsf{Complex}^{\uparrow}$ *output row, the componentwise* hsame *transports, the displayed* Cont *routes, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{ContourIntegralOperation}^{\uparrow}}$ *row. It exports no host analytic integral, path quotient, residue theorem, global branch selector, or analytic-continuation principle.*

Proof. Begin with the NameCert obligations of Definition 521.2. They expose the carrier rows and bind classifier stability, operation-law ledger exactness, uniqueness, and non-escape to the finite packet.

Use the PL-contour boundary of Definition 521.3 and the Riemann-sum ledger of Definition 521.4. These keep the path side on the displayed $\mathsf{PLContour}$ row and the approximation side on the finite ledger plus modulus row.

Finally apply the public export and classifier-stability theorems, Definition 521.5 and Definition 521.10. The bridge-facing read is therefore the same finite operation packet under transport, with no coordinate from which host analytic integration, path quotients, residue calculus, global branch selection, or analytic continuation could be exported. □

Lean4 ✓ `BEDC.Derived.ContourIntegralOperationUp.ContourIntegralOperationBridgeEnvelope`

Closure status for $\mathsf{NameCert}_{\mathsf{ContourIntegralOperation}^{\uparrow}}$.

Constructive story: A $\mathsf{ContourIntegralOperation}^{\uparrow}$ packet is generated from a displayed $\mathsf{PLContour}$ row, a $\mathsf{Holomorphic}^{\uparrow}$ input row, a finite Riemann-sum ledger, an explicit modulus row, an output $\mathsf{Complex}^{\uparrow}$ history, componentwise hsame transports, finite Cont routes, Pkg provenance, and a local $\mathsf{NameCert}$ row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ContourIntegralOperation}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 521.1, Definition 521.2, Definition 521.5, Definition 521.6, Definition 521.7, and Definition 521.9 bind exactly the displayed PLContour row, Holomorphic$^{\uparrow}$ input row, Riemann-sum ledger, modulus row, Complex$^{\uparrow}$ output row, hsame, Cont, Pkg, and NameCert rows already named in the chapter.

Formal verification: FormalStatus(NameCert$_{\mathsf{ContourIntegralOperation}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close Cauchy's theorem, residue calculus, RH zero-location consequences, global branch selection, Lean verification, or bridge checking.

Upgrade path: Formal progress requires Lean verification and bridge checking for the same PL-contour, holomorphic-input, Riemann-sum, modulus, output, hsame, Cont, Pkg, and NameCert rows.

Chapter 522

A Concrete Naming Certificate for $\mathsf{RecursorInducedNameCert}^{\uparrow}$

The $\mathsf{RecursorInducedNameCert}^{\uparrow}$ surface turns a legal host-CIC recursor use into finite BEDC certificate data. It records the accepted inductive signature, the motive row, the branch package, the generated proof or definition output, the audit replay row, package provenance, and the local naming row. The packet is not an unrestricted induction principle and does not certify terms whose dependency trace reaches a forbidden host principle.

It consumes the recursor-generator family through chapter 534 and chapter 525. Those sibling surfaces supply the accepted-signature rows, branch-exhaustion rows, audit-provenance rows, and output-naming rows that this chapter repackages as an induced $\mathsf{NameCert}$.

Definition 522.1 (Recursor-induced NameCert carrier)**.** *A* $\mathsf{RecursorInducedNameCert}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (S, M, B, O, A, H, C, P, N)$$

with the following displayed rows:

1. *S is the accepted inductive-signature row, naming the finite constructor family and the kernel admission event that makes the associated recursor available;*
2. *M is the motive row, recording the target family or target judgment selected by the recursor call;*
3. *B is the branch-package row, with one checked branch for each constructor exposed by S and with recursive hypotheses only at the structurally smaller sites allowed by the recursor;*
4. *O is the generated-output row, naming the proof object, definition body, or certificate row produced by applying the recursor to M and B;*
5. *A is the audit-replay row, recording kernel replay of the recursor call together with the source-axiom and forbidden-dependency checks relevant to O;*
6. *H records componentwise* hsame *transports for S, M, B, O, A, the continuation row, the package row, and the local naming row;*
7. *C records the displayed* Cont *routes by which consumers read the signature, motive, branch package, output, audit replay, provenance, and local certificate;*
8. *P is the* Pkg *provenance over* BHist*, accepted inductive signatures, recursor motives, branch packages, generated outputs, audit rows,* hsame*,* Cont*, and local naming;*

9. N is the local $\mathsf{NameCert}_{\mathsf{RecursorInducedNameCert}^{\uparrow}}$ *row.*

The carrier exposes only these finite rows. In particular, it contains no free choice row, no quotient-soundness row, no propositional-extensionality row, no non-structural recursive call, and no branch for a constructor absent from the accepted signature.

Lean4 ✓ `BEDC.Derived.RecursorInducedNameCertUp.RecursorInducedNameCertTasteGate single carrier alignment`

Definition 522.2 (Recursor generator classifier)**.** *The* $\mathsf{RecursorInducedNameCert}^{\uparrow}$ *classifier compares two carriers only through their displayed signature, motive, branch, output, audit replay, transport, continuation, package, and local naming rows. A row is accepted by the classifier exactly when it is reachable from an accepted inductive signature through a kernel-accepted motive, a complete constructor-indexed branch package, a generated output row, and an audit replay row that records no forbidden-principle dependency for the generated output.*

Theorem 522.3 (Recursor generator NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{RecursorInducedNameCert}^{\uparrow}}$ *surface for the carrier of Definition 522.1 consists of five BEDC-native obligations:*

1. *carrier exposure for the finite packet* $R = (S, M, B, O, A, H, C, P, N)$*;*
2. *signature admission stating that* S *names an accepted inductive constructor family and no constructor outside that family;*
3. *branch completeness stating that* B *supplies exactly the constructor-indexed branches required by* S *for the motive row* M*;*
4. *output exactness stating that* O *is the generated proof, definition, or certificate row obtained from the recursor call determined by* S, M, B*;*
5. *audit replay stating that* A *replays the generated output through kernel checking, source-axiom refusal, and forbidden-dependency refusal before* N *exports the local name.*

Proof. Carrier exposure is projection from Definition 522.1. The rows $S, M, B, O, A, H, C, P, N$ are the only admitted coordinates of the packet.

Signature admission and branch completeness are read from S and B. The accepted signature fixes the constructor list, and the branch package has one branch for each listed constructor with recursive hypotheses only where the recursor permits them.

Output exactness and audit replay are then read from O and A. The output row is named only after the recursor call has been replayed against its motive and branch rows, and the local certificate row exports no name until the audit row records the absence of the forbidden-principle channels. □

Theorem 522.4 (Recursor generator audit boundary)**.** *For an accepted* $\mathsf{RecursorInducedNameCert}^{\uparrow}$ *carrier, the audit row* A *is the exact public boundary for trusting the generated output row* O*. A downstream consumer may read* O *as a recursor-induced certificate only through the finite tuple consisting of the signature row, motive row, branch package, generated output row, audit replay row, componentwise transport, continuation route, package provenance, and local* $\mathsf{NameCert}_{\mathsf{RecursorInducedNameCert}^{\uparrow}}$ *row.*

This boundary does not assert a theorem of host-kernel completeness, semantic completeness of all possible recursor calls, or trust in any output whose reported dependency trace includes Classical.choice*,* Quot.sound*, or* propext*.*

Lean4 ✓ `BEDC.Derived.RecursorInducedNameCertUp.RecursorInducedNameCertAuditBoundary replay route`

Proof. Project the audit row from the carrier. It records the replay surface attached to the generated output row, so a consumer receives the output only together with the displayed signature, motive, branch package, and audit report.

Transport and continuation access are confined by H and C. These rows can move and read the displayed packet, but they do not add host-kernel completeness or an unlisted dependency theorem.

The forbidden-principle exclusions follow from the final clause of Definition 522.2. A dependency trace reporting one of the listed principles lacks an accepted classifier row, so it is recorded outside the recursor-induced certificate surface rather than exported by N. □

Theorem 522.5 (Recursor generator non-escape boundary)**.** *If two accepted* $\mathsf{RecursorInducedNameCert}^{\uparrow}$ *carriers agree on the displayed signature, motive, branch package, generated output, audit replay,* hsame *transports,* Cont *routes,* Pkg *provenance, and local naming rows, then every public consumer route sees the same recursor-induced NameCert surface. The agreement does not identify terms generated by a different inductive signature, an incomplete branch package, a non-structural recursive call, an unreported dependency chain, or a forbidden-principle proof object.*

Proof. Use the classifier of Definition 522.2. It compares only the rows displayed by the carrier, so agreement on those rows fixes the public certificate surface.

The continuation routes then replay the same reads for every downstream consumer. Since package provenance and the local naming row are part of the agreement, the consumer receives the same recursor-induced name and the same audit-facing boundary.

The exclusions are immediate from the carrier inventory and classifier condition. Different signatures, missing branches, non-structural calls, unreported dependencies, and forbidden-principle proof objects have no coordinate that can be projected from an accepted packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{RecursorInducedNameCert}^{\uparrow}}$.

Constructive story: A $\mathsf{RecursorInducedNameCert}^{\uparrow}$ packet is generated from an accepted inductive signature, a motive row, a complete branch package, a generated output row, an audit replay row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RecursorInducedNameCert}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 522.1, Definition 522.2, Definition 522.3, Definition 522.4, and Definition 522.5 bind recursor-produced proof and definition outputs as finite NameCert packets.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RecursorInducedNameCert}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a Lean implementation, bridge checking, host-kernel completeness, all possible recursor calls, non-structural recursion, or outputs depending on forbidden host principles.

Upgrade path: Obligation closure requires Lean encoding of the displayed carrier and checked theorems for branch completeness, generated-output exactness, audit replay, and forbidden-principle non-escape.

Chapter 523

A Concrete Naming Certificate for $\mathsf{TranscendentalSupplyTaxonomy}^{\uparrow}$

The $\mathsf{TranscendentalSupplyTaxonomy}^{\uparrow}$ surface turns the seven socket-kind table of chapter 9394 into a finite NameCert packet. It records the socket kind, requested supply shape, audit gate, site row, and local routing data for a reported Gap boundary. The packet classifies the boundary; it does not discharge the requested supply, add a new substrate axiom, or turn the apophatic endpoint into an internal BEDC constructor.

The taxonomy packet is consumed through the concrete ledger route of chapter 528, which records the finite socket kind, audit gate, provenance, and continuation rows before any boundary classifier is read.

Definition 523.1 (TranscendentalSupplyTaxonomy carrier)**.** *A* $\mathsf{TranscendentalSupplyTaxonomy}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (K, S, G, A, L, H, C, P, N)$$

with the following displayed rows:

1. *K is one of the seven socket-kind rows: free-floating induction, unwitnessed witness, extensional identification, causal continuity, inter-history coordination, inscription novelty, or self-reference closure;*
2. *S is the requested supply shape, stated as the exact missing item that the local construction would consume;*
3. *G is the visible* Gap *tag that keeps the request outside the closed substrate;*
4. *A is the audit-gate row: generator closure, witness visibility, extensional-collapse refusal, records-versus-prediction separation, locality discipline, aspect separation, or reflection stratification;*
5. *L is the concrete site row naming the paper or formal location where the request would be consumed;*
6. *H records componentwise* hsame *transport for K, S, G, A, L, package provenance, and the local naming row;*
7. *C records the displayed* Cont *routes that read the site, expose the* Gap *tag, classify the requested supply, and return the audit gate to downstream consumers;*

8. *P is the* Pkg *provenance over* BHist, Gap, *the seven socket-kind rows, requested supply shapes, audit gates, site rows,* hsame, Cont, *and* NameCert*;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{TranscendentalSupplyTaxonomy}^{\uparrow}}$ *row.*

The carrier contains no coordinate for a supplied witness, unrestricted induction principle, quotient equality, future empirical law, shared first-person history, agency explanation, or truth-total self-validator.

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyTaxonomyUp.TranscendentalSupplyTaxonomyTasteGate single carrier alignment`

Theorem 523.2 (TranscendentalSupplyTaxonomy NameCert obligations)**.** *For the carrier of Definition 523.1, the local* $\mathsf{NameCert}_{\mathsf{TranscendentalSupplyTaxonomy}^{\uparrow}}$ *surface consists exactly of socket-kind exposure, requested-supply accountability, audit-gate routing, site-row locality, classifier transport, continuation locality, package provenance, and non-discharge of the requested supply. A consumer accepts the taxonomy row only by projecting*

$$(K, S, G, A, L, H, C, P, N)$$

and checking that K is one of the seven displayed socket kinds, that S names the missing shape consumed at L, and that A is the gate preventing S from being internalised as a substrate theorem.

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyTaxonomyUp.TranscendentalSupplyTaxonomyNameCert obligations`

Proof. Carrier exposure is projection from Definition 523.1. The packet lists the socket kind, requested supply shape, Gap tag, audit gate, site row, transport ledger, continuation ledger, provenance, and local naming row.

Requested-supply accountability is the pair (S, L). The site row states where the missing item would be consumed, and the requested-shape row states what the missing item is.

Audit-gate routing is the pair (G, A). The Gap tag keeps the request outside the closed substrate, while the audit gate names the discipline that blocks silent internalisation of the requested shape.

Classifier transport is componentwise transport through H, and continuation locality is replay through C. These rows move the displayed taxonomy packet without replacing its socket kind or adding a discharged supply coordinate.

Package provenance and non-discharge follow from P and from the carrier inventory. Since the tuple has no row for the requested witness, induction principle, equality token, future law, shared locality cell, inscription source, or truth-total validator, the NameCert surface classifies the socket without closing it. □

Theorem 523.3 (TranscendentalSupplyTaxonomy boundary exhaustion)**.** *Every accepted* TranscendentalSupplyTa *packet exports exactly one finite taxonomy row*

$$K \to S \to G \to A \to L \to H \to C \to P \to N.$$

Any downstream consumer can read the socket kind, requested supply shape, audit gate, site row, transport data, continuation routes, provenance, and local name, but cannot extract from the packet the supply whose absence the Gap *tag records.*

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyTaxonomyUp.TranscendentalSupplyTaxonomyBoundaryExhaustion`

Proof. Project the accepted carrier $T = (K, S, G, A, L, H, C, P, N)$. The only taxonomy-facing coordinates are the displayed finite rows named in the statement.

Use the NameCert obligations of Definition 523.2. They force the downstream read to pass through the requested-supply row, the Gap row, and the audit-gate row before the site can be treated as classified.

The non-discharge clause then exhausts the boundary. A consumer may learn which of the seven socket kinds has appeared and which gate governs it, but no coordinate in the packet supplies the missing witness, universal rule, identity token, empirical persistence, inter-history recognition, inscription source, or self-reference closure. □

Theorem 523.4 (TranscendentalSupplyTaxonomy socket-kind totality)**.** *For every accepted* TranscendentalSupplyT *packet*

$$T = (K, S, G, A, L, H, C, P, N),$$

the socket-kind row K is exhausted by exactly the seven displayed rows: free-floating induction, unwitnessed witness, extensional identification, causal continuity, inter-history coordination, inscription novelty, or self-reference closure. No accepted classifier read exposes an eighth socket kind, an ambient supply class, or a hidden discharge row.

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyTaxonomyUp.TranscendentalSupplyTaxonomySocketKindTotality`

Proof. Project the carrier of Definition 523.1. Its first coordinate K is declared to be one of the seven displayed socket-kind rows, and the remaining coordinates record the request, Gap, gate, site, transport, continuation, provenance, and local name.

Apply boundary exhaustion from Definition 523.3. A downstream consumer can read the socket kind and the gate that governs it, but cannot extract a supplied witness, induction rule, equality token, empirical persistence row, inter-history recognition object, inscription source, or self-reference validator.

The classifier is therefore total only over the seven named rows. Since the carrier has no coordinate for another kind or a discharge row, no accepted read can extend the taxonomy beyond that finite list. □

Theorem 523.5 (TranscendentalSupplyTaxonomy site locality)**.** *For every accepted* TranscendentalSupplyTaxonom *packet*

$$T = (K, S, G, A, L, H, C, P, N),$$

the site row L is the only locality at which the requested supply shape S is consumed. Transport through H and replay through C may expose the classified request at that same site, but they cannot move the requested supply to an unrecorded paper location, formal location, or substrate row.

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyTaxonomyUp.TranscendentalSupplyTaxonomySiteLocality`

Proof. Read the requested-supply accountability clause of Definition 523.2. It binds the requested shape and the place where it would be consumed as the pair (S, L).

Use the carrier inventory to inspect the remaining rows. The Gap tag G and audit gate A explain why S is outside the closed substrate, while H, C, P, N transport, replay, package, and name the same finite packet.

No second site coordinate is present. Hence any accepted consumer must treat L as the unique locality of the request, and any attempted relocation outside L leaves the displayed taxonomy packet. □

Theorem 523.6 (TranscendentalSupplyTaxonomy nondischarge ledger)**.** *For every accepted* TranscendentalSupplyT *packet*

$$T = (K, S, G, A, L, H, C, P, N),$$

no ledger row other than a displayed discharge of the requested supply can be converted into supplied content. In the present packet every non-discharge row remains classificatory: K classifies the socket, G marks the Gap*, A records the audit gate, L locates the request, and H, C, P, N transport, replay, package, and name the boundary.*

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyTaxonomyUp.TranscendentalSupplyTaxonomyCarrier nondischarge ledger`

Proof. Start from Definition 523.3. It says a consumer may recover the socket kind, requested supply shape, audit gate, site row, transport data, continuation routes, provenance, and local name, but not the absent supply itself.

Now inspect the non-discharge rows. The classifier row, Gap row, gate row, site row, transport row, continuation row, provenance row, and naming row are all boundary data; none is a witness, induction principle, equality token, empirical law, shared locality cell, inscription source, or truth-total validator.

Therefore the ledger cannot convert a non-discharge row into supplied content. It records why the request remains classified at the boundary instead of being internalised as a substrate theorem. □

Theorem 523.7 (TranscendentalSupplyTaxonomy closure surface)**.** *The* TranscendentalSupplyTaxonomy$^{\uparrow}$ *packet supplies a seed closure surface for the seven socket-kind taxonomy: finite carrier exposure, local NameCert obligations, and boundary exhaustion. Its public meaning is classificatory only. It preserves the single* T *supply position by recording aspect-position rows without adding a substrate-visible source object for any type.*

Proof. The carrier of Definition 523.1 provides the finite packet. The NameCert obligations of Definition 523.2 state exactly which classifier, routing, provenance, and non-discharge rows are visible.

Boundary exhaustion in Definition 523.3 prevents a consumer from reading the requested supply itself. Thus the taxonomy row is not a hidden constructor for T and not a discharge of any Gap.

The closure surface is therefore seed-level: it binds the finite packet and the local classification obligations while leaving Lean encoding, checked transport, public bridge data, and any stronger paper package outside the present chapter. □

Theorem 523.8 (TranscendentalSupplyTaxonomy bridge precondition)**.** *Any standard-bridge-facing read of* TranscendentalSupplyTaxonomy$^{\uparrow}$ *must first display the seven socket-kind row, requested-supply row,* Gap *tag, audit gate, site row, componentwise transport, continuation route, package provenance, and local* NameCert *row. Only after those rows are visible may the packet be treated as a bridge candidate, and the candidate remains a classified boundary rather than a discharged supply.*

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyTaxonomyUp.TranscendentalSupplyTaxonomyCarrier bridge precondition`

Proof. Project the carrier of Definition 523.1. It exposes exactly the tuple $(K, S, G, A, L, H, C, P, N)$, where K is the seven-kind socket row, S is the requested-supply row, G is the Gap tag, A is the audit gate, and L is the site row.

Apply the NameCert obligations of Definition 523.2. They require classifier transport, continuation locality, package provenance, and local naming before a consumer accepts the taxonomy packet.

Boundary exhaustion and socket-kind totality, Definition 523.3 and Definition 523.4, then keep the read finite and classificatory. Hence the displayed packet is a bridge precondition, not a supplied witness or a completed bridge. □

Theorem 523.9 (TranscendentalSupplyTaxonomy socket ledger readback)**.** *Downstream consumers read* TranscendentalSupplyTaxonomy$^{\uparrow}$ *through the* SupplySocketLedger$^{\uparrow}$ *sibling route. The finite ledger exposes the socket kind, requested supply,* Gap *tag, audit gate, site row, transport, continuation, provenance, and local naming data, and no consumer may bypass that route to read a hidden supply coordinate.*

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyTaxonomyUp.TranscendentalSupplyTaxonomySocket ledger readback`

Proof. Begin with the ledger dependency stated at the chapter opening: the taxonomy packet is consumed through chapter 528. That sibling records socket kind, audit gate, provenance, and continuation rows before the boundary classifier is read.

Use site locality from Definition 523.5. The requested supply shape S is tied to the displayed site row L, so a consumer cannot move the request to another site outside the ledger.

Finally apply the nondischarge ledger, Definition 523.6. Since non-discharge rows remain classificatory, the ledger route cannot be bypassed to obtain a witness, induction principle, equality token, or truth-total validator. □

Theorem 523.10 (TranscendentalSupplyTaxonomy GAP nondischarge)**.** *The bridge-facing* TranscendentalSupplyT *packet preserves the requested-supply absence marked by G. It does not turn the boundary into a witness, an unrestricted induction principle, a quotient equality, a future empirical law, an inter-history recognition object, an inscription source, or a truth-total validator.*

Proof. Read boundary exhaustion from Definition 523.3. A consumer can recover the finite taxonomy rows, but cannot extract the supply whose absence the Gap tag records.

Now apply the nondischarge ledger of Definition 523.6. The rows K, G, A, L, H, C, P, N classify, locate, transport, replay, package, and name the request; none is supplied content.

The bridge precondition of Definition 523.8 therefore preserves absence while making the packet readable. It gives a bridge-facing obligation surface without converting the boundary into any of the forbidden discharge objects. □

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyTaxonomyUp.TranscendentalSupplyTaxonomyGap nondischarge`

Closure status for NameCert$_{\text{TranscendentalSupplyTaxonomy}^{\uparrow}}$.

Constructive story: A TranscendentalSupplyTaxonomy$^{\uparrow}$ packet is generated from a seven-kind socket row, a requested supply shape, an explicit Gap tag, an audit gate, a site row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{TranscendentalSupplyTaxonomy}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 523.1, Definition 523.2, Definition 523.3, Definition 523.4, Definition 523.5, Definition 523.6, and Definition 523.7 bind the finite carrier, seven-kind classifier, requested-supply accountability, audit-gate routing, site-row locality, socket-kind exhaustion, and non-discharge boundary.

Formal verification: FormalStatus(NameCert$_{\text{TranscendentalSupplyTaxonomy}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyTaxonomyUp.taste gate`

Not claimed: This chapter does not close Lean verification, any Gap discharge, unrestricted induction, hidden witness selection, quotient equality, empirical persistence, inter-history recognition, inscription-source explanation, self-reference closure, or a public standard bridge.

Upgrade path: No further paper-side closure grade remains; Lean verification and bridge checking remain verification-axis work.

Chapter 524

A Concrete Naming Certificate for $\mathsf{AuditMembrane}^{\uparrow}$

The $\mathsf{AuditMembrane}^{\uparrow}$ packet turns the audit-gate boundary into a finite local certificate. It records the gate surface, the content refused at that surface, the visible result of the refusal, the route by which paper-Lean drift is resolved, the transport and replay rows, the package provenance, and the local naming certificate available to downstream discipline chapters.

It consumes the audit-gate refusal surface of chapter 526: the membrane carrier repackages that boundary as the downstream gate, boundary-content, refusal-result, drift-route, transport, replay, provenance, and local NameCert rows used below.

Definition 524.1 (AuditMembrane carrier)**.** *An* $\mathsf{AuditMembrane}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (G, B, R, D, H, C, P, N)$$

with the following displayed rows:

1. *G is the gate-surface row, recording the source-token scan, dependency ancestry scan, marker-resolution scan, and origin-flow scan as one finite audit face;*
2. *B is the boundary-content row, recording the proposed crossings through source axioms, forbidden host dependencies, unresolved Lean names, and untracked origin/import flow;*
3. *R is the refusal-result row, recording for each boundary item whether the membrane admits it as displayed certificate content or refuses it as non-substrate supply;*
4. *D is the drift-resolution route row, recording the named paper marker, the candidate Lean declaration, and the finite resolve-or-refuse result;*
5. *H records componentwise* hsame *transports for G, B, R, D, the continuation row, the package row, and the local naming row;*
6. *C records the displayed* Cont *routes by which consumers inspect the gate surface, boundary content, refusal result, drift route, provenance, and local certificate;*
7. *P is the* Pkg *provenance over* BHist, Hist, GAP, hsame, Cont, Pkg, $\mathsf{NameCert}$, *audit rows, marker names, and origin ledgers;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{AuditMembrane}^{\uparrow}}$ *row.*

The carrier contains exactly these rows. It has no coordinate for a hidden global audit theorem, no permission to replace an unresolved name by a nearby theorem, no semantic proof that every import is conservative, and no route by which refused boundary content becomes substrate-internal theorem content.

Lean4 ✓ `BEDC.Derived.AuditMembraneUp.AuditMembraneTasteGate single carrier alignment`

Theorem 524.2 (AuditMembrane NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{AuditMembrane}^{\uparrow}}$ *surface for the carrier of Definition 524.1 consists of carrier admission for*

$$M = (G, B, R, D, H, C, P, N),$$

gate-surface exactness, boundary-content display, refusal-result determinacy, paper-Lean drift resolution, componentwise hsame *stability, displayed* Cont *replay,* Pkg *provenance, and non-escape for hidden global correctness, fuzzy target resolution, source-axiom admission, forbidden host-dependency admission, and untracked origin flow.*

Lean4 ✓ `BEDC.Derived.AuditMembraneUp.AuditMembraneCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 524.1. The packet admits exactly the rows G, B, R, D, H, C, P, N.

The audit obligations are then read row by row. The gate face is supplied by G, the boundary content by B, the refusal result by R, and the paper-Lean drift route by D.

Transport and consumer access are confined by H and C. These rows replay the displayed audit packet under componentwise hsame movement and expose only the recorded routes.

Finally P and N record provenance and the local naming certificate. Since the excluded objects have no coordinate in the packet, the NameCert surface cannot export them. □

Theorem 524.3 (AuditMembrane boundary refusal)**.** *For an accepted* $\mathsf{AuditMembrane}^{\uparrow}$ *packet, the refusal row R is the complete public result of applying the gate surface G to the boundary-content row B. A consumer may read admitted certificate content only through G, B, R, H, C, P, N, and any source axiom, forbidden host dependency, unresolved target name, or untracked origin edge marked as refused in R has no exported route into substrate theorem content.*

Lean4 ✓ `BEDC.Derived.AuditMembraneUp.AuditMembraneCarrier refusal replay closure`

Proof. Project the carrier and read the gate surface G together with the boundary-content row B. These rows list the finite audit face and the finite items presented to that face.

The refusal result is the row R. Because R is part of the same finite packet, every admitted or refused item remains tied to the displayed gate surface that classified it.

The replay rows H, C, P, N preserve and expose the classification. They transport, route, record provenance, and name the packet, but they do not add a new coordinate by which a refused item can be read as theorem content. □

Theorem 524.4 (AuditMembrane drift resolution)**.** *For an accepted* $\mathsf{AuditMembrane}^{\uparrow}$ *packet, the drift-resolution row D is the only route by which a paper marker becomes a local naming certificate. The route must display the marker text, the proposed Lean target name, the finite resolution result, the componentwise* hsame *transport row, the* Cont *replay row, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{AuditMembrane}^{\uparrow}}$ *row.*

If D records refusal, the packet exports no replacement by similar spelling, neighboring namespace, prose interpretation, or consumer preference.

Lean4 ✓ `BEDC.Derived.AuditMembraneUp.AuditMembraneCarrier drift resolution`

Proof. Project D from the carrier. It contains the paper marker, the candidate Lean declaration, and the finite resolve-or-refuse result.

Move the row only through the displayed transport and replay data. The rows H and C preserve the same marker and the same resolution result, while P and N record provenance and the local name.

No carrier coordinate stores fuzzy matching, namespace guessing, prose reinterpretation, or consumer-selected substitution. A refused drift row therefore remains refused at every exported read. □

Theorem 524.5 (AuditMembrane visible audit induction)**.** *Let*

$$M = (G, B, R, D, H, C, P, N)$$

be an accepted $\mathsf{AuditMembrane}^{\uparrow}$ *packet, and let L be a finite list of displayed* BHist *audit-event rows. Suppose each row of L is admitted through the same audit-gate-boundary content route as B, carries the displayed* hsame, Cont, *and* Pkg *provenance required by H, C, P, and presents no object outside the boundary-content format of chapter 526. Then extending B by the rows of L preserves the membrane verdict recorded by R: admitted rows remain admitted as displayed certificate content, refused rows remain refused boundary content, and no row of L exports global audit completeness, arbitrary import conservativity, or host-kernel completeness.*

Proof. Induct on the finite list L of displayed BHist rows.

For the empty list, the extended boundary row is just the original B. The verdict is therefore the existing membrane verdict R, read through Definition 524.3.

For the successor step, write the list as one displayed audit event followed by a tail. The head event is first consumed as an audit-gate-boundary row: it is presented to the same gate surface G, with the displayed content format required by B and with the hsame, Cont, and Pkg rows required by H, C, P.

The boundary-refusal theorem applies to that one displayed row, so its admitted or refused verdict is recorded by R and not by any hidden audit theorem. The induction hypothesis then applies to the remaining finite tail, preserving the verdict for every later displayed row.

Thus every finite extension by displayed audit events remains inside the membrane packet. The argument proves only this finite induction route over visible BHist rows; it does not assert global audit completeness, conservativity for arbitrary imports, or host-kernel completeness. □

Theorem 524.6 (AuditMembrane consumer boundary)**.** *Every downstream consumer of an accepted* $\mathsf{AuditMembrane}^{\uparrow}$ *packet factors through the finite rows*

$$G, B, R, D, H, C, P, N.$$

Such a consumer may inspect the gate surface, boundary content, refusal result, paper-Lean resolution route, transport rows, replay rows, provenance, and local naming certificate, but it cannot extract a global audit-completeness theorem, a semantic conservativity theorem for arbitrary imports, a host-kernel completeness proof, or a theorem object for refused boundary content.

Lean4 ✓ `BEDC.Derived.AuditMembraneUp.AuditMembraneCarrier consumer boundary`

Proof. Let a downstream consumer route be given. By Definition 524.1, the source carrier is the finite tuple G, B, R, D, H, C, P, N.

The consumer first reads the gate and boundary rows, then the refusal and drift-resolution rows. The rows H and C supply all permitted transport and replay, and P, N supply provenance and the local certificate.

The non-escape claim follows from the carrier inventory. None of the forbidden objects appears among the displayed rows, so no consumer route out of the packet can project it. □

Closure status for $\mathsf{NameCert}_{\mathsf{AuditMembrane}^{\uparrow}}$.

Constructive story: An $\mathsf{AuditMembrane}^{\uparrow}$ packet is generated from a finite audit gate surface, a displayed boundary-content row, a refusal-result row, a paper-Lean drift-resolution route, componentwise hsame transports, displayed Cont replay routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AuditMembrane}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 524.1, Definition 524.2, Definition 524.3, Definition 524.4, Definition 524.6, and bridge witness Definition 524.7 specify the finite audit membrane carrier, local naming obligations, refusal surface, marker-resolution route, transport replay, package provenance, consumer boundary, and public exported refusal bridge.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{AuditMembrane}^{\uparrow}}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.AuditMembraneUp.AuditMembraneCarrier\_consumer\_boundary`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close global audit completeness, arbitrary import conservativity, host-kernel completeness, or Lean-side formal verification for $\mathsf{AuditMembrane}^{\uparrow}$.

Upgrade path: No further formal bridge-axis upgrade remains for the displayed standard bridge.

Theorem 524.7 (AuditGateBoundary to AuditMembrane refusal bridge)**.** *Let*

$$A = (S, D_A, L, O, H_A, C_A, P_A, G_A, N_A)$$

be an accepted $\mathsf{AuditGateBoundary}^{\uparrow}$ *packet, and let*

$$M = (G_M, B, R, D_M, H_M, C_M, P_M, N_M)$$

be an accepted $\mathsf{AuditMembrane}^{\uparrow}$ *packet. Suppose that the membrane gate surface G_M is the finite audit face obtained from the source-token row S, the dependency row D_A, the paper-Lean target-resolution row L, the origin/import row O, and the* GAP *row G_A of A. Then every boundary item refused by the corresponding* $\mathsf{AuditGateBoundary}^{\uparrow}$ *row remains refused by the membrane row R. In particular, a refused source axiom, forbidden host dependency, unresolved target name, untracked origin/import edge, or hidden global-correctness crossing has no exported route from M into substrate theorem content.*

Lean4 ✓ `BEDC.Derived.AuditMembraneUp.AuditMembraneUp StdBridge`

Proof. Project the gate-boundary packet by Definition 526.1. Its displayed audit face consists of the source-token row S, the dependency row D_A, the paper-Lean target row L, the origin/import row O, and the GAP row G_A, together with transport, continuation, provenance, and local naming rows.

The refusal content of these rows is fixed inside the gate-boundary packet. By Definition 526.2, source-axiom admission, forbidden host-dependency admission, unresolved marker names, untracked origin flow, global semantic conservativity, and host-kernel completeness are non-escaping objects for A. By Definition 526.3, the rows S and D_A decide the source-token and forbidden-dependency boundary displayed by A. By Definition 526.4, L permits only the named finite resolution result and gives no route through a nearby declaration or unresolved string. By Definition 526.5, O exposes only the finite origin/import ledger and gives no semantic conservativity

theorem for arbitrary import flow. The row G_A records the matching GAP boundary: the gate refuses the displayed boundary crossings and does not provide a hidden theorem of global correctness.

Now project the membrane packet by Definition 524.1. The hypothesis identifies its gate surface G_M with precisely the displayed audit face S, D_A, L, O, G_A read from A. Hence an item refused at the gate-boundary side is the same displayed boundary item when it is presented in the membrane boundary-content row B: source axioms are read through S, forbidden dependencies through D_A, target names through L, origin/import edges through O, and hidden global-correctness crossings through G_A.

By Definition 524.3, the membrane refusal row R is the complete public result of applying G_M to B. Therefore the classification already refused by the corresponding row of A cannot be changed by the membrane packet; it appears in R as refused boundary content rather than admitted substrate supply.

Finally, Definition 524.6 confines every downstream consumer of M to the finite rows $G_M, B, R, D_M, H_M, C_M, P$ These rows allow inspection, transport, replay, provenance, and local naming, but none of them exports a theorem object for refused boundary content. Thus every item refused by the instantiated $\mathsf{AuditGateBoundary}^{\uparrow}$ surface remains refused at the $\mathsf{AuditMembrane}^{\uparrow}$ boundary and cannot become substrate theorem content. □

Theorem 524.8 (AuditMembrane repeated consumer replay boundary)**.** *Let*

$$M = (G_M, B, R, D_M, H_M, C_M, P_M, N_M)$$

be an accepted $\mathsf{AuditMembrane}^{\uparrow}$ *packet. Any finite sequence of downstream reads of M factors through the same displayed rows $G_M, B, R, D_M, H_M, C_M, P_M, N_M$. Hence refused source axioms, forbidden dependencies, unresolved targets, and untracked origin edges remain refused under replay; no repeated consumer read exports them as substrate theorem content.*

Proof. Start with the refusal row. By Definition 524.3, the row R is the complete public result of applying the gate surface G_M to the boundary-content row B, and refused boundary content has no exported theorem route.

Now read a downstream consumer. The consumer boundary theorem, Definition 524.6, forces the read through the finite rows $G_M, B, R, D_M, H_M, C_M, P_M, N_M$ and provides no coordinate outside those rows.

For repeated reads, apply the same consumer-boundary factorization at each replay step. The refusal bridge of Definition 524.7 identifies the refused boundary items with the membrane refusal row, so replay cannot reclassify a refused source axiom, forbidden dependency, unresolved target, or untracked origin edge.

Thus every finite downstream replay remains inside the displayed membrane packet and preserves the refusal result. □

Chapter 525

A Concrete Naming Certificate for $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$

The $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ surface turns the recursor authorization principle of chapter 9373 into a finite NameCert packet. The packet records an accepted constructor signature, a legal eliminator name, complete branch data, structural descent evidence, output naming, audit provenance, and the visible boundary at which BEDC relies on the host kernel's acceptance of the recursor call. It does not add a new eliminator, a new induction principle, or a hidden source of proof terms outside the accepted signature.

The audit-provenance row A is the local consumer of the $\mathsf{OperationalMembrane}^{\uparrow}$ audit carrier in chapter 533. It reads source-axiom refusal, axiom-purity ancestry, and import-separation rows before the recursor output row O becomes public.

Definition 525.1 (AuthorizedGeneratorRecursor carrier)**.** *An* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N)$$

with the following displayed rows:

1. *I is the accepted constructor-signature row, naming the finite constructors of the inductive carrier and the strict-positivity gate that admits them;*
2. *E is the emitted eliminator row, naming the corresponding recursor I.rec as the only generator admitted by this packet;*
3. *M is the checked motive row, recording the output family or target judgment selected for the recursor call;*
4. *B is the branch-package row, containing exactly one accepted branch for each constructor listed by I;*
5. *D is the structural-descent row, recording the recursive arguments and the kernel-visible decrease or constructor subterm relation used by the call;*
6. *O is the output-name row, naming the term, proof object, or definition produced by the recursor call;*
7. *A is the audit-provenance row, recording the build check, source-axiom refusal, and transitive dependency refusal relevant to the generated output;*

8. *H records componentwise* hsame *transport for I, E, M, B, D, O, A, package provenance, boundary data, and the local naming row;*
9. *C records the displayed* Cont *routes by which downstream consumers read the signature, eliminator, motive, branch package, descent row, output name, and audit provenance;*
10. *P is the* Pkg *provenance over* BHist*, constructor signatures, recursor names, motive rows, branch packages, structural-descent rows, output names, audit reports,* hsame*,* Cont*,* GAP*, and* NameCert*;*
11. *G is the* GAP *boundary row recording that the packet relies on host-kernel acceptance of the displayed signature and recursor call, while refusing any unlisted branch, non-structural recursion channel, external axiom, or hidden proof-producing generator;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *row.*

The carrier contains no coordinate for an extra constructor, a missing branch, an unchecked motive, a non-decreasing recursive call, an output without a name, an unaudited dependency channel, or a proof term generated outside I.rec and the accepted constructor signature.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorTasteGate single carrier alignment`

Theorem 525.2 (AuthorizedGeneratorRecursor branch exhaustion)**.** *For an accepted* AuthorizedGeneratorRecursor *packet, the branch-package row B exhausts the generator surface named by E. Every public use of the packet reads one branch for each constructor displayed in I, transports those branches only through the componentwise row H, and cannot recover any additional branch or constructor case from the packet.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorBranchExhaustion`

Proof. Project the carrier of Definition 525.1. The constructor signature I and emitted eliminator E are displayed together, and B is declared to contain exactly one accepted branch for each constructor listed by I.

Read downstream access through C. A consumer reaches the branch package only by the displayed continuation route, so the public surface is the finite list already paired with I.

Transport through H preserves the same component rows. Since the tuple has no coordinate for an extra constructor or unlisted branch, the branch surface is exhausted by the entries already recorded in B. □

Theorem 525.3 (AuthorizedGeneratorRecursor NameCert surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *surface for the carrier of Definition 525.1 consists exactly of signature admission, recursor naming, motive checking, branch exhaustion, structural-descent visibility, output naming, audit provenance, componentwise transport, continuation locality, package provenance, and the displayed* GAP *boundary. A downstream consumer may treat O as a recursor-generated named output only through the packet*

$$(I, E, M, B, D, O, A, H, C, P, G, N).$$

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorNameCertSurface`

Proof. Carrier exposure supplies the finite tuple. The rows $I, E, M, B, D, O, A, H, C, P, G, N$ are the only rows admitted to the local NameCert surface.

Signature admission and recursor naming are read from I and E. Motive checking, branch exhaustion, and structural-descent visibility are read from M, B, D, with branch exhaustion supplied by Definition 525.2.

The output becomes public through O only after the audit row A, transport row H, continuation row C, package row P, boundary row G, and local certificate row N are retained. No coordinate in the packet can replace these rows with an unnamed proof term or an external generator. □

Theorem 525.4 (AuthorizedGeneratorRecursor audit boundary)**.** *An accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet binds the audit boundary for recursor-authorized proof generation. The packet certifies that the displayed output is public only as the named result of the accepted signature, emitted eliminator, checked motive, complete branch package, structural-descent row, and audit-provenance row. It does not certify kernel completeness, global termination theory, semantic conservativity for all inductive declarations, or any output whose dependency chain escapes the displayed audit provenance.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorAuditBoundary`

Proof. Start with the NameCert surface of Definition 525.3. It forces the output row O to be read together with the constructor signature, eliminator, motive, branch package, descent row, and audit row.

The boundary row G records the host-kernel handoff. It names the reliance on kernel acceptance of the signature and recursor call while refusing unlisted branches, non-structural recursion, external axioms, and hidden proof generators.

The excluded claims have no coordinate in the carrier. Therefore the packet gives a seed certificate for the displayed recursor-generated output and does not export global kernel completeness, unrestricted termination, general semantic conservativity, or an unaudited dependency surface. □

Theorem 525.5 (AuthorizedGeneratorRecursor structural descent locality)**.** *Every public recursive read of an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet factors through the displayed constructor signature I, emitted eliminator E, checked motive M, branch package B, and structural-descent row D. The packet admits no public recursive call whose descent is not recorded in D, and it admits no branch read outside the constructor list displayed by I and exhausted by B.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorUp structural descent locality`

Proof. Project the carrier

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

The only recursive generator named by the packet is the emitted eliminator row E, and it is paired with the constructor signature I, motive row M, branch package B, and descent row D.

Read access through C exposes those rows as the local public interface. By Definition 525.2, the branch package already contains exactly the public branches available for the constructors displayed in I.

The boundary row G refuses non-structural recursion and unlisted branches. Since the tuple has no coordinate for a second recursion channel, a non-decreasing recursive call, or an extra branch source, every public recursive read is local to I, E, M, B, D. □

Theorem 525.6 (AuthorizedGeneratorRecursor audit provenance factorization)**.** *For an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, the output row O becomes public only after the audit-provenance row A, componentwise transports H, continuation routes C, package row P, boundary row G, and local name row N are retained. Thus public output exposure factors through the audit boundary of Definition 525.4 and cannot be read as an unaudited recursor result.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorAuditProvenanceFactorizat`
Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursor audit provenance factorization`

Proof. Project the carrier and retain the rows O, A, H, C, P, G, N. The NameCert surface of Definition 525.3 states that O is part of the local certificate only inside the displayed packet.

Apply Definition 525.4. It binds the public output to the accepted signature, emitted eliminator, checked motive, complete branch package, structural-descent row, and audit-provenance row.

The rows H, C, P, G, N keep the transports, public routes, package provenance, boundary refusal, and local naming certificate attached to that exposure. No coordinate remains from which a consumer can read O apart from A, H, C, P, G, N, so the output factors through the displayed audit provenance. □

Theorem 525.7 (AuthorizedGeneratorRecursor ground-compiler handoff)**.** *The* `\origin{ai}` *TasteGate marker for this chapter is consumed only as the single-carrier alignment witness for the finite* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet. It does not replace the paper-side obligations for branch exhaustion, structural-descent locality, audit provenance factorization, or the visible handoff to the host kernel at G.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorGroundCompilerHandoff`

Proof. The checked TasteGate marker attached to Definition 525.1 identifies the chapter's finite carrier as the aligned object used by the recursor packet. It does not add a new theorem row to the carrier and does not alter the closure status of any paper-side claim.

Branch exhaustion is supplied by Definition 525.2. Structural-descent locality is supplied by Definition 525.5, and audit exposure is supplied by Definition 525.6.

The handoff to the ground compiler is therefore explicit: the TasteGate witness aligns the finite carrier, while the displayed rows $I, E, M, B, D, O, A, H, C, P, G, N$ continue to carry the branch, descent, provenance, and boundary obligations inside the paper. □

Theorem 525.8 (AuthorizedGeneratorRecursor host-kernel handoff)**.** *Every accepted* AuthorizedGeneratorRecursor *packet that reaches the host-kernel boundary row G first exposes the authorized generator branch row B, structural-descent row D, audit-provenance row A, visible* Cont *route C, and local* NameCert$_{\text{AuthorizedGeneratorRecurs}}$ *row N. The handoff exports no free induction principle, hidden branch source, or proof-producing generator outside the displayed constructor signature and accepted generator row.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorHostKernelHandoff`

Proof. Start with branch exhaustion and branch-descent totality, Definition 525.2 and Definition 525.13. They force public recursive reads to stay on the accepted constructor signature, branch package, and displayed descent row.

Use audit provenance factorization from Definition 525.6. It keeps public output attached to the audit row, continuation route, package provenance, boundary row, and local name row.

Finally cite the TasteGate handoff only as the single-carrier alignment witness, through Definition 525.7. Since the aligned carrier has no coordinate for a free induction principle or hidden generator, the host-kernel row G receives exactly the displayed branch, descent, audit, route, and local NameCert surface. □

Theorem 525.9 (AuthorizedGeneratorRecursor kernel-boundary exhaustion)**.** *Every public recursor read of an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet factors through exactly*

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

The read cannot introduce an unlisted constructor, a missing branch, a non-structural recursive call, an external axiom, or a hidden proof generator beyond the host-kernel boundary recorded by G.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorKernelBoundaryExhaustion`

Proof. Start from the carrier definition in Definition 525.1. It displays the full packet and leaves no coordinate outside $I, E, M, B, D, O, A, H, C, P, G, N$.

Branch coverage is exhausted by Definition 525.2, while the local NameCert surface is fixed by Definition 525.3. Thus a consumer may read only the listed constructor, eliminator, motive, branch, output, transport, route, package, boundary, and naming rows.

Structural recursion is confined by Definition 525.5. Audit exposure is confined by Definition 525.4 and Definition 525.6.

Finally apply Definition 525.7. The TasteGate handoff aligns the same finite carrier and does not add a constructor, branch, recursion channel, axiom row, or proof-producing generator outside the displayed kernel boundary. □

Theorem 525.10 (AuthorizedGeneratorRecursor output-name stability)**.** *For an accepted* AuthorizedGeneratorRec *packet, the output-name row O is stable only when the accepted signature I, eliminator E, motive M, branch package B, descent row D, audit row A, componentwise transports H, displayed routes C, boundary row G, and local name row N are transported together. A consumer cannot keep the public output name while replacing any one of these supporting rows by an unlisted row.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorOutputNameStability`

Proof. Project the carrier of Definition 525.1. The row O is not a standalone output; it is one coordinate of the displayed packet with $I, E, M, B, D, A, H, C, P, G, N$.

Use Definition 525.3 to read the output through the local certificate, and use Definition 525.2 with Definition 525.5 to keep the signature, branch package, and descent row attached to that read.

Now apply Definition 525.4 and Definition 525.6. They keep the audit row, transports, routes, package provenance, boundary row, and naming row attached before O becomes public.

The TasteGate handoff of Definition 525.7 consumes the same carrier. Therefore any transported public output name preserves the whole displayed packet surface, not a detached name row. □

Theorem 525.11 (AuthorizedGeneratorRecursor audit-row completeness)**.** *The audit row A is complete for the accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet in the following finite sense: before O is public, A must expose the build check, source-axiom refusal, dependency refusal, and operational-membrane provenance consumed by the packet. This audit completeness does not prove kernel completeness, global termination, or a proof generator outside the accepted recursor boundary.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorAuditRowCompleteness`

Proof. Begin with the carrier definition and its audit-provenance row. The displayed packet places A before public output exposure and ties it to $I, E, M, B, D, O, H, C, P, G, N$.

Apply Definition 525.4. It states that public output is certified only as the named result of the accepted signature, emitted eliminator, checked motive, complete branch package, structural-descent row, and audit-provenance row.

Next use Definition 525.6. The build check, source-axiom refusal, dependency refusal, operational provenance, transports, routes, boundary, and local name remain in the same packet before O is exposed.

Branch exhaustion, structural descent locality, and the TasteGate handoff are supplied by Definition 525.2, Definition 525.5, and Definition 525.7. Since the carrier has no coordinate for kernel completeness or global termination, the audit row is complete only for the finite packet boundary stated above. □

Theorem 525.12 (AuthorizedGeneratorRecursor operational membrane audit handoff)**.** *For an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, the audit row A must consume the* OperationalMembrane$^{\uparrow}$ *provenance before the output row O becomes public. The public output route therefore factors through the displayed build check, source-axiom refusal, dependency refusal, operational-membrane provenance, output-name row, and local* NameCert *row, all inside*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorOperationalMembraneAuditH`

Proof. Project the carrier of Definition 525.1. The row A records the build check, source-axiom refusal, dependency refusal, and operational-membrane provenance, while O is only the displayed output-name row of the same packet.

Apply Definition 525.4 and Definition 525.6. These rows place public exposure of O behind the audit boundary and keep A, H, C, P, G, N attached to that exposure.

Use Definition 525.10 with Definition 525.11. The output name cannot be transported apart from the audit row, and the audit row is complete only after it exposes the operational-membrane provenance consumed by the packet. □

Theorem 525.13 (AuthorizedGeneratorRecursor branch descent totality)**.** *For an accepted* AuthorizedGeneratorRe *packet, the accepted branch package B and structural-descent row D jointly exhaust all public recursive reads. A public read may reach the constructor signature, emitted eliminator, checked motive, accepted branches, descent evidence, output name, audit row, transports, routes, package provenance, boundary row, and local certificate, but it cannot read a recursive branch outside B or a recursive call whose descent is absent from D.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorBranchDescentTotality`

Proof. Start from the carrier definition. The only public recursive generator named by the packet is the emitted eliminator E, and the rows adjacent to it are the accepted signature I, checked motive M, branch package B, and descent row D.

Apply Definition 525.2. It says that B contains exactly the public branch surface associated with the constructors listed by I.

Apply Definition 525.5. It confines every public recursive read to the displayed signature, eliminator, motive, branch package, and structural-descent row.

The audit boundary and output-name stability, supplied by Definition 525.4 and Definition 525.10, keep the resulting public output attached to the same packet. Thus B and D jointly exhaust the recursive read surface. □

Theorem 525.14 (AuthorizedGeneratorRecursor hidden generator exclusion)**.** *No public route out of an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet can recover an unlisted constructor, unchecked branch, non-structural recursion channel, external axiom, or hidden proof generator. Every public route is a projection of the carrier rows $I, E, M, B, D, O, A, H, C, P, G, N$ together with the displayed* GAP *boundary.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorHiddenGeneratorExclusion`

Proof. Read the carrier definition and the boundary row G. The tuple has no coordinate for an extra constructor, unchecked branch, non-structural recursion channel, external axiom, or hidden proof-producing generator.

Use branch exhaustion and branch-descent totality. By Definition 525.2 and Definition 525.13, the public recursive surface is exhausted by the displayed constructors, accepted branches, and structural descent row.

Use audit provenance and output-name stability. By Definition 525.6, Definition 525.11, and Definition 525.10, public output remains attached to the audit row and cannot detach into an unaudited generator route.

Finally apply Definition 525.7. The checked carrier alignment is consumed only for the same finite packet, so it cannot add an external axiom or hidden generator beyond G. □

Theorem 525.15 (AuthorizedGeneratorRecursor scoped packet)**.** *The branch exhaustion row, local* NameCert *surface, structural-descent locality row, audit-provenance factorization row, operational-membrane audit handoff, branch-descent totality row, hidden-generator exclusion row,* GAP *boundary row, and checked TasteGate single-carrier handoff form the scoped finite packet for* AuthorizedGeneratorRecursor$^{\uparrow}$ *The packet exposes only the accepted constructor signature, emitted eliminator, checked motive, complete branch package, structural-descent row, named output, audit provenance, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance,* GAP *boundary, and local* NameCert *row.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorScopePackage`

Proof. Start with Definition 525.2 and Definition 525.3. They bind the constructor signature, emitted eliminator, motive, branch package, output name, transport, route, provenance, boundary, and local naming rows to the same finite carrier.

Next apply Definition 525.5. It keeps every public recursive read on the displayed signature, eliminator, motive, branch package, and structural-descent row.

Use Definition 525.4 and Definition 525.6 to attach the audit-provenance row and GAP boundary to the public output route.

Use Definition 525.12, Definition 525.13, and Definition 525.14. These rows make the operational audit handoff, the exhaustive recursive-read surface, and the refusal of hidden generators explicit inside the same packet.

Finally apply Definition 525.7. The checked TasteGate alignment row is read only as the existing single-carrier handoff, so the scoped packet remains the displayed finite tuple and does not export an unlisted branch, non-structural recursion channel, unaudited output, or hidden proof-producing generator. □

Theorem 525.16 (AuthorizedGeneratorRecursor signature route totality)**.** *Every public read of an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet is total only as a route through the accepted signature I, eliminator E, motive M, branch package B, descent row D, output name O, audit row A, componentwise transports H, displayed routes C, provenance row P,* GAP *row G, and local name N. No downstream recursor consumer can detach the public output from the accepted signature route.*

Proof. Start with Definition 525.2 and Definition 525.3. They bind the constructor signature, eliminator, motive, branch package, output name, transport, route, provenance, boundary, and local naming rows to one finite packet.

Next apply Definition 525.5. Every recursive read stays on the displayed signature, eliminator, motive, branch package, and descent row.

Finally use Definition 525.10 and Definition 525.14. The output name cannot be transported apart from the signature, descent, audit, and boundary rows, and the packet has no coordinate for a hidden generator. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorSignatureRouteTotality`

Theorem 525.17 (AuthorizedGeneratorRecursor output audit ledger)**.** *For an accepted* AuthorizedGeneratorRecurs *packet, the output name O is public only together with the audit row A, transports H, routes C, provenance P, boundary G, and local name N over the same I, E, M, B, D recursor route. The ledger refuses any public output whose dependency or audit provenance escapes the displayed packet.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorOutputAuditLedger`

Proof. Begin with Definition 525.4. It places the public output behind the accepted signature, emitted eliminator, checked motive, complete branch package, structural-descent row, and audit row.

Apply Definition 525.6 and Definition 525.12. These attach build checking, source-axiom refusal, dependency refusal, operational provenance, transports, routes, package provenance, boundary, and local naming before O is public.

Use Definition 525.10. It keeps O tied to the same $I, E, M, B, D, A, H, C, P, G, N$ rows, so the audit ledger cannot be bypassed by an unaudited output route. □

Theorem 525.18 (AuthorizedGeneratorRecursor public consumer boundary)**.** *Every downstream consumer of an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet reads the public boundary through $I, E, M, B, D, O, A, H, C, P, G, N$. The boundary contains branch coverage, structural descent, audit provenance, operational membrane handoff, output-name stability, and hidden-generator refusal, and it contains no unlisted branch, detached output name, non-structural recursion channel, external axiom, or proof-producing generator outside G.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorPublicConsumerBoundary`

Proof. First combine Definition 525.16 and Definition 525.17. The public consumer receives the accepted signature route and the audit ledger as one packet.

Next apply Definition 525.13 with Definition 525.12. These rows exhaust recursive branch reads and attach the operational membrane audit surface before the output is exposed.

Finally use Definition 525.14 and Definition 525.7. The checked carrier alignment is only the handoff for the same finite packet, so no unlisted branch, detached output, external axiom, or hidden proof generator can cross the public boundary. □

Theorem 525.19 (AuthorizedGeneratorRecursor root branch row totality)**.** *For an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet*

$$(I, E, M, B, D, O, A, H, C, P, G, N),$$

every branch row used by the recursor is exposed in the displayed branch packet B *before any output row* O *is public. The public output cannot be supplied by a hidden generator, an omitted branch, or a route outside the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootBranchRowTotality`

Proof. Start from the carrier definition and Definition 525.2. The accepted packet has one displayed constructor signature, emitted eliminator, checked motive, and complete branch package, so every recursive branch read is already accounted for in B.

Apply Definition 525.4 and Definition 525.17. These results place the output row behind the same signature, branch, descent, audit, transport, continuation, provenance, boundary, and local-name rows.

Finally use Definition 525.14 and Definition 525.18. They rule out a proof-producing generator or omitted branch coordinate outside the displayed packet, so O can become public only after branch totality has been read through B. □

Theorem 525.20 (AuthorizedGeneratorRecursor audit descent row)**.** *For an accepted* AuthorizedGeneratorRecursor *packet* $(I, E, M, B, D, O, A, H, C, P, G, N)$*, the structural descent row* D *and audit row* A *are read through the same* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *packet. Audit provenance therefore cannot detach from the recursor branch route, and no descent certificate may be consumed without the displayed audit boundary.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorAuditDescentRow`

Proof. Use the carrier definition together with Definition 525.5. The descent row belongs to the same finite tuple as the signature, eliminator, motive, and branch package, and every recursive read stays on those displayed coordinates.

Next apply Definition 525.4 and Definition 525.17. The audit row is exposed only through the continuation, transport, package, boundary, and local naming data attached to the same packet.

The non-detachment claim follows from Definition 525.14 and Definition 525.18. Since no hidden generator, omitted branch, or outside output route can cross the public boundary, the audit row and descent row remain one packet-local route. □

Theorem 525.21 (AuthorizedGeneratorRecursor NameCert root unblock package)**.** *The carrier row, branch-totality row, audit-descent row, hidden-generator exclusion, output audit ledger, and public consumer boundary form the root* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *obligation package for downstream consumers of the displayed packet* $(I, E, M, B, D, O, A, H, C, P, G, N)$*. A consumer may use the authorized recursor output only through that package.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorNameCertRootUnblockPackag`

Proof. First combine the carrier definition with Definition 525.19. The root package begins with the displayed packet and the complete branch surface that precedes public output.

Next use Definition 525.20 and Definition 525.17. These bind structural descent, audit provenance, output exposure, transport, route, and package provenance into one BHist-local NameCert object.

Finally apply Definition 525.14 and Definition 525.18. The downstream consumer receives exactly the displayed root package, with no unlisted branch, hidden generator, detached audit row, or outside public-output route. □

Theorem 525.22 (AuthorizedGeneratorRecursor accepted signature cover)**.** *Every public route exposing the emitted eliminator E, checked motive M, branch package B, structural descent row D, or output name O of an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet first exposes the accepted constructor-signature row I. Outside the I, E surface, the packet provides no unlisted constructor signature and no alternate eliminator.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorAcceptedSignatureCover`

Proof. Project the public carrier through Definition 525.3. The displayed surface lists $I, E, M, B, D, O, A, H, C, P, G$ as one finite packet, so the eliminator, motive, branch, descent, and output rows are not independent public entries.

Apply Definition 525.2. It keeps all branch reads on the accepted constructor signature and the emitted eliminator, so a consumer cannot obtain M, B, D, or O before the I, E route has been read.

Finally use Definition 525.14. The carrier has no coordinate for a hidden proof-producing generator, unlisted constructor, or alternate eliminator, so the accepted signature cover exhausts the public recursor route. □

Theorem 525.23 (AuthorizedGeneratorRecursor motive branch totality)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, the checked motive row M and branch package row B are consumed together with the structural descent row D. No branch can become public without the motive that types it and the descent row that authorizes its recursive reads.*

Proof. Start with Definition 525.5. It places every public recursive read on the same signature, eliminator, motive, branch package, and structural-descent row.

Next apply Definition 525.13. The branch surface is exhaustive only as a package over the checked motive and the descent row, so no single branch can be projected as a public route apart from M and D.

Use Definition 525.10. The output name remains tied to the same I, E, M, B, D route, which prevents a branch consumer from exporting a detached branch result under a stable public name. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorMotiveBranchTotality`

Theorem 525.24 (AuthorizedGeneratorRecursor GAP boundary refusal)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, the* GAP *boundary row G refuses external axioms, hidden proof generators, non-structural recursion, and unlisted branches. The output name O becomes public only through the audit row A, transports H, routes C, provenance P, boundary G, and local name N.*

Proof. Begin with Definition 525.4. It places public output behind the accepted signature route, checked motive, complete branch package, structural descent, and audit row.

Apply Definition 525.6. The audit provenance factors through the displayed transport, route, package, and boundary rows, so O has no public path that bypasses A, H, C, P, G, N.

Next use Definition 525.12. The operational membrane reads the same finite packet and does not add a non-structural recursion channel or an unlisted branch.

Finally apply Definition 525.14. Since the carrier has no hidden proof-generator coordinate, the GAP row is the public refusal boundary for external axioms, hidden generators, non-structural recursion, and branch escape. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorGapBoundaryRefusal`

Theorem 525.25 (AuthorizedGeneratorRecursor output boundary non-escape)**.** *For an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, the output row O cannot be read apart from the accepted signature I, emitted eliminator E, checked motive M, branch package B, structural-descent row D, audit row A, transports H, routes C, provenance P, boundary row G, and local name N. The packet exports no detached output, hidden generator, external proof term, or output route outside these displayed rows.*

Proof. Start from branch exhaustion and the local NameCert surface. Definition 525.2 and Definition 525.3 force the output read to retain the accepted signature, eliminator, motive, complete branch package, descent row, output naming row, audit provenance, routes, package provenance, boundary row, and local certificate.

Next use audit boundary, audit provenance, and output-name stability. Definition 525.4, Definition 525.6, and Definition 525.10 keep O attached to A, H, C, P, G, N before it is exposed.

Finally apply audit-row completeness, branch descent totality, hidden-generator exclusion, and the TasteGate handoff. Definition 525.11, Definition 525.13, Definition 525.14, and Definition 525.7 leave no coordinate for a detached output or proof-producing generator. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorOutputBoundaryNonescape`

Theorem 525.26 (AuthorizedGeneratorRecursor GAP boundary totality)**.** *Every host-kernel handoff through the boundary row G of an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet is preceded by the signature row I, branch package B, structural-descent row D, audit row A, displayed route row C, package row P, and local* NameCert *row N. The* GAP *boundary receives only the displayed recursor packet and never receives a hidden branch source, unchecked descent claim, unaudited dependency channel, or proof-producing generator outside the packet.*

Proof. Begin with the host-kernel boundary rows. Definition 525.8 sends any G-read through the branch, descent, audit, route, and local certificate rows, while Definition 525.16 attaches the signature route to the same packet.

Use the audit and branch synchronization supplied by the chapter. Definition 525.6, Definition 525.11, and Definition 525.13 place the audit, package, branch, and descent rows before any boundary exposure.

Finally use hidden-generator exclusion and the TasteGate handoff. Definition 525.14 blocks external generators, and Definition 525.7 reads the checked carrier alignment only as the finite packet handoff. Thus the G boundary is total for the displayed signature, branch, descent, audit, route, package, and naming rows. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorGapBoundaryTotality`

Theorem 525.27 (AuthorizedGeneratorRecursor audit branch synchronization)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, branch exhaustion and audit provenance are synchronized before any public output exposure. A consumer that reads O must first read the complete branch package B, structural-descent row D, audit row A, operational audit handoff, output-name row, transports, routes, provenance, boundary row, and local name together, and it cannot separate the audit ledger from the public branch descent route.*

Lean4 ✓ BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorAuditBranchSynchronizatio

Proof. First synchronize the branch rows. Definition 525.2 and Definition 525.13 exhaust public recursive reads through the accepted branch package and structural descent row.

Next synchronize the audit rows. Definition 525.4, Definition 525.6, Definition 525.11, and Definition 525.12 place audit provenance before public exposure of O.

Finally attach output naming and the public handoff. Definition 525.10, Definition 525.14, and Definition 525.7 prevent a detached output name, hidden generator, or carrier-alignment read from bypassing the synchronized branch and audit rows. □

Theorem 525.28 (AuthorizedGeneratorRecursor kernel acceptance scope)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, any public host-kernel handoff through the boundary row G is scoped by the displayed rows $I, E, M, B, D, O, A, H, C, P, N$. The handoff authorizes only the finite carrier tuple of Definition 525.1; it cannot be read as an unbounded eliminator principle, a global induction rule, or a public recursion channel outside those rows.*

Lean4 ✓ BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorKernelAcceptanceScope

Proof. Project the carrier tuple $(I, E, M, B, D, O, A, H, C, P, G, N)$. The rows I, E, M, B, D give the accepted signature, emitted eliminator, checked motive, branch package, and structural descent surface, while O, A, H, C, P, N give the named output, audit row, transports, routes, provenance, and local certificate.

Use branch exhaustion and structural locality. By Definition 525.2 and Definition 525.5, every public recursive read stays on the accepted constructor signature, the checked motive, the branch package, and the structural-descent row.

Attach the audit and output rows. Apply Definition 525.4 and Definition 525.10; public exposure of O remains behind the audit surface and cannot keep a stable name after any supporting row is detached.

Finally use hidden-generator exclusion and the ground-compiler handoff. Definition 525.14 and Definition 525.7 leave no carrier coordinate for an unbounded eliminator, global induction rule, or external recursion source beyond the displayed G handoff. □

Theorem 525.29 (AuthorizedGeneratorRecursor branch motive pairing)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, the motive row M and branch row B are paired constructor-by-constructor against the accepted signature row I. A downstream recursor consumer may not detach a branch from the motive that types it or from the constructor case in I that it covers.*

Lean4 ✓ BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorBranchMotivePairing

Proof. Project the same carrier tuple and read the I, M, B, D coordinates together. The accepted signature supplies the constructor cases, the motive supplies the target family for those cases, the branch row supplies the case data, and the descent row supplies the legal recursive reads.

Apply branch exhaustion and structural descent locality. By Definition 525.2 and Definition 525.5, branch coverage is exhausted only as a package over the accepted constructors and the checked motive, with recursive reads confined to the displayed descent row.

Use the audit boundary and output-name stability to make the pairing public. Definition 525.4 places output exposure behind the same I, M, B, D, A packet, and Definition 525.10 prevents a stable public output from retaining B while dropping M or I.

Finally cite hidden-generator exclusion and the ground-compiler handoff. Definition 525.14 blocks a replacement branch source, and Definition 525.7 reads the TasteGate alignment only for the finite packet. Hence each branch remains paired with its motive and constructor case. □

Theorem 525.30 (AuthorizedGeneratorRecursor audit dependency refusal)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, the audit row A refuses external axiom channels and hidden dependency surfaces before the output row O becomes public. The refusal is the same operational-membrane route used by Definition 525.12 and the same audit boundary used by the displayed packet.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorAuditDependencyRefusal`

Proof. Project $(I, E, M, B, D, O, A, H, C, P, G, N)$. The audit row is not a detached label: it is packaged with the accepted signature, emitted eliminator, motive, branch data, structural descent, transports, routes, provenance, boundary, and local certificate before O is exposed.

Use branch exhaustion and structural locality first. By Definition 525.2 and Definition 525.5, any dependency surface visible to a public branch read is already confined to the accepted constructors, motive, branch package, and descent row.

Now apply the audit boundary and the operational membrane handoff. Definition 525.4 and Definition 525.12 place public exposure of O behind the build check, source-axiom refusal, dependency refusal, and operational-membrane provenance carried by A.

Close the dependency refusal with output-name stability, hidden-generator exclusion, and the ground-compiler handoff. Definition 525.10, Definition 525.14, and Definition 525.7 prevent a stable output name, hidden generator, or host-kernel handoff from bypassing the audited dependency surface. □

Theorem 525.31 (AuthorizedGeneratorRecursor branch-ledger disjointness)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, a row consumed as branch data in B cannot also be consumed as an audit row in A or as a structural-descent row in D. The public recursor surface keeps branch coverage, descent reads, and audit provenance as disjoint displayed ledger roles inside the single carrier.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorBranchLedgerDisjointness`

Proof. Project the carrier $(I, E, M, B, D, O, A, H, C, P, G, N)$ of Definition 525.1. The branch, descent, and audit coordinates are separately named rows of the finite packet, and their consumer roles are introduced by the local NameCert surface rather than by a shared ambient row.

Use Definition 525.2 for the branch side and Definition 525.5 for the descent side. These theorems confine branch coverage to the accepted constructor and motive rows, while descent reads remain tied to the displayed structural-decrease row.

For the audit side, apply Definition 525.4 and Definition 525.6. They expose A only as the provenance and refusal surface behind public output, not as branch payload or recursive descent data.

Finally Definition 525.7 reads the same separated carrier coordinates at the TasteGate handoff. Thus no public consumer can reclassify a branch row as audit or descent while retaining an accepted AuthorizedGeneratorRecursor$^{\uparrow}$ packet. □

Theorem 525.32 (AuthorizedGeneratorRecursor descent-output lock)**.** *For every accepted* AuthorizedGeneratorRec *packet, the public output row O remains locked to the displayed structural-descent row D. A consumer may expose O only through the same finite descent ledger that licensed the recursive reads used by the packet.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorDescentOutputLock`

Proof. Read O and D from the carrier of Definition 525.1. The output row is not a detached result name: it is packaged with the accepted signature, motive, branch data, structural descent, audit surface, transports, routes, provenance, and local certificate.

Apply Definition 525.5. Every recursive read used by the packet is confined to the displayed structural descent row D.

Next combine Definition 525.13 with Definition 525.10. Branch coverage supplies public output only together with its descent obligations, and the output name loses stability if the supporting descent row is detached.

The audit boundary and ground-compiler handoff preserve the same lock. Definition 525.4 keeps public exposure behind the finite packet, and Definition 525.7 transfers only that packet to the TasteGate surface. Hence O cannot be exposed apart from the structural descent row D. □

Theorem 525.33 (AuthorizedGeneratorRecursor audit-provenance cover)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, each public exposure of the output row O consumes the audit provenance rows already listed in the carrier. No output exposure may cite an external audit source or omit the displayed provenance factorization.*

Proof. Begin with the carrier inventory in Definition 525.1. The audit row A and provenance row P are displayed before any public route exposes O, and the local certificate names them as part of the same finite packet.

Apply Definition 525.4. Public output exposure is behind the audit boundary, so it must pass through the displayed audit surface.

Use Definition 525.6 to resolve that surface into the provenance rows already carried by P and A. The operational route of Definition 525.12 then presents the same provenance to the consumer side.

Finally Definition 525.7 permits the ground compiler to read only the finite carrier packet. Therefore every public exposure of O consumes the listed audit provenance rows and cannot draw authority from an external audit channel. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier audit provenance cover`

Theorem 525.34 (AuthorizedGeneratorRecursor carrier admission)**.** *Every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *root packet is admitted only as the finite* BHist *row*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N)$$

of Definition 525.1. The rows I, E, M, B, D, O, A display the accepted signature, emitted recursor, motive, branch package, structural descent, output name, and audit provenance, while H, C, P, G, N supply the componentwise hsame *transport, displayed* Cont *routes,* Pkg *provenance, visible boundary, and local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *row.*

Proof. Project the carrier definition. It lists exactly the rows $I, E, M, B, D, O, A, H, C, P, G, N$ and admits no additional source for an authorized generator or recursor call.

Apply Definition 525.3. The local NameCert surface reads the accepted signature, emitted eliminator, checked motive, complete branch package, structural descent, output row, and audit row only inside the same finite packet.

The remaining rows are structural rather than generative. The hsame, Cont, Pkg, boundary, and local NameCert rows record transport, replay, provenance, the visible host boundary, and naming for the displayed carrier, so carrier admission is exhausted by the finite BHist row. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier admission surface`

Theorem 525.35 (AuthorizedGeneratorRecursor ledger descent)**.** *Every public ledger read of an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *root packet descends through the displayed generator and recursor rows*

$$I \to E \to M \to B \to D \to O \to A$$

before it may reach the componentwise hsame *row* H*, displayed* Cont *row* C*,* Pkg *row* P*, boundary row* G*, or local* NameCert *row* N*. The descent cannot be replaced by an unregistered branch ledger, hidden output source, or external recursor certificate.*

Proof. Start from carrier admission in Definition 525.34. The admitted BHist packet exposes the accepted signature and emitted recursor before motive checking, branch coverage, structural descent, output naming, and audit provenance.

Use Definition 525.5 and Definition 525.13. These rows force branch consumption through the structural descent coordinate D and keep the output row attached to the displayed branch package rather than to an external ledger.

Finally apply the NameCert surface. The rows H, C, P, G, N only transport, replay, package, bound, and name the same route, so no hidden branch ledger or external recursor certificate can replace the displayed descent chain. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorLedgerDescent`

Theorem 525.36 (AuthorizedGeneratorRecursor consumer nonescape)**.** *No downstream consumer of an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *root packet can demand an unregistered recursion principle, hidden host induction, unchecked generator row, or proof-producing branch source outside the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. Every consumer-facing read must factor through carrier admission and ledger descent for* $R = (I, E, M, B, D, O, A, H, C, P, G, N)$*.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorConsumerNonescape`

Proof. First use carrier admission to identify the finite packet and ledger descent to identify the only route by which the accepted generator and recursor rows reach the output and audit rows.

Next apply Definition 525.14. It rules out a hidden generator source beyond the accepted constructor signature, emitted eliminator, motive, complete branch package, descent row, output row, audit row, and local certificate.

It remains to account for consumers. The public consumer boundary of Definition 525.18 and the root consumer factorization of Definition 525.52 keep every downstream read inside the same BHist, hsame, Cont, Pkg, and NameCert surface. Hence an unregistered recursion principle or hidden host induction has no coordinate through which to enter the packet. □

Corollary 525.37 (AuthorizedGeneratorRecursor admission strict obstruction)**.** *Let*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N)$$

be an accepted AuthorizedGeneratorRecursor$^{\uparrow}$ *root packet. Suppose a displayed failure, refusal, separation, or countermodel row is cited against a named converse or reuse route in the root admission surface of* R*. Then that row is a strict local obstruction: it blocks only the named route whose consumer-facing read tries to add, omit, replace, detach, or bypass one of the displayed admission coordinates*

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

Every permitted consumer-facing use factors through the finite BHist *carrier, the componentwise* hsame *transport row, the displayed* Cont *routes, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecurs}}$ *row. The same displayed row cannot be reinterpreted as a global impossibility, a host theorem about recursor admission, hidden external validation of the failed route, an unregistered recursion principle, hidden host induction, an unchecked generator row, or an off-packet proof-producing branch source.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorAdmissionStrictObstructio`

Proof. Carrier admission, Definition 525.34, fixes the admitted object as the single finite BHist row

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

The generative part of admission is exhausted by I, E, M, B, D, O, A: accepted signature, emitted recursor, checked motive, branch package, structural descent, output name, and audit provenance. The remaining rows H, C, P, G, N are structural admission data: componentwise transport, displayed continuation routes, package provenance, visible boundary, and local naming. Thus admission supplies no coordinate for a second generator, an omitted branch source, a host-side recursion theorem, an external validation channel, or an off-packet proof producer.

Consumer nonescape, Definition 525.36, turns that carrier statement into the consumer-facing constraint. Every downstream read must factor through carrier admission and ledger descent for the same R, and no consumer may demand an unregistered recursion principle, hidden host induction, unchecked generator row, or proof-producing branch source outside the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Now consider the displayed failure, refusal, separation, or countermodel row. If the named converse or reuse route asks for one of the listed coordinates and the displayed row denies that read, the obstruction blocks that named route at that coordinate. If the same route instead asks to read a global impossibility, a host recursor theorem, hidden external validation, an unregistered recursion principle, hidden host induction, an unchecked generator row, or an off-packet proof-producing branch source, it asks for a coordinate absent from carrier admission and rejected by consumer nonescape. Hence the displayed row has force only as local data against the named route, while every listed consumer read that remains on $I, E, M, B, D, O, A, H, C, P, G, N$ stays within the accepted packet. □

Theorem 525.38 (AuthorizedGeneratorRecursor root authorization downstream surface)**.** *Every downstream read of an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *root packet is authorized only through the finite carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

The authorization row, output audit row, componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, host-boundary row, and local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *row must remain in the same* BHist *packet before a consumer may read the emitted recursor, branch package, structural descent, or output row.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootAuthorizationDownstre`

Proof. Begin with Definition 525.34. It admits the root object only as the displayed finite carrier and leaves no separate authorization channel.

Apply Definition 525.35 and Definition 525.36. Together they force downstream consumers to traverse the accepted signature, emitted recursor, motive, branch package, descent row, output

row, audit row, transport, continuation, provenance, boundary, and local naming rows in one packet.

Finally use the root obligation surfaces in Definition 525.76 and Definition 525.81. The output audit and authorization ledgers therefore reach downstream consumers only through finite BHist, hsame, Cont, Pkg, and NameCert rows. □

Theorem 525.39 (AuthorizedGeneratorRecursor Real stream handoff row)**.** *If an accepted* AuthorizedGeneratorRec *packet is used by an L10* Real$^{\uparrow}$, StreamName$^{\uparrow}$, *or* RegSeqRat$^{\uparrow}$ *consumer, then the handoff is the same authorized route* $I, E, M, B, D, O, A, H, C, P, G, N$. *The Real, stream-name, and regular-rational data may enter only as finite source rows carried by the displayed* BHist, *transported by* hsame, *replayed by* Cont, *packaged by* Pkg, *and named by the local* NameCert *row; no selected Real limit, quotient stream equality, host evaluation, or detached generator state is exported.*

Proof. Start with Definition 525.203. It already places every L10 Real, stream-name, and regular-rational read on the displayed packet.

Use Definition 525.86 to keep the output row behind the same authorized carrier before any downstream consumer receives it.

Finally apply Definition 525.38. The handoff row is therefore a finite authorized route with audit, transport, continuation, package, boundary, and local naming data, not a host-side stream or Real interface. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRealStreamHandoffRow`

Theorem 525.40 (AuthorizedGeneratorRecursor closed substitution gate row)**.** *The closed-substitution gate for an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet opens only after authorization, branch coverage, structural descent, output audit, Real/StreamName/RegSeqRat handoff,* hsame *transport,* Cont *replay,* Pkg *provenance, host-boundary exposure, and local* NameCert *certification are all present in the finite route* $I, E, M, B, D, O, A, H, C, P, G, N$. *It cannot be opened by unrestricted substitution, unchecked recursion, external proof generation, host equality, or a private audit channel.*

Proof. First read the closed-substitution handoff of Definition 525.86. It keeps closed-substitution consumers on the displayed route and excludes unrestricted substitution and external proof generation.

Next attach the L10 handoff row from Definition 525.39. This supplies the Real, stream-name, and regular-rational source rows without leaving the finite carrier.

The gate is then closed by Definition 525.38 together with Definition 525.204. Authorization, audit, transport, continuation, provenance, boundary, and naming all remain packet-local, so there is no coordinate for unchecked recursion, host equality, or a private audit channel. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorClosedSubstitutionGateRow`

Lemma 525.41 (AuthorizedGeneratorRecursor root authorization bridge determinacy)**.** *Let an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *root packet be consumed through any downstream route, componentwise transport, readback, or L10 handoff. Then that consumer-facing bridge is determined by the finite carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

The route part factors through I, E, M, B, D, O, A, *the transport and readback part factors through* H, C, P, *and the boundary-certificate part factors through* G, N. *For an L10* Real$^{\uparrow}$, StreamName$^{\uparrow}$, *or* RegSeqRat$^{\uparrow}$ *consumer, the source rows may enter only as packet-local* BHist, hsame, Cont,

Pkg, *boundary, and local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *data. No unlisted bridge coordinate is available for a selected Real limit, quotient stream equality, host evaluation, detached generator state, private audit row, off-packet readback, second transport, or second local naming certificate.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootAuthorizationBridgeDe`

Proof. Start with the root authorization downstream surface, Definition 525.38. It authorizes every downstream read of an accepted root packet only through the finite carrier $R = (I, E, M, B, D, O, A, H, C, P, G, N)$. The same theorem requires the authorization row, output audit row, componentwise hsame transport, displayed Cont replay, Pkg provenance, host-boundary row, and local $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ row to remain in one BHist packet before the emitted recursor, branch package, structural descent, or output row can be read. Thus any consumer-facing bridge already has its route side confined to I, E, M, B, D, O, A and its audit-facing continuation confined to the displayed packet.

Apply the Real stream handoff row, Definition 525.39. It says that every L10 $\mathsf{Real}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, or $\mathsf{RegSeqRat}^{\uparrow}$ use of the accepted packet is the same authorized route $I, E, M, B, D, O, A, H, C, P, G, N$. Its source data enter only as finite rows carried by BHist, transported by hsame, replayed by Cont, packaged by Pkg, and named by the local NameCert row. Hence a Real, stream-name, or regular-rational reading is not an additional bridge coordinate; it is the same route with the source rows read through H, C, P, G, N.

The two cited surfaces cover all bridge forms named in the statement. A displayed route is covered by the carrier rows and authorization ledger of Definition 525.38. A componentwise transport is exactly the retained hsame row H, a readback is exactly the displayed Cont replay and Pkg provenance rows C, P, and an L10 handoff is exactly the specialization supplied by Definition 525.39. The host boundary and local naming side is exhausted by G, N in the same packet.

It remains to exclude alternate bridges. Any selected Real limit, quotient stream equality, host evaluation, detached generator state, private audit row, off-packet readback, second transport, or second local naming certificate would have to be either a row of R or an exported interface allowed by the L10 handoff. The carrier displays no such row, and Definition 525.39 explicitly keeps the L10 data inside finite BHist, hsame, Cont, Pkg, boundary, and local NameCert rows. Therefore every consumer-facing route, transport, readback, or handoff factors through the cited local rows, while unlisted bridge coordinates remain unavailable. □

Corollary 525.42 (AuthorizedGeneratorRecursor root authorization determinacy)**.** *Let*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N)$$

be the fixed finite carrier of an accepted $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *root packet. Once the authorization row, output audit row, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, host-boundary row, and local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *row of R are fixed, every accepted consumer-facing use of root authorization must use the same chapter-named finite route, packet-local normal-form reading, or exactness decision. The route side is fixed by I, E, M, B, D, O, A, the transport and readback side is fixed by H, C, P, and the boundary-certificate side is fixed by G, N. Hence two accepted consumers over the fixed rows cannot choose different authorization coordinates, a detached normal-form source, an off-packet readback, a private audit channel, a second transport, a second local naming certificate, or a duplicate classifier source.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier root authorization determinacy`

Proof. First apply Definition 525.38. It authorizes every downstream read of an accepted root packet only through the displayed finite carrier $R = (I, E, M, B, D, O, A, H, C, P, G, N)$, and it requires the authorization row, output audit row, componentwise hsame transport, displayed Cont replay, Pkg provenance, host-boundary row, and local $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ row to remain in the same BHist packet before a consumer may read the emitted recursor, branch package, structural descent, or output row. Thus an accepted consumer-facing route, normal-form reading, or exactness decision has no starting point outside those packet rows: it must read the recursor, descent, output, audit, transport, continuation, provenance, boundary, and local certificate as one finite surface.

Now use Definition 525.41. That lemma separates the fixed packet into the relevant roles. The route part factors through I, E, M, B, D, O, A, the transport and readback part factors through H, C, P, and the boundary-certificate part factors through G, N. It also covers the L10 $\mathsf{Real}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{RegSeqRat}^{\uparrow}$ handoff by forcing those source rows to enter only as packet-local BHist, hsame, Cont, Pkg, boundary, and local $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ data. Therefore a consumer-facing normal-form reading or exactness decision is not an independent classifier; it is the same fixed route read through the displayed transport, readback, provenance, boundary, and certificate rows.

It remains to rule out competing choices. Any alternate authorization coordinate, detached normal-form source, off-packet readback, private audit channel, second transport, second local naming certificate, or duplicate classifier source would have to supply either an additional row of R or an exported consumer interface not mediated by the rows named above. The downstream surface supplies no such row, and the bridge-determinacy lemma explicitly excludes unlisted bridge coordinates for selected Real limits, quotient stream equality, host evaluation, detached generator state, private audit rows, off-packet readbacks, second transports, and second local naming certificates. A duplicate classifier source would enter only through one of those excluded interfaces or through a carrier coordinate outside R. Since the rows of R are fixed and every accepted consumer use factors through them, all accepted consumers determine the same finite route and the same packet-local normal-form or exactness decision named by the chapter. □

Theorem 525.43 (AuthorizedGeneratorRecursor root branch row exposure)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

the root branch row B is exposed before any downstream closed-normal or generator-audit consumer may read the output row O. The exposure is a projection of the carrier of Definition 525.1 through the local NameCert surface of Definition 525.3, and it is exhaustive by Definition 525.2.

Proof. Project the displayed packet $R = (I, E, M, B, D, O, A, H, C, P, G, N)$ from Definition 525.1. The branch row B is one of its public coordinates, not a hidden generator source.

Apply the local NameCert surface. It exposes the output only together with the accepted signature, emitted eliminator, checked motive, branch package, structural descent, audit, transport, route, provenance, boundary, and local name rows.

Finally use branch exhaustion. The branch row contains exactly the public branch surface for the constructors displayed in I, so a downstream consumer cannot read O while bypassing B or inventing an additional branch row. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootBranchRowExposure`

Theorem 525.44 (AuthorizedGeneratorRecursor root descent row exposure)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

the structural-descent row D is exposed on every root-facing recursive read. The exposure is a projection of Definition 525.1 through Definition 525.3, and the locality of that row is forced by Definition 525.5.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootDescentRowExposure`

Proof. Read the carrier row D from $R = (I, E, M, B, D, O, A, H, C, P, G, N)$. It is displayed beside the accepted signature, emitted eliminator, checked motive, branch package, output name, audit row, and structural rows.

Use the NameCert surface to keep D attached to every public recursive read. The surface does not expose a recursive route whose descent evidence is absent from the packet.

Apply structural descent locality. It confines public recursion to the displayed signature, eliminator, motive, branch package, and descent row, so closed-normal and generator-audit consumers receive D before they can use O as an authorized recursor output. □

Theorem 525.45 (AuthorizedGeneratorRecursor root audit boundary exposure)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

the audit-boundary rows A, H, C, P, G, N are exposed before any root consumer reads O as a recursor-authorized output. The exposure is a projection of Definition 525.1 through Definition 525.3, and it factors through Definition 525.6 together with the audit boundary of Definition 525.4.

Proof. Project A, H, C, P, G, N from the displayed packet. These rows carry audit provenance, componentwise transport, displayed continuation routes, package provenance, the GAP boundary, and the local name row.

Apply the NameCert surface. It exposes the output row only inside the same finite carrier as the branch, descent, audit, transport, route, provenance, boundary, and naming rows.

Use the audit boundary and audit provenance factorization. They place public output behind the accepted signature, emitted eliminator, checked motive, complete branch package, structural descent, audit provenance, continuation route, package row, boundary row, and local certificate, so no root consumer receives an unaudited recursor result. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootAuditBoundaryExposure`

Theorem 525.46 (AuthorizedGeneratorRecursor root output audit totality)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, every public read of the output row O passes through the accepted constructor signature I, emitted eliminator E, checked motive M, branch package B, structural-descent row D, audit row A, transport row H, continuation row C, package provenance P, host-kernel boundary row G, and local name row N. Thus the public output is total only as the displayed NameCert packet*

$$(I, E, M, B, D, O, A, H, C, P, G, N),$$

not as a detached recursor result.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursor root output audit totality`

Proof. Start with the carrier and branch surface. The carrier of Definition 525.1 displays all rows named in the conclusion, and Definition 525.2 forces each branch read to stay on the constructor signature I, eliminator E, checked motive M, and branch package B.

Next add the recursive and audit rows. Definition 525.5 confines public recursive reads to the displayed descent row D, while Definition 525.4 places public exposure of O behind the audit row A.

It remains to keep the public output attached to the downstream rows. Definition 525.6 retains H, C, P, G, N at the output boundary, and Definition 525.10 prevents a stable public output from dropping the signature, motive, branch, descent, or audit rows. Therefore every public read of O consumes the whole displayed packet. □

Theorem 525.47 (AuthorizedGeneratorRecursor root boundary nonescape)**.** *Once an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet reaches the host-kernel boundary row G, it exports no free induction principle, no hidden proof generator, no external axiom channel, and no unaudited dependency route. The only public generator authority remaining at G is the accepted recursor call named by E over the finite rows $(I, M, B, D, O, A, H, C, P, N)$.*

Proof. First isolate the hidden-generator case. Definition 525.14 excludes any proof-producing source outside the accepted signature and recursor row.

The host-kernel handoff preserves that exclusion rather than widening it. Definition 525.7 reads the TasteGate marker only as the single-carrier alignment witness for the finite packet, so G does not export a second induction principle or a new proof generator.

Finally apply the audit refusal surface. Definition 525.30 blocks external axiom channels and hidden dependency routes before O becomes public. Hence a packet that has reached G has no non-displayed route by which generator authority, axiom authority, or audit authority can escape the carrier. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootBoundaryNonescape`

Theorem 525.48 (AuthorizedGeneratorRecursor root NameCert consumer readiness)**.** *The rows*

$$(I, E, M, B, D, O, A, H, C, P, G, N)$$

of an accepted $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet form the root consumer-readiness surface for downstream closed-normal and generator-audit packets. A downstream consumer may cite this surface only as the conjunction of root output audit totality, root boundary nonescape, the* $\mathsf{OperationalMembrane}^{\uparrow}$ *audit handoff of chapter 533, and the local TasteGate alignment marker attached to Definition 525.1.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootNameCertConsumerReadi`

Proof. The output side is supplied by Definition 525.46. It requires every public read of O to consume the accepted signature, eliminator, motive, branch, descent, audit, transport, continuation, provenance, boundary, and local name rows.

The nonescape side is supplied by Definition 525.47. It prevents the same packet from exporting a free induction principle, hidden proof generator, external axiom channel, or unaudited dependency route after the boundary row G is reached.

The audit handoff is the local consumer of chapter 533. Together with Definition 525.12 and the displayed TasteGate alignment marker, it makes the packet ready for downstream closed-normal and generator-audit consumers without granting any authority beyond the finite NameCert surface. □

Theorem 525.49 (AuthorizedGeneratorRecursor obligation triad)**.** *For every accepted* AuthorizedGeneratorRecurso *packet* $R = (I, E, M, B, D, O, A, H, C, P, G, N)$*, obligation closure is reached only through the triad of branch-package exhaustion over* I, E, B*, structural-descent locality over* M, D*, and audit-provenance factorization over* O, A, H, C, P, G, N*. No output row* O *may be public when any one of these three components is absent from the same carrier packet.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorObligationTriad`

Proof. Read the packet coordinates from Definition 525.1. The carrier presents one finite surface, so branch data, descent data, audit provenance, routes, package provenance, boundary rows, and the local certificate are consumed as coordinates of the same accepted packet.

The first component is branch coverage. Apply Definition 525.2 to force the public branch package to exhaust the constructors displayed by I and the emitted eliminator row E.

The second component is descent locality. Apply Definition 525.5 to keep recursive reads on the motive and structural-descent rows M, D, rather than on a detached generator route.

The third component is audit provenance. Use Definition 525.6 and Definition 525.33 to attach public exposure of O to the audit, transport, continuation, provenance, boundary, and local naming rows A, H, C, P, G, N.

Finally Definition 525.7 transfers only this finite packet to the TasteGate handoff. If one triad component is missing, the handoff has no carrier coordinate licensing a public output row, so obligation closure cannot expose O. □

Theorem 525.50 (AuthorizedGeneratorRecursor root normalization boundary)**.** *Let* $R = (I, E, M, B, D, O, A, H,$ *be an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet. Any public output row* O *consumed by a normalization or closed-substitution consumer must first pass through the accepted signature rows* I, E, M*, branch coverage* B*, structural descent* D*, audit provenance* A, H, C, P*, the ground-compiler boundary* G*, and the sibling* ClosedTermSubstitutionBoundary$^{\uparrow}$ *rows named by chapter 527. The consumer then reaches* MetaCICNormalizationFrontier$^{\uparrow}$ *only as a finite boundary route, not as an output detached from the authorized generator packet.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootNormalizationBoundary`

Proof. Start from the local carrier and readiness rows. The carrier of Definition 525.1 displays $I, E, M, B, D, O, A, H, C, P, G, N$, while Definition 525.46 and Definition 525.49 force a public read of O through signature admission, branch coverage, structural descent, and audit provenance.

Next attach the compiler-facing handoff. Apply Definition 525.7 and Definition 525.47. These keep the public output inside the accepted recursor packet at G and exclude hidden generators, free induction principles, external axioms, and unaudited dependency routes.

Finally route the consumer through the sibling boundaries. The ClosedTermSubstitutionBoundary$^{\uparrow}$ chapter supplies the closed shift and substitution rows that a closed-substitution consumer must read, while the MetaCICNormalizationFrontier$^{\uparrow}$ chapter supplies the candidate and endpoint frontier rows for normalization consumers. Since neither sibling adds an off-carrier public output coordinate, the consumed output remains the displayed O reached through the finite authorized generator route. □

Theorem 525.51 (AuthorizedGeneratorRecursor consumer NameCert totality)**.** *For an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, the complete consumer-facing NameCert route for normalization and closed-substitution consumers is the finite route*

$$I \longmapsto E \longmapsto M \longmapsto B \longmapsto D \longmapsto O \longmapsto A \longmapsto H \longmapsto C \longmapsto P \longmapsto G \longmapsto N$$

together with the closed-boundary rows of $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$ *and the candidate-frontier rows of* $\mathsf{MetaCICNormalizationFrontier}^{\uparrow}$*. No consumer may replace this route by a detached recursor output, an unchecked substitution row, a blanket normalization theorem, an ambient termination principle, or a hidden generator channel.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorConsumerNameCertTotality`

Proof. First build the authorized generator side. Use Definition 525.50 to place every normalization or closed-substitution consumer after accepted signature, branch coverage, structural descent, audit provenance, and ground-compiler handoff rows.

Next use local consumer readiness. Definition 525.48 packages the rows of the accepted recursor packet as a downstream-ready NameCert surface, and Definition 525.14 blocks public routes outside the displayed carrier.

It remains to name the two downstream boundaries. $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$ supplies the finite closed-term shift and substitution route, and $\mathsf{MetaCICNormalizationFrontier}^{\uparrow}$ supplies the candidate-mediated normalization frontier. Combining these sibling surfaces with the authorized generator route yields the displayed consumer-facing NameCert totality statement and leaves no coordinate for the excluded replacements. □

Theorem 525.52 (AuthorizedGeneratorRecursor root consumer factorization)**.** *Every downstream closed-normal or generator-audit consumer of an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *root packet factors through the finite carrier rows*

$$(I, E, M, B, D, O, A, H, C, P, G, N).$$

The consumer may read the accepted signature, emitted eliminator, motive, complete branch package, descent row, output name, audit row, transports, continuations, package provenance, boundary row, and local name, but it receives no free induction principle, hidden proof generator, external axiom, or unaudited dependency route.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootConsumerFactorizatio`

Proof. Begin with root NameCert consumer readiness from Definition 525.48. It already identifies the rows $I, E, M, B, D, O, A, H, C, P, G, N$ as the surface available to downstream closed-normal and generator-audit packets.

Use root output audit totality, Definition 525.46, to keep every public output read attached to the accepted signature, eliminator, motive, branch package, descent row, audit row, and structural rows.

Finally apply root boundary nonescape, Definition 525.47. The boundary row G exports only the accepted recursor call over the finite packet, so the downstream consumer has no off-packet generator authority. □

Theorem 525.53 (AuthorizedGeneratorRecursor root readiness exhaustion)**.** *The root readiness surface for* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *is exhausted by root output audit totality, root boundary nonescape, root NameCert consumer readiness, and the obligation triad. Any downstream root*

consumer that asks for a closed-normal or generator-audit handoff must cite those four rows and cannot demand an additional primitive outside the displayed packet.

Proof. Read the readiness theorem Definition 525.48. It packages the downstream surface for closed-normal and generator-audit consumers.

The output component is exactly Definition 525.46, and the boundary component is exactly Definition 525.47. Together they account for the public output row and the host-kernel boundary row.

It remains to account for the internal obligations. Apply Definition 525.49. Branch-package exhaustion, structural-descent locality, and audit-provenance factorization cover the remaining readiness checks, so no further primitive is available to a root consumer. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootReadinessExhaustion`

Theorem 525.54 (AuthorizedGeneratorRecursor root audit handoff lock)**.** *The* $\mathsf{OperationalMembrane}^{\uparrow}$ *and TasteGate handoff for an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *root packet is locked to the same finite carrier*

$$(I, E, M, B, D, O, A, H, C, P, G, N).$$

The handoff refuses free induction, hidden proof generators, external axioms, and unaudited dependency routes; it can only expose the audited recursor output already covered by the root readiness surface.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootAuditHandoffLock`

Proof. Start with the operational audit handoff Definition 525.12. It places the audit row A before public exposure of the output row and keeps operational provenance inside the same packet.

Next use Definition 525.52. Any downstream closed-normal or generator-audit consumer must read through the same finite carrier rows, so the handoff cannot introduce a second consumer route.

Finally apply Definition 525.53 together with Definition 525.7. The readiness surface has no remaining primitive outside the displayed packet, and the TasteGate handoff reads only the aligned finite carrier. Therefore free induction, hidden proof generators, external axioms, and unaudited dependency routes are refused at the handoff. □

Theorem 525.55 (AuthorizedGeneratorRecursor root consumer fact downstream coverage)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *root packet, every accepted local downstream consumer fact whose handoff is closed-normal or generator-audit is exhausted by the displayed finite surface*

$$(I, E, M, B, D, O, A, H, C, P, G, N).$$

The constructor alternatives and recursive calls are covered by I, E, M, B, D*; the output, audit, transport, continuation, provenance, boundary, and local naming ledgers are covered by* O, A, H, C, P, G, N*; and any remaining readiness demand is covered by root output audit totality, root boundary nonescape, root NameCert consumer readiness, and the obligation triad. Hence an unlisted constructor, detached branch table, unchecked motive, non-structural recursion channel, hidden proof generator, external axiom channel, unaudited dependency route, off-packet substitution authority, or naming certificate outside the packet remains outside the BEDC packet exposed to that consumer.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootConsumerFactDownstrea`

Proof. Apply Definition 525.52. It forces every downstream closed-normal or generator-audit consumer of an accepted root packet to factor through the finite carrier rows $I, E, M, B, D, O, A, H, C, P, G, N$. Thus the consumer has no independent read surface beyond the accepted signature, eliminator, motive, branch package, descent row, output name, audit row, transports, continuations, package provenance, boundary row, and local name.

The finite carrier splits the possible consumer facts into the three displayed kinds. Branch alternatives and recursive-read coverage are read through I, E, M, B, D; output and audit-ledger facts are read through O, A, H, C, P, G, N; and boundary-facing refusal facts are read at G together with the same local name row N. Since the factorization theorem grants no free induction principle, hidden proof generator, external axiom, or unaudited dependency route, none of the excluded alternatives can be reintroduced as a second consumer fact.

It remains to check that no readiness demand is left over after this split. By Definition 525.53, any downstream root consumer asking for a closed-normal or generator-audit handoff must cite root output audit totality, root boundary nonescape, root NameCert consumer readiness, and the obligation triad, and cannot demand an additional primitive outside the displayed packet. These four rows are exactly the output-ledger, boundary-refusal, consumer-surface, and branch-descent-audit coverage rows named above. Therefore every accepted local consumer fact is exhausted by the finite alternatives, ledgers, or coverage rows already displayed, while all excluded alternatives remain outside the BEDC packet. □

Theorem 525.56 (AuthorizedGeneratorRecursor route-pack exactness)**.** *For every accepted* AuthorizedGeneratorRe *packet*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

every accepted recursor route factors through the finite packet rows displayed in Definition 525.1. The route may expose the accepted constructor signature, emitted eliminator, checked motive, branch package, structural descent, output name, audit provenance, componentwise hsame *transport, displayed* Cont *route,* Pkg *provenance,* GAP *boundary, and local* NameCert *row, but it cannot add a row outside that packet.*

Proof. Project the carrier of Definition 525.1. The displayed tuple is the whole route package, and each public recursor read is one of the listed rows.

Use the local NameCert surface of Definition 525.3. It identifies the same rows as the naming certificate for the authorized recursor output and requires a consumer to read O only through the packet.

Finally apply the audit and boundary results. The audit boundary of Definition 525.4 and the kernel acceptance scope of Definition 525.28 keep the host-kernel handoff at G on the displayed tuple. Since no carrier coordinate exists beyond $I, E, M, B, D, O, A, H, C, P, G, N$, route-pack exactness follows. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRoutePackExactness`

Theorem 525.57 (AuthorizedGeneratorRecursor branch-budget exhaustion)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, the branch package B and structural-descent row D exhaust every public branch read. A public consumer may read only constructor branches listed by I and authorized through E, M, B, D; it cannot import an unlisted constructor branch, a detached recursive call, or a second branch budget outside the displayed carrier.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorBranchBudgetExhaustion`

Proof. Start with branch exhaustion from Definition 525.2. The row B contains exactly the accepted branch surface for the constructors displayed by I, and downstream access reaches it only through the displayed continuation route.

Add structural locality from Definition 525.5 and Definition 525.13. These rows bind public recursive reads to the checked motive and structural-descent row, so every recursive branch read remains inside E, M, B, D.

The refusal side is supplied by Definition 525.14 and Definition 525.24. The carrier has no coordinate for an imported constructor branch, non-structural recursion channel, or hidden proof generator, so the displayed branch budget is exhausted. □

Theorem 525.58 (AuthorizedGeneratorRecursor consumer ledger cover)**.** *Every downstream* $\mathsf{RecursorGenerator}^{\uparrow}$, $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$, *and* TasteGate *consumer of an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet receives only the carrier, branch, descent, audit,* hsame, Cont, Pkg, GAP, *and local* NameCert *rows displayed by*

$$(I, E, M, B, D, O, A, H, C, P, G, N).$$

No such consumer receives an extra generator row, substitution authority, unlisted branch, unaudited dependency channel, or naming certificate outside the packet.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorConsumerLedgerCover`

Proof. The carrier side is fixed by Definition 525.56. It makes the finite tuple the exact route package available to any consumer.

The branch and descent side is fixed by Definition 525.57. Thus a $\mathsf{RecursorGenerator}^{\uparrow}$ consumer can read only the accepted signature, eliminator, motive, branch package, and structural-descent rows already present in the packet.

The audit and ledger side is fixed by Definition 525.48 and Definition 525.49. They attach the output, audit row, transports, continuation routes, package provenance, boundary row, and local certificate before downstream closed-normal or generator-audit consumers can cite the surface.

Finally the TasteGate handoff of Definition 525.7 reads only the same single carrier alignment witness. Since the ledger has no coordinate for substitution authority, an extra generator, or an outside naming certificate, the listed consumers receive exactly the displayed rows. □

Lemma 525.59 (AuthorizedGeneratorRecursor route-pack downstream coverage)**.** *Let c be an accepted local consumer of an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet with displayed route pack*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

Then the read made by c is exhausted by the finite alternatives already displayed in the packet. Its branch-facing part is one of the constructor, eliminator, motive, branch-package, or structural-descent rows I, E, M, B, D; its output-facing ledger part is one of O, A, H, C, P, G, N; and its consumer-facing coverage row is one of the carrier, branch, descent, audit, hsame, Cont, Pkg, GAP, *or local* NameCert *rows enumerated for the packet. Consequently an unlisted constructor alternative, detached recursive call, second branch budget, extra generator row, off-packet substitution authority, unaudited dependency channel, or outside naming certificate remains outside the BEDC packet and has no accepted local consumer route.*

Proof. Fix an accepted local consumer c of the displayed packet. By Definition 525.56, every accepted recursor route factors through the finite carrier of Definition 525.1. Thus the consumer-facing route of c has no coordinate except the displayed rows $I, E, M, B, D, O, A, H, C, P, G, N$.

Apply Definition 525.57 to the branch-facing part of the read. Any public branch read must use only the constructor branches listed by I and authorized through E, M, B, D. Hence the alternatives available to c on the branch side are exactly the displayed constructor, eliminator, motive, branch-package, and structural-descent rows, and there is no accepted coordinate for an unlisted constructor branch, detached recursive call, or second branch budget.

For the downstream ledger side, use Definition 525.58. It confines every downstream $\mathsf{RecursorGenerator}^{\uparrow}$, $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$, and $\mathsf{TasteGate}$ consumer to the carrier, branch, descent, audit, hsame, Cont, Pkg, GAP, and local $\mathsf{NameCert}$ rows displayed by the same tuple. Therefore the output-facing part of c can reach only O, A, H, C, P, G, N after the admitted branch and descent rows have been read.

Combining the route exactness, branch-budget exhaustion, and consumer-ledger cover leaves no remaining packet coordinate from which c could obtain an extra generator row, off-packet substitution authority, unaudited dependency channel, or outside naming certificate. All excluded alternatives are therefore refused by absence of a displayed BEDC row, and every accepted local consumer read is exhausted by the finite route pack. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRoutePackDownstreamCovera`

Theorem 525.60 (AuthorizedGeneratorRecursor root signature row totality)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, each public root read exposes the entire row family*

$$I, E, M, B, D, O, A, H, C, P, G, N$$

as the local BHist *packet with componentwise* hsame *transport, displayed* Cont *routes, and the local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *surface. No public root read may expose only a partial signature, branch, descent, audit, or output row while suppressing the remaining displayed rows.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootSignatureRowTotality`

Proof. Project the carrier of Definition 525.1. It names the finite BHist packet $R = (I, E, M, B, D, O, A, H, C, P, G,$ and gives no coordinate for a second root signature or a detached public route.

Use the local surface of Definition 525.3. The $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ row reads the accepted signature, recursor name, motive, branch package, descent row, output name, audit provenance, transports, routes, package provenance, boundary, and local naming row as one public packet.

Branch and recursive-read coverage are supplied by Definition 525.2 and Definition 525.5. The audit and handoff side is supplied by Definition 525.6 and Definition 525.7. Together these results make every root read total over the displayed BHist, hsame, Cont, and $\mathsf{NameCert}$ rows. □

Theorem 525.61 (AuthorizedGeneratorRecursor root descent audit coupling)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, the structural descent row D and audit row A must be transported together before the output row O is public. A public output exposure cannot retain D while dropping A, cannot retain A while dropping D, and cannot route O through an audit surface detached from the accepted structural-descent row.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursor root descent audit coupling`

Proof. Start with the carrier and the structural locality theorem. The displayed packet of Definition 525.1 places D in the same tuple as $I, E, M, B, O, A, H, C, P, G, N$, while Definition 525.5

confines public recursive reads to the accepted signature, eliminator, motive, branch package, and descent row.

Next apply the audit boundary and audit-provenance factorization. Definition 525.4 requires public output to pass through the accepted signature, checked motive, complete branch package, structural descent, and audit provenance. Definition 525.6 keeps O attached to A, H, C, P, G, N before exposure.

Finally use branch exhaustion and the TasteGate handoff. By Definition 525.2, no branch read can escape the accepted constructor list; by Definition 525.7, the checked alignment witness consumes only the same finite carrier. Hence the descent row and audit row are coupled before O becomes public. □

Theorem 525.62 (AuthorizedGeneratorRecursor root output NameCert saturation)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, public output exposure is saturated by the local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *surface over*

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

The exposure cannot add an unlisted constructor, an extra branch, a second recursion channel, an axiom row, or a hidden generator outside the displayed packet.

Proof. Use the carrier definition and the local NameCert surface. The carrier in Definition 525.1 is exactly the displayed tuple, and Definition 525.3 makes O public only through that tuple.

Branch and descent saturation follow from Definition 525.2 and Definition 525.5. These results rule out an unlisted constructor, an extra branch, or a recursive read whose descent is absent from D.

Audit saturation follows from Definition 525.4 and Definition 525.6. They keep O behind A, H, C, P, G, N and refuse an unaudited dependency channel. The TasteGate handoff of Definition 525.7 consumes only the same aligned carrier, so no axiom row or hidden generator can be introduced by the output exposure. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootOutputNameCertSaturat`

Theorem 525.63 (AuthorizedGeneratorRecursor root signature downstream coverage)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, every accepted local consumer downstream of a public root signature read is exhausted by the finite root rows*

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

More precisely, such a consumer can only use the signature, eliminator, motive, branch, and descent alternatives I, E, M, B, D*, the output and audit ledger rows* O, A, H, C, P, G, N*, or the coverage surface obtained by reading the displayed* BHist*, componentwise* hsame*,* Cont*, and local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *rows together. A request for an unlisted constructor, extra branch, second recursion channel, detached audit route, axiom row, hidden generator, or off-packet naming certificate remains outside the accepted* BEDC *packet.*

Proof. Fix an accepted packet and a public root signature read. By Definition 525.60, the read exposes the full row family

$$I, E, M, B, D, O, A, H, C, P, G, N$$

as one local BHist packet with componentwise hsame transport, displayed Cont routes, and the local $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ surface. The same theorem rules out a partial public root read:

no consumer can keep only a signature, branch, descent, audit, or output row while suppressing the remaining displayed rows.

The possible downstream uses therefore have only the displayed coordinates available. The root signature side supplies I, E, M, B, D as the accepted signature, emitted eliminator, checked motive, branch package, and structural-descent alternatives. The output side supplies O, A, H, C, P, G, N as the output, audit provenance, transport, continuation, package provenance, boundary, and local naming ledger. The coverage surface is not a further coordinate; it is the simultaneous exposure of the displayed BHist, hsame, Cont, and NameCert rows forced by the root signature totality theorem.

Apply Definition 525.62 to the output-facing part of the same packet. Public output exposure is saturated by the local $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ surface over exactly the displayed rows, and cannot add an unlisted constructor, an extra branch, a second recursion channel, an axiom row, or a hidden generator outside the packet. Combining this saturation with root signature row totality leaves no coordinate for a detached audit route or off-packet naming certificate either: any such request would require either a partial root read or an output exposure beyond the saturated local NameCert surface. Hence every accepted local downstream consumer is exhausted by the finite alternatives, ledger rows, and coverage rows displayed above, while every excluded alternative remains outside the accepted BEDC packet. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootSignatureDownstreamCo`

525.1 AuthorizedGeneratorRecursor displayed route surface

Definition 525.64 (AuthorizedGeneratorRecursor displayed route)**.** *An* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *displayed route is a finite* BHist *packet*

$$R = (A, G, F, K, P, N)$$

whose rows are:

1. *A, the authorization row for the accepted generator signature;*
2. *G, the generator row naming the generator whose recursor is being read;*
3. *F, the recursion-fuel row bounding the displayed recursive descent;*
4. *K, the continuation route that exposes each branch, recursive call, and output row through displayed* Cont *data;*
5. *P, the package provenance over the accepted signature, generator row, fuel row, branch package, output route,* BHist, hsame, Cont, *and* NameCert *rows;*
6. *N, the local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *row for this displayed route.*

The route has no coordinate for an unrecorded host recursor, an unbounded recursion principle, an extra generator branch, or a detached output channel.

Theorem 525.65 (AuthorizedGeneratorRecursor ledger exhaustion)**.** *Every consumer read of an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *displayed route factors through the authorization row A, generator row G, recursion-fuel row F, continuation route K, package provenance P, and local naming row N. No consumer can import an unrecorded host recursor, bypass the displayed fuel row, or read a generator output detached from these rows.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursor ledger exhaustion`

Proof. Project the displayed route of Definition 525.64. Its only public coordinates are A, G, F, K, P, N, and the route contains no second recursor channel.

The authorization and generator rows must be read first. They identify the accepted generator signature and the generator whose recursor output is public, so a consumer that lacks either row has no accepted root route to consume.

The recursion-fuel and continuation rows then exhaust recursive access. Every branch, recursive call, and output exposure is routed through F and K, with provenance and local naming supplied by P, N.

Therefore an unrecorded host recursor, an unbounded recursion principle, or a detached output channel would require a coordinate outside R, and no such coordinate is present. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorDisplayedRoute ledger exhaustion`

Theorem 525.66 (AuthorizedGeneratorRecursor NameCert route)**.** *For an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *displayed route, the local* NameCert *obligation surface consists exactly of carrier exposure for* $R = (A, G, F, K, P, N)$*, classifier transport of these six rows by the displayed* hsame *data, route determinacy through* K*, ledger exhaustion through Definition 525.65, and non-escape from unrecorded host recursors or detached generator outputs.*

Proof. Carrier exposure is the finite route packet of Definition 525.64. It displays the authorization, generator, fuel, continuation, provenance, and naming rows as one BHist surface.

Classifier transport is componentwise: an accepted comparison preserves A, G, F, K, P, N through the stored hsame rows and replays the same public reads through the displayed Cont route K.

Route determinacy follows because K is the only continuation coordinate. Once A, G, F, P, N are fixed, every branch, recursive call, and output read must pass through that route.

Ledger exhaustion and non-escape are exactly the content of Definition 525.65. The route therefore packages the carrier, classifier, deterministic continuation, exhaustive ledger, and refusal of unrecorded host recursors into the local NameCert surface. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorNameCertRoute`

Lemma 525.67 (AuthorizedGeneratorRecursor displayed route downstream coverage)**.** *Let* c *be an accepted local consumer of an* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *displayed route. Then the consumer read is exhausted by the finite displayed-route packet*

$$R = (A, G, F, K, P, N)$$

of Definition 525.64. More precisely, c *factors through one of the following local alternatives:*

1. *the authorization row* A *for the accepted generator signature;*
2. *the generator row* G *naming the generator whose recursor is being read;*
3. *the recursion-fuel row* F *bounding the displayed recursive descent;*
4. *the continuation route* K *exposing each branch, recursive call, and output row through displayed* Cont *data;*
5. *the package provenance row* P *over the accepted signature, generator row, fuel row, branch package, output route,* BHist*,* hsame*,* Cont*, and* NameCert *rows;*
6. *the local* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *row* N *for the displayed route.*

Consequently every request for an unrecorded host recursor, an unbounded recursion principle, an extra generator branch, or a detached output channel has no accepted coordinate in the $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *displayed-route packet.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorDisplayedRoute downstream coverage`

Proof. Start with an accepted local consumer read of the displayed route. By Definition 525.65, every consumer read of an accepted $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ displayed route factors through the authorization row A, generator row G, recursion-fuel row F, continuation route K, package provenance row P, and local naming row N.

Project those rows through Definition 525.64. The displayed route is the finite BHist packet $R = (A, G, F, K, P, N)$, and the definition assigns each public coordinate a fixed role: A admits the accepted generator signature, G names the generator whose recursor is public, F bounds the recursive descent, K carries the displayed continuation data for branches, recursive calls, and output rows, P records the package provenance for the route data, and N supplies the local $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ row. Thus the factorization supplied by ledger exhaustion lands in exactly the six alternatives listed in the statement.

It remains to exclude requests not listed among those alternatives. An unrecorded host recursor would require a second recursor coordinate, but Definition 525.64 states that the route has no coordinate for one and Definition 525.65 blocks importing one through a consumer read. An unbounded recursion principle would have to bypass F, while ledger exhaustion requires every recursive access to factor through the displayed fuel row. An extra generator branch would require a branch coordinate outside the continuation route K, but the displayed route exposes branches only through K. A detached output channel would require an output read not attached to A, G, F, K, P, N, while ledger exhaustion states that no consumer can read such an output. Hence every accepted local consumer is covered by the displayed finite rows, and every unlisted alternative remains outside the BEDC packet. □

Theorem 525.68 (AuthorizedGeneratorRecursor public route)**.** *For an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *displayed route*

$$R = (A, G, F, K, P, N),$$

the public finite export surface for generator-recursor consumers is exactly the displayed route of Definition 525.64, the ledger exhaustion of Definition 525.65, the NameCert route of Definition 525.66, and the downstream coverage of Definition 525.67. A consumer may read authorization, generator identity, recursion fuel, continuation data, provenance, and local naming from this surface, but it receives no unrecorded host recursor, unbounded recursion principle, extra generator branch, or detached output channel.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorPublicRoute`

Proof. First expose the displayed route. The definition fixes the six public rows A, G, F, K, P, N and rules out any second recursor coordinate.

Next apply ledger exhaustion. Every consumer read factors through those six rows, with recursive access routed through the fuel and continuation rows.

Apply the NameCert route to package carrier exposure, classifier transport, route determinacy, ledger exhaustion, and non-escape as the local certificate surface.

Finally apply downstream coverage. It identifies the accepted local consumer alternatives with the same six rows and excludes every request outside them, so the public export surface is exactly the displayed route together with its ledger and NameCert route. □

Theorem 525.69 (AuthorizedGeneratorRecursor root branch-package coverage)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *root packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

the branch-package surface exposes every constructor branch only through the accepted signature, emitted eliminator, checked motive, branch package, and structural-descent rows I, E, M, B, D. Any branch not listed by I and not carried by B is rejected before a downstream generator-audit or closed-normal consumer can read the output row O.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootBranchPackageCoverage`

Proof. Project the carrier of Definition 525.1. The rows I, E, M, B, D are displayed before O, and the carrier has no coordinate for an extra constructor, missing branch, or detached branch table.

Use the local NameCert surface and the root row exposure results. By Definition 525.3, Definition 525.43, and Definition 525.60, the branch package is read as part of the same finite packet rather than through a hidden generator route.

Finally apply Definition 525.2, Definition 525.57, and Definition 525.49. They force branch coverage to stay on the constructor list displayed by I, the recursor row E, the checked motive M, the branch package B, and the descent row D. Thus an unlisted branch has no public route to O. □

Theorem 525.70 (AuthorizedGeneratorRecursor root motive descent stability)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *root packet, structural descent through D preserves the checked motive row M before the output row O is exposed. A public recursive read cannot retain the descent row while replacing the motive, cannot read O from a motive-free descent surface, and cannot route the recursor through a branch package detached from M.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootMotiveDescentStabilit`

Proof. Start with the carrier and root descent exposure. The packet of Definition 525.1 places M and D in the same displayed tuple, while Definition 525.44 exposes the descent row on every root-facing recursive read.

The stability step is supplied by structural locality. Apply Definition 525.5, Definition 525.13, and Definition 525.61. These results keep the recursive read on the accepted signature, emitted eliminator, checked motive, branch package, descent row, and audit row together.

It remains to reach the output boundary. By Definition 525.46 and Definition 525.62, public exposure of O consumes the same packet. The TasteGate target named `BEDC.Derived.AuthorizedGeneratorRecurs` is used only as the aligned-carrier marker from Definition 525.7; the paper-side motive and descent obligations are carried by the cited root theorems. □

Theorem 525.71 (AuthorizedGeneratorRecursor root audit ledger exactness)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *root packet, public output reads factor through exactly the output, audit, transport, continuation, package, boundary, and local-name rows O, A, H, C, P, G, N after branch and descent admission. The packet exports no hidden generator, unaudited dependency route, external axiom channel, or naming certificate outside the displayed audit ledger.*

Proof. Read the audit ledger from the carrier

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

The rows O, A, H, C, P, G, N are public only as coordinates of this packet, and Definition 525.4 places output exposure behind the accepted signature, motive, branch package, structural descent, and audit provenance.

Use factorization through the sibling root surfaces. Definition 525.6, Definition 525.45, Definition 525.52, and Definition 525.58 attach O to A, H, C, P, G, N before any downstream consumer can cite the recursor output.

Finally apply the refusal and readiness results. Definition 525.47, Definition 525.54, and Definition 525.53 exclude hidden generators, unaudited dependency routes, and off-packet naming. Therefore the public ledger is exact for the displayed audit route and exports nothing beyond it. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursor root audit ledger exactness`

Theorem 525.72 (AuthorizedGeneratorRecursor root branch audit coupling)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *root packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

every public read of the output row O couples the branch package B to the audit row A through the same signature, eliminator, motive, descent, transport, continuation, package, boundary, and local-name rows. No downstream recursor or generator-audit consumer can read O from a branch package that is detached from the audit ledger.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootBranchAuditCoupling`

Proof. Project the displayed carrier R. The branch row B and audit row A occur as coordinates of the same finite packet, with $I, E, M, D, O, H, C, P, G, N$ recording the surrounding admission, output, transport, route, provenance, boundary, and local naming rows.

Apply Definition 525.69. It forces every branch exposed to a consumer to pass through the accepted signature, emitted eliminator, checked motive, branch package, and structural-descent rows I, E, M, B, D before O is public.

Now apply Definition 525.71. That theorem attaches public output reads to O, A, H, C, P, G, N after branch and descent admission. The TasteGate marker `BEDC.Derived.AuthorizedGeneratorRecursorUp.tas` is used only as the carrier alignment cited by the chapter, not as a replacement for this branch-audit obligation. Thus every public branch read remains coupled to the audit ledger of R. □

Theorem 525.73 (AuthorizedGeneratorRecursor root descent output factorization)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *root packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

any output-facing recursive read factors through the checked motive row M and structural-descent row D before it reaches O, and then through A, H, C, P, G, N before any downstream closed-normal or generator-audit consumer can cite the output. The factorization has no hidden proof generator, non-structural recursion channel, external axiom row, or off-packet naming certificate.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootDescentOutputFactoriz`

Proof. Read M, D, O as coordinates of the displayed packet R. The packet contains no second motive row, no detached descent row, and no output coordinate outside the same finite carrier.

Apply Definition 525.70. It keeps structural descent through D tied to the checked motive row M before output exposure, and it blocks a motive-free descent surface.

Then apply Definition 525.71. The output read continues through A, H, C, P, G, N after branch and descent admission, so the public consumer receives an audited output route rather than a hidden generator route. The TasteGate marker `BEDC.Derived.AuthorizedGeneratorRecursorUp.taste_gate` remains only the aligned-carrier witness; the paper-side descent and output factorization is carried by the cited root theorems. □

Theorem 525.74 (AuthorizedGeneratorRecursor root boundary ledger totality)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *root packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

the output boundary ledger visible to downstream recursor, closed-normal, generator-audit, and TasteGate consumers is exhausted by $I, E, M, B, D, O, A, H, C, P, G, N$. The boundary row G and local name row N do not expose a hidden generator, unaudited dependency route, external axiom channel, host-kernel completeness claim, or naming certificate outside the displayed packet.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootBoundaryLedgerTotalit`

Proof. Start from the full carrier R. The rows I, E, M, B, D supply branch and descent admission, O, A supply the output and audit ledger, and H, C, P, G, N supply transport, continuation, provenance, boundary, and local naming.

Use Definition 525.69 and Definition 525.70 to account for the admission side. Together they force branch coverage and descent stability to remain inside I, E, M, B, D before public output is read.

Use Definition 525.71 for the output side. It exhausts public output reads by O, A, H, C, P, G, N after branch and descent admission. The TasteGate marker `BEDC.Derived.AuthorizedGeneratorRecursorUp.tas` only aligns this finite carrier with the chapter handoff, so it does not supply an additional boundary or ledger row. Hence the visible boundary ledger is total for exactly the displayed packet. □

Theorem 525.75 (AuthorizedGeneratorRecursor root branch-audit downstream coverage)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *root packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

every accepted local downstream consumer of the root branch-audit output is exhausted by the finite rows displayed in this carrier. More precisely, the consumer can read only a branch-admission alternative in I, E, M, B, D, an output-audit ledger row in O, A, H, C, P, G, N, or the boundary coverage row obtained by keeping these two surfaces coupled inside the same packet. Any candidate consumer that asks for a detached branch package, unaudited output route, hidden generator, external axiom channel, host-kernel completeness claim, or off-packet naming certificate remains outside the accepted BEDC *packet.*

Proof. Fix an accepted root packet and project the displayed carrier

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

The branch side of any local consumer is finite because the exposed branch package is not a free generator surface. By Definition 525.72, every public read of O couples the branch package B to

the audit row A through the same signature, eliminator, motive, descent, transport, continuation, package, boundary, and local-name rows. Hence a local consumer cannot first read a branch alternative and then detach that alternative from the audit ledger of R.

The downstream side is total because the boundary ledger has no further public coordinates. By Definition 525.74, the output boundary visible to recursor, closed-normal, generator-audit, and TasteGate consumers is exhausted by

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

Thus any accepted consumer that reaches the output must land either on the admission rows I, E, M, B, D before O, or on the audit, transport, continuation, package, boundary, and local-name rows O, A, H, C, P, G, N after O.

It remains only to exclude apparent alternatives. A detached branch package is rejected by the coupling theorem, since no downstream recursor or generator-audit consumer can read O from a branch package separated from A. An unaudited output route, hidden generator, external axiom channel, host-kernel completeness claim, or off-packet naming certificate is rejected by the boundary-ledger totality theorem, since none of those objects is a coordinate of the displayed carrier. Therefore the accepted local downstream coverage is exactly the finite branch alternatives, ledgers, and coverage rows already displayed in R, and every excluded alternative remains outside the accepted BEDC packet. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootBranchAuditDownstrea`

Definition 525.76 (AuthorizedGeneratorRecursor root output boundary package)**.** *The root output boundary package for an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet is the finite* BHist *carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N)$$

of Definition 525.1, read with the following boundary roles. The rows I, E, M, B, D form the signature, eliminator, motive, branch, and structural-descent admission surface. The row O is the public output name. The rows A, H, C, P, G, N form the audit provenance, componentwise transport, continuation, package provenance, host-boundary, and local $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *surface. The package admits O only as a row of this displayed packet, after the branch package, descent locality, audit provenance, operational-membrane handoff, kernel-boundary exhaustion, and TasteGate carrier handoff have all been retained.*

Lean4 (definition) `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootOutputBoundar`

Theorem 525.77 (AuthorizedGeneratorRecursor root branch output closed boundary)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, public output reads from the root output boundary package of Definition 525.76 occur only after the accepted signature row I, emitted eliminator row E, checked motive row M, branch-package row B, and structural-descent row D have been retained. No public read of O can detach the output from the constructor signature, eliminator, motive, branch package, or structural descent rows.*

Proof. Project the carrier named by Definition 525.1. The package of Definition 525.76 uses the same displayed tuple

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

Branch coverage is forced before any output read. Apply Definition 525.2; the row B contains exactly the branches associated with the accepted constructors displayed by I and the eliminator named by E.

Descent locality then binds the recursive read to the motive and descent rows. By Definition 525.5, a public recursive read cannot pass through a generator route detached from M and D.

Finally use Definition 525.7. The TasteGate handoff consumes only the same finite carrier, so it cannot supply an output route that bypasses I, E, M, B, D. Therefore public access to O is closed under the displayed branch and descent boundary. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursor root branch output closed boundary`

Theorem 525.78 (AuthorizedGeneratorRecursor root audit membrane source refusal)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, the audit row A of the root output boundary package consumes* $\mathsf{OperationalMembrane}^{\uparrow}$ *provenance, source-axiom refusal, and dependency refusal before the output row O is public. Thus O cannot be read as a public output through an audit route that omits operational provenance, source refusal, or transitive dependency refusal.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootAuditMembraneSourceRe`

Proof. Begin with the audit side of Definition 525.76. The rows O, A, H, C, P, G, N are retained together, and A is the row that records the build check, source-axiom refusal, dependency refusal, and operational-membrane provenance.

Apply Definition 525.6. It prevents O from becoming public apart from A, H, C, P, G, N, so the output row cannot be read as an unaudited recursor result.

Now apply Definition 525.12. The audit row must consume the $\mathsf{OperationalMembrane}^{\uparrow}$ provenance before public exposure of O, and the same row carries source-axiom and dependency refusal for the packet.

The carrier alignment of Definition 525.7 supplies no substitute audit channel. Hence a public output read must pass through operational provenance, source refusal, and dependency refusal before O leaves the package boundary. □

Theorem 525.79 (AuthorizedGeneratorRecursor root host-boundary NameCert exhaustion)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, the host-boundary row G of the root output boundary package is exhausted by the displayed* $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ *packet. At G the packet cannot export a free induction principle, hidden branch source, external axiom, or proof generator outside*

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootHostBoundaryNameCertP`

Proof. Read the host-boundary row from Definition 525.76. The row G is not a second generator surface; it is one coordinate of the same finite carrier displayed in Definition 525.1.

Branch and descent escape are already excluded inside the packet. Use Definition 525.2 and Definition 525.5 to keep every branch source and recursive call on I, E, M, B, D.

Audit escape is excluded before the boundary row becomes useful to a consumer. By Definition 525.6 and Definition 525.12, public output remains attached to the audit provenance, operational membrane, source refusal, dependency refusal, transport, continuation, package, and local name rows.

Finally apply Definition 525.9 together with Definition 525.7. The boundary row is exhausted by the displayed NameCert packet and the TasteGate carrier handoff adds no free induction principle, hidden branch source, external axiom, or proof generator. □

Corollary 525.80 (AuthorizedGeneratorRecursor root output boundary strict obstruction)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet, any displayed failure, refusal, separation, or countermodel row attached to the root output boundary package of Definition 525.76 is a strict local obstruction. It blocks only the named converse or reuse route that would read* O *without the displayed audit and boundary rows. It does not state a global impossibility for recursors, does not become a host theorem about all generators, and does not supply hidden external validation. Equivalently, every consumer-facing use of the obstruction factors through the finite rows*

$$I, E, M, B, D, O, A, H, C, P, G, N,$$

and every unlisted coordinate is rejected as outside the local $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRootOutputBoundaryStrict(`

Proof. Start from the package definition. By Definition 525.76, the root output boundary is the single finite BHist carrier

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

The row O is public only as the output row of this carrier. The rows I, E, M, B, D supply the accepted signature, emitted eliminator, checked motive, branch package, and structural descent surface, while A, H, C, P, G, N supply audit provenance, componentwise transport, continuation, package provenance, host boundary, and local $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ data. Thus a consumer-facing use cannot begin from an isolated output token; it must enter through one of the displayed rows.

Apply Definition 525.78. The only obstruction supplied by the audit side is the refusal of an output read whose audit route omits $\mathsf{OperationalMembrane}^{\uparrow}$ provenance, source-axiom refusal, or transitive dependency refusal. This is a local refusal at A and its attached output ledger O, A, H, C, P, G, N. It blocks the converse route that tries to reuse O as unaudited output, but it does not assert that no accepted recursor output exists and does not certify any fact outside the displayed packet.

Apply Definition 525.79. At the host-boundary row G, the packet exports no free induction principle, hidden branch source, external axiom, or proof generator outside

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

Therefore the boundary obstruction blocks only the attempted reuse of G as a host-side generator or external validation channel. It cannot be reinterpreted as a host theorem about all generator mechanisms, because the cited theorem exhausts G by the same local $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ carrier.

It remains to exclude unlisted consumer coordinates. If a consumer-facing use were global, host-theoretic, or externally validated, it would need a coordinate not among the admission rows I, E, M, B, D, the output and audit rows O, A, H, C, P, or the boundary and name rows G, N. The package definition supplies no such coordinate; the audit refusal eliminates unaudited output reuse; and the host-boundary exhaustion eliminates free host proof production at G. Hence each displayed failure, refusal, separation, or countermodel row is strict in exactly the local sense: it obstructs the named converse or reuse route inside the root output boundary package, while every broader reading remains outside the BEDC packet. □

Theorem 525.81 (AuthorizedGeneratorRecursor branch output closure row)**.** *For every accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *root packet, the public branch output row remains behind the displayed carrier rows*

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

In particular, a downstream public read of O *cannot detach the recursor output from the accepted signature row* I*, emitted eliminator row* E*, checked motive row* M*, branch package row* B*, structural-descent row* D*, audit row* A*, transport row* H*, continuation row* C*, package row* P*, boundary row* G*, or local* NameCert *row* N*.*

Proof. Project the root output boundary package of Definition 525.76. It presents O only as one coordinate of the displayed packet, not as a standalone generator result.

The branch side is fixed by Definition 525.77. It keeps public output reads behind I, E, M, B, D and refuses an output route detached from the constructor signature, emitted eliminator, checked motive, complete branch package, and structural descent.

The audit side is fixed by Definition 525.78 and Definition 525.79. These rows retain A, H, C, P, G, N before the boundary can expose O to a consumer.

Finally cite Definition 525.7 only as carrier alignment. The TasteGate handoff reads the same finite packet and supplies no independent branch output channel, so the public branch output remains closed behind exactly the displayed rows. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorBranchOutputClosureRow`

Theorem 525.82 (AuthorizedGeneratorRecursor audit provenance row)**.** *For every accepted* AuthorizedGeneratorR *root packet, the rows* A, H, C, P, G, N *are retained before public output exposure. The audit provenance row, componentwise transport row, continuation route row, package provenance row, host-boundary row, and local* NameCert *row therefore form the required downstream provenance package for any public read of* O*.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursor audit provenance row`

Proof. Begin with audit provenance factorization, Definition 525.6. It states that O becomes public only after the audit row A, transports H, continuation routes C, package row P, boundary row G, and local name row N are retained.

The root package strengthens this retention at the output boundary. By Definition 525.78, A carries operational provenance, source refusal, and dependency refusal before O leaves the package boundary.

The boundary and local naming side is supplied by Definition 525.79. The row G is exhausted by the same displayed $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ packet and cannot export a hidden generator or off-packet certificate.

Use Definition 525.7 only to identify the carrier consumed by the TasteGate handoff. Since that handoff adds no theorem row and no substitute audit route, A, H, C, P, G, N remain the provenance package required before public exposure of O. □

Theorem 525.83 (AuthorizedGeneratorRecursor closed substitution consumer row)**.** *Every* ClosedTermSubstitutio *consumer of an accepted* $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *root packet reaches the recursor output only through the displayed branch, descent, audit, route, package, and* NameCert *rows. Such a consumer has no direct substitution authority over* O *outside the carrier*

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

Lean4 ✓ BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorClosedSubstitutionConsume

Proof. Start from Definition 525.58. It already includes $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$ among the downstream consumers that receive only the carrier, branch, descent, audit, transport, continuation, package, boundary, and local certificate rows displayed by the packet.

The branch and descent route is closed by Definition 525.81. A substitution-boundary consumer therefore reaches O only after I, E, M, B, D have been retained with the output boundary.

The audit and provenance route is closed by Definition 525.82. It keeps A, H, C, P, G, N attached before the public output can be consumed downstream.

Finally apply Definition 525.52. Downstream consumers factor through the finite carrier and receive no free induction principle, hidden proof generator, external axiom, unaudited dependency route, or off-packet substitution channel. Hence every closed-substitution consumer reaches the recursor output only through the displayed branch, descent, audit, route, package, and local NameCert rows. □

Theorem 525.84 (AuthorizedGeneratorRecursor output readiness)**.** *For every accepted* AuthorizedGeneratorRecurs *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

the output row O is ready for downstream closed-substitution and generator-audit consumers only after the accepted signature I, emitted recursor E, checked motive M, branch package B, structural-descent row D, audit row A, componentwise hsame *row H, displayed* Cont *route C,* Pkg *provenance P, host-boundary row G, and local* NameCert *row N have all been retained in the same packet.*

Proof. Project the carrier of Definition 525.1. It exposes O only as a coordinate of the finite tuple R, not as a detached generator result.

Use the root output boundary package and root boundary ledger totality. The packet of Definition 525.76 and the theorem Definition 525.74 keep O tied to the branch, descent, audit, transport, continuation, provenance, boundary, and naming rows.

Finally compare with the closed-term substitution boundary of chapter 527 and the recursor generator of chapter 534. They may consume the output surface only through the displayed BHist, hsame, Cont, Pkg, and NameCert packet, so readiness is exactly the retained carrier R. □

Lean4 ✓ BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier output readiness

Theorem 525.85 (AuthorizedGeneratorRecursor branch audit ledger)**.** *For every accepted* AuthorizedGeneratorRec *packet, the branch package B and audit row A form one branch-audit ledger over the same* BHist *carrier. A public branch read that reaches O must pass through I, E, M, B, D and then through A, H, C, P, G, N; it cannot cite the closed-substitution boundary, recursor generator, or authorization row through a branch table detached from the audit ledger.*

Lean4 ✓ BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorBranchAuditLedger

Proof. Start with the root branch audit coupling theorem. Theorem 525.72 already couples B and A through the same displayed carrier before O is public.

Read the authorization side next. The root authorization obligations and displayed route surface keep accepted signatures, generator rows, branch packages, and local naming inside the same $\mathsf{NameCert}_{\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}}$ packet.

The closed-substitution handoff is therefore ledgered rather than ambient. Any route from a branch to a closed-substitution consumer must replay the same Cont row C and provenance row P while preserving componentwise hsame through H. A detached branch table has no carrier coordinate from which to export O. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier branch audit ledger`

Theorem 525.86 (AuthorizedGeneratorRecursor closed substitution handoff)**.** *Every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet hands its output row O to a* ClosedSubstitutionBoundary$^{\uparrow}$, ClosedTermSubstitution$^{\uparrow}$, *or generator-audit consumer only through the displayed finite route*

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

The handoff preserves the closed-term substitution boundary, recursor generator, and authorization rows as finite BHist, hsame, Cont, Pkg, *and* NameCert *data, and it exports no unrestricted substitution calculus, subject-reduction theorem, proof generator, external axiom channel, host equality, or off-packet recursor certificate.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier closed substitution handoff`

Proof. First use output readiness. The output row is not public until all rows of R have been retained, so a closed-substitution consumer begins from the same accepted carrier as any generator-audit consumer.

Next use the branch audit ledger. It ties the branch package and audit row together before the handoff, preventing a consumer from reading branch output apart from authorization, motive checking, structural descent, and audit provenance.

Finally apply root host-boundary NameCert exhaustion and the closed-substitution boundary sibling. The boundary row G exports only the displayed NameCert packet, while ClosedSubstitutionBoundary$^{\uparrow}$ and ClosedTermSubstitution$^{\uparrow}$ consume closed substitution as finite boundary rows rather than as a general substitution theorem. Hence the handoff remains inside $I, E, M, B, D, O, A, H, C, P, G, N$ and none of the excluded external principles is exported. □

Lemma 525.87 (AuthorizedGeneratorRecursor output readiness bridge determinacy)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

any downstream consumer that reads the output row O as a route, transport, readback, or closed-substitution handoff factors through the same finite rows

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

The route part is I, E, M, B, D, O, A, the transport and readback part is H, C, P, and the boundary-certificate part is G, N. In particular, there is no consumer-facing bridge coordinate for an unlisted branch table, detached transport, off-packet readback, ambient substitution calculus, hidden generator, host equality, external axiom channel, or second NameCert *row.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorOutputReadinessBridgeDete`

Proof. Start with output readiness. By Definition 525.84, the row O is public for downstream closed-substitution and generator-audit consumers only after the accepted signature, emitted recursor, motive, branch package, descent row, audit row, componentwise transport, continuation route, package provenance, host-boundary row, and local naming row have all been retained in the same packet. Thus a consumer-facing read of O already begins from the displayed carrier R, not from an independent output surface.

Apply the branch audit ledger to the route side. Definition 525.85 says that any public branch read reaching O must pass through I, E, M, B, D and then through A, H, C, P, G, N. This makes the bridge deterministic on branch routes: the consumer may cite the branch package only together with the audit ledger and the later transport, continuation, provenance, boundary, and naming rows, so a detached branch table has no route to the closed-substitution boundary, recursor generator, or authorization row.

Now apply the closed-substitution handoff. Definition 525.86 sends every closed-substitution, closed-term substitution, and generator-audit consumer through the displayed finite route $I, E, M, B, D, O, A, H, C,$ It also states that the handoff preserves the boundary, recursor-generator, and authorization data only as finite BHist, hsame, Cont, Pkg, and NameCert rows. Hence the transport and readback surfaces are exactly H, C, P attached to O, A, and the boundary certificate surface is exactly G, N.

The cited rows exhaust the consumer-facing bridge. A displayed route is covered by the branch-audit prefix and audit suffix, a transport or readback is covered by the hsame, Cont, and Pkg rows, and a closed-substitution handoff is covered by the boundary and local NameCert rows of the same packet. Since the carrier of Definition 525.1 displays no coordinate outside R, an unlisted bridge coordinate has no factor through which a consumer can read O. □

Corollary 525.88 (AuthorizedGeneratorRecursor output readiness determinacy)**.** *Let*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N)$$

be an accepted AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, and fix the displayed rows of R. Any accepted downstream use of the output readiness surface that reads O as a finite route, packet-local normal-form readiness claim, readback, closed-substitution handoff, or exactness decision must use the route, transport, readback, boundary, and local certificate already named by those rows. The route side is fixed by I, E, M, B, D, O, A, the transport and readback side is fixed by H, C, P, and the boundary-certificate side is fixed by G, N. Hence two accepted consumers over the fixed rows determine the same finite route and the same packet-local readiness or exactness decision named by the chapter; there is no alternate hidden coordinate, detached branch table, off-packet readback, ambient substitution calculus, hidden generator, host equality, external axiom channel, second* NameCert *row, or duplicate classifier source.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorOutputReadinessDeterminac`

Proof. Apply Definition 525.87. It says that every downstream consumer reading O as a route, transport, readback, or closed-substitution handoff factors through the same finite rows

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

It also separates the rows by role: the route part is I, E, M, B, D, O, A, the transport and readback part is H, C, P, and the boundary-certificate part is G, N. Thus a consumer-facing normal-form readiness claim or exactness decision has no independent surface; it is a packet-local reading of the displayed route, transport, readback, and boundary rows attached to O.

Use Definition 525.85 on the route side. Any public branch read that reaches O must pass through I, E, M, B, D and then through A, H, C, P, G, N, and it cannot cite a branch table detached from the audit ledger. Therefore the branch package cannot supply a second source for the same output readiness decision after the rows of R have been fixed.

The remaining possible alternatives are exactly the interfaces excluded by the bridge determinacy lemma: an unlisted branch table, detached transport, off-packet readback, ambient substitution calculus, hidden generator, host equality, external axiom channel, or second NameCert row. A duplicate classifier source would have to enter through one of those excluded interfaces or through an additional carrier coordinate outside R. Since the fixed carrier displays no such coordinate, every accepted consumer use factors through the same listed rows and therefore selects the same chapter-named route, readiness readback, or exactness decision. □

Theorem 525.89 (AuthorizedGeneratorRecursor route totality lock)**.** *For every accepted* AuthorizedGeneratorRecu *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

every accepted recursor route factors through exactly the displayed signature row I, eliminator row E, motive row M, branch package B, descent row D, output row O, audit row A, componentwise hsame *transport H, displayed* Cont *route C,* Pkg *provenance P, closed host-boundary row G, and local* NameCert *row N. No accepted route has a second eliminator, branch table, descent proof, output channel, audit packet, transport row, continuation, provenance row, or naming certificate outside this finite surface.*

Proof. Start from the displayed NameCert route, Definition 525.66. It identifies the public recursor route with the carrier rows $I, E, M, B, D, O, A, H, C, P, G, N$ and gives no detached route coordinate.

Apply the closed-substitution handoff, Definition 525.86. Any consumer that reaches the generated output must still pass through the same output, audit, transport, continuation, provenance, boundary, and naming rows.

Finally use root host-boundary NameCert exhaustion, Definition 525.79. The boundary row G exports only the local certificate surface of the accepted packet, so the route is total exactly over the displayed rows. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier route totality lock`

Theorem 525.90 (AuthorizedGeneratorRecursor closed substitution budget lock)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

the closed-substitution handoff consumes ClosedTermSubstitutionBoundary$^{\uparrow}$ *only through the displayed finite boundary rows G, H, C, P, N together with the authorized generator rows I, E, M, B, D, O, A. The handoff cannot import an unrestricted substitution calculus, subject-reduction theorem, semantic evaluator state, proof generator, host equality, or off-packet certificate as a boundary budget.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier closed substitution budget lock`

Proof. First invoke Definition 525.86. It places every ClosedSubstitutionBoundary$^{\uparrow}$ or ClosedTermSubstitution$^{\uparrow}$ consumer on the finite route $I, E, M, B, D, O, A, H, C, P, G, N$.

Use Definition 525.89 to lock that route before the boundary is consumed. The accepted recursor route has no auxiliary boundary channel beyond G and the visible hsame, Cont, Pkg, and NameCert rows.

Root host-boundary NameCert exhaustion then prevents any boundary budget from being read as host equality, subject reduction, or evaluator state. The consumed budget is precisely the displayed finite boundary surface. □

Theorem 525.91 (AuthorizedGeneratorRecursor output route audit cover)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

every generated output row O is covered by the audit and provenance rows A, H, C, P, G, N before any downstream consumer reads it. An output route cannot bypass audit, provenance, closed-boundary naming, or componentwise transport, and it cannot import host equality, hidden evaluator state, subject reduction, an unrestricted substitution theorem, or an off-packet generator certificate.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier output route audit cover`

Proof. Begin with the route totality lock. It keeps every accepted recursor route inside $I, E, M, B, D, O, A, H, C, P,$ so an output read begins with the packet's own audit and provenance coordinates.

Apply the closed-substitution handoff. It shows that output consumers, including closed-substitution and generator-audit consumers, receive O only through the displayed handoff route.

Finally use root host-boundary NameCert exhaustion. The boundary row exports no host equality, hidden evaluator state, subject-reduction theorem, or off-packet certificate, so the audit cover is exactly the packet-local A, H, C, P, G, N surface. □

Lemma 525.92 (AuthorizedGeneratorRecursor route totality local downstream coverage)**.** *Let c be an accepted local downstream consumer of an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N).$$

Then the consumer-facing read made by c is exhausted by the finite route, ledger, and coverage rows already displayed in R. More precisely, c either reads a route alternative among the accepted signature row I, eliminator row E, motive row M, branch package B, descent row D, output row O, and audit row A, or it reads the downstream output ledger covered by O, A, H, C, P, G, N, where H is the componentwise hsame *transport, C is the displayed* Cont *route, P is the* Pkg *provenance, G is the closed host-boundary row, and N is the local* NameCert *row. Consequently a second eliminator, detached branch table, off-route descent proof, second output channel, unaudited output read, hidden audit packet, detached transport row, private continuation, off-packet provenance row, host equality, hidden evaluator state, unrestricted substitution theorem, subject-reduction theorem, off-packet generator certificate, or outside naming certificate has no accepted local consumer coordinate in the* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet.*

Proof. Fix an accepted local downstream consumer c of the displayed carrier R. By Definition 525.89, every accepted recursor route factors through exactly the displayed rows

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

That theorem also rules out a second eliminator, branch table, descent proof, output channel, audit packet, transport row, continuation, provenance row, or naming certificate outside this finite surface. Thus the initial consumer-facing route of c has no coordinate except the rows listed in R.

Separate the read according to whether it reaches the generated output row. If c reads a route coordinate before output exposure, the totality lock already places it among the route alternatives I, E, M, B, D, O, A together with the attached transport, continuation, provenance, boundary, and naming rows. If c reads the generated output row O, then Definition 525.91 applies. It says that every generated output row is covered by the audit and provenance rows A, H, C, P, G, N before any downstream consumer reads it, and that the output route cannot bypass audit, provenance, closed-boundary naming, or componentwise transport.

The two cited theorems exhaust the downstream cases. The totality lock supplies the finite route surface and excludes any unlisted route coordinate. The audit-cover theorem supplies the output-facing ledger and keeps downstream output exposure behind A, H, C, P, G, N. Hence an accepted local consumer can only land on the displayed route alternatives, the displayed output ledger, or the displayed coverage rows of the same packet.

It remains to check the excluded alternatives. A second eliminator, detached branch table, off-route descent proof, second output channel, hidden audit packet, detached transport row, private continuation, off-packet provenance row, or outside naming certificate would be a route coordinate outside R, contradicting Definition 525.89. An unaudited output read, host equality, hidden evaluator state, unrestricted substitution theorem, subject-reduction theorem, or off-packet generator certificate would be an output-facing bypass of the audit and boundary surface, contradicting Definition 525.91. Therefore every accepted local downstream consumer is covered by the finite rows already enumerated in R, and every excluded alternative remains outside the accepted $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ packet. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier route totality local downstream coverage`

Theorem 525.93 (AuthorizedGeneratorRecursor route authorization)**.** *For every accepted* AuthorizedGeneratorRec *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

the public recursor route exposes only the authorized generator rows carried by I, E, M, B, D, O, A, the displayed descent routes in D, the componentwise hsame *transport in H, the replayed* Cont *route in C,* Pkg *provenance in P, and the local* NameCert *row N. No consumer receives a generator row outside this carrier or a route around the displayed descent and audit rows.*

Proof. Project the carrier of Definition 525.1. The accepted signature, emitted recursor, motive, branch package, descent row, output row, and audit row are the only generator-facing coordinates.

Use the displayed route surface and root authorization obligations. They force any public read of the recursor through the same BHist packet, with D supplying descent, H transporting presentations, C replaying the continuation route, P recording provenance, and N recording the local certificate.

Therefore an exposed generator row is authorized exactly when it is one of the displayed rows of R. A route outside $I, E, M, B, D, O, A, H, C, P, G, N$ would require a carrier coordinate absent from the accepted packet. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorCarrier route authorization`

Theorem 525.94 (AuthorizedGeneratorRecursor output ledger exactness)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet, each generated output row O is read through the same finite authorized route*

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

The output ledger has no detached generator result, off-route branch output, hidden structural descent certificate, or provenance row outside the displayed BHist, hsame, Cont, Pkg, *and* NameCert *surface.*

Proof. Begin with route authorization. It identifies the only public recursor route and fixes the generator-facing rows before any output can be consumed.

Apply output readiness and the branch audit ledger. Readiness keeps O unavailable until all rows of R are present, while the branch audit ledger ties B, D, O, A to the same audit surface.

The exact output ledger is therefore the displayed route itself. Since O is a coordinate of R and not an external result object, every output read factors through the same transport, continuation, provenance, and local naming rows. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorOutputLedgerExactness`

Theorem 525.95 (AuthorizedGeneratorRecursor substitution handoff nonescape)**.** *Every* ClosedSubstitutionBound *or* ClosedTermSubstitution$^{\uparrow}$ *consumer of an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet receives the authorized finite route*

$$I, E, M, B, D, O, A, H, C, P, G, N$$

and no hidden recursor, host recursion principle, unledgered generator, unrestricted substitution calculus, proof generator, external axiom channel, host equality, or off-packet certificate.

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorSubstitutionHandoffNones`

Proof. Start from output ledger exactness. The generated output row is already tied to the authorized route, so a closed-substitution consumer begins with the same packet rather than with a detached generator product.

Use the closed-substitution handoff. It routes the handoff through the closed-boundary row G and the same BHist, hsame, Cont, Pkg, and NameCert coordinates used by the recursor packet.

Finally apply the root output boundary package. That boundary admits only the displayed handoff route, so there is no coordinate from which to export a hidden recursor, a host recursion principle, or an unledgered generator. □

Corollary 525.96 (AuthorizedGeneratorRecursor route-authorization obstruction locality)**.** *Let an accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet be read by a* ClosedSubstitutionBoundary$^{\uparrow}$ *or* ClosedTermSubstitutio *consumer through the displayed route*

$$I, E, M, B, D, O, A, H, C, P, G, N.$$

If a displayed failure, refusal, separation, or countermodel row is cited against a converse or reuse route for this packet, then the citation is a strict local obstruction to that named route only. It blocks exactly the request that tries to leave the displayed packet by importing a hidden recursor, host recursion principle, unledgered generator, unrestricted substitution calculus, proof generator, external axiom channel, host equality, or off-packet certificate. It cannot be reinterpreted as a global impossibility theorem for recursors, as a host theorem about substitution systems, or as hidden external validation for any route not displayed in the packet.

Proof. By Definition 525.93, the public recursor route exposes only the carrier rows $I, E, M, B, D, O, A, H, C, P, G, N$. The generator-facing rows are I, E, M, B, D, O, A; the remaining public route data are the displayed descent route in D, componentwise hsame transport in H, the replayed Cont route in C, Pkg provenance in P, the closed-boundary row G, and the local NameCert row N.

By Definition 525.95, every ClosedSubstitutionBoundary$^{\uparrow}$ or ClosedTermSubstitution$^{\uparrow}$ consumer receives that same finite route and receives no hidden recursor, host recursion principle, unledgered generator, unrestricted substitution calculus, proof generator, external axiom channel, host equality, or off-packet certificate. Hence any consumer-facing use of a displayed obstruction row must factor through one of the listed coordinates: source and branch data through I, E, M, B, D, O, A, presentation transport through H, continuation replay through C, provenance through P, boundary handoff through G, and local naming through N.

Now suppose the cited obstruction is read as more than a block on the named converse or reuse route. A global impossibility reading would require a coordinate ranging over recursors outside the accepted packet; a host-theorem reading would require a host recursion, equality, or substitution principle; and a hidden-validation reading would require an external certificate not carried by N or the displayed provenance row P. Each required coordinate is absent from the route authorized by Definition 525.93 and is expressly excluded from the substitution handoff by Definition 525.95. Therefore the obstruction remains strict and local: it rejects the unlisted converse or reuse request and asserts nothing beyond the displayed packet. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorRouteAuthorizationObstruc`

Theorem 525.97 (AuthorizedGeneratorRecursor terminal consumer readiness)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet with displayed carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

every terminal normalization or closed-substitution consumer may read the recursor output only after the finite packet of Definition 525.1, the route authorization of Definition 525.93, the output ledger exactness of Definition 525.94, and the substitution handoff nonescape of Definition 525.95 have all been displayed. Such a consumer receives O as a row of R, with branch, descent, audit, boundary, and local naming data still attached, and not as a detached recursor theorem.

Proof. Project the finite BHist packet from Definition 525.1. The rows $I, E, M, B, D, O, A, H, C, P, G, N$ are the only displayed coordinates, so the terminal consumer starts from the packet rather than from an ambient generator principle.

Apply Definition 525.93 to route the public output through accepted signature, emitted recursor, motive, branch package, structural descent, audit, transport, continuation, provenance, boundary, and local NameCert rows. Then apply Definition 525.94 to keep O in the same ledger.

Finally use Definition 525.95. The handoff to the sibling boundaries of chapter 527 and chapter 892 is therefore a displayed BEDC row read, not a hidden induction source, unchecked generator, detached normalization proof, or external proof-producing channel. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorTerminalConsumerReadiness`

Theorem 525.98 (AuthorizedGeneratorRecursor boundary factorization)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet with carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

any public route from the recursor output O into a ClosedTermSubstitutionBoundary$^{\uparrow}$ *consumer or a* MetaCICNormalizationFrontier$^{\uparrow}$ *consumer factors through the displayed rows B, D, A, H, C, P, G, N after I, E, M have admitted the generator surface. In particular, the boundary route is the carrier route certified by Definition 525.1, Definition 525.93, Definition 525.94, and Definition 525.95.*

Proof. Begin with the route authorization theorem. It fixes the public recursor route at the rows of R, so a consumer path to O must pass through the branch row B, the descent row D, and the audit row A before any boundary read is available.

Use output ledger exactness to attach H, C, P, G, N to the same route. The componentwise transport, continuation replay, package provenance, boundary row, and local certificate are not auxiliary witnesses outside the packet; they are the boundary-facing coordinates of the packet itself.

The closed-term and normalization-frontier sibling chapters can therefore consume only this factored carrier route. A route that skipped B, D, A, H, C, P, G, N would need a boundary coordinate outside R, but Definition 525.1 displays no such coordinate. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorBoundaryFactorization`

Theorem 525.99 (AuthorizedGeneratorRecursor normalization consumer nonescape)**.** *For every accepted* AuthorizedGeneratorRecursor$^{\uparrow}$ *packet with carrier*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N),$$

a MetaCICNormalizationFrontier$^{\uparrow}$ *consumer receives the recursor-generated output only as the authorized finite route already consumable by* ClosedTermSubstitutionBoundary$^{\uparrow}$*. The normalization consumer cannot reinterpret O as hidden induction, an unchecked generator, a detached normalization theorem, a subject-reduction source, a host equality principle, or an external proof-producing source.*

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorNormalizationConsumerNone`

Proof. First read the route through Definition 525.97. Terminal readiness keeps the normalization consumer behind the same displayed finite packet as the closed-substitution consumer.

Next apply Definition 525.98. The route into chapter 892 must factor through the branch, descent, audit, transport, continuation, provenance, boundary, and local naming rows already exposed to chapter 527.

It remains to exclude non-displayed sources. Since Definition 525.95 exports no hidden recursor, unrestricted substitution calculus, proof generator, external axiom channel, host equality, or off-packet certificate, the normalization consumer has no coordinate from which to acquire hidden induction, an unchecked generator, detached normalization, subject reduction, or an external proof-producing source. □

Corollary 525.100 (AuthorizedGeneratorRecursor terminal consumer strict obstruction)**.** *Let*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N)$$

be an accepted AuthorizedGeneratorRecursor$^{\uparrow}$ *packet. Suppose a displayed failure, refusal, separation, or countermodel row is cited against a named converse, reuse, separation, or readback route for the terminal consumer surface of R. Then the cited row is a strict local obstruction. It blocks only the named route whose consumer-facing use tries to read the terminal output O, normalization readiness, or closed-substitution handoff away from the displayed packet rows*

$I, E, M, B, D, O, A, H, C, P, G, N$. Every admitted consumer-facing use factors through the packet carrier, route authorization, output-ledger exactness, substitution handoff, boundary factorization, and normalization-consumer nonescape rows already displayed for R. The same cited row cannot be reinterpreted as a global impossibility theorem for recursors, a host theorem about normalization or substitution, hidden external validation of the failed route, or an obstruction to any consumer route that still factors through the displayed rows of R.

Proof. Start with terminal consumer readiness, Definition 525.97. A terminal normalization or closed-substitution consumer may read the recursor output only after the finite carrier of Definition 525.1, route authorization, output ledger exactness, and substitution handoff nonescape have all been displayed. Thus the consumer receives O as a row of R, with branch, descent, audit, boundary, and local naming data still attached, and not as a detached recursor theorem.

Apply normalization consumer nonescape, Definition 525.99. It says that a $\mathsf{MetaCICNormalizationFrontier}^{\uparrow}$ consumer receives the recursor-generated output only as the authorized finite route already consumable by $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$. The listed failed readings are hidden induction, an unchecked generator, a detached normalization theorem, a subject-reduction source, a host equality principle, and an external proof-producing source.

The required factorization is therefore finite and rowwise. By readiness, the consumer-facing read begins at the displayed carrier R and cannot start from an ambient generator principle. By boundary factorization, the route from O into the closed-substitution or normalization-frontier consumer passes through B, D, A, H, C, P, G, N after I, E, M have admitted the generator surface. By normalization nonescape, no further coordinate is exported for hidden induction, unchecked generation, detached normalization, subject reduction, host equality, or external proof production.

Now take the cited failure, refusal, separation, or countermodel row. If it is used against the named converse, reuse, separation, or readback route, the preceding paragraph forces that use to land at the exact displayed coordinate where the named route tries to omit, replace, detach, or bypass one of the packet rows. That is the strict local obstruction.

Any stronger reading would require data not supplied by the terminal consumer surface. A global impossibility theorem would require a recursor-wide theorem row outside the accepted packet. A host theorem about normalization or substitution would require host normalization, host equality, or host substitution data outside R. Hidden external validation would require an external certificate or proof-producing channel not carried by P, G, or N. These are exactly the readings excluded by terminal readiness and normalization consumer nonescape. Hence the obstruction blocks only the named local route and does not obstruct any consumer route that continues to factor through the displayed packet rows of R. □

Lean4 ✓ `BEDC.Derived.AuthorizedGeneratorRecursorUp.AuthorizedGeneratorRecursorTerminalConsumerStrictObs`

Lemma 525.101 (AuthorizedGeneratorRecursor terminal output MetaCIC reuse boundary)**.** *Let*

$$R = (I, E, M, B, D, O, A, H, C, P, G, N)$$

be an accepted $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ *packet. Reusing the terminal output O inside a* $\mathsf{MetaCICNormalizationF}$ *consumer is admissible only when the reuse first factors through the same* $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$ *carrier route*

$$B, D, A, H, C, P, G, N$$

after I, E, M have admitted the generator surface. A read that treats O as detached subject reduction, host equality, a hidden generator, or a proof-producing channel is outside the terminal consumer surface of R.
