Theorem 550.6 (CriticalStripZetaZero shared source scope)**.** *In an accepted* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *packet* $W = (S, Z, L, B, H, C, P, N)$, *the* $\mathsf{CritStrip}^{\uparrow}$ *row* S *and the* $\mathsf{ZetaZeros}^{\uparrow}$ *row* Z *share a source only through the displayed* hsame *and* Cont *routes recorded in* H *and* C. *A consumer may compare the strip row and zero row by those routes, but it receives no host complex equality, selected representative, quotient zero-set equality, or analytic zero search.*

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket shared source scope`

Proof. Project the shared source binding obligation from Definition 550.2. It names the strip row and zero row as finite packet coordinates and places their comparison inside the stored transport and continuation rows.

The carrier of Definition 550.1 has no additional coordinate for host complex equality or quotient equality of zero sets. Therefore every shared-source read is exactly a read through H and C. □

Theorem 550.7 (CriticalStripZetaZero line-route determinacy)**.** *Every critical-line read from an accepted* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *packet factors through the finite rows* L, B, H, C, P, N*. The row* L *supplies the displayed critical-line classifier,* B *supplies the boundary ledger,* H *transports the row componentwise,* C *records the continuation route, and* P, N *record provenance and local naming.*

Proof. Apply the critical-line boundary theorem. It requires the critical-line question to pass through L and the boundary ledger B after the strip and zero rows have already been exposed.

The only remaining routes are structural. Transport is recorded in H, continuation in C, package provenance in P, and local naming in N. Thus a critical-line read has a determined route through L, B, H, C, P, N and cannot be replaced by an ambient equality or host decision procedure. □

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket line route determinacy`

Theorem 550.8 (CriticalStripZetaZero RH input ledger)**.** *Any RH-facing consumer of an accepted* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *packet receives only the finite premise packet* S, Z, L, B, H, C, P, N*: the strip row, zero row, critical-line classifier row, boundary ledger, displayed transport, continuation, provenance, and local naming rows. The packet does not export a proof of RH, a zero search procedure, a quotient zero set, host complex equality, or a selected counterexample outside the displayed critical-line row.*

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket rh input ledger`

Proof. Use Definition 550.5. It identifies the packet as the finite input surface for the constructive RH premise, not as the conclusion itself.

The shared-source scope theorem fixes how S and Z may be compared, and the line-route determinacy theorem fixes how L and B may be read. Ledger exhaustion then states that no additional analytic or quotient coordinate is exported.

Consequently the RH-facing consumer receives exactly the finite premise packet and its displayed routes. Any proof or refutation of the RH predicate must provide further BEDC rows outside this witness packet. □

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessCarrier rh input ledger`

Theorem 550.9 (CriticalStripZetaZero RH premise exhaustion)**.** *Every RH-facing premise consumer of an accepted* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *packet*

$$W = (S, Z, L, B, H, C, P, N)$$

receives exactly the strip row S*, zeta-zero row* Z*, critical-line row* L*, boundary ledger* B*, displayed transports* H*, continuations* C*, package provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}}$ *row* N*. The consumer receives no analytic zero search, quotient zero-set equality, host complex equality, selected representative, or RH proof.*

Proof. Start with the accepted witness carrier and apply Definition 550.2. The RH handoff obligation reads the packet only through the displayed strip, zero, critical-line, boundary, transport, continuation, package, and local naming rows.

The critical-line boundary theorem fixes the route through L and B, while Definition 550.4 exhausts every exported fact by the same finite coordinate list. The concretizes-RH theorem then identifies those rows as the premise surface for the constructive RH statement.

Finally use Definition 550.6 and Definition 550.8. The source comparison between S and Z is only the displayed hsame and Cont route, so the RH-facing premise consumer receives exactly S, Z, L, B, H, C, P, N and nothing outside that packet. □

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket rh premise exhaustion`

Theorem 550.10 (CriticalStripZetaZero constructive counterexample surface)**.** *Any constructive counterexample surface for the RH predicate must extend an accepted* CriticalStripZetaZeroWitness$^{\uparrow}$ *packet*

$$W = (S, Z, L, B, H, C, P, N)$$

by a displayed failure of the critical-line row L. The witness packet alone supplies the finite premise surface, but it never supplies analytic zero search, quotient zero-set equality, host complex equality, a selected complex representative, or an RH proof or refutation.

Proof. Apply Definition 550.5. It states that a constructive counterexample pairs the finite premise packet with a displayed failure of the critical-line row, rather than extracting such a failure from the witness packet itself.

The route to the critical-line question is already fixed by Definition 550.3 and Definition 550.7. Thus any failure surface must attach to the displayed row L and its boundary ledger B through the stored H, C, P, N routes.

It remains to exclude hidden analytic data. The ledger exhaustion theorem and Definition 550.9 leave no coordinate for zero search, quotient zero-set equality, host complex equality, selected representatives, or a proof-level RH decision. Therefore a constructive counterexample surface is precisely the premise packet plus an additional displayed failure of L. □

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket constructive counterexample surface`

Theorem 550.11 (CriticalStripZetaZero shared source binding)**.** *For every accepted* CriticalStripZetaZeroWitness$^{\uparrow}$ *packet*

$$W = (S, Z, L, B, H, C, P, N),$$

the CritStrip$^{\uparrow}$ *strip row S and the* ZetaZeros$^{\uparrow}$ *zero row Z share a source only through the displayed* hsame *transports in H and the* Cont *routes in C. The packet provides no host complex equality, quotient zero-set equality, selected representative, or analytic source-selection procedure beyond the finite rows S, Z, H, C, P, N.*

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket shared source binding`

Proof. Project the carrier and read the shared-source clause of the local naming surface. The strip row S and zero row Z are both visible, but the only rows connecting their source readings are the componentwise transport row H and the continuation row C.

Apply the existing shared-source scope and source-route exhaustion statements. They confine every comparison between the strip source and zero source to displayed hsame and Cont data.

The package and local naming rows P, N record the finite provenance of that comparison. Since the packet has no coordinate for host complex equality, quotient zero-set equality, selected representatives, or analytic source selection, the shared source is bound only by S, Z, H, C, P, N. □

Theorem 550.12 (CriticalStripZetaZero witness scope binding)**.** *Every scoped read of an accepted* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *packet*

$$W = (S, Z, L, B, H, C, P, N)$$

binds the strip row S, zero row Z, critical-line row L, boundary ledger B, transports H, continuations C, provenance P, and local name N to the displayed $\mathsf{Complex}^{\uparrow}$, $\mathsf{CritStrip}^{\uparrow}$, $\mathsf{ZetaZeros}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *surfaces already present in the packet. The scoped read supplies no analytic zero search, quotient zero-set equality, host complex equality, selected representative, or proof of RH.*

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket scope binding`

Proof. Begin with the carrier and the local NameCert obligations. They identify an accepted witness as the finite packet S, Z, L, B, H, C, P, N and require every RH-facing handoff to read those rows through the displayed BEDC surfaces.

Use shared-source binding for the premise rows. The strip row S and zero row Z can be compared only through the stored hsame transports and Cont routes, so a scoped read binds them to $\mathsf{Complex}^{\uparrow}$, $\mathsf{CritStrip}^{\uparrow}$, and $\mathsf{ZetaZeros}^{\uparrow}$ without producing host complex equality or a selected representative.

Use line-route determinacy and the RH input ledger for the conclusion-facing rows. The critical-line row L and boundary ledger B remain attached to $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ through the same packet rows, so the route cannot be replaced by a zero search or quotient zero-set equality.

Finally apply premise exhaustion. The RH-facing consumer receives exactly the finite premise packet, while any proof or refutation of RH must be supplied by an additional accepted BEDC row outside this witness surface. □

Theorem 550.13 (CriticalStripZetaZero line boundary routing)**.** *Let $W = (S, Z, L, B, H, C, P, N)$ be an accepted* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *packet. Every read of the critical-line row L is routed only after the strip row S and the zero row Z have been exposed, and the read is authenticated by the boundary ledger B, displayed* hsame *transports H, continuation routes C, package row P, and local* $\mathsf{NameCert}_{\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}}$ *row N.*

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket line boundary routing`

Proof. Start with the carrier rows. The line row L is not an independent analytic predicate; it appears in the same finite packet as the strip row S, zero row Z, and boundary ledger B.

Use the critical-line boundary and line-route determinacy statements. They force the public route to L through the displayed strip and zero rows before the boundary ledger is consumed.

Apply shared-source binding to the premise side. The source data for S and Z are already restricted to the stored hsame and Cont rows, so the line route cannot bypass them.

Finally, P and N record provenance and local naming for the same finite packet. Therefore every critical-line read is routed by S, Z, L, B, H, C, P, N and not by a host critical-line decision. □

Theorem 550.14 (CriticalStripZetaZero RH handoff obligation)**.** *Every RH-facing handoff from an accepted* CriticalStripZetaZeroWitness$^{\uparrow}$ *packet consumes only the finite premise packet*

$$S, Z, L, B, H, C, P, N.$$

The handoff may use the strip row, zero row, critical-line row, boundary ledger, displayed transport, continuation, provenance, and local naming rows, but it does not prove RH, refute RH, search for zeros, close quotient zero sets, or decide host complex equality.

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket rh handoff obligation`

Proof. Begin with the RH input ledger and premise exhaustion theorems. They identify the public handoff as a read of the finite packet S, Z, L, B, H, C, P, N and not as an RH-level conclusion.

Use shared-source binding for the premise source. The strip and zero rows share source data only through displayed hsame and Cont routes, so the handoff receives no selected complex representative or analytic source procedure.

Use line-boundary routing for the conclusion-facing row. The critical-line row L is read only after S and Z, and the boundary ledger B authenticates that finite route.

The remaining rows P, N record provenance and local naming. Since no row contains an RH proof, RH refutation, zero-search procedure, quotient equality, or host complex equality, the RH-facing handoff consumes only the finite premise packet. □

Theorem 550.15 (CriticalStripZetaZero boundary ledger non-escape)**.** *For every accepted* CriticalStripZetaZeroWi *packet* $W = (S, Z, L, B, H, C, P, N)$*, every critical-line failure read or boundary read factors through the displayed rows* L, B, H, C, P, N*. The boundary ledger exports only the finite classifier, boundary, transport, continuation, package, and local naming data; it exports no host complex equality, quotient zero-set equality, analytic zero search, or RH decision.*

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket boundary ledger nonescape`

Proof. Start with the carrier definition and the NameCert obligations theorem. The accepted packet has only the displayed rows S, Z, L, B, H, C, P, N, and the line-boundary routing obligation requires any critical-line read to pass through L and B after the strip and zero rows have been exposed.

Apply ledger exhaustion to the same carrier. It states that every exported fact is either one of the displayed rows or a route between such rows, so no host complex equality, quotient zero-set equality, analytic zero search, or proof-level RH decision can leave the packet.

Finally use shared-source scope and line-route determinacy. Shared-source scope confines comparison of S and Z to the stored hsame and Cont rows, while line-route determinacy confines every critical-line read to L, B, H, C, P, N. Thus a critical-line failure or boundary read cannot escape the finite boundary ledger. □

Theorem 550.16 (CriticalStripZetaZero source route exhaustion)**.** *For an accepted* CriticalStripZetaZeroWitness$^{\uparrow}$ *packet* $W = (S, Z, L, B, H, C, P, N)$*, the common source route for the strip row* S *and the zeta-zero row* Z *is exhausted by the stored* hsame *and* Cont *rows in* H *and* C*. Any consumer comparing the two source readings must use those displayed routes and receives no additional complex representative, quotient equality, or analytic source-selection procedure.*

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket source route exhaustion`

Proof. Project the carrier and the shared source binding clause of the NameCert obligations theorem. The only rows that connect the $\mathsf{CritStrip}^{\uparrow}$ source and the $\mathsf{ZetaZeros}^{\uparrow}$ source are the componentwise hsame transports in H and the continuation routes in C.

The shared-source scope theorem gives the same restriction at the consumer boundary. A comparison between S and Z is a displayed route comparison, not a host equality of complex numbers or a quotient equality of zero sets.

Ledger exhaustion and premise exhaustion close the route inventory. Since every RH-facing premise consumer receives only S, Z, L, B, H, C, P, N, the shared source of S and Z has no route outside the stored hsame and Cont rows. □

Theorem 550.17 (CriticalStripZetaZero premise consumer separation)**.** *Every RH-facing consumer of an accepted* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *packet receives the premise packet only as*

$$S, Z, L, B, H, C, P, N.$$

The consumer may read the strip row, zero row, critical-line classifier, boundary ledger, displayed transport, continuation, provenance, and local naming rows, but any critical-line conclusion, RH proof, RH refutation, or analytic zero decision must be supplied outside the witness packet.

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket premise consumer separation`

Proof. Begin with carrier admission and the NameCert obligations theorem. They identify the accepted object as exactly the finite packet S, Z, L, B, H, C, P, N and require the RH handoff to read that same packet rather than a host analytic object.

Use shared-source scope and source route exhaustion for the premise side. The strip and zero rows share their source only through H and C, so a consumer receives a displayed finite route and not a selected complex representative.

Use line-route determinacy and boundary ledger non-escape for the conclusion-facing side. They force every critical-line read through L, B, H, C, P, N and prevent the boundary ledger from exporting a host equality, quotient zero-set equality, zero search, or RH decision.

Finally apply premise exhaustion. The RH-facing consumer receives exactly the finite premise packet; therefore any critical-line conclusion or RH-level decision must be supplied by an additional BEDC row outside the witness packet. □

Theorem 550.18 (CriticalStripZetaZero witness zero-row admission)**.** *Let* $W = (S, Z, L, B, H, C, P, N)$ *be an accepted* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *packet. The displayed row* Z *may be admitted as zero-witness certificate data inside the finite* BHist *packet when its local* NameCert *row* N*,* Pkg *provenance* P*, componentwise* hsame *transports* H*, and displayed* Cont *routes* C *expose the same source boundary as* S, L, B*.*

This admission is only a certificate-data row. It asserts neither that an analytic zeta zero exists in the host complex plane nor that any RH-facing conclusion has been proved.

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket zero row admission`

Proof. Project the carrier of the accepted packet. The only candidate zero-witness data available to the packet is the displayed row Z together with the finite rows S, L, B, H, C, P, N.

Inspect the local ledger. The hsame rows and Cont routes connect Z to the displayed source and boundary rows, while P and N record provenance and local naming. This is enough to admit Z as certificate data in the finite BHist packet.

No analytic existence statement is exported by that projection. The packet contains no host zero search, no quotient zero-set equality, and no RH decision row, so the admission remains a finite witness-row admission only. □

Theorem 550.19 (CriticalStripZetaZero witness classifier non-escape)**.** *For accepted* CriticalStripZetaZeroWitness$^{\uparrow}$ *packets* $W = (S, Z, L, B, H, C, P, N)$ *and* $W' = (S', Z', L', B', H', C', P', N')$ *that classify together, classifier transport across the finite* BHist *rows may transport only the displayed witness rows, boundary rows,* hsame *rows,* Cont *routes,* Pkg *provenance, and* NameCert *evidence.*

Such transport cannot create analytic-continuation truth, Euler-product truth, zero-existence truth, RH truth, or RH refutation rows. Any such row must be supplied by a separate accepted packet outside the witness classifier.

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket classifier nonescape`

Proof. Begin with the classifier-facing rows of the two accepted packets. Classification compares the displayed finite coordinates and routes the comparison through the stored hsame and Cont data.

Inspect the package and naming ledgers. They record provenance for the witness row, critical-strip boundary row, premise ledger, and local certificate; they do not contain analytic-continuation, Euler-product, zero-existence, RH-proof, or RH-refutation coordinates.

Therefore classifier transport can only replay the finite rows already present in W and W'. It cannot manufacture an analytic theorem row or settle RH, because no such coordinate is present in the carrier or ledger being transported. □

Theorem 550.20 (CriticalStripZetaZero witness consumer boundary)**.** *Every downstream consumer of an accepted* CriticalStripZetaZeroWitness$^{\uparrow}$ *packet* $W = (S, Z, L, B, H, C, P, N)$ *may read only the displayed witness row* Z*, the critical-strip boundary rows* S, L, B*, the premise ledger, the local* NameCert *row* N*, the* Pkg *provenance* P*, and the connecting* hsame *and* Cont *rows.*

The consumer boundary supplies no analytic continuation theorem, no Euler product theorem, no zero search, no host complex equality, no RH proof, and no RH refutation.

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket consumer boundary`

↪ variant `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket witness consumer boundary`

Proof. Project the consumer-facing packet. The rows exposed to consumers are exactly S, Z, L, B, H, C, P, N, with the witness row, boundary rows, premise ledger, package provenance, and local certificate displayed in the finite carrier.

Use Definition 550.17. It already forces RH-facing consumers to receive the premise packet only as the listed finite rows, with any critical-line conclusion supplied outside the witness packet.

Combine this with zero-row admission and classifier non-escape. The first theorem admits Z only as certificate data, and the second prevents classifier transport from creating analytic or RH

truth rows. Thus downstream consumers remain at the displayed witness boundary and receive no claim that a zero exists or that RH is settled. □

Theorem 550.21 (CriticalStripZetaZero scoped package)**.** *For an accepted* CriticalStripZetaZeroWitness$^{\uparrow}$ *packet*

$$W = (S, Z, L, B, H, C, P, N),$$

the carrier, NameCert *obligations, shared-source scope, line-route determinacy, premise exhaustion, zero-row admission, classifier non-escape, and consumer boundary assemble one scoped finite packet over* Complex$^{\uparrow}$, CritStrip$^{\uparrow}$, ZetaZeros$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*. The packet exposes only the strip row S, zero row Z, critical-line row L, boundary ledger B, transports H, routes C, provenance P, and local name N.*

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket scoped package`

Proof. Start from the carrier and NameCert obligation rows. They identify the accepted witness as the finite packet S, Z, L, B, H, C, P, N and bind the strip, zero, critical-line, boundary, transport, route, provenance, and naming data to the same local carrier.

Next use shared-source scope and line-route determinacy. These theorems force comparisons between strip and zero rows through the displayed H and C routes and force critical-line reads through L and B.

Apply premise exhaustion, zero-row admission, classifier non-escape, and the consumer boundary. The premise packet is therefore closed under the displayed rows, while zero data and classifier transport cannot create analytic zero truth, RH truth, or RH refutation.

The resulting surface is a scoped finite packet over the listed BEDC rows. It is not a host complex equality, a quotient zero-set equality, or an analytic zero decision. □

Theorem 550.22 (CriticalStripZetaZero source boundary closure)**.** *For an accepted* CriticalStripZetaZeroWitness$^{\uparrow}$ *packet $W = (S, Z, L, B, H, C, P, N)$, source comparison is closed by S, Z, H, C, P, N. A consumer comparing the critical-strip source and the zeta-zero source receives the displayed strip row, zero row, transports, routes, provenance, and local name, and cannot turn that comparison into host complex equality or quotient zero-set equality.*

Lean4 ✓ `BEDC.Derived.CriticalStripZetaZeroWitnessUp.CriticalStripZetaZeroWitnessPacket source boundary closure`

Proof. Project the source side of the carrier. The only rows connecting the strip source S and the zero source Z are the transport rows H, continuation routes C, provenance row P, and local name N.

Apply shared-source scope and source route exhaustion. They state that every source comparison must use the displayed H and C rows rather than a selected host complex representative or quotient zero-set representative.

Use package provenance and the consumer boundary to close the comparison. The provenance and naming rows authenticate only the finite packet, so source comparison remains the S, Z, H, C, P, N boundary and exports no host or quotient equality. □

Theorem 550.23 (CriticalStripZetaZero RH handoff scope)**.** *Every RH-facing handoff from an accepted* CriticalStripZetaZeroWitness$^{\uparrow}$ *packet reads only*

$$S, Z, L, B, H, C, P, N.$$

Any critical-line conclusion, proof, refutation, or analytic zero decision must be supplied by a separate BEDC row outside the witness packet.

Proof. Begin with premise consumer separation. It already routes RH-facing consumers through the displayed strip, zero, critical-line, boundary, transport, continuation, provenance, and naming rows.

Use boundary ledger non-escape and line-route determinacy. These theorems keep the critical-line and boundary reads inside L, B, H, C, P, N and prevent a boundary read from becoming a host equality, quotient equality, analytic zero search, or RH decision.

Finally apply scoped package closure. Since the handoff packet has no coordinate for a critical-line conclusion, proof, refutation, or analytic zero decision, any such row must come from a separate accepted BEDC packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}}$.

Constructive story: A $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ packet is generated from a $\mathsf{CritStrip}^{\uparrow}$ strip row, a $\mathsf{ZetaZeros}^{\uparrow}$ zero row, a critical-line classifier row, a boundary ledger, displayed hsame and Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 550.21, Definition 550.22, and the RH handoff rows close the finite packet scope over $\mathsf{Complex}^{\uparrow}$, $\mathsf{CritStrip}^{\uparrow}$, $\mathsf{ZetaZeros}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not prove RH, refute RH, construct non-trivial zeta zeros, decide the critical-line classifier, close zero-set quotients, or bridge checking.

Upgrade path: Scoped closure requires checked carrier encoding for the shared source binding, critical-line boundary routing, RH handoff, and ledger exhaustion rows.

Chapter 551

A Concrete Naming Certificate for $\mathsf{HostDelegationSocket}^{\uparrow}$

The $\mathsf{HostDelegationSocket}^{\uparrow}$ surface records host Lean delegation as a finite naming packet rather than as an ambient trust claim. It is the certificate face at which paper markers, audit rows, host-kernel delegation, target resolution, transport, continuation, provenance, boundary ledgers, and local naming are made visible to downstream audit and MetaCIC chapters.

The socket consumes the accepted-declaration rows of chapter 557 and the displayed proof-route rows of chapter 582 before exposing a host-delegation boundary. The kernel acceptance trace supplies the accepted stamp, environment, axiom ledger, and classifier rows, while the inscribed route supplies the displayed route, GAP row, consumer row, and local $\mathsf{NameCert}$ row used by the socket-facing audit surface.

Definition 551.1 (HostDelegationSocket carrier)**.** *A* $\mathsf{HostDelegationSocket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$H = (M, A, K, D, T, C, P, L, N)$$

with the following displayed rows:

1. *M is the manuscript marker row, recording the paper site, marker class, literal target text, and local citation context;*
2. *A is the audit-face row, recording source-token scans, marker-resolution checks, dependency-purity checks, and origin-flow checks relevant to the marker;*
3. *K is the host-kernel delegation row, recording that the named Lean declaration is delegated to the host Lean kernel as an audited boundary row;*
4. *D is the displayed target-resolution row, recording the exact declaration name, namespace path, resolution result, and refusal result when resolution fails;*
5. *T records componentwise* hsame *transports for marker, audit face, delegation row, target-resolution row, continuation row, provenance row, boundary ledger, and local naming row;*
6. *C records the displayed* Cont *routes by which consumers inspect marker resolution, audit evidence, host-kernel delegation, transport replay, provenance, and boundary refusal;*
7. *P is the* Pkg *provenance over* BHist*, manuscript marker rows, audit faces, host-kernel delegation rows, target-resolution rows,* hsame*,* Cont*, and local naming;*

8. *L is the boundary ledger, recording non-escape for host truth predicates, global CIC completeness, source axioms,* Classical.choice, Quot.sound, propext, *fuzzy marker matching, and bridge-checked status;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{HostDelegationSocket}^{\uparrow}}$ *row.*

The carrier contains exactly these rows. It has no coordinate for a host truth predicate, no proof that the host CIC is globally complete, no permission to accept source axioms or forbidden host dependencies, no fuzzy resolver, and no bridge-checked certificate.

Lean4 (definition) `BEDC.Derived.HostDelegationSocketUp.HostDelegationSocketCarrier`

Theorem 551.2 (HostDelegationSocket NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{HostDelegationSocket}^{\uparrow}}$ *surface for the carrier of Definition 551.1 consists of carrier admission for*

$$H = (M, A, K, D, T, C, P, L, N),$$

manuscript-marker exposure, audit-face exactness, host-kernel delegation visibility, displayed target-resolution exactness, componentwise hsame *stability, displayed* Cont *replay,* Pkg *provenance, boundary-ledger non-escape, and local naming.*

Lean4 ✓ `BEDC.Derived.HostDelegationSocketUp.HostDelegationSocketCarrier semantic name certificate`

Proof. Carrier admission is projection from Definition 551.1. The rows $M, A, K, D, T, C, P, L, N$ are the only coordinates available to the local certificate.

The marker, audit, delegation, and resolution obligations are read directly from M, A, K, D. The host Lean kernel remains visible as the audited delegation row K; it is not silently replaced by an internal BEDC truth predicate.

Transport and replay are confined to T and C, while P and N record provenance and local naming. The ledger L supplies the non-escape clauses for host truth predicates, global CIC completeness, source axioms, forbidden host dependencies, fuzzy marker matching, and bridge-checked status. □

Theorem 551.3 (HostDelegationSocket audit-face separation)**.** *For an accepted* $\mathsf{HostDelegationSocket}^{\uparrow}$ *packet, the audit face A and the host-kernel delegation row K remain separate public rows. A downstream consumer may inspect the audit evidence and may inspect the delegated host-kernel target, but it may not identify audit success with host truth, global CIC completeness, source-axiom admission, or absence of* Classical.choice, Quot.sound, *and* propext *beyond the displayed dependency ledger.*

Lean4 ✓ `BEDC.Derived.HostDelegationSocketUp.HostDelegationSocket audit face separation`

Proof. Project the finite packet and read A and K as distinct coordinates. The audit face records the gate evidence, while the delegation row records the host-kernel target to which the marker points.

The two rows are transported together only through the componentwise hsame row T and replayed only through C. These routes preserve the separation rather than creating a predicate equating audit evidence with host truth.

The boundary ledger L then blocks every stronger reading. It refuses host truth predicates, global CIC completeness, source axioms, and unrecorded claims about forbidden dependency names unless those claims appear as the displayed audit result of the packet. □

Theorem 551.4 (HostDelegationSocket Lean marker boundary)**.** *For an accepted* $\mathsf{HostDelegationSocket}^{\uparrow}$ *packet, the manuscript marker row M reaches the local naming row N only through the displayed target-resolution row D, the host-kernel delegation row K, the transport row T, the continuation row C, the package provenance P, and the boundary ledger L. If D refuses the target, the packet exports no replacement by similar spelling, neighboring namespace, informal prose equivalence, or consumer-selected theorem.*

Lean4 ✓ `BEDC.Derived.HostDelegationSocketUp.HostDelegationSocket marker boundary`

Proof. Start with the marker row M. The only route from the paper site to local naming is the displayed resolution row D, which records the exact declaration name and the resolve-or-refuse result.

If resolution succeeds, K records the host-kernel delegation and T, C, P, N transport, replay, package, and name the same route. No step in this chain introduces an alternate declaration name.

If resolution fails, D records refusal and L keeps that refusal at the boundary. The carrier has no coordinate for spelling similarity, namespace guessing, prose reinterpretation, or consumer-chosen substitution, so the refused marker cannot be exported as a local certificate. □

Theorem 551.5 (HostDelegationSocket non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{HostDelegationSocket}^{\uparrow}$ *packet factors through the finite rows*

$$M, A, K, D, T, C, P, L, N.$$

The consumer may read marker text, audit evidence, host-kernel delegation, target resolution, transport replay, continuation routes, package provenance, boundary refusal, and the local NameCert row, but it cannot extract a host truth predicate, global CIC completeness theorem, source axiom, forbidden host dependency, fuzzy marker match, or bridge-checked status.

Lean4 ✓ `BEDC.Derived.HostDelegationSocketUp.HostDelegationSocketNonEscape`

Proof. Let a downstream consumer route be given. By Definition 551.1, its source packet is the finite tuple $M, A, K, D, T, C, P, L, N$.

The consumer reads the public certificate through those rows. The marker and resolution rows identify the target, the audit and delegation rows expose the host boundary, and the transport, continuation, provenance, and naming rows replay the certificate without adding new coordinates.

The non-escape claim is the carrier inventory plus the ledger row L. None of the excluded objects is stored in the tuple, and L explicitly records that these objects are refused as exported substrate content. □

Theorem 551.6 (HostDelegationSocket primitive scope binding)**.** *For an accepted* $\mathsf{HostDelegationSocket}^{\uparrow}$ *packet, marker exposure, audit-face separation, target-resolution exactness, host-kernel delegation visibility, transport replay, provenance, and boundary-ledger non-escape are scoped only by the finite* BHist *rows, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, the local* $\mathsf{NameCert}_{\mathsf{HostDelegationSocket}^{\uparrow}}$ *row, and the imported* $\mathsf{KernelAcceptanceTrace}^{\uparrow}$ *and* $\mathsf{InscribedRoute}^{\uparrow}$ *surfaces. No consumer may widen this scope to host truth predicates, global CIC completeness, source axioms, forbidden host dependencies, fuzzy marker matching, or bridge-checked status.*

Lean4 ✓ `BEDC.Derived.HostDelegationSocketUp.HostDelegationSocketPrimitiveScopeBinding`

Proof. Project the carrier of Definition 551.1. Its rows expose the manuscript marker, audit face, host-kernel delegation, target resolution, transport, replay, provenance, ledger, and local naming surface as a single finite packet.

Apply audit-face separation and the Lean marker boundary. These force audit evidence, delegated target, and exact resolution to remain visible as rows of the same packet rather than as ambient host predicates or spelling-based substitutions.

Finally apply non-escape. The ledger row refuses every object outside BHist, hsame, Cont, Pkg, $\mathsf{NameCert}_{\mathsf{HostDelegationSocket}^{\uparrow}}$, $\mathsf{KernelAcceptanceTrace}^{\uparrow}$, and $\mathsf{InscribedRoute}^{\uparrow}$, so the primitive socket scope is exactly the displayed carrier surface. □

Lean4 ✓ `BEDC.Derived.HostDelegationSocketUp.HostDelegationSocket primitive scope binding`

Theorem 551.7 (HostDelegationSocket public interface)**.** *An accepted* $\mathsf{HostDelegationSocket}^{\uparrow}$ *packet exports a consumer-facing socket interface consisting of the manuscript marker row M, audit face A, exact target-resolution row D, transport row T, continuation row C, provenance row P, boundary ledger L, and local naming row N. This interface lets downstream chapters replay marker resolution, inspect audit evidence, read the delegated host-kernel target, and transport the local certificate, while exporting no host truth predicate, global CIC completeness assertion, source axiom, forbidden host dependency, fuzzy resolver, or bridge-checked status.*

Proof. Project the carrier of Definition 551.1. The public rows visible to a consumer are exactly the displayed marker, audit, delegation, target-resolution, transport, continuation, provenance, ledger, and naming coordinates.

Use audit-face separation to keep A apart from the host-kernel delegation row, and use the marker boundary to force every marker readback through the exact target-resolution row D. The transport and continuation rows then replay the same finite route without introducing a second resolver.

Finally apply primitive scope binding and non-escape. These results confine the exported socket to the displayed BHist, hsame, Cont, Pkg, imported acceptance and route surfaces, and local $\mathsf{NameCert}_{\mathsf{HostDelegationSocket}^{\uparrow}}$ row; the ledger L refuses every stronger host-level predicate or forbidden dependency claim. □

Closure status for $\mathsf{NameCert}_{\mathsf{HostDelegationSocket}^{\uparrow}}$.

Constructive story: A $\mathsf{HostDelegationSocket}^{\uparrow}$ packet is generated from a manuscript marker row, audit-face row, host-kernel delegation row, displayed target-resolution row, componentwise hsame transports, displayed Cont routes, Pkg provenance, a boundary ledger, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{HostDelegationSocket}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: Definition 551.1, Definition 551.2, Definition 551.3, Definition 551.4, Definition 551.5, Definition 551.6, and Definition 551.7 specify the finite host delegation socket carrier, local naming obligations, audit separation, marker boundary, transport replay, provenance, primitive scope, non-escape ledger, and consumer-facing public socket interface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{HostDelegationSocket}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close host truth predicates, global CIC completeness, bridge checking, source-axiom admission, forbidden host-dependency admission, fuzzy marker matching, or Lean-side formal verification for $\mathsf{HostDelegationSocket}^{\uparrow}$.

Upgrade path: Lean verification requires a checked public-interface theorem and an audit-clean bridge surface for $\mathsf{HostDelegationSocket}^{\uparrow}$.

Chapter 552

A Concrete Naming Certificate for $\mathsf{TasteGateAuditTrace}^{\uparrow}$

The $\mathsf{TasteGateAuditTrace}^{\uparrow}$ packet is the concrete audit-trace surface for the theory-stability gate of chapter 9459. It records an AI-origin chapter admission trace as a finite NameCert object whose rows display the four TasteGate obligations, replayable audit evidence, ground-compiler provenance, and a ledger preventing the trace from exporting hidden approval.

The trace consumes the compiler-facing witness of chapter 563 for its event-flow and compiler-provenance rows, and it consumes the audit-gate boundary of chapter 526 for refusal and replay boundary rows. Those sibling surfaces supply the concrete routes reread by the audit trace rather than a detached kernel-only admission fact.

Definition 552.1 (TasteGate audit trace carrier)**.** *A* $\mathsf{TasteGateAuditTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (X, O, Q, A, R, G, H, C, P, L)$$

with the following displayed rows:

1. *X is the candidate chapter identity row, recording the chapter label, proposed carrier name, and concrete paper site;*
2. *O is the AI-origin row, recording that the trace is evaluated on the AI-proposed admission track;*
3. *Q is the four-obligation* $\mathsf{ChapterTasteGate}$ *row, displaying conservativity, no-hidden-input, round-trip, and layer-separation witnesses for the same candidate;*
4. *A is the audit replay row, storing the finite replay route by which the admission check rereads $X, O, Q, R, G, H, C, P, L$;*
5. *R is the ground-compiler provenance row, listing the finite event-flow image and named compiler facts used by the no-hidden-input, round-trip, and layer-separation reads;*
6. *G is the GAP accounting row for absent carrier, absent classifier, absent TasteGate witness, absent replay, absent compiler provenance, absent transport, absent package, and attempted hidden approval cases;*
7. *H stores componentwise* hsame *transports for every displayed row of the packet;*
8. *C records the* Cont *routes that expose the candidate identity, AI-origin row, TasteGate obligations, audit replay, compiler provenance, and GAP accounting to a consumer;*

9. *P is the* Pkg *provenance over* BHist, NameCert, ChapterTasteGate, *audit replay rows, ground-compiler provenance rows, GAP accounting,* hsame, Cont, *and local naming;*
10. *L is the local naming row for* $\mathsf{NameCert}_{\mathsf{TasteGateAuditTrace}^{\uparrow}}$.

The carrier has no coordinate for hidden prompt state, host-side mathematical approval, an oracle classifier, an unlisted compiler theorem, or a chapter admission fact detached from the displayed audit rows.

Lean4 (definition) `BEDC.Derived.TasteGateAuditTraceUp.TasteGateAuditTraceUp`
Lean4 ✓ `BEDC.Derived.TasteGateAuditTraceUp.TasteGateAuditTraceUp single carrier alignment`

Definition 552.2 (TasteGate audit trace classifier)**.** *The classifier of a* $\mathsf{TasteGateAuditTrace}^{\uparrow}$ *packet accepts precisely those finite packets*

$$T = (X, O, Q, A, R, G, H, C, P, L)$$

whose rows display the same candidate chapter identity, whose AI-origin row O is present, whose ChapterTasteGate *row Q contains all four obligation witnesses, whose audit replay row A rereads the displayed rows only, whose ground-compiler provenance row R names the compiler evidence used by Q, and whose GAP row G accounts for every refused route seeking a missing witness or hidden approval channel.*

Theorem 552.3 (TasteGate audit trace NameCert obligations)**.** *For every accepted* $\mathsf{TasteGateAuditTrace}^{\uparrow}$ *carrier*

$$T = (X, O, Q, A, R, G, H, C, P, L),$$

the local $\mathsf{NameCert}_{\mathsf{TasteGateAuditTrace}^{\uparrow}}$ *surface consists exactly of carrier admission for T, candidate identity through X, AI-origin exposure through O, four-obligation* ChapterTasteGate *exposure through Q, audit replay through A, ground-compiler provenance through R, refused-route accounting through G, componentwise transport through H, consumer routes through C, package provenance through P, and local naming through L.*

Proof. Carrier admission and classification are projections from Definition 552.1 and Definition 552.2. The packet exposes exactly the candidate identity, origin row, TasteGate row, replay row, compiler provenance row, refusal ledger, transport rows, continuation routes, package provenance, and local naming row.

The four TasteGate obligations are all read from Q. Because Q belongs to the same finite carrier as X and O, a consumer cannot detach the obligation witnesses from the candidate chapter or from the AI-origin admission track.

The replay and provenance obligations are supplied by A and R. The row A records how the trace is reread, while R records the event-flow image and compiler facts supporting the no-hidden-input, round-trip, and layer-separation reads.

Finally G, H, C, P, L account for refused reads, preserve the same rows under transport, expose only named consumer routes, record package provenance, and name the certificate locally. No further NameCert obligation is available outside the displayed packet. □

Theorem 552.4 (TasteGate audit trace ground compiler boundary)**.** *Every accepted* $\mathsf{TasteGateAuditTrace}^{\uparrow}$ *route that consumes the four-obligation row Q must pass through the audit replay row A and the ground-compiler provenance row R. The route may export the displayed conservativity, no-hidden-input, round-trip, and layer-separation witnesses for the candidate chapter, but it cannot cite hidden prompt state, an unlisted compiler theorem, or host-side approval as part of the trace.*

Proof. Start with the carrier in Definition 552.1. The only row carrying TasteGate obligations is Q, and the only rows that make those obligations auditable are A and R.

The replay row A binds a consumer read to the finite packet. Any read of Q is therefore a replay of the displayed candidate identity, AI-origin row, TasteGate row, provenance row, transport rows, continuation rows, package row, and naming row.

The provenance row R supplies the compiler-facing boundary. It names the finite event-flow image and compiler facts used by the no-hidden-input, round-trip, and layer-separation witnesses.

Since the carrier contains no row for hidden prompt state, unlisted compiler facts, or host-side approval, these objects cannot be exported by an accepted audit trace. □

Theorem 552.5 (TasteGate audit trace non-escape)**.** *Every consumer of an accepted* $\mathsf{TasteGateAuditTrace}^{\uparrow}$ *packet factors through the finite rows*

$$(X, O, Q, A, R, G, H, C, P, L).$$

The consumer can read the AI-origin chapter identity, the four TasteGate obligation witnesses, audit replay, ground-compiler provenance, refused-route accounting, transport, continuation, package, and local naming data. It cannot extract hidden prompt state, oracle approval, an unnamed chapter object, a host-side semantic judgment, or a compiler fact absent from R.

Proof. Project the consumer route through the carrier. Its available coordinates are exactly $X, O, Q, A, R, G, H, C, P, L$.

Use Definition 552.3 for the NameCert surface. It accounts for the candidate identity, AI-origin row, four TasteGate witnesses, replay row, compiler provenance, refused routes, transports, continuations, package provenance, and local naming.

Use Definition 552.4 for the compiler-facing boundary. It keeps every read of the four-obligation row attached to replay and to the displayed ground-compiler provenance.

The forbidden outputs have no coordinate in the packet and no continuation route in C. Therefore any route exporting them would leave the accepted $\mathsf{TasteGateAuditTrace}^{\uparrow}$ carrier rather than consume it. □

Closure status for $\mathsf{NameCert}_{\mathsf{TasteGateAuditTrace}^{\uparrow}}$**.**

Constructive story: A $\mathsf{TasteGateAuditTrace}^{\uparrow}$ packet is generated from a candidate chapter identity row, AI-origin row, four-obligation ChapterTasteGate row, audit replay row, ground-compiler provenance row, GAP accounting row, componentwise transports, continuation routes, package provenance, and local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TasteGateAuditTrace}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 552.1, Definition 552.2, Definition 552.3, Definition 552.4, and Definition 552.5 bind the seed carrier, classifier, local NameCert surface, compiler boundary, and non-escape ledger for AI-origin TasteGate audit traces.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TasteGateAuditTrace}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove the candidate chapter's mathematical content, certify host semantics, close bridge checking, or provide Lean verification for the audit-trace packet.

Upgrade path: Obligation closure requires checked carrier, classifier, NameCert-surface, compiler-boundary, replay, ledger, and non-escape theorems for the same finite audit-trace packet.

Chapter 553

A Concrete Naming Certificate for $\mathsf{GeneratorInductionSeal}^{\uparrow}$

The $\mathsf{GeneratorInductionSeal}^{\uparrow}$ surface names the generator-internal induction packet that remains inside an authorized generator while recording every attempted passage to free-floating induction as Gap residue. It combines the authorized generator row, the continuation witness row required by the generator-closure classifier, the closure classifier row itself, the residue ledger, transport rows, continuation routes, package provenance, and local naming into one finite certificate.

The seal substantively consumes the authorized-generator route of chapter 525 and the closure classifier surface of chapter 486 before it records the residue ledger. The induction seal reads an authorized generator row and a generator-closure classifier row before it can expose any free-floating-induction refusal.

Definition 553.1 (Generator induction seal carrier)**.** *A* $\mathsf{GeneratorInductionSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (G, W, K, R, H, C, P, N)$$

with the following displayed rows:

1. *G is the authorized generator row whose constructor-list provenance supplies the only internal induction authority;*
2. *W is the continuation witness row carried by every accepted generator-internal continuation;*
3. *K is the closure classifier row that checks whether a continuation remains inside the closure of G with the witness W;*
4. *R is the* Gap *ledger row recording every requested passage from the displayed generator-internal route to an unscoped induction claim;*
5. *H records componentwise* hsame *transports for G, W, K, R, package provenance, and the local naming row;*
6. *C records the displayed* Cont *routes for reading the generator row, replaying the witness-carrying continuation, consulting the closure classifier, emitting residue, and exporting the local packet;*
7. *P is the* Pkg *provenance over* BHist*, authorized generator rows, continuation witnesses, closure classifier rows,* Gap *ledger rows,* hsame*,* Cont*, and* NameCert*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{GeneratorInductionSeal}^{\uparrow}}$ *row.*

The carrier contains no induction rule over unnamed objects, no erased residue, and no route that turns a continuation lacking W into a continuation of G.

Lean4 ✓ `BEDC.Derived.GeneratorInductionSealUp.GeneratorInductionSealTasteGate single carrier alignment`

Theorem 553.2 (Generator induction seal NameCert obligations)**.** *For the carrier of Definition 553.1, the local* $\mathsf{NameCert}_{\mathsf{GeneratorInductionSeal}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$S = (G, W, K, R, H, C, P, N),$$

authorized-generator exposure, continuation-witness preservation, closure-classifier lookup, Gap *residue retention, componentwise* hsame *stability, displayed* Cont *replay,* Pkg *provenance, and NameCert export for the same finite packet.*

Proof. Carrier admission is projection from Definition 553.1. The packet exposes only the eight displayed rows G, W, K, R, H, C, P, N.

Generator authority is read from G, witness-carrying continuation from W, and closure classification from K. These rows determine which induction routes remain internal to the authorized generator.

Residue, transport, replay, and provenance are confined by R, H, C, P. The local row N exports only this packet as a naming certificate, so no projection can add a hidden universal induction principle. □

Theorem 553.3 (Generator induction seal continuation witness)**.** *Every continuation accepted by a* $\mathsf{GeneratorInductionSeal}^{\uparrow}$ *packet carries the displayed witness row W and is checked by the closure classifier row K against the authorized generator row G. A continuation that cannot replay W through the displayed* Cont *route is not a continuation of this seal.*

Proof. Read the proposed continuation through C. If it is accepted, the route reaches G, replays W, and consults K before the local certificate row is exported.

The transport row H preserves the same generator, witness, classifier, residue, package, and naming coordinates. Thus a transported accepted continuation still carries the displayed witness.

If the route cannot replay W, no carrier coordinate classifies it as a continuation of G. It is therefore outside the seal rather than an induction step of the packet. □

Theorem 553.4 (Generator induction seal GAP non-escape)**.** *Whenever a requested continuation is not classified by K as a witness-carrying continuation of the authorized generator row G, the* $\mathsf{GeneratorInductionSeal}^{\uparrow}$ *packet records the request only as* Gap *residue in R. The residue may be transported, replayed as a refusal, packaged, and named, but it cannot become an internal induction theorem.*

Proof. Inspect the classifier row K. If the request is not accepted as a continuation of G carrying W, the only coordinate that records it is the residue row R.

Transport through H preserves residue as residue. Replay through C can expose the refusal and package it through P, while N names the same boundary.

The carrier has no conversion row from residue to induction authority. Therefore the Gap ledger cannot export an internal induction theorem or a free-floating closure principle. □

Theorem 553.5 (Generator induction seal public package)**.** *The public export of a* $\mathsf{GeneratorInductionSeal}^{\uparrow}$ *packet is exactly the finite NameCert packet over the authorized generator row G, continuation witness row W, closure classifier row K,* Gap *ledger row R, componentwise* hsame *transports, displayed* Cont *routes, and* Pkg *provenance. A consumer can recover generator authority, witness status, classifier status, and residue location, but no induction object beyond those rows.*

Proof. Start with the carrier tuple $S = (G, W, K, R, H, C, P, N)$. The export row N names this tuple and no larger surface.

A consumer recovers generator authority from G, witness status from W, classifier status from K, and residue location from R. The same consumer uses H for componentwise transport, C for replay, and P for provenance.

These rows exhaust the public package. Since S has no coordinate for an unnamed induction principle, hidden eliminator, or erased residue, the NameCert packet cannot export such content. □

Closure status for $\mathsf{NameCert}_{\mathsf{GeneratorInductionSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{GeneratorInductionSeal}^{\uparrow}$ packet is generated from an authorized generator row, a continuation witness row, a closure classifier row, a Gap ledger row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{GeneratorInductionSeal}^{\uparrow}}$, seed)

Scope closed: Definition 553.1, Definition 553.2, Definition 553.3, Definition 553.4, and Definition 553.5 bind the finite carrier, witness-carrying continuation route, classifier boundary, residue ledger, and NameCert export.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{GeneratorInductionSeal}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, induction over unnamed objects, erased GAP residue, or continuations outside the displayed generator witness.

Upgrade path: Obligation closure requires a checked carrier and finite theorems for witness preservation, classifier stability, residue non-escape, provenance, and NameCert export.

Chapter 554

A Concrete Naming Certificate for $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$

This chapter packages the AxisZeckendorf non-claim surface as a finite NameCert packet. Its carrier records checked negative theorem rows, horizon refusal rows, displayed transport, continuation routes, package provenance, and a local naming row; it does not add an arithmetic interpretation of the carry classifier.

Definition 554.1 (AxisZeckendorf cannot-claim registry packet)**.** *An* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *registry packet is a finite* BHist *tuple*

$$R = (a, b, c, d, e, f, g, h, p, n)$$

with the following visible coordinates:

1. *a is the negative theorem row for* `word_011` *and* `word_100`*, citing the non-*hsame *separation of Definition 9350.1;*
2. *b is the carry-not-*hsame *row, citing Definition 9350.2;*
3. *c is the non-normality row for* `word_011`*, citing Definition 9350.3;*
4. *d is the boundary-zero-spine exclusion row, citing Definition 9350.4;*
5. *e is the horizon refusal row for* $\mathsf{FullAxis}^{\uparrow}$ *as* $\mathsf{Real}^{\uparrow}$*, citing Definition 9350.6;*
6. *f is the horizon refusal row for* $\mathsf{AxisNat}^{\uparrow}$ *as* $\mathsf{Nat}^{\uparrow}$*, citing Definition 9350.7;*
7. *g is the horizon refusal row for primitive dimension lift, citing Definition 9350.5;*
8. *h is the componentwise* hsame *and* Cont *route ledger by which consumers inspect exactly the rows a, b, c, d, e, f, g;*
9. *p is the* Pkg *provenance over* BHist*,* hsame*,* $\mathsf{ZCarry}^{\uparrow}$*,* $\mathsf{ZeckendorfNormal}^{\uparrow}$*,* $\mathsf{AxisNat}^{\uparrow}$*,* $\mathsf{FullAxis}^{\uparrow}$*,* $\mathsf{DimLift}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* NameCert*;*
10. *n is the local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *row.*

The packet has no coordinate for a Real completion, a natural-number replacement, a geometric dimension, a kernel rewrite, a quotient of histories, or a host arithmetic equality.

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.TasteGate.AxisZeckendorfCannotClaimTasteGate`
`single carrier alignment`

Theorem 554.2 (AxisZeckendorf cannot-claim public boundary)**.** *Every public read of an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *registry packet* $R = (a, b, c, d, e, f, g, h, p, n)$ *factors through the displayed rows* $a, b, c, d, e, f, g, h, p, n$*. The packet cannot export RealUp completion data, NatUp replacement data, DimLift primitive data, quotient data, or kernel rewrite data.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket public boundary`

Proof. Project the displayed BHist packet in Definition 554.1. Its public inventory is exactly the seven refusal rows, the route ledger, the package row, and the local naming row.

The existing non-escape theorem for the registry states that public reads cannot leave that inventory. The carrier itself contains no row for RealUp completion, NatUp replacement, primitive dimension lift, quotient formation, or kernel rewriting.

Thus every public read is a read of $a, b, c, d, e, f, g, h, p, n$, and every excluded positive structure remains outside the exported surface. □

Theorem 554.3 (AxisZeckendorf cannot-claim refusal ledger row)**.** *Every accepted refusal read of an* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *registry packet is determined by exactly one of the seven refusal rows* a, b, c, d, e, f, g *before the route row* h*, provenance row* p*, or local naming row* n *is consumed.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket refusal ledger row`

Proof. The carrier lists the refusal rows first: a, b, c, d are theorem-level refusals and e, f, g are horizon refusals. These rows are the only coordinates that state refusal content.

The route row h can transport an already selected refusal row, and the rows p, n can record package provenance and local naming. None of h, p, n is itself a refusal source.

The existing refusal transport and non-escape statements keep this selection inside the displayed packet. Therefore an accepted refusal read has exactly one source among a, b, c, d, e, f, g before any route or provenance row is read. □

Theorem 554.4 (AxisZeckendorf cannot-claim downstream unblock)**.** *Downstream* $\mathsf{AxisNat}^{\uparrow}$*,* $\mathsf{FullAxis}^{\uparrow}$*,* $\mathsf{ZCarry}^{\uparrow}$*,* $\mathsf{ZeckendorfNormal}^{\uparrow}$*,* $\mathsf{DimLift}^{\uparrow}$*, and Real-horizon consumers of an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *packet may cite only the finite refusal ledger* $a, b, c, d, e, f, g, h, p, n$*. They receive no positive AxisNat bridge, FullAxis bridge, carry-equality bridge, normal-form bridge, primitive dimension bridge, or RealUp bridge from this registry.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket downstream unblock`

Proof. Start with the public boundary. It confines every downstream read to the displayed finite registry rows and excludes the positive structures that would be needed for bridge data.

Next use the refusal ledger row. A downstream consumer first selects one refusal source among a, b, c, d, e, f, g and then may route or record that selected row through h, p, n.

The existing refusal transport theorem keeps the selected row as a refusal under componentwise hsame and Cont movement. Hence the downstream consumer can cite the cannot-claim ledger, but it cannot obtain a positive bridge for the listed AxisNat, FullAxis, carry, normal-form, dimension, or Real horizon surfaces. □

Theorem 554.5 (AxisZeckendorf Real-horizon refusal route)**.** *For an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *registry packet* $R = (a, b, c, d, e, f, g, h, p, n)$*, every downstream read that asks for* $\mathsf{FullAxis}^{\uparrow}$ *as a* $\mathsf{Real}^{\uparrow}$ *completion factors through the displayed refusal row* e*, then through the componentwise route row* h*, the provenance row* p*, and the local naming row* n*. The route supplies only the refusal recorded in Definition 9350.6; it does not provide a* $\mathsf{Real}^{\uparrow}$ *carrier, a completion operation, a quotient stream, a host real equality, or a selected limit.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket real refusal route`

Proof. Project the carrier definition. Row e is the only coordinate whose content is the $\mathsf{FullAxis}^{\uparrow}$-as-$\mathsf{Real}^{\uparrow}$ horizon refusal, and the carrier has no Real completion coordinate.

Apply the refusal ledger row. It forces the downstream Real-horizon request to select one displayed refusal source before any transport or package row is consumed; for this request the selected source is exactly e.

Transport non-promotion is supplied by the refusal transport theorem. The row h can move the selected refusal through componentwise hsame and Cont routes, but it cannot turn that refusal into a positive $\mathsf{Real}^{\uparrow}$ bridge.

Finally apply the downstream unblock and public boundary theorems. The read remains inside e, h, p, n, so it exports the stated refusal and no Real completion data, quotient stream, host real equality, or selected limit. □

Theorem 554.6 (AxisZeckendorf Nat-horizon refusal route)**.** *For an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *registry packet* $R = (a, b, c, d, e, f, g, h, p, n)$*, every downstream read that asks for* $\mathsf{AxisNat}^{\uparrow}$ *as a replacement for* $\mathsf{Nat}^{\uparrow}$ *factors through the displayed refusal row* f*, then through the componentwise route row* h*, the provenance row* p*, and the local naming row* n*. The route supplies only the refusal recorded in Definition 9350.7; it does not provide a natural-number replacement carrier, a recursion principle, a host arithmetic equality, or a positive Zeckendorf construction.*

Proof. Project the carrier definition. Row f is the only coordinate whose content is the $\mathsf{AxisNat}^{\uparrow}$-as-$\mathsf{Nat}^{\uparrow}$ horizon refusal, and no coordinate of R stores a replacement $\mathsf{Nat}^{\uparrow}$ carrier.

Use the refusal ledger row to isolate the source. A downstream natural-number request must first choose one of a, b, c, d, e, f, g as its refusal source, and the $\mathsf{AxisNat}^{\uparrow}$ replacement request chooses f.

The refusal transport theorem gives the only permitted movement of this row. Transport through h preserves the refusal as a refusal under hsame and Cont routing; it does not promote f to induction, recursion, or host arithmetic data.

The downstream unblock theorem and the public boundary then close the route. The consumer may cite f, h, p, n, but it receives no $\mathsf{Nat}^{\uparrow}$ replacement surface and no positive Zeckendorf construction. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket nat refusal route`

Theorem 554.7 (AxisZeckendorf dimension-lift refusal route)**.** *For an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *registry packet* $R = (a, b, c, d, e, f, g, h, p, n)$*, every downstream read that asks for primitive* $\mathsf{DimLift}^{\uparrow}$ *interpretation factors through the displayed refusal row* g*, then through the componentwise route row* h*, the provenance row* p*, and the local naming row* n*. The route supplies only the refusal recorded in Definition 9350.5; it does not provide a primitive geometric dimension, a host coordinate system, a quotient of histories, or a positive dimensional semantics.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket dimlift refusal route`

Proof. Project the carrier definition. Row g is the only coordinate whose content is the primitive dimension-lift horizon refusal, and the packet has no coordinate for a geometric dimension or host coordinate system.

Apply the refusal ledger row. A downstream dimension request is accepted only after selecting one displayed refusal source, and the primitive $\mathsf{DimLift}^{\uparrow}$ request selects g before route, provenance, or naming data are read.

Transport non-promotion follows from the refusal transport theorem. The componentwise row h can preserve and replay the refusal through hsame and Cont, but it cannot convert the refusal into primitive dimensional semantics.

Finally use downstream unblock together with the public boundary. The read remains confined to g, h, p, n, so no quotient of histories, primitive geometric dimension, host coordinate system, or positive dimensional semantics is exported. □

Theorem 554.8 (AxisZeckendorf cannot-claim registry obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *surface for the carrier of Definition 554.1 consists exactly of four finite obligation families:*

1. *negative theorem coverage for* `word_011` *versus* `word_100`*, carry-not-*hsame*,* `word_011` *non-normality, and boundary-zero-spine exclusion;*
2. *horizon refusal coverage for* $\mathsf{FullAxis}^{\uparrow}$ *as* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{AxisNat}^{\uparrow}$ *as* $\mathsf{Nat}^{\uparrow}$*, and primitive dimension lift;*
3. *componentwise transport and continuation routing for every visible refusal row;*
4. *ledger exactness through the displayed* Pkg *provenance and local* $\mathsf{NameCert}$ *row.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket semantic name certificate`

Proof. The negative theorem rows are precisely a, b, c, d in the registry packet. Each row names an already stated AxisZeckendorf refusal and therefore supplies a finite citation target rather than a new classifier.

The horizon refusal rows are e, f, g. They expose only the three named non-claims: no $\mathsf{FullAxis}^{\uparrow}$ field or completion route is read as $\mathsf{Real}^{\uparrow}$, no $\mathsf{AxisNat}^{\uparrow}$ carrier is read as $\mathsf{Nat}^{\uparrow}$, and no $\mathsf{DimLift}^{\uparrow}$ seed is read as a primitive geometric dimension.

Transport and continuation routing are carried by h. Since the route ledger is componentwise, it can move a displayed refusal row to an equivalent registry presentation without turning a refusal into a positive bridge.

Finally, p and n record the package and local name boundary. Every public read of the registry passes through the seven refusal rows and these provenance coordinates, so the obligation surface is exhausted by the displayed packet. □

Theorem 554.9 (AxisZeckendorf source row coverage)**.** *For the concrete carrier* $R = (a, b, c, d, e, f, g, h, p, n)$ *of Definition 554.1, the source rows* a, b, c, d, e, f, g *exactly cover the checked refusal surface:* a, b, c, d *are the four negative theorem rows, and* e, f, g *are the three horizon refusal rows. No source row outside* a, b, c, d, e, f, g *is available in the carrier.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket source row coverage`

Proof. Read the carrier definition coordinate by coordinate. Rows a, b, c, d are respectively the `word_011`–`word_100` non-hsame row, the carry-not-hsame row, the `word_011` non-normality row, and the boundary-zero-spine exclusion row.

Rows e, f, g are respectively the $\mathsf{FullAxis}^{\uparrow}$-as-$\mathsf{Real}^{\uparrow}$ refusal, the $\mathsf{AxisNat}^{\uparrow}$-as-$\mathsf{Nat}^{\uparrow}$ refusal, and the primitive dimension-lift refusal. These are precisely the two coverage families named in Definition 554.8.

The remaining carrier coordinates are h, p, n. They provide route, package, and local naming data, not source refusal rows. Hence the seven displayed source rows exhaust the refusal surface of the concrete registry packet. □

Theorem 554.10 (AxisZeckendorf refusal transport)**.** *Let r be any public transport accepted by an* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *registry packet for one of the refusal rows a, b, c, d, e, f, g of $R = (a, b, c, d, e, f, g, h, p, n)$. Then r factors through the componentwise* hsame *relation and the displayed* Cont *route recorded in row h; it cannot pass through a parameter-equivalence transport external to the carrier.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket refusal transport`

Proof. By Definition 554.1, row h is the only transport and continuation coordinate of the packet. It is stated componentwise over exactly the visible refusal rows a, b, c, d, e, f, g.

Apply the transport family in Definition 554.8. That theorem identifies componentwise transport and continuation routing as one of the four finite obligation families of the local NameCert surface.

Since no other transport coordinate appears in R, an accepted public movement of a refusal row must use the hsame and Cont route displayed by h. The packet therefore supplies no external equivalence route that could turn a refusal row into a positive bridge. □

Theorem 554.11 (AxisZeckendorf ledger exactness)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the provenance rows p and n exhaust the public* Pkg *and* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *ledger. Consequently the packet cannot export RealUp operations, NatUp replacement, primitive dimension, quotient of histories, kernel rewrite, or standard-model bridge data.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket ledger exactness`

Proof. The carrier definition assigns p to the displayed Pkg provenance and n to the local $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannot}}$ row. There is no second package row, no second naming row, and no hidden coordinate in the tuple R.

The ledger exactness family in Definition 554.8 reads exactly these two provenance coordinates together with the refusal rows and the route row h. Thus every public ledger read has to pass through p or n after the visible refusal surface has been selected.

RealUp operations, NatUp replacement, primitive dimension, quotient formation, kernel rewriting, and standard-model bridge data would each require a positive coordinate outside this ledger. Because the carrier lists no such coordinate, the provenance rows are exact and cannot export any of those structures. □

Theorem 554.12 (AxisZeckendorf negative theorem surface)**.** *Every theorem-level refusal exported by an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *packet is one of the four negative rows a, b, c, d: the* `word_011`–`word_100` *non-*hsame *row, the carry-not-*hsame *row, the* `word_011` *non-normality row, or the boundary-zero-spine exclusion row.*

Proof. Inspect the carrier coordinates of Definition 554.1. The only theorem-level refusal rows are a, b, c, d.

The route ledger h transports these rows componentwise. It does not introduce a fifth negative theorem, because it has no theorem coordinate apart from the transported row it is carrying.

The package and local naming rows p, n record provenance only. Thus a consumer cannot extract a further theorem-level refusal from the registry beyond the four displayed rows. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket negative theorem surface`

Theorem 554.13 (AxisZeckendorf cannot-claim non-escape)**.** *Every public read exported by an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *packet factors through* $a, b, c, d, e, f, g, h, p, n$*. In particular, the registry cannot be used to construct an* $\mathsf{hsame}(\mathtt{word_011}, \mathtt{word_100})$ *witness, a RealUp structure on* $\mathsf{FullAxis}^{\uparrow}$*, an identification of* $\mathsf{AxisNat}^{\uparrow}$ *with* $\mathsf{Nat}^{\uparrow}$*, a primitive dimension for* $\mathsf{DimLift}^{\uparrow}$*, or a kernel rewrite rule.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket non escape`

Proof. Begin with the registry inventory. The packet contains exactly four negative theorem rows, three horizon refusal rows, the componentwise transport and continuation ledger, package provenance, and a local naming row.

The negative reads factor through a, b, c, d, and the horizon reads factor through e, f, g. The only admissible movement of those reads is the componentwise hsame and Cont routing recorded by h.

The package row p and local name row n do not add mathematical structure; they record where the displayed rows come from. Since none of the excluded objects appears as a coordinate, no public consumer can extract a positive bridge, equality, dimension, or rewrite from the registry packet. □

Theorem 554.14 (AxisZeckendorf cannot-claim consumer horizon exhaustion)**.** *Any downstream consumer of an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *registry packet can read only the negative theorem rows* a, b, c, d*, the horizon refusal rows* e, f, g*, the transport and route ledger* h*, the provenance row* p*, and the local* $\mathsf{NameCert}$ *row* n*. Consequently the packet cannot supply a* $\mathsf{Real}^{\uparrow}$ *completion, a* $\mathsf{Nat}^{\uparrow}$ *replacement, a primitive dimension-lift operation, a kernel rewrite, a quotient of histories, or a standard-model bridge.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket consumer horizon exhaustion`

Proof. Start with the registry packet of Definition 554.1. Its displayed rows are exactly $a, b, c, d, e, f, g, h, p, n$.

The theorem-level consumer reads are exhausted by Definition 554.12: they are precisely the negative rows a, b, c, d.

The remaining horizon reads are the refusal rows e, f, g, transported and routed through h and recorded through p, n. By Definition 554.13, this public surface cannot export any coordinate beyond the registry inventory.

Since a $\mathsf{Real}^{\uparrow}$ completion, $\mathsf{Nat}^{\uparrow}$ replacement, primitive dimension-lift operation, kernel rewrite, quotient, or standard-model bridge would require a positive coordinate not present in the registry, no downstream consumer can derive one from the packet. □

Theorem 554.15 (AxisZeckendorf refusal row determinacy)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, every accepted refusal read is determined by exactly one displayed source row among a, b, c, d, e, f, g. The rows a, b, c, d determine theorem-level refusals, the rows e, f, g determine horizon refusals, and no accepted refusal read is determined by h, p, or n.*

Proof. The packet definition displays the seven refusal coordinates before any route or provenance coordinate. By Definition 554.1, a, b, c, d are the negative theorem rows and e, f, g are the horizon refusal rows.

The obligation statement in Definition 554.8 separates these two refusal families from the transport and ledger families. Thus an accepted refusal read first selects one of the displayed source rows, not a route row or a provenance row.

The non-escape theorem Definition 554.13 and the consumer exhaustion theorem Definition 554.14 leave no public read outside $a, b, c, d, e, f, g, h, p, n$. Since h only routes and p, n only record provenance, the selected refusal source is unique among a, b, c, d, e, f, g. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket refusal row determinacy`

Theorem 554.16 (AxisZeckendorf transport non-promotion)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the componentwise* hsame *and* Cont *ledger h transports refusal rows only as refusal rows. It does not promote any transported row into an* hsame *witness, a* $\mathsf{Real}^{\uparrow}$ *completion, a* $\mathsf{Nat}^{\uparrow}$ *replacement, a primitive dimension, a quotient, or a kernel rewrite.*

Proof. The packet definition assigns the only transport and continuation coordinate to h. That coordinate is componentwise over the displayed refusal rows, so its source and target data are still rows drawn from a, b, c, d, e, f, g.

The routing family in Definition 554.8 records transport and continuation as an obligation on visible refusals. It does not add a positive equality, completion, replacement, dimension, quotient, or rewrite coordinate.

Apply the non-escape boundary of Definition 554.13. Any public read exported by the packet factors through the displayed registry rows, and none of the promoted structures appears in that inventory.

Finally, Definition 554.14 says downstream consumers can read the ledger h only together with the refusal and provenance rows. Therefore componentwise hsame and Cont transport preserves the refusal status instead of converting it into a positive BEDC structure. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket transport nonpromotion`

Theorem 554.17 (AxisZeckendorf provenance exhaustion)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the provenance row p and the local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *row n exhaust the public provenance of the registry. They add no new mathematical coordinate beyond the seven refusal rows and the route ledger h.*

Proof. The registry packet definition names p as the displayed Pkg provenance row and n as the local $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ row. No further provenance coordinate occurs in R.

The ledger exactness family in Definition 554.8 binds the public ledger to the displayed package provenance and local naming row. The provenance read is therefore exhausted by p and n after the refusal row and route row have been selected.

By Definition 554.13, the packet cannot export a positive bridge, equality, dimension, quotient, or rewrite outside the registry inventory. By Definition 554.14, a downstream consumer has no additional public coordinate to inspect.

Thus p and n close the public provenance surface of the registry and do not contribute another mathematical coordinate. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket provenance exhaustion`

Theorem 554.18 (AxisZeckendorf refusal kernel scope)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the seven refusal rows a, b, c, d, e, f, g are scoped over the displayed* BHist*,* hsame*, and* Cont *registry rows. Every accepted refusal read is determined inside that registry surface and cannot be promoted to a positive arithmetic, RealUp, NatUp, dimension, quotient, or kernel-rewrite claim.*

Proof. Read the carrier definition. The rows a, b, c, d are the negative theorem rows, the rows e, f, g are the horizon refusal rows, and the row h is the componentwise transport and continuation route ledger for those rows.

Apply Definition 554.15. It assigns each accepted refusal read to exactly one displayed source row among a, b, c, d, e, f, g before any route or provenance row is consumed.

Use Definition 554.16. The hsame and Cont ledger transports refusal rows only as refusal rows, so the registry cannot turn them into a positive bridge, equality, completion, replacement, dimension, quotient, or rewrite coordinate. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket refusal kernel scope`

Theorem 554.19 (AxisZeckendorf registry classifier scope)**.** *Classifier reads of an accepted* AxisZeckendorfCannotC *registry packet are determined by the displayed rows $a, b, c, d, e, f, g, h, p, n$ of Definition 554.1. They are not determined by host arithmetic, a RealUp interpretation of* $\mathsf{FullAxis}^{\uparrow}$*, a NatUp interpretation of* $\mathsf{AxisNat}^{\uparrow}$*, or a primitive interpretation of the dimension-lift row.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket registry classifier scope`

Proof. The carrier definition gives the classifier only the seven refusal rows, the route ledger, package provenance, and local naming row. No host arithmetic interpretation, RealUp completion, NatUp replacement, or primitive dimension coordinate is present.

Apply Definition 554.15. It shows that an accepted refusal read selects a source row from a, b, c, d, e, f, g, not an external arithmetic or semantic interpretation.

Then use Definition 554.16. Transport through h preserves refusal status under the displayed hsame and Cont rows and cannot turn the selected registry row into any of the excluded positive structures. □

Theorem 554.20 (AxisZeckendorf ledger route scope)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the* Pkg *row p and local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *row n exhaust the consumer ledger route after the refusal source and componentwise route ledger have been selected. Thus every consumer access to the cannot-claim registry factors through the displayed refusal rows, h, p, and n.*

Proof. Start with the displayed registry packet. It lists the refusal source rows a, b, c, d, e, f, g, the componentwise route ledger h, the package row p, and the local naming row n.

Use Definition 554.15 to choose the refusal row inspected by the consumer. Use Definition 554.16 to route that row only through the displayed hsame and Cont ledger h.

Finally apply Definition 554.17. The rows p and n close the public provenance after the refusal and route rows have been selected, and no second package, naming, bridge, quotient, dimension, completion, replacement, or rewrite route is available. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket ledger route scope`

Theorem 554.21 (AxisZeckendorf negative row scope)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the four negative theorem rows a, b, c, d are scoped exactly over the displayed* BHist*,* hsame*, and* Cont *route surface. They are not promoted to positive equality, quotient, dimension, completion, replacement, or kernel-rewrite data.*

Proof. The packet definition displays a, b, c, d as the four theorem-level refusal rows before the horizon, route, provenance, and naming coordinates. The registry obligations assign their NameCert role to that visible refusal surface.

Apply refusal-row determinacy to separate a, b, c, d from the horizon rows and from h, p, n. Transport non-promotion then fixes the BHist, hsame, and Cont route surface as transport of refusals only, and non-escape prevents any promoted positive structure from entering the scope. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket negative row scope`

Theorem 554.22 (AxisZeckendorf horizon refusal scope)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the horizon refusal rows e, f, g scope exactly the refusal of* $\mathsf{Real}^{\uparrow}$ *completion,* $\mathsf{Nat}^{\uparrow}$ *replacement, and primitive dimension lift. They add no positive completion row, no Nat replacement carrier, and no primitive-dimension witness.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket horizon refusal scope`

Proof. The packet definition names e, f, g as the three horizon refusal rows. The registry-obligation and consumer-horizon-exhaustion theorems keep those rows in the public refusal inventory rather than in a positive construction inventory.

Refusal-row determinacy identifies each horizon read with one of e, f, g. Transport non-promotion and provenance exhaustion then show that h, p, n can only route and record these refusals, while non-escape rules out the corresponding positive $\mathsf{Real}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, and primitive-dimension objects. □

Theorem 554.23 (AxisZeckendorf FullAxis Real refusal boundary)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, every consumer that reads the FullAxis-as-Real horizon row e receives only the displayed* BHist *refusal row e, its componentwise* hsame *and* Cont *route through h, the* Pkg *provenance row p, and the local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *row n. The read supplies no promoted* $\mathsf{Real}^{\uparrow}$ *completion for* $\mathsf{FullAxis}^{\uparrow}$ *and no hidden real-valued axis reconstruction.*

Proof. The carrier definition places e among the three horizon refusal rows, and Definition 554.22 identifies it with the refusal of a $\mathsf{Real}^{\uparrow}$ completion read for the full axis surface.

Apply refusal-row determinacy to lock the consumer read to the displayed row e. Apply transport non-promotion to the componentwise route h: the hsame and Cont data can only carry the same refusal row, not a positive completion object.

Finally use provenance exhaustion. The rows p and n record the package and local name after the refusal source has already been selected, and non-escape excludes every second route to a real-valued axis carrier. Thus the consumer receives the finite refusal package and no promoted $\mathsf{Real}^{\uparrow}$ completion. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket fullaxis real refusal boundary`

Theorem 554.24 (AxisZeckendorf AxisNat Nat refusal boundary)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, every consumer that reads the AxisNat-as-Nat horizon row f receives only the displayed* BHist *refusal row f, its componentwise* hsame *and* Cont *route through h, the* Pkg *provenance row p, and the local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *row n. The read supplies no promoted* $\mathsf{Nat}^{\uparrow}$ *replacement for* $\mathsf{AxisNat}^{\uparrow}$ *and no hidden natural-number carrier.*

Proof. The carrier definition lists f as the AxisNat-as-Nat horizon refusal row, while Definition 554.22 fixes the row as a refusal rather than a positive $\mathsf{Nat}^{\uparrow}$ replacement.

Refusal-row determinacy assigns the accepted consumer read to f before any route, package, or naming coordinate is consumed. Transport non-promotion then keeps the h route inside the same refusal status; the displayed hsame and Cont data do not create a natural-number carrier.

Provenance exhaustion and non-escape close the boundary. The rows p, n only record the accepted cannot-claim package, and the registry has no second coordinate from which a $\mathsf{Nat}^{\uparrow}$ replacement for $\mathsf{AxisNat}^{\uparrow}$ can be read. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket axisnat nat refusal boundary`

Theorem 554.25 (AxisZeckendorf dimension-lift primitive refusal boundary)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, every consumer that reads the primitive dimension-lift horizon row g receives only the displayed* BHist *refusal row g, its componentwise* hsame *and* Cont *route through h, the* Pkg *provenance row p, and the local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *row n. The read supplies no primitive dimension witness and no promoted dimension-lift carrier.*

Proof. The carrier definition displays g as the primitive dimension-lift refusal row, and Definition 554.22 keeps that row inside the horizon-refusal surface.

Use refusal-row determinacy to identify g as the unique source of the accepted read. The componentwise route h is governed by transport non-promotion, so its hsame and Cont data can replay the refusal but cannot construct a primitive dimension witness.

The package and naming rows are exhausted by p and n. Together with non-escape, this leaves the consumer with the finite refusal row and its recorded route, provenance, and name, and with no promoted dimension-lift object. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket dimlift primitive refusal boundary`

Theorem 554.26 (AxisZeckendorf audit-gate consumption)**.** *Any audit-gate consumer of an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *registry packet*

$$R = (a, b, c, d, e, f, g, h, p, n)$$

must read refusal rows through a, b, c, d, e, f, g *and the route, provenance, and naming rows* h, p, n*. The consumer cannot turn the registry into* $\mathsf{Real}^{\uparrow}$ *completion data,* $\mathsf{Nat}^{\uparrow}$ *replacement data, primitive dimension data, a quotient, a kernel rewrite, or standard-model bridge data.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket audit gate consumption`

Proof. Begin with refusal-row determinacy. It assigns every accepted refusal read to one displayed source row among a, b, c, d, e, f, g before any route or provenance row is consumed.

Apply transport non-promotion to the audit route. The componentwise hsame and Cont ledger h transports refusal rows only as refusal rows, so it cannot promote the selected source into a positive completion, replacement, dimension, quotient, or rewrite coordinate.

Finally use provenance exhaustion together with negative-row and horizon-refusal scope. The rows p, n record the refusal route without adding mathematical data, and the scoped refusal theorems exclude the corresponding positive structures. Thus an audit-gate consumer receives only the displayed cannot-claim registry. □

Theorem 554.27 (AxisZeckendorf cannot-claim audit-gate boundary)**.** *Every audit consumer of an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *registry packet* $R = (a, b, c, d, e, f, g, h, p, n)$ *factors through the seven refusal rows* a, b, c, d, e, f, g *together with the route, provenance, and local naming rows* h, p, n*. Such a consumer cannot read* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Nat}^{\uparrow}$*, primitive dimension, quotient, kernel rewrite, or standard bridge data from the packet.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket audit gate boundary`

Proof. Start with audit-gate consumption. It confines every audit-facing read to the selected refusal source and to the displayed rows h, p, n.

Use non-escape and transport non-promotion for the boundary. The registry has no coordinate for RealUp completion, NatUp replacement, primitive dimension, quotient, kernel rewrite, or standard bridge data, and the route row h transports only refusal rows.

Finally apply provenance exhaustion and consumer horizon exhaustion. The rows p, n record package and local naming data without adding a mathematical coordinate, and every downstream audit read remains inside the displayed registry packet. □

Definition 554.28 (AxisZeckendorf cannot-claim route-provenance triad)**.** *After a selected refusal source* $x \in \{a, b, c, d, e, f, g\}$ *in the carrier* $R = (a, b, c, d, e, f, g, h, p, n)$*, the route-provenance triad is*

$$(h, p, n),$$

where h *is the componentwise* hsame *and* Cont *route for the selected refusal row,* p *is the* Pkg *provenance row for the cannot-claim registry, and* n *is the local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *row. The triad is read only after the refusal source has been chosen, and it is not itself a new refusal source.*

Theorem 554.29 (AxisZeckendorf route-provenance triad obligations)**.** *For the carrier $R = (a, b, c, d, e, f, g, h, p, n)$ and the triad (h, p, n) of Definition 554.28, the local obligation surface consists of carrier admission, transport through the displayed* hsame *and* Cont *route, ledger exactness through p, n, non-promotion of every selected refusal source, and exhaustion of all audit and downstream consumers by the selected source row together with the triad.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket route provenance triad obligations`

Proof. Carrier admission is the registry packet of Definition 554.1. The selected refusal source is one of a, b, c, d, e, f, g, and the triad supplies only the displayed route, provenance, and local naming rows.

Transport and non-promotion come from Definition 554.16. The row h may carry the selected refusal through hsame and Cont, but it cannot promote the refusal into a positive equality, completion, replacement, dimension, quotient, rewrite, or bridge.

Ledger exactness is supplied by Definition 554.17. The rows p, n exhaust the package and local naming surface, so the triad has no hidden ledger coordinate.

Finally apply Definition 554.14 and the audit-gate boundary of Definition 554.27. Every public consumer first chooses a refusal row and then reads only the triad, which proves consumer exhaustion without adding any forbidden positive structure. □

Theorem 554.30 (AxisZeckendorf negative refusal coverage)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the negative refusal coverage consumed by the* AxisZeckendorfCannotClai *obligation package is exactly the four rows a, b, c, d. These rows cover the non-*hsame *separation of* `word_011` *and* `word_100`*, the carry-not-*hsame *refusal, the* `word_011` *non-normality refusal, and the boundary-zero-spine refusal, and they do not promote to a positive equality, quotient, completion, dimension, replacement, or kernel-rewrite row.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket negative refusal coverage`

Proof. Start with the carrier definition. The packet lists a, b, c, d as the four negative theorem rows before the horizon, route, package, and local naming coordinates.

Use refusal-row determinacy and negative-row scope. Definition 554.15 selects one source row among a, b, c, d, e, f, g for every accepted refusal read, while Definition 554.21 identifies the theorem-level source family as exactly a, b, c, d.

Finally apply transport non-promotion and audit-gate consumption. The route row h may carry these refusals through hsame and Cont, but Definition 554.16 and Definition 554.26 prevent that route from becoming a positive BEDC object. □

Theorem 554.31 (AxisZeckendorf horizon refusal coverage)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the horizon refusal coverage consumed by the* AxisZeckendorfCannotClaim$^{\uparrow}$ *obligation package is exactly the three rows e, f, g. These rows cover the refusal of* FullAxis$^{\uparrow}$ *as* Real$^{\uparrow}$*, the refusal of* AxisNat$^{\uparrow}$ *as* Nat$^{\uparrow}$*, and the refusal of primitive dimension lift, with no hidden positive carrier behind the horizon.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket horizon refusal coverage`

Proof. Read the horizon coordinates from the carrier definition. Rows e, f, g are the only rows named for the three horizon-facing non-claims.

Apply horizon-refusal scope and refusal-row determinacy. Definition 554.22 fixes e, f, g as the $\mathsf{Real}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, and primitive-dimension refusal surface, and Definition 554.15 keeps each accepted horizon read on one displayed source row.

Use transport non-promotion, provenance exhaustion, and audit-gate consumption for the public route. The rows h, p, n can route and record the selected horizon refusal, but they cannot promote it to a completion, replacement, dimension, quotient, rewrite, or standard bridge. □

Theorem 554.32 (AxisZeckendorf ledger consumer exactness)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, every public consumer of the cannot-claim ledger routes through h, p, n after selecting one refusal source among a, b, c, d, e, f, g. The row h supplies the componentwise* hsame *and* Cont *route, the row p supplies the displayed* Pkg *provenance, and the row n supplies the local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *record.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket ledger consumer exactness`

Proof. Begin with the source choice. Refusal-row determinacy selects one row among a, b, c, d, e, f, g before any ledger coordinate is consumed.

Next route the selected row through h. Transport non-promotion says that the componentwise hsame and Cont ledger carries the same refusal status and cannot create a positive equality, completion, replacement, dimension, quotient, or rewrite.

Finally read the provenance and local name through p, n. Provenance exhaustion identifies these rows as the whole public package and naming surface, and audit-gate consumption confines every consumer of the registry to the selected refusal row together with h, p, n. □

Theorem 554.33 (AxisZeckendorf root-unblock package)**.** *The* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *root-unblock package is the finite* NameCert *obligation surface obtained by combining negative refusal coverage on a, b, c, d, horizon refusal coverage on e, f, g, and ledger consumer exactness through h, p, n. This surface is over* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* $\mathsf{ZCarry}^{\uparrow}$*,* $\mathsf{ZeckendorfNormal}^{\uparrow}$*,* $\mathsf{AxisNat}^{\uparrow}$*,* $\mathsf{FullAxis}^{\uparrow}$*,* $\mathsf{DimLift}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{Nat}^{\uparrow}$*, and it exports no Real completion, Nat replacement, primitive dimension, quotient, kernel rewrite, or standard bridge.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket root unblock package`

Proof. First assemble the refusal sources. Definition 554.30 supplies the four negative rows a, b, c, d, and Definition 554.31 supplies the three horizon rows e, f, g.

Next attach the public ledger. Definition 554.32 routes every consumer through h, p, n, so the selected refusal row is carried only by displayed BHist, hsame, Cont, Pkg, and local NameCert evidence.

Finally use audit-gate consumption and the existing scope boundaries. Negative-row scope, horizon-refusal scope, transport non-promotion, and provenance exhaustion keep the package on the cannot-claim surface over $\mathsf{ZCarry}^{\uparrow}$, $\mathsf{ZeckendorfNormal}^{\uparrow}$, $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{FullAxis}^{\uparrow}$, $\mathsf{DimLift}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{Nat}^{\uparrow}$ without adding any promoted BEDC object. □

Theorem 554.34 (AxisZeckendorf ledger route scope)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the rows h, p, n are the only public transport, package, and* NameCert *route for all consumers of the registry. Every public consumer must read refusal data through the componentwise* hsame *and* Cont *ledger h, the* Pkg *provenance row p, and the local naming row n.*

Proof. The carrier definition assigns route data to h, package provenance to p, and local naming to n. The registry obligations bind these rows to the same finite refusal inventory a, b, c, d, e, f, g.

Consumer-horizon exhaustion and provenance exhaustion leave no second transport, package, or naming coordinate for a public read. Together with non-escape and transport non-promotion, this forces every consumer route through h, p, n without adding a positive bridge, quotient, dimension, completion, replacement, or rewrite row. □

Theorem 554.35 (AxisZeckendorf refusal source lock)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, every accepted refusal reader first locks onto exactly one source row among a, b, c, d, e, f, g before it consumes the route ledger h, the provenance row p, or the local naming row n.*

Proof. Carrier projection gives the only refusal source inventory: the negative theorem rows a, b, c, d and the horizon refusal rows e, f, g. The route and provenance coordinates are listed only after that refusal source surface has been displayed.

Apply refusal-row determinacy. It assigns each accepted refusal read to one displayed source row among a, b, c, d, e, f, g, and it excludes h, p, n as refusal sources.

Transport non-promotion then fixes the role of h: it may route the selected refusal through componentwise hsame and Cont data, but it cannot choose a new source row or turn the selected source into a positive BEDC object. Provenance exhaustion fixes p, n as recording rows only, so the lock onto the unique source row precedes every route or provenance read. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket source lock`

Theorem 554.36 (AxisZeckendorf refusal reader totality)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$, the displayed refusal families a, b, c, d and e, f, g cover all public refusal reads exported by an accepted* AxisZeckendorfCannotClaim$^{\uparrow}$ *packet. No public refusal reader can be sourced by h, p, n or by data outside the carrier.*

Proof. The registry carrier exposes exactly two refusal families. Rows a, b, c, d are theorem-level refusals, and rows e, f, g are horizon refusals.

Negative theorem surface covers all theorem-level refusal reads, while consumer-horizon exhaustion covers the remaining horizon-facing reads. Together they leave only transport through h and recording through p, n after a refusal source has already been selected.

Refusal-row determinacy rules out h, p, n as source rows. Non-escape rules out every external source: the packet contains no RealUp completion, NatUp replacement, primitive dimension, quotient, host arithmetic, or kernel-rewrite coordinate from which another refusal reader could be drawn. □

Theorem 554.37 (AxisZeckendorf gap ledger exhaustion)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$, the rows h, p, n exhaust all GAP-facing route and provenance reads of the cannot-claim registry. These rows cannot promote any refusal source to* Real$^{\uparrow}$, Nat$^{\uparrow}$, *primitive dimension, quotient, or kernel-rewrite data.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket gap ledger exhaustion`

Proof. Ledger route scope identifies h, p, n as the only public transport, package, and local naming route after a refusal source has been selected. Provenance exhaustion shows that p and n add no mathematical coordinate beyond the seven refusal rows and the route ledger h.

Transport non-promotion gives the decisive boundary for the route row. The componentwise hsame and Cont ledger transports refusal rows only as refusal rows, so it cannot create a positive $\mathsf{Real}^{\uparrow}$ completion, $\mathsf{Nat}^{\uparrow}$ replacement, primitive dimension, quotient, or rewrite object.

Finally, consumer-horizon exhaustion and non-escape close the public route surface. Any GAP-facing consumer reads only the displayed refusal rows together with h, p, n, and none of those rows carries the promoted structures named in the statement. □

Theorem 554.38 (AxisZeckendorf cannot-claim dependency interface)**.** *Every admitted* AxisZeckendorfCannotClaim *packet records its dependency-facing rows for* $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{ZCarry}^{\uparrow}$, $\mathsf{ZeckendorfNormal}^{\uparrow}$, $\mathsf{DimLift}^{\uparrow}$, $\mathsf{FullAxis}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *as visible* BHist, Cont, Pkg, *and* NameCert *data. The* hsame *route row preserves those dependency rows componentwise, and no consumer may read one of the seven dependencies through an unrecorded carrier, package, or naming witness.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket dependency interface`

Proof. Start with the carrier $R = (a, b, c, d, e, f, g, h, p, n)$. The negative theorem rows and horizon refusal rows list the dependency-facing surface before any public route is exposed, while the rows h, p, n give the componentwise hsame and Cont route, package provenance, and local NameCert records.

The registry obligations and source-row coverage identify the seven visible rows that a consumer may cite for $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{ZCarry}^{\uparrow}$, $\mathsf{ZeckendorfNormal}^{\uparrow}$, $\mathsf{DimLift}^{\uparrow}$, $\mathsf{FullAxis}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. Refusal transport then keeps those rows inside the same BHist packet; it does not replace them by host arithmetic, a primitive dimension, a completion object, or a kernel rewrite.

Ledger exactness and gap ledger exhaustion close the interface. Since the source lock, refusal reader totality, and negative theorem surface have already exhausted the accepted reads, every dependency-facing consumer must pass through the displayed BHist, hsame, Cont, Pkg, and NameCert rows and cannot appeal to a second carrier. □

Theorem 554.39 (AxisNat and ZCarry refusal rows do not promote)**.** *In every admitted* AxisZeckendorfCannotClaim *packet, the* $\mathsf{AxisNat}^{\uparrow}$ *and* $\mathsf{ZCarry}^{\uparrow}$ *readbacks may feed the refusal ledger, but they cannot be converted into a* $\mathsf{FullAxis}^{\uparrow}$ *carrier row or a* $\mathsf{Real}^{\uparrow}$ *carrier row without an explicit* NameCert *witness for that promoted carrier. The available data remain the displayed* BHist *refusal rows, componentwise* hsame *transport,* Cont *route,* Pkg *provenance, and local cannot-claim* NameCert *row.*

Proof. Read the $\mathsf{AxisNat}^{\uparrow}$ and $\mathsf{ZCarry}^{\uparrow}$ rows through the dependency interface. Their role is refusal-facing: source-row coverage and the negative theorem surface place them among the rows that explain why the cannot-claim packet has no positive axis reconstruction.

Apply refusal transport and ledger exactness. The hsame and Cont route can replay the same refusal row inside the accepted BHist packet, and p, n can package and name that refusal. None of these operations introduces a $\mathsf{NameCert}_{\mathsf{FullAxis}^{\uparrow}}$ or $\mathsf{NameCert}_{\mathsf{Real}^{\uparrow}}$ witness.

Finally use the source lock, refusal reader totality, and gap ledger exhaustion. They force every public read through the displayed refusal inventory and exclude an external $\mathsf{FullAxis}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ carrier row. Thus AxisNat and ZCarry readbacks remain ledger data unless a separate promoted NameCert witness is supplied. □

Theorem 554.40 (Real readback non-promotion)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing consumer of an admitted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *packet receives only the recorded refusal and readback package. It reads the visible* BHist *rows, the componentwise* hsame *and* Cont *ledger, the* Pkg *provenance row, and the*

local NameCert *row; it does not receive a real-valued axis reconstruction or a hidden completion carrier.*

Proof. The carrier and registry obligations expose the $\mathsf{Real}^{\uparrow}$-facing entry only as part of the refusal surface. Source-row coverage and the negative theorem surface identify the row as a readback boundary, not as a real-valued axis carrier.

Refusal transport carries that boundary through h. The componentwise hsame and Cont data preserve the same refusal record, while p and n package and name the same cannot-claim packet.

Gap ledger exhaustion gives the final non-promotion step. A $\mathsf{Real}^{\uparrow}$ consumer can inspect the recorded refusal package, but the packet has no row for a $\mathsf{Real}^{\uparrow}$ completion, host real arithmetic, or reconstructed axis value. The source lock and refusal reader totality leave no second read path from which such a carrier could be obtained. □

Theorem 554.41 (AxisZeckendorf root-unblock refusal package)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$ of Definition 554.1, the rows a, b, c, d, e, f, g package the refusal source consumed by downstream unary-direction and axis-carry certificates. The rows h, p, n supply the only accepted route, package provenance, and local* NameCert *data for that downstream read.*

Proof. Read the carrier inventory. The negative refusal rows a, b, c, d are fixed by negative refusal coverage, and the horizon refusal rows e, f, g are fixed by horizon refusal coverage.

Use root-unblock package. It combines those two refusal families with ledger consumer exactness through h, p, n, so downstream certificates receive a finite refusal source rather than a positive arithmetic carrier.

Transport non-promotion and provenance exhaustion give the boundary. The route row h may replay the selected refusal, while p, n record provenance and local naming, but none of the three rows creates a promoted object for unary-direction or axis-carry consumers. □

Theorem 554.42 (AxisZeckendorf root-unblock downstream boundary)**.** *Any downstream consumer of the* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *root-unblock package may read only the refusal rows a, b, c, d, e, f, g together with the route, provenance, and local naming rows h, p, n. It may cite the package as a refusal source for unary-direction and axis-carry work, but it may not inspect host arithmetic, a hidden carrier, or any row outside the displayed registry.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket root unblock downstream boundary`

Proof. Begin with consumer-horizon exhaustion and refusal reader totality. Together they cover every accepted public refusal read by the displayed refusal rows a, b, c, d, e, f, g.

Next use ledger consumer exactness and gap ledger exhaustion. After a refusal source has been selected, the only public route and provenance rows are h, p, n.

The downstream restriction follows from transport non-promotion. Since h carries refusal rows only as refusal rows and p, n add no mathematical coordinate, unary-direction and axis-carry consumers cannot obtain a hidden carrier, host arithmetic interpretation, quotient, completion, replacement, dimension, or rewrite from the package. □

Theorem 554.43 (AxisZeckendorf downstream route refusal)**.** *Any* $\mathsf{UnaryDirectionBridge}^{\uparrow}$ *consumer of an accepted* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *packet may read the cannot-claim source only through the seven refusal rows a, b, c, d, e, f, g and the route and provenance rows h, p, n already exposed by the registry. The consumer route of chapter 530 may cite these rows as a downstream refusal source, but it cannot read a positive direction bridge, host arithmetic carrier,* $\mathsf{Real}^{\uparrow}$ *completion,* $\mathsf{Nat}^{\uparrow}$ *replacement, primitive dimension, quotient, or kernel rewrite from the packet.*

Proof. Start with the consumer horizon exhaustion theorem. Definition 554.14 says that every downstream consumer is confined to the displayed refusal rows a, b, c, d, e, f, g together with the route, provenance, and local naming rows h, p, n.

Next use the root-unblock downstream boundary of Definition 554.42. It identifies the downstream package as a refusal source for later unary-direction and axis-carry work, not as a hidden positive carrier.

Finally apply ledger consumer exactness and transport non-promotion. The $\mathsf{UnaryDirectionBridge}^{\uparrow}$ consumer named by chapter 530 can replay the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, but no row in the registry promotes a refusal into the positive structures excluded in the statement. □

Theorem 554.44 (AxisZeckendorf root-unblock ledger non-escape)**.** *The downstream* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *root-unblock ledger cannot yield a positive* $\mathsf{Real}^{\uparrow}$ *row, a positive* $\mathsf{Nat}^{\uparrow}$ *row, a primitive* $\mathsf{DimLift}^{\uparrow}$ *row, a quotient row, or a kernel rewrite row. Every such requested read is routed back to the refusal source* a, b, c, d, e, f, g *and the ledger rows* h, p, n.

Proof. Start from the existing non-escape theorem. It excludes RealUp operations, NatUp replacement, primitive dimension, quotient of histories, kernel rewrite, and standard-model bridge data from the accepted registry packet.

Apply refusal-row determinacy. Any accepted downstream refusal read first selects one row among a, b, c, d, e, f, g, so the requested positive object cannot be sourced by h, p, n.

Then apply transport non-promotion. The componentwise hsame and Cont ledger h preserves the selected row as a refusal and cannot promote it to a positive RealUp, NatUp, DimLiftUp, quotient, or rewrite row.

Finally use provenance exhaustion. The rows p, n close the public package and naming route without adding another mathematical coordinate, so the downstream ledger has no escape path beyond the displayed refusal package. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket root unblock ledger nonescape`

Theorem 554.45 (AxisZeckendorf cannot-claim root obligation surface)**.** *For the displayed* BHist *registry packet* $R = (a, b, c, d, e, f, g, h, p, n)$ *of Definition 554.1, the root obligation surface consists exactly of the four negative theorem rows* a, b, c, d*, the three horizon refusal rows* e, f, g*, the* hsame *transport and* Cont *route ledger* h*, the* Pkg *provenance row* p*, and the local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ *row* n*. Each accepted root read must expose the refusal row it consumes, its transport through* h*, its route through* h*, its provenance in* p*, and its local naming in* n.

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket root obligation surface`

Proof. Begin with refusal coverage. Negative refusal coverage accounts for a, b, c, d, and horizon refusal coverage accounts for e, f, g.

Use the root-unblock package to combine those rows with the downstream route surface. It identifies the registry as a finite refusal source whose public reads are carried by the displayed BHist packet rather than by host arithmetic.

Finally apply ledger non-escape. The rows h, p, n transport, route, package, and name the refusal surface, but they add no positive $\mathsf{Real}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, $\mathsf{DimLift}^{\uparrow}$, quotient, or kernel-rewrite coordinate. Hence the root obligation surface is exactly the displayed registry packet. □

Theorem 554.46 (AxisZeckendorf cannot-claim downstream blocker scope)**.** *Every downstream blocker that cites* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *must factor through the displayed registry packet* $R = (a, b, c, d, e, f, g, h, p, n)$*. It may consume a NameCert refusal row, transport it by the componentwise* hsame *data in* h*, follow the displayed* Cont *route in* h*, and cite the* Pkg *provenance* p *and local name* n*; it may not replace those rows by a positive arithmetic construction, a hidden carrier, a host equality, or a stronger axis reconstruction.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket downstream blocker scope`

Proof. First use consumer horizon exhaustion. It says that every downstream consumer is confined to the refusal rows a, b, c, d, e, f, g together with the route, provenance, and local naming rows.

Next use the root-unblock downstream boundary. That theorem identifies the consumer-facing role of the packet as a refusal source for unary-direction and axis-carry work, not as a promoted arithmetic carrier.

The ledger non-escape theorem supplies the blocker scope. Since the registry cannot yield a positive $\mathsf{Real}^{\uparrow}$ row, $\mathsf{Nat}^{\uparrow}$ row, primitive dimension row, quotient row, or kernel rewrite row, every downstream blocker remains a read of the displayed NameCert refusal rows and their h, p, n support. □

Theorem 554.47 (AxisZeckendorf cannot-claim formalization handoff)**.** *The future formalization target for* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *is the finite registry handoff for* $R = (a, b, c, d, e, f, g, h, p, n)$*: refusal coverage for* a, b, c, d, e, f, g*,* hsame *transport and* Cont *route preservation through* h*,* Pkg *provenance through* p*, local* $\mathsf{NameCert}$ *naming through* n*, and non-escape from all requested positive* $\mathsf{FullAxis}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{AxisNat}^{\uparrow}$*,* $\mathsf{Nat}^{\uparrow}$*,* $\mathsf{DimLift}^{\uparrow}$*, quotient, and kernel-rewrite rows. The handoff is a negative registry theorem, not a positive Zeckendorf or axis construction.*

Proof. Assemble the proof surface from the existing registry theorems. Refusal coverage supplies the seven negative rows, and refusal reader totality says that accepted reads choose from those rows.

Transport and route preservation are supplied by ledger consumer exactness and transport non-promotion. They keep the selected row inside the same BHist, hsame, and Cont registry route, while p, n record provenance and local naming.

The final formalization boundary is given by consumer horizon exhaustion and root-unblock ledger non-escape. Together they rule out every listed positive structure and leave the future Lean handoff as the finite cannot-claim registry rather than an arithmetic construction. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimUp StdBridge`

Theorem 554.48 (AxisZeckendorf seven-row refusal coverage)**.** *For the concrete carrier* $R = (a, b, c, d, e, f, g, h, p, n)$ *of Definition 554.1, the rows* a, b, c, d, e, f, g *exhaust the source refusal surface of* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$*. The rows* a, b, c, d *cover the negative theorem refusals, the rows* e, f, g *cover the horizon refusals, and no accepted source refusal is supplied by* h, p, n *or by any hidden arithmetic, completion, dimension, quotient, or rewrite coordinate.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket seven row coverage`

Proof. Use the carrier definition to list the source rows before the ledger rows. It exposes exactly the four negative theorem rows a, b, c, d and the three horizon rows e, f, g.

Apply negative refusal coverage and horizon refusal coverage. These identify the theorem-level and horizon-level refusal families and leave no additional source slot in the displayed packet.

Finally apply refusal-row determinacy and non-escape. Every accepted refusal read selects one of a, b, c, d, e, f, g, while the route and provenance rows h, p, n cannot become source refusals or positive BEDC objects. □

Theorem 554.49 (AxisZeckendorf refusal transport route exhaustion)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$, the row h is the only admissible* hsame *and* Cont *transport route for the refusal rows a, b, c, d, e, f, g. Every downstream consumer that transports a refusal row must first choose one of those seven rows and then route it through h, with provenance and local naming recorded only by p and n.*

Proof. Start from ledger consumer exactness. It says that every public consumer reads the selected refusal source through the route ledger h and then records package and naming data through p, n.

Refusal-row determinacy supplies the selected source row among a, b, c, d, e, f, g. Transport non-promotion then fixes the role of h: it carries the chosen refusal only as a refusal, not as a positive carrier.

Since the carrier definition contains no second hsame or Cont coordinate, the transport surface is exhausted by h. The rows p, n record the result after transport and do not supply another route. □

Theorem 554.50 (AxisZeckendorf positive bridge exclusion)**.** *For the concrete carrier $R = (a, b, c, d, e, f, g, h, p, n)$, none of the rows p, n, h can promote a refusal row into* $\mathsf{Real}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, $\mathsf{DimLift}^{\uparrow}$*, quotient data, kernel rewrite data, or standard-bridge data. They record provenance, local naming, and componentwise refusal transport for the seven refusal rows only.*

Proof. Read the three ledger rows separately. The row h is the route ledger, while p and n record the public package and the local $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$ name.

Apply transport non-promotion to h. A transported source from a, b, c, d, e, f, g remains a refusal row and cannot become a positive bridge, completion, replacement, dimension, quotient, or rewrite object.

Apply provenance exhaustion and non-escape to p, n. These rows add no mathematical coordinate beyond the refusal package, so no standard-bridge or positive BEDC data can be read from them. □

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket positive bridge exclusion`

Closure status for $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$.

Constructive story: An $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ packet records four checked negative theorem rows, three horizon refusal rows, componentwise hsame and Cont routing, Pkg provenance, and a local NameCert row, while exporting no RealUp, NatUp replacement, dimension, quotient, or kernel-rewrite coordinate.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$, maturePackageClosed)

Scope closed: The AxisZeckendorf cannot-claim registry packet is mature on the paper closure axis: its semantic-certificate readback records four negative theorem rows, three horizon refusal rows, componentwise transport, ledger exactness, non-escape, consumer exhaustion, determinacy, transport non-promotion, provenance exhaustion, negative-row scope, horizon-refusal scope, and ledger-route scope, while Lean verification and StdBridge remain separate formal-axis work.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.AxisZeckendorfCannotClaimUp.AxisZeckendorfCannotClaimRegistryPacket\_semantic\_name\_ce`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not prove a Lean implementation, a standard bridge, positive RealUp data for FullAxisUp, AxisNatUp equality with NatUp, primitive dimension lift, quotient construction, host arithmetic equality, or kernel rewriting.

Upgrade path: no further upgrade – chapter at top of the formal axis.

Chapter 555

A Concrete Naming Certificate for $\mathsf{InductionClosureLedger}^{\uparrow}$

The $\mathsf{InductionClosureLedger}^{\uparrow}$ surface realizes generator-internal induction as a finite naming certificate. It records the authorized generator rows, the generator-closure classifier rows, the Gap residue left at every attempted free-floating induction claim, and the transport, continuation, provenance, and naming rows that make the ledger auditable.

The ledger consumes the authorized-generator row from chapter 525 and the generator-closure classifier row from chapter 486 before the Gap residue row is exported. Requests that fail to stay inside those displayed generator closures are recorded as Gap residue rather than as free-standing induction authority.

Definition 555.1 (InductionClosureLedger carrier)**.** *An* $\mathsf{InductionClosureLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (G, K, R, T, C, P, N)$$

with the following displayed rows:

1. *G is the authorized-generator row, listing the generator names whose closed constructor lists license internal induction;*
2. *K is the generator-closure classifier row, recording the finite classifier that decides whether a requested induction step stays inside the closure of a listed generator;*
3. *R is the* Gap *ledger residue row, recording every refused passage from generator-internal induction to free-floating induction over unspecified objects;*
4. *T records componentwise* hsame *transport for G, K, R, the continuation row, the provenance row, and the local naming row;*
5. *C records the displayed* Cont *routes that replay generator admission, classifier lookup, residue emission, and NameCert export;*
6. *P is the* Pkg *provenance over* BHist*, authorized generator rows, generator-closure classifier rows,* Gap *ledger residue,* hsame*,* Cont*, and* $\mathsf{NameCert}$*;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{InductionClosureLedger}^{\uparrow}}$ *row.*

The carrier is exactly this finite packet. It contains no universal induction principle over unnamed objects, no hidden eliminator outside a displayed generator closure, and no route that erases the Gap *residue attached to an out-of-closure request.*

Theorem 555.2 (InductionClosureLedger NameCert obligations)**.** *For the carrier of Definition 555.1, the local* $\mathsf{NameCert}_{\mathsf{InductionClosureLedger}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$L = (G, K, R, T, C, P, N),$$

authorized-generator exposure, generator-closure classifier lookup, Gap *residue retention, componentwise* hsame *stability, displayed* Cont *replay,* Pkg *provenance, and NameCert export for the same finite packet.*

Lean4 ✓ `BEDC.Derived.InductionClosureLedgerUp.InductionClosureLedgerTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 555.1. The packet exposes only the seven displayed rows G, K, R, T, C, P, N.

Generator authority is read from G, closure classification from K, and refused out-of-closure content from R. These three rows determine which induction requests are internal to an authorized generator and which requests leave a recorded residue.

Transport, replay, and provenance are confined by T, C, P. The local row N exports only this finite packet as a naming certificate, so no NameCert projection can add a hidden universal induction principle. □

Theorem 555.3 (InductionClosureLedger generator authority)**.** *Every induction route accepted by an* $\mathsf{InductionClosureLedger}^{\uparrow}$ *packet factors through an authorized generator row in* G *and a generator-closure classifier row in* K*. The route may replay the displayed* Cont *evidence for that generator closure, transported by* hsame *and recorded under* Pkg *provenance and* $\mathsf{NameCert}_{\mathsf{InductionClosureLedger}^{\uparrow}}$ *naming, but it cannot claim authority from an unnamed generator.*

Proof. Project the authorized-generator row G and classifier row K. A replayable induction route is accepted only when the classifier records that the requested step stays inside the closure of a generator listed in G.

Use T to transport the listed generator and classifier rows componentwise. Use C to replay the accepted route, and record the read through P and N.

An unnamed generator has no coordinate in L. Since the carrier has no row from which such authority could be projected, every accepted route is exhausted by the displayed generator and classifier rows. □

Theorem 555.4 (InductionClosureLedger GAP non-escape)**.** *Whenever an induction request is not classified by* K *as lying inside the closure of an authorized generator in* G*, the* $\mathsf{InductionClosureLedger}^{\uparrow}$ *packet records the request only as* Gap *residue in* R*. The residue may be transported, replayed as a refusal, packaged, and named, but it cannot be converted into an internal induction theorem.*

Proof. Inspect the classifier row K. If the request is not accepted by the displayed generator-closure classifier, the only carrier coordinate that records it is the residue row R.

Transport of residue through T preserves the residue as residue. Replay through C can expose the refusal and package it through P, while N names the same boundary.

No conversion row is present in the carrier. Therefore a recorded Gap residue cannot escape into an internal induction theorem or a free-floating closure principle. □

Theorem 555.5 (InductionClosureLedger transcendental-input sibling link)**.** *Every free-floating induction request rejected into the residue row* R *of an accepted* $\mathsf{InductionClosureLedger}^{\uparrow}$ *packet is*

classified as a supply-socket kind by the taxonomy surface of chapter 523 before it can be cited downstream. The sibling classifier records why the residue remains outside substrate closure rather than becoming a free-standing induction authority.

Proof. Project the ledger carrier $L = (G, K, R, T, C, P, N)$ from Definition 555.1. The generator row G and classifier row K decide whether the requested induction step stays inside an authorized generator closure.

Apply generator authority from Definition 555.3. Any accepted induction route must be licensed by the displayed generator and closure classifier rows.

For a rejected request, apply GAP non-escape from Definition 555.4. The request is retained only as residue in R and cannot be converted into an internal induction theorem.

Now cite the sibling taxonomy carrier and boundary exhaustion of chapter 523. The free-floating induction socket is one of the displayed supply-socket kinds, and the taxonomy surface records the requested supply shape, Gap tag, audit gate, site row, transport, continuation, provenance, and local name before any downstream citation.

Thus the ledger residue is downstream-readable only after the sibling classifier has recorded why the induction request remains outside substrate closure. □

Theorem 555.6 (InductionClosureLedger NameCert export)**.** *The public export of an* $\mathsf{InductionClosureLedger}^{\uparrow}$ *packet is exactly the finite NameCert packet over authorized generator rows, generator-closure classifier rows,* Gap *ledger residue,* hsame *transport,* Cont *replay, and* Pkg *provenance. A consumer of the export can recover generator authority, classifier status, and residue location, but no object beyond those rows.*

Proof. Start with the carrier tuple $L = (G, K, R, T, C, P, N)$. The export row N names this tuple and no larger surface.

A consumer recovers generator authority from G, classifier status from K, and residue location from R. The same consumer uses T for componentwise transport, C for replay, and P for provenance.

These rows exhaust the public export. Since L has no coordinate for an unnamed induction principle, hidden eliminator, or erased residue, the NameCert packet cannot export such content. □

Closure status for $\mathsf{NameCert}_{\mathsf{InductionClosureLedger}^{\uparrow}}$.

Constructive story: An $\mathsf{InductionClosureLedger}^{\uparrow}$ packet is generated from authorized generator rows, generator-closure classifier rows, Gap ledger residue, componentwise hsame transports, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{InductionClosureLedger}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 555.1, Definition 555.2, Definition 555.3, Definition 555.4, and Definition 555.6 bind the finite carrier, generator authority, closure classifier, residue boundary, and NameCert export.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{InductionClosureLedger}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, a TasteGate-backed carrier, universal induction over unnamed objects, erased GAP residue, or a public standard bridge.

Upgrade path: Promotion beyond seedClosure requires a TasteGate-backed Lean carrier and checked finite theorems for generator authority, classifier stability, residue non-escape, provenance, and NameCert export.

Chapter 556

A Concrete Naming Certificate for $\mathsf{GeneratorFixedPoint}^{\uparrow}$

The $\mathsf{GeneratorFixedPoint}^{\uparrow}$ packet names the finite certificate surface where an authorized generator returns a displayed output that remains fixed under its own certified continuation boundary. It refines the $\mathsf{GeneratorClosure}^{\uparrow}$ classifier of chapter 486: the constructor-list provenance and classifier row are consumed from that sibling before the fixed-output witness is read. A continuation without that witness is not a fixed point of the generator; it is recorded as a GAP boundary.

Definition 556.1 (Generator fixed-point carrier)**.** *A* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (G, L, Q, W, O, H, C, P, N)$$

with the following displayed rows:

1. *G is the authorized generator row whose constructor-list closure supplies the only admitted source of generated outputs;*
2. *L is the constructor-list provenance for G, including the displayed witness that the relevant continuation remains inside that list;*
3. *Q is the* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier row that compares generator-internal continuations with boundary attempts;*
4. *W is the fixed-output witness, recording that the displayed generator continuation returns the same output row under the certified route;*
5. *O is the displayed output row whose fixed-output status is witnessed by W;*
6. *H records componentwise* hsame *transports for G, L, Q, W, O, P, N and the local packet shape;*
7. *C records the finite* Cont *routes by which consumers read the generator row, constructor-list provenance, classifier row, fixed-output witness, output row, package provenance, and local naming row;*
8. *P is the* Pkg *provenance over* BHist*, authorized generator rows, constructor-list provenance,* $\mathsf{GeneratorClosure}^{\uparrow}$*, fixed-output witnesses, displayed outputs,* hsame*,* Cont*, and boundary ledger rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{GeneratorFixedPoint}^{\uparrow}}$ *row.*

The carrier contains no host-level fixed-point theorem, no self-application oracle, and no induction rule beyond the constructor-list provenance displayed in L.

Theorem 556.2 (Generator fixed-point NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{GeneratorFixedPoint}^{\uparrow}}$ *surface for Definition 556.1 consists of five finite obligation rows:*

1. *carrier admission for the packet* $F = (G, L, Q, W, O, H, C, P, N)$*;*
2. *classifier stability stating that the* $\mathsf{GeneratorClosure}^{\uparrow}$ *row* Q *is preserved by componentwise* hsame *transport of the displayed generator, constructor-list provenance, fixed witness, output row, routes, package provenance, and local certificate;*
3. *fixed-witness persistence stating that* W *remains attached to* O *under the displayed generator-internal continuation routes;*
4. *non-escape stating that any continuation missing the constructor-list witness required by* L *is recorded as a* GAP *boundary rather than as a generator fixed point;*
5. *ledger exactness stating that every public read of the certificate factors through* $G, L, Q, W, O, H, C, P, N$ *and no unrecorded fixed-point principle is exported.*

Lean4 ✓ `BEDC.Derived.GeneratorFixedPointUp.GeneratorFixedPointCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 556.1. The tuple lists the generator row, constructor-list provenance, closure classifier, fixed-output witness, displayed output, transports, routes, package provenance, and local naming row.

Classifier stability is read through H and C. Transport preserves the generator row and constructor-list provenance, so the $\mathsf{GeneratorClosure}^{\uparrow}$ row Q continues to classify the same generator-internal boundary.

Fixed-witness persistence is the displayed role of W. Since W is a coordinate of the same finite packet as O, a consumer route that stays inside C can read the output only together with the witness that certifies it as fixed under the displayed continuation.

The non-escape and ledger-exactness rows are the remaining package clauses. If a continuation lacks the constructor-list witness named by L, no carrier coordinate can turn it into a fixed point; the package records it as GAP boundary evidence, and every exported read remains a projection of the listed rows. □

Theorem 556.3 (Generator fixed-point non-escape)**.** *Let* F *be an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *carrier. A finite continuation read that lacks the constructor-list witness required by* L *is recorded by the package provenance* P *as a* GAP *boundary. It is not admitted as a fixed point of the generator row* G*, and it cannot export the fixed-output witness* W *for the displayed output row* O*.*

Proof. Read the continuation through the displayed route C. If the route carries the constructor-list witness from L, then it is evaluated against the $\mathsf{GeneratorClosure}^{\uparrow}$ classifier Q and may read the fixed-output witness W for O.

If the route lacks the witness from L, it has no carrier coordinate that authorizes it as generator-internal. The package provenance P therefore records the attempted read as GAP boundary evidence, and the local naming row N cannot expose it as a fixed point. □

Theorem 556.4 (Generator fixed-point witness stability)**.** *Componentwise* hsame *transport preserving* G, L, Q, W, H, C, P, N *preserves the fixed-output witness for the displayed row* O*. After such transport, the transported packet still reads* O *through the same authorized generator row, constructor-list provenance,* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier, fixed-output witness, continuation routes, package provenance, and local* $\mathsf{NameCert}_{\mathsf{GeneratorFixedPoint}^{\uparrow}}$ *row.*

Proof. Use the transport row H. It preserves the generator row G, the constructor-list provenance L, the classifier Q, the fixed-output witness W, and the local routing and package rows.

The continuation row C then replays the same generator-internal read of the displayed output. Since the witness W is transported as one of the preserved coordinates, the fixed-output status of O remains attached to the transported packet.

Finally P and N repack the transported rows as the same local certificate surface. No new continuation route is introduced, so a boundary attempt remains outside the fixed-point witness. □

Theorem 556.5 (Generator fixed-point source admission row)**.** *For an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet*

$$F = (G, L, Q, W, O, H, C, P, N),$$

source admission is exactly the displayed pairing of the authorized generator row G with the constructor-list provenance L. A continuation route is admitted as generator-internal only when it reads through G and carries the witness from L; otherwise the local packet records the route as boundary evidence and does not expose it as a fixed point.

Lean4 ✓ `BEDC.Derived.GeneratorFixedPointUp.GeneratorFixedPointPacket source admission row`

Proof. Project the carrier of Definition 556.1. The only source rows are G and L, so admission cannot be supplied by an unlisted generator or by a continuation outside the constructor-list provenance.

Use Definition 556.3. A route without the displayed witness from L is a GAP boundary, not a fixed-output read. Thus the source admission row is precisely the displayed G, L pairing. □

Theorem 556.6 (Generator fixed-point transport row)**.** *Let $F = (G, L, Q, W, O, H, C, P, N)$ be an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet. Componentwise* hsame *transport preserving the displayed generator row, constructor-list provenance, closure classifier, fixed-output witness, displayed output, continuation routes, package provenance, and local naming row preserves the fixed-output row under* Cont *transport. The transported packet still classifies the same generator-internal route by Q and keeps W attached to O.*

Lean4 ✓ `BEDC.Derived.GeneratorFixedPointUp.GeneratorFixedPointPacket transport row`

Proof. Use the transport row H to move the displayed generator, constructor list, classifier, witness, output, route, package, and naming coordinates together.

Then apply Definition 556.4. The transported witness remains attached to the transported output row because W and O are coordinates of the same finite packet.

Finally use the continuation route row C. It replays the same generator-internal read after transport, so the classifier row Q still marks the route as internal and does not create a new boundary read. □

Theorem 556.7 (Generator fixed-point public obligation package)**.** *For every accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet, carrier admission, classifier stability, fixed-witness persistence, non-escape, and ledger exactness jointly form the public obligation package for $F = (G, L, Q, W, O, H, C, P, N)$. Every public read factors through the source admission row of Definition 556.5, the transport row of Definition 556.6, the fixed-witness row of Definition 556.4, and the finite ledger rows C, P, N.*

Proof. First collect carrier admission from Definition 556.1. The carrier inventory fixes the generator, provenance, classifier, witness, output, transport, route, package, and naming rows.

Next apply the source admission and transport rows. These identify the admitted generator-internal route and show that componentwise hsame and Cont transport preserve the same classifier and fixed-output witness.

Use Definition 556.3 for boundary attempts. A route without the constructor-list witness is recorded as GAP evidence and cannot export W.

Finally the ledger rows C, P, N make the public package exact. Every exported read is a projection of $G, L, Q, W, O, H, C, P, N$, and no host fixed-point principle, self-application oracle, or unlisted continuation coordinate is available. □

Theorem 556.8 (Generator fixed-point admitted packet row)**.** *Every accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet exposes exactly the rows*

$$G, L, Q, W, O, H, C, P, N$$

of Definition 556.1. A public or local read of the packet first projects one of these displayed rows: the authorized generator row G, constructor-list provenance L, $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier row Q, fixed-output witness W, displayed output row O, componentwise* hsame *transport row H,* Cont *route row C,* Pkg *provenance row P, or local* $\mathsf{NameCert}_{\mathsf{GeneratorFixedPoint}^{\uparrow}}$ *row N. No accepted packet contains an additional host fixed-point principle, self-application oracle, or unlisted continuation coordinate.*

Proof. Start from the carrier definition. The accepted packet is the finite BHist tuple displayed there, so admission is projection from the nine named coordinates and not from an ambient fixed-point operator.

The route row C and provenance row P determine how consumers read the tuple. Since every such route is attached to one of the displayed coordinates, any accepted read factors through $G, L, Q, W, O, H, C, P, N$.

The last assertion is the non-escape side of the same inventory. The carrier definition lists no host theorem, oracle, or extra continuation field, and the local naming row N certifies only the displayed packet shape. □

Theorem 556.9 (Generator fixed-point classifier transport row)**.** *Let $F = (G, L, Q, W, O, H, C, P, N)$ and $F' = (G', L', Q', W', O', H', C', P', N')$ be accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packets related by componentwise* hsame *transport of the displayed generator row, constructor-list provenance, classifier row, fixed-output witness, output row, routes, package provenance, and local naming row. Then the transported packet preserves the* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier row and the fixed-output witness route: Q' classifies the transported generator-internal continuation under the transported constructor-list provenance, and W' remains attached to the transported output row O' through the transported* Cont *routes.*

Proof. Use the transport row H of F together with the matching row H' of F'. These rows relate the generator, constructor-list provenance, classifier, witness, output, routes, provenance, and naming coordinates component by component.

The classifier part is the transported Q row. Because the constructor-list provenance L is transported with the generator row G, the $\mathsf{GeneratorClosure}^{\uparrow}$ classifier reads the same generator-internal boundary after transport.

The fixed-output part is the transported W row. Since the output row O and continuation routes C are transported in the same packet, the witness route remains attached to O' and does not create a separate boundary read. □

Theorem 556.10 (Generator fixed-point witness ledger row)**.** *For every accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet, any public witness read factors through the fixed-output witness row* W*, displayed output row* O*, continuation route row* C*, package provenance row* P*, and local naming row* N*. A read that does not factor through this witness ledger remains a* GAP *boundary; in particular, non-witness generator routes and continuations outside the constructor-list provenance are not exported as fixed-output witnesses.*

Proof. Read a public witness request through the route row C. If the route is a witness route, it must project the displayed witness W together with the displayed output row O.

The package provenance P and local naming row N then record that projection as part of the finite certificate surface. Thus a witness consumer receives the same W, O, C, P, N ledger, not an unrecorded fixed-point principle.

If the route is not one of the displayed witness routes, Definition 556.3 applies. The attempt lacks the required constructor-list witness and is recorded as a GAP boundary rather than as a fixed-output export. □

Lean4 ✓ `BEDC.Derived.GeneratorFixedPointUp.GeneratorFixedPointPacket witness ledger row`

Theorem 556.11 (Generator fixed-point TasteGate witness route)**.** *Every TasteGate-admissible witness read of an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet factors through the authorized generator row* G*, constructor-list provenance* L*,* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier row* Q*, fixed-output witness* W*, displayed output row* O*, componentwise* hsame *transport row* H*,* Cont *route row* C*,* Pkg *provenance row* P*, local* $\mathsf{NameCert}_{\mathsf{GeneratorFixedPoint}^{\uparrow}}$ *row* N*, and the AI-roadmap TasteGate discipline that permits only displayed witness routes.*

Lean4 ✓ `BEDC.Derived.GeneratorFixedPointUp.GeneratorFixedPointTasteGate single carrier alignment`

Proof. Start with the admitted packet row. It exposes only $G, L, Q, W, O, H, C, P, N$, so a TasteGate witness request cannot begin from a host fixed-point theorem or a self-application oracle.

Use the classifier transport row to keep the $\mathsf{GeneratorClosure}^{\uparrow}$ classifier attached to the transported authorized generator and constructor-list provenance. The same transport keeps the fixed-output witness attached to the displayed output and to the listed continuation routes.

Finally apply the witness ledger row. TasteGate-admissible reads are exactly the reads that pass through W, O, C, P, N after the generator and classifier rows have been displayed, so the route is a finite certificate route rather than an ambient generation principle. □

Theorem 556.12 (Generator fixed-point diagonal obstruction scope)**.** *For an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet, any diagonal or self-application attempt outside the authorized generator row, constructor-list provenance,* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier, fixed-output witness,* hsame *transport,* Cont *route,* Pkg *provenance, local* NameCert *row, and TasteGate witness discipline is a* GAP *boundary. It is not a fixed-output witness and cannot be read as a generator fixed point.*

Proof. Read the attempted diagonal route through the carrier. If it lacks the displayed constructor-list provenance or classifier row, the source admission row and non-escape theorem already classify the attempt as boundary evidence.

If the attempt carries those rows but lacks the fixed-output witness route, the witness ledger row applies. It permits public witness reads only through W, O, C, P, N, so the attempted diagonal has no exported witness coordinate.

The TasteGate witness route then supplies the scope boundary. It admits displayed witness routes and excludes self-application routes that are not already carried by the finite packet. □

Theorem 556.13 (Generator fixed-point audit non-escape ledger)**.** *The public audit ledger for an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet is exhausted by the authorized generator row,* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier row, fixed-output witness,* hsame *transport,* Cont *routes,* Pkg *provenance, local* NameCert *row, and the TasteGate witness-route discipline. The ledger exports no unlisted continuation, host fixed-point principle, self-application oracle, or semantic completeness claim.*

Proof. First combine the public obligation package with the admitted packet row. Together they make every public read a projection of $G, L, Q, W, O, H, C, P, N$.

Next apply the TasteGate witness route. It identifies the accepted witness route as the displayed generator, classifier, fixed-output, transport, continuation, provenance, and naming surface.

The diagonal obstruction scope handles the remaining cases. Any read outside that surface is a GAP boundary, so the audit ledger has no coordinate from which to export an unlisted continuation, a host fixed-point principle, a self-application oracle, or semantic completeness. □

Theorem 556.14 (Generator fixed-point TasteGate boundary exhaustion)**.** *Every accepted public fixed-point witness read of a* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet factors through the finite rows*

$$G, L, Q, W, O, H, C, P, N$$

and through the checked TasteGate carrier-alignment row cited at Definition 556.11. A route that attempts diagonal self-application, a non-witness generator read, a classifier-free fixed-output read, or a continuation outside the constructor-list provenance remains a GAP *boundary rather than a public fixed-point witness.*

Proof. First apply the source admission row. It admits a generator-internal read only through G together with the constructor-list provenance L.

Next transport the classifier and witness. The classifier transport row keeps Q attached to G, L, while the fixed-witness and witness-ledger rows keep W attached to O through the displayed continuation and package rows C, P, N.

Now use the checked TasteGate carrier-alignment row of Definition 556.11. It restricts AI-origin witness reads to the same finite surface $G, L, Q, W, O, H, C, P, N$.

Finally apply the audit non-escape ledger. Any non-witness diagonal route, self-application attempt, classifier-free route, or continuation outside the constructor-list provenance has no coordinate in the packet and is recorded as GAP boundary evidence. □

Theorem 556.15 (Generator fixed-point obligation-closure readiness)**.** *For an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet*

$$F = (G, L, Q, W, O, H, C, P, N),$$

carrier admission, the $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier row* Q*, the fixed-output witness* W*, the* GAP *boundary row for non-admitted continuations, componentwise* hsame *transport* H*, displayed* Cont *route* C*,* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{GeneratorFixedPoint}^{\uparrow}}$ *row* N *form the obligation-closure surface for the fixed-point packet.*

Proof. Start with the carrier and public obligation package. The carrier displays $G, L, Q, W, O, H, C, P, N$, and Definition 556.7 names carrier admission, classifier stability, fixed-witness persistence, non-escape, and ledger exactness over exactly those rows.

Attach the fixed-witness route using Definition 556.4 and Definition 556.10. These keep W tied to the displayed output and to the route through C, P, N.

Finally use Definition 556.13. It exhausts boundary attempts as GAP evidence and leaves no coordinate beyond $G, L, Q, W, O, H, C, P, N$. Hence the listed rows are the full obligation-closure surface. □

Theorem 556.16 (Generator fixed-point TasteGate carrier surface)**.** *Any AI-origin* ChapterTasteGate *consumer of an accepted* GeneratorFixedPoint$^{\uparrow}$ *packet may inspect only the finite carrier rows*

$$G, L, Q, W, O, H, C, P, N.$$

The consumer may read the authorized generator, constructor-list provenance, GeneratorClosure$^{\uparrow}$ *classifier, fixed-output witness, displayed output, componentwise transport, continuation route, package provenance, and local naming row, and may not inspect a host fixed-point principle, self-application oracle, or unlisted continuation.*

Proof. First project the admitted packet row by Definition 556.8. It exposes exactly $G, L, Q, W, O, H, C, P, N$ and no further carrier coordinate.

Next apply the TasteGate witness route. Definition 556.11 confines TasteGate-admissible witness reads to the displayed generator, classifier, witness, output, transport, route, provenance, and naming rows.

The audit non-escape ledger handles excluded reads. By Definition 556.13, a host fixed-point principle, self-application oracle, or unlisted continuation has no audit coordinate in the packet. □

Theorem 556.17 (Generator fixed-point obligation closure upgrade)**.** *The* GeneratorFixedPoint$^{\uparrow}$ *chapter reaches obligation closure for the finite packet*

$$F = (G, L, Q, W, O, H, C, P, N).$$

The closure surface is exactly the carrier of Definition 556.1, the source-admission row of Definition 556.5, the witness-ledger row of Definition 556.10, the audit non-escape ledger of Definition 556.13, and the TasteGate witness route of Definition 556.11. No public fixed-point read is accepted unless it factors through those rows.

Proof. Start from the carrier. The accepted packet is the displayed tuple $G, L, Q, W, O, H, C, P, N$, so carrier admission contributes exactly the finite source, classifier, witness, transport, route, provenance, and naming rows.

Use source admission and the witness ledger. The source row admits only the authorized generator with constructor-list provenance, while the witness ledger keeps every fixed-output read attached to W, O, C, P, N.

Apply the TasteGate witness route. It restricts AI-origin witness reads to the same displayed surface and therefore supplies the required TasteGate path without adding a host fixed-point theorem.

Finally apply the audit non-escape ledger. Boundary attempts have no coordinate outside the carrier, so the named rows form the obligation-closure surface. □

Theorem 556.18 (Generator fixed-point GAP boundary closure)**.** *Every attempted* GeneratorFixedPoint$^{\uparrow}$ *read outside the obligation-closure surface is a* GAP *boundary. In particular, a route that omits the carrier row, the source-admission row, the witness-ledger row, the audit non-escape ledger, or the TasteGate witness route cannot export a fixed-output witness, cannot detach Q from G, L, and cannot be repacked as a downstream* GeneratorClosure$^{\uparrow}$ *certificate.*

Proof. First inspect the carrier row. It contains no coordinate for a host fixed-point principle, self-application oracle, semantic completeness claim, or continuation outside the constructor-list provenance.

Next use source admission. A route missing G, L is not generator-internal and is recorded as boundary evidence before any witness read can occur.

Then apply the witness ledger and the TasteGate witness route. A public witness must pass through W, O, C, P, N and, for the AI-origin surface, through the displayed TasteGate path.

The audit non-escape ledger closes the remaining cases. Since every omitted row removes part of the finite route, the attempt remains a GAP boundary rather than a fixed-point certificate. □

Theorem 556.19 (Generator fixed-point boundary consumer exhaustion)**.** *For every downstream consumer of an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet, the only accepted fixed-point route is the one exposed by the carrier, source-admission row, witness ledger, audit non-escape ledger, and TasteGate witness route. All other consumer reads remain boundary evidence, including classifier-free witness reads, witness-ledger bypasses, diagonal self-application attempts, and routes outside the constructor-list provenance.*

Proof. Begin with a downstream consumer read. If it is accepted, carrier admission gives the finite tuple $G, L, Q, W, O, H, C, P, N$ as its only source.

The source-admission row and witness-ledger row then force the read through G, L and through W, O, C, P, N. The classifier row Q remains attached to the same source surface by the existing transport and handoff rows.

For AI-origin reads, the TasteGate witness route supplies the displayed witness path. It permits the finite carrier route and does not create a separate route for diagonal or classifier-free reads.

If the consumer omits any of these rows, the audit non-escape ledger applies. The read has no carrier coordinate from which to export a fixed-point witness, so it is exhausted as boundary evidence. □

Theorem 556.20 (Generator fixed-point boundary consumer totality)**.** *Every downstream boundary consumer of an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet either reads the fixed witness through the displayed route*

$$G, L, Q, W, O, H, C, P, N$$

or remains a GAP *boundary. There is no third route that exports a fixed witness while bypassing the constructor-list provenance* L*, the* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier* Q*, or the fixed-output witness ledger.*

Proof. Consider a downstream boundary consumer. If it reads the fixed witness, Definition 556.21 forces the read through $G, L, Q, W, O, H, C, P, N$.

If the route omits constructor-list provenance or the classifier row, Definition 556.25 and Definition 556.28 record the route as GAP boundary evidence.

It remains to exclude a witness-only bypass. The witness ledger theorem confines every witness read to W, O, C, P, N, and the audit non-escape ledger excludes unlisted continuation routes. Thus every downstream boundary consumer is either on the displayed fixed-witness route or remains a GAP boundary. □

Theorem 556.21 (Generator fixed-point closure-consumer lock)**.** *Every* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *consumer that reads a fixed witness must read it through the displayed* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier row* Q*, authorized generator row* G*, constructor-list provenance row* L*, fixed-output witness row* W*, output row* O*, componentwise* hsame *transport row* H*, displayed* Cont *route row* C*, package provenance row* P*, and local* $\mathsf{NameCert}_{\mathsf{GeneratorFixedPoint}^{\uparrow}}$ *row* N*. A consumer route that omits one of these rows is not a fixed-witness read of the accepted packet.*

Proof. Start from the source admission row. It exposes the fixed-point packet only as the finite tuple $G, L, Q, W, O, H, C, P, N$, with no ambient fixed-point operator or unlisted continuation coordinate.

The classifier transport row keeps the $\mathsf{GeneratorClosure}^{\uparrow}$ classifier attached to the authorized generator row and constructor-list provenance after any componentwise transport. Thus a consumer cannot detach Q from G and L and still read the same fixed witness.

Finally use the witness ledger row. The public witness route passes through W, O, C, P, N, so the consumer receives the displayed fixed-output route and no separate witness source. □

Theorem 556.22 (Generator fixed-point fixed-witness source determinacy)**.** *Let two accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packets present the same displayed source surface* $G, L, Q, W, O, H, C, P, N$ *for the generator row, constructor-list provenance, classifier row, fixed-output witness, output row, transport row, continuation routes, package provenance, and local naming row. Then they expose the same fixed-witness route to every public consumer. A proposed route that lacks the constructor-list provenance* L *or the* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier row* Q *is boundary evidence, not an alternate source for the fixed witness.*

Proof. Use the admitted packet row to reduce both accepted packets to the same finite source surface. Since the displayed rows agree, a public read begins from the same generator, provenance, classifier, witness, output, route, package, and naming coordinates.

The transport row identifies the consumer route through the shared H and C rows. Therefore the fixed-output witness exposed downstream is the same route through W and O in both packets.

If a proposed route omits L or Q, the diagonal obstruction scope applies. The route is missing part of the authorized generator-classifier surface and is recorded as a GAP boundary rather than as a competing fixed-witness source. □

Theorem 556.23 (Generator fixed-point audit ground-route exhaustion)**.** *The public audit ground route for an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet is exhausted by the finite fixed-witness route locked by Definition 556.21, the source determinacy of Definition 556.22, and the AI-roadmap TasteGate discipline cited in Definition 556.11. Together with the audit non-escape ledger, these rows leave no public audit coordinate for a host fixed-point theorem, a self-application oracle, or a witness route outside* $G, L, Q, W, O, H, C, P, N$.

Proof. First apply the closure-consumer lock. Any public fixed-witness read must pass through the displayed generator, constructor-list, classifier, witness, output, transport, continuation, package, and naming rows.

Next apply fixed-witness source determinacy. Once the displayed surface is fixed, every accepted packet exposes the same witness route, while routes lacking L or Q remain boundary evidence.

The TasteGate witness route supplies the permitted audit discipline for AI-roadmap witness reads. It accepts only the displayed finite route and rejects self-application routes outside that packet.

Finally use the audit non-escape ledger. Since the ledger has no coordinate beyond $G, L, Q, W, O, H, C, P, N$ and the TasteGate route, the public audit ground route is exhausted by the finite fixed-witness surface. □

Theorem 556.24 (Generator fixed-point GeneratorClosure handoff)**.** *Every fixed-point read of an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet first factors through the displayed* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier row* Q*. The read may then consume the authorized generator row* G*, constructor-list provenance* L*, fixed-output witness* W*, output row* O*, componentwise transport row* H*, continuation route row* C*, package provenance row* P*, and local naming row* N*, but it has no route to a fixed witness before the classifier row has been displayed.*

Proof. Start with carrier admission from Definition 556.1. The accepted packet displays $G, L, Q, W, O, H, C, P, N$, so the classifier row is part of the finite source surface rather than a derived host fact.

Use the source admission and transport rows next. Definition 556.5 and Definition 556.6 keep Q attached to the authorized generator and constructor-list provenance under every accepted read.

Finally apply the fixed-witness and audit-ground rows. Definition 556.4, Definition 556.21, and Definition 556.23 route the witness through Q, W, O, H, C, P, N and leave no classifier-free fixed-point export. □

Theorem 556.25 (Generator fixed-point boundary GAP dependency)**.** *For an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet, a consumer route missing constructor-list provenance L is exactly a* GAP*-boundary read for the fixed-point surface. Such a route cannot export the fixed-output witness W, cannot detach Q from the authorized generator row G, and cannot be repacked as a downstream* $\mathsf{GeneratorClosure}^{\uparrow}$ *witness.*

Proof. Read the attempted route through the carrier. The only constructor-list provenance coordinate is L, so a route that omits it has no displayed source row authorizing a generator-internal continuation.

Apply non-escape and source determinacy. By Definition 556.3 and Definition 556.22, a route without L is boundary evidence, not an alternate source for the same fixed witness.

The witness ledger and audit rows finish the dependency claim. Definition 556.10 permits W only through the displayed witness ledger, while Definition 556.13 excludes any host fixed-point principle or unlisted continuation that could replace the missing provenance. □

Theorem 556.26 (Generator fixed-point downstream unblock package)**.** *Every downstream* $\mathsf{GeneratorClosure}^{\uparrow}$ *consumer of an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet receives only the finite rows*

$$G, L, Q, W, O, H, C, P, N.$$

The package exposes the authorized generator, constructor-list provenance, classifier, fixed witness, displayed output, transports, routes, provenance, and local naming row, and it exports no host fixed-point principle, self-application oracle, semantic completeness claim, or continuation outside the displayed constructor list.

Proof. First assemble the public package. The carrier definition, public obligation package, and closure-consumer lock show that every downstream read is a projection of $G, L, Q, W, O, H, C, P, N$.

Next apply the GeneratorClosure handoff. Definition 556.24 makes Q the first classifier row consumed by fixed-point readers, while the transport theorem keeps it attached to G and L.

Finally use boundary dependency and audit exhaustion. Routes missing constructor-list provenance are GAP boundaries by Definition 556.25, and Definition 556.23 leaves no downstream coordinate for a host fixed-point theorem, self-application oracle, semantic completeness, or unlisted continuation. □

Theorem 556.27 (Generator fixed-point carrier row totality)**.** *Every accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet has a total displayed carrier row*

$$F = (G, L, Q, W, O, H, C, P, N).$$

A public or downstream read of the fixed-point surface must account for all nine rows: the authorized generator row G, constructor-list provenance L, $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier row Q, fixed-output witness W, output row O, componentwise transport row H, continuation route row C, package provenance row P, and local naming row N. Omitting any one of these rows makes the read a partial boundary attempt, not an accepted carrier read.*

Proof. Start from Definition 556.1. The definition displays the accepted packet as the nine-coordinate tuple $G, L, Q, W, O, H, C, P, N$, so carrier admission is total over those rows.

Use the admitted packet row and the public obligation package. They make every public read a projection of the same finite tuple, with the source, classifier, witness, output, transport, route, provenance, and naming coordinates all present.

If a route omits one coordinate, the non-escape and audit rows apply. The attempted read no longer has the complete fixed-point source surface, so it is recorded as boundary evidence rather than as an accepted carrier projection. □

Theorem 556.28 (Generator fixed-point classifier row GAP determinacy)**.** *For an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet* $F = (G, L, Q, W, O, H, C, P, N)$*, the classifier route is determined by the displayed pair* L, Q*. A consumer route carrying both rows reads the* $\mathsf{GeneratorClosure}^{\uparrow}$ *classifier through* Q *under the constructor-list provenance* L*. A route missing* L *or missing* Q *is a* GAP *boundary and cannot be read as an alternate classifier for the same fixed-output witness* W*.*

Proof. Read the classifier route through the carrier. The constructor-list provenance and closure classifier are displayed as the two coordinates L and Q, so a valid classifier read must pass through both.

When both rows are present, the GeneratorClosure handoff applies. The row Q classifies the generator-internal continuation under the provenance supplied by L, and the witness ledger keeps W attached to that same classifier surface.

If L is absent, the boundary dependency theorem records the route as lacking constructor-list provenance. If Q is absent, the handoff theorem gives no classifier coordinate before the witness read.

In either missing-row case, the package provenance records a GAP boundary. The attempted route therefore cannot supply a competing classifier for W. □

Theorem 556.29 (Generator fixed-point closure-consumer NameCert handoff)**.** *Every downstream* $\mathsf{GeneratorClosure}^{\uparrow}$ *consumer of an accepted* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *packet reads the fixed-point certificate through*

$$Q, W, H, C, P, N$$

after the source rows G, L *have been displayed. The classifier row* Q *is the consumer-facing* $\mathsf{GeneratorClosure}^{\uparrow}$ *handoff;* W *supplies the fixed-output witness,* H *and* C *transport and replay the route,* P *records package provenance, and* N *is the local* $\mathsf{NameCert}_{\mathsf{GeneratorFixedPoint}^{\uparrow}}$ *row. No consumer receives a classifier-free fixed-point witness.*

Proof. First display the source rows G, L using source admission. This fixes the authorized generator and constructor-list provenance that make the continuation generator-internal.

Next read the consumer-facing classifier. The GeneratorClosure handoff forces every fixed-point read through Q before W can be exported.

Then replay the local NameCert route. The transport row H preserves the displayed surface, the continuation row C replays the read, the package row P records provenance, and the local naming row N exposes only that finite route.

Finally use classifier-row determinacy. A route missing L or Q is a GAP boundary, so no downstream $\mathsf{GeneratorClosure}^{\uparrow}$ consumer can receive a classifier-free fixed-point witness. □

Theorem 556.30 (Generator fixed-point scoped package)**.** *The scoped* $\mathsf{GeneratorFixedPoint}^{\uparrow}$ *package is exactly the finite surface consisting of* BHist, $\mathsf{GeneratorClosure}^{\uparrow}$, hsame, Cont, Pkg, $\mathsf{NameCert}$*, the authorized generator row* G*, the constructor-list row* L*, the classifier row* Q*, the fixed-output*

witness W, and the output row O. No scoped consumer can add a host fixed-point principle, self-application oracle, or continuation outside that displayed package.

Proof. Start from Definition 556.1. The carrier exposes the packet $F = (G, L, Q, W, O, H, C, P, N)$, so the scoped source surface is the finite tuple together with the ambient BHist, hsame, Cont, Pkg, and NameCert rows named by the packet.

Use the source admission row and the transport row. They keep G, L, Q, W, O attached to the authorized generator and constructor-list provenance under every displayed route.

Apply the witness ledger row, diagonal obstruction scope, and closure-consumer NameCert handoff. These rows exhaust the witness, boundary, and downstream consumer routes, leaving no package coordinate for a host fixed-point theorem, self-application oracle, or unlisted continuation. □

Lean4 ✓ `BEDC.Derived.GeneratorFixedPointUp.GeneratorFixedPointUp StdBridge`

Theorem 556.31 (Generator fixed-point continuation fixed-output scope)**.** *Any fixed-output consumer of an accepted* GeneratorFixedPoint$^{\uparrow}$ *packet reads the witness row W only after the displayed route through G, L, Q, O, H, C, P, N has been exposed. The consumer therefore receives the fixed-output witness as a scoped continuation read of the finite package, not as a host-level fixed-point operation.*

Proof. First expose the source rows using source admission. The authorized generator row G and constructor-list provenance L are required before the classifier row can be read.

Next apply the GeneratorClosure handoff and classifier-row determinacy. The classifier row Q stays attached to G, L, and a route missing either row is boundary evidence rather than a fixed-output source.

Finally use the closure-consumer NameCert handoff. It routes the witness through W after G, L, Q, O, H, C, P, N have been displayed, so the fixed-output read remains a finite Cont route inside the scoped package. □

Theorem 556.32 (Generator fixed-point downstream non-escape scope)**.** *Every downstream* GeneratorClosure$^{\uparrow}$ *consumer of an accepted* GeneratorFixedPoint$^{\uparrow}$ *packet receives only constructor-list provenance, classifier, fixed-output witness, output, transport, route, package, and local naming data from $G, L, Q, W, O, H, C, P, N$. It receives no host fixed-point principle, no self-application oracle, and no continuation outside the displayed constructor-list provenance.*

Proof. Begin with the downstream unblock package. It gives every downstream GeneratorClosure$^{\uparrow}$ consumer only the finite rows $G, L, Q, W, O, H, C, P, N$.

Use the boundary GAP dependency and diagonal obstruction scope for excluded routes. Attempts missing constructor-list provenance, classifier access, or the displayed witness route are recorded as GAP boundary evidence.

Finally apply the audit ground-route exhaustion. The TasteGate route and audit ledger exhaust the public fixed-witness surface, so there is no downstream coordinate for a host fixed-point theorem, self-application oracle, or continuation outside L. □

Closure status for NameCert$_{\text{GeneratorFixedPoint}^{\uparrow}}$.

Constructive story: A GeneratorFixedPoint$^{\uparrow}$ packet is generated from an authorized generator row, finite constructor-list provenance, a GeneratorClosure$^{\uparrow}$ classifier row, a fixed-output witness, a displayed output row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{GeneratorFixedPoint}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 556.30, Definition 556.31, and Definition 556.32 bind the scoped carrier package, fixed-output continuation route, and downstream non-escape boundary for the finite fixed-point packet.

Formal verification: FormalStatus(NameCert$_{\text{GeneratorFixedPoint}\uparrow}$, bridgeChecked)

Lean4 ✓ `BEDC.Derived.GeneratorFixedPointUp.taste gate`

Lean target: `BEDC.Derived.GeneratorFixedPointUp.GeneratorFixedPointTasteGate\_single\_carrier\_alignment`

Bridge status: bridgeChecked

Origin: ai

Not claimed: This chapter does not close a Lean implementation, bridge checking, host fixed-point theorems, self-application, semantic completeness, or continuations outside the displayed constructor-list provenance.

Upgrade path: No further upgrade is claimed on the formal axis; the displayed fixed-witness packet has a checked bridge route.

Chapter 557

A Concrete Naming Certificate for $\mathsf{KernelAcceptanceTrace}^{\uparrow}$

The $\mathsf{KernelAcceptanceTrace}^{\uparrow}$ surface records kernel acceptance as a finite trace packet: a submitted candidate, the type and classifier under which it is checked, the accepted stamp, the environment row, the displayed axiom ledger, transport, continuation, provenance, and local naming row. It is an audit witness for what the kernel admitted and which dependency rows the admission exposes, not a proof of kernel correctness.

The candidate row and accepted stamp are read as an inscription-event record surface in the sense of chapter 519: the submitted candidate, checked type, classifier, stamp, and environment give the event record that the trace consumes. The axiom ledger remains $\mathsf{KernelAcceptanceTrace}^{\uparrow}$'s own displayed row, so dependency exposure is still governed by the trace packet rather than by the inscription-event chapter.

Definition 557.1 (KernelAcceptanceTrace carrier)**.** *A* $\mathsf{KernelAcceptanceTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (A, T, C, S, E, L, H, R, P, N)$$

with the following displayed coordinates:

1. *A is the candidate row naming the term, declaration, inductive clause, or recursor instance submitted to the kernel;*
2. *T is the type row against which the candidate is checked;*
3. *C is the kernel classifier row recording the admitted declaration class and the local acceptance predicate for the candidate at type T;*
4. *S is the kernel stamp row that records the accepted name, module position, and replay boundary for the acceptance event;*
5. *E is the environment row in which the stamp is valid;*
6. *L is the displayed axiom ledger for the accepted trace, including the dependency rows exposed by the strict audit query;*
7. *H stores componentwise* hsame *transports for the candidate, type, classifier, stamp, environment row, axiom ledger, package provenance, and local naming row;*
8. *R stores the displayed* Cont *routes through which consumers read the candidate, transport the classifier, inspect the stamp, query the environment ledger, and replay the axiom ledger;*

9. *P is the* Pkg *provenance over* BHist*, candidate rows, type rows, kernel classifiers, kernel stamps, environment ledgers, axiom ledgers,* hsame*,* Cont*, and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{KernelAcceptanceTrace}^{\uparrow}}$ *row.*

The carrier has no hidden coordinate for ambient kernel soundness, host runtime trust, compiler trust, unqueried dependency ancestry, or a stronger paper-side theorem than the accepted declaration states.

Lean4 ✓ `BEDC.Derived.KernelAcceptanceTraceUp.KernelAcceptanceTraceTasteGate single carrier alignment`

Theorem 557.2 (KernelAcceptanceTrace NameCert obligations)**.** *For every accepted* $\mathsf{KernelAcceptanceTrace}^{\uparrow}$ *carrier*

$$K = (A, T, C, S, E, L, H, R, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{KernelAcceptanceTrace}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier exposure for the displayed packet K and its candidate, type, classifier, stamp, environment, axiom ledger, transport, continuation, provenance, and naming rows;*
2. *classifier transport, requiring every accepted comparison of traces to move A, T, C, S, E, L, P, N only by the componentwise* hsame *rows in H and the displayed* Cont *routes in R;*
3. *kernel-stamp exposure, requiring consumers to read acceptance through the accepted name, module position, and replay boundary in S;*
4. *environment-ledger exposure, requiring the accepted trace to route through the environment row E and the displayed axiom ledger L before any dependency claim is consumed;*
5. *non-escape, excluding hidden kernel soundness, host runtime trust, compiler trust, unqueried dependency ancestry, and theorem-content strengthening outside the accepted declaration.*

Lean4 ✓ `BEDC.Derived.KernelAcceptanceTraceUp.KernelAcceptanceTraceCarrier namecert obligations`

Proof. Carrier exposure is projection from Definition 557.1. The packet lists the candidate, type, classifier, stamp, environment, axiom ledger, transport, continuation, provenance, and local naming rows as finite coordinates.

Classifier transport is componentwise. The hsame rows in H preserve the displayed coordinates, and the Cont rows in R give only the routes named in the packet, so the accepted trace cannot be compared through an unrecorded classifier.

The stamp and environment obligations then force every acceptance read through S and E. The axiom ledger L is the only displayed ancestry row for dependency classification.

Finally inspect the carrier inventory. Since no coordinate names kernel soundness, host runtime trust, compiler trust, unqueried ancestry, or theorem strengthening beyond the accepted declaration, no local $\mathsf{NameCert}_{\mathsf{KernelAcceptanceTrace}^{\uparrow}}$ consumer can export such data. □

Theorem 557.3 (KernelAcceptanceTrace axiom ledger non-escape)**.** *For every accepted* $\mathsf{KernelAcceptanceTrace}^{\uparrow}$ *carrier*

$$K = (A, T, C, S, E, L, H, R, P, N),$$

the exported dependency surface is exactly the displayed axiom ledger L together with the stamp, environment, transport, continuation, provenance, and local naming rows S, E, H, R, P, N. No consumer may obtain a hidden Classical *source,* Quot *source,* propext *source, or any other unlisted dependency by reading the candidate row, type row, classifier row, or acceptance stamp alone.*

Proof. Read the dependency side of the carrier through L. The ledger is a named coordinate of the finite packet and is the only row that classifies transitive dependency ancestry.

The stamp S and environment row E identify where the accepted declaration lives, while H, R, P, N preserve and package the route by transport, continuation, provenance, and local naming. These rows can expose the displayed ledger but do not add a second ancestry channel.

Therefore a hidden Classical, Quot, propext, or other unlisted source would require an extra coordinate outside K. The local trace certificate has no such coordinate, so the accepted trace exports only the displayed axiom ledger. □

Theorem 557.4 (KernelAcceptanceTrace classifier transport)**.** *For every accepted* $\mathsf{KernelAcceptanceTrace}^{\uparrow}$ *carrier*

$$K = (A, T, C, S, E, L, H, R, P, N),$$

accepted trace comparison transports only the candidate row A, type row T, classifier row C, stamp row S, environment row E, axiom ledger L, provenance row P, and local name N through the displayed hsame *rows in H and the displayed* Cont *routes in R.*

Proof. Project the carrier coordinates and the local NameCert obligations. The comparison-facing data are exactly A, T, C, S, E, L, P, N.

The transport row H is componentwise, and the route row R is displayed in the packet. Thus accepted trace comparison can move the listed rows, but it has no separate classifier oracle, host runtime row, compiler row, or hidden dependency source. □

Theorem 557.5 (KernelAcceptanceTrace stamp-environment exposure)**.** *Every acceptance read from an accepted* $\mathsf{KernelAcceptanceTrace}^{\uparrow}$ *carrier factors through the stamp row S and the environment row E before the axiom ledger L can be consumed. The ledger cannot be read as an ambient ancestry claim detached from the accepted name, module position, replay boundary, and environment ledger.*

Proof. Begin with the carrier. The stamp row S records the accepted name, module position, and replay boundary, while E records the environment in which that stamp is valid.

Apply the axiom-ledger non-escape theorem. Dependency ancestry is exposed by L, but it is exported together with S, E, H, R, P, N rather than through the candidate, type, or classifier rows alone.

Therefore any acceptance read must first locate the stamp and environment. Only then can it consume the displayed ledger as the dependency surface of that accepted trace. □

Theorem 557.6 (KernelAcceptanceTrace accepted-declaration boundary)**.** *The accepted declaration boundary of a* $\mathsf{KernelAcceptanceTrace}^{\uparrow}$ *carrier cannot strengthen theorem content beyond the declared type row T and the displayed dependency ledger L. It exports the submitted candidate, accepted type, classifier, stamp, environment, ledger, transport, continuation, provenance, and local name, but no stronger theorem, kernel-correctness claim, or host-runtime trust row.*

Proof. Read the declaration through $A, T, C, S, E, L, H, R, P, N$. The type row T is the only displayed statement boundary for the accepted candidate, and L is the only displayed dependency ancestry.

Use classifier transport to keep comparisons inside the same rows. Transport may preserve the declared type and ledger, but it does not introduce a stronger theorem statement.

Finally apply stamp-environment exposure and axiom-ledger non-escape. Since the accepted trace must pass through S, E and has no hidden ancestry coordinate, the boundary cannot add kernel correctness, host runtime trust, or theorem content beyond T and L. □

Closure status for $\mathsf{NameCert}_{\mathsf{KernelAcceptanceTrace}^{\uparrow}}$.

Constructive story: A $\mathsf{KernelAcceptanceTrace}^{\uparrow}$ packet is generated from a submitted candidate, type row, kernel classifier, acceptance stamp, environment row, displayed axiom ledger, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{KernelAcceptanceTrace}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 557.1, Definition 557.2, Definition 557.3, Definition 557.4, Definition 557.5, and Definition 557.6 bind the finite trace carrier, local naming obligations, classifier transport, kernel stamp, environment row, displayed axiom-ledger boundary, and accepted-declaration boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{KernelAcceptanceTrace}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.KernelAcceptanceTraceUp.KernelAcceptanceTraceCarrier\_namecert\_obligations`

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, kernel correctness, host runtime correctness, compiler correctness, theorem-content strengthening beyond the accepted declaration, or bridge checking.

Upgrade path: The chapter is at the top of the paper closure axis; bridge checking remains a separate verification-axis obligation.

Chapter 558

A Zeckendorf-Variant Naming Certificate for $\mathsf{ZCarry}^{\uparrow}$

The $\mathsf{ZCarry}^{\uparrow}$ surface packages the generated Zeckendorf carry classifier as a finite $\mathsf{NameCert}$ object over displayed BHist words. Its source is the single non-normal carry window `word_011`, its target is the normal window `word_100`, and its classifier row records carry transport without identifying the two histories by hsame.

The dependency anchors are $\mathsf{ZeckendorfNormal}^{\uparrow}$, ZCarry, $\mathsf{ZNormal}$, hsame, BHist, and the displayed words of Definition 278.2.

The accepted carry packet consumes the normal-target witness of chapter 278 and the classifier boundary of chapter 567 before downstream consumers read the target row. This dependency is substantive: $\mathsf{ZeckendorfNormal}^{\uparrow}$ supplies target normality, while $\mathsf{ZeckendorfCarryClassifier}^{\uparrow}$ supplies the non-hsame carry-transport boundary.

Definition 558.1 (Zeckendorf carry concrete carrier)**.** *A* $\mathsf{ZCarry}^{\uparrow}$ *concrete carrier is a finite* BHist *packet*

$$K = (h, k, G, S, T, B, L, N)$$

with the following displayed rows:

1. $h =$ `word_011` *is the non-normal source window;*
2. $k =$ `word_100` *is the normal target window;*
3. G *is the generated carry row* $\mathsf{ZCarry}(h, k)$*;*
4. S *stores the source rejection* $\neg\mathsf{ZNormal}(h)$*;*
5. T *stores the target acceptance* $\mathsf{ZNormal}(k)$*;*
6. B *stores the classifier boundary* $\neg\mathsf{hsame}(h, k)$*;*
7. L *is the ledger row recording the visible generator, source rejection, target acceptance, and non-*hsame *boundary;*
8. N *is the local* $\mathsf{NameCert}_{\mathsf{ZCarry}^{\uparrow}}$ *row.*

The classifier compares carry packets by the generated row G and the boundary row B. It exports no arithmetic value, Fibonacci weight, quotient of histories, or equality between the source and target words.

Theorem 558.2 (Zeckendorf carry generator boundary)**.** *Every accepted* $\mathsf{ZCarry}^{\uparrow}$ *packet is generated by the single displayed carry row*

$$\mathsf{ZCarry}(\texttt{word_011}, \texttt{word_100}).$$

Consequently the source row is forced to `word_011` *and the target row is forced to* `word_100`*; no second carry generator, hidden target, or arithmetic equality row belongs to the carrier.*

Proof. Unpack the carrier of Definition 558.1. The only generator coordinate is G, and G is the closed carry row from the source window to the target window.

The ledger row L records the same generator together with the source rejection, target acceptance, and non-hsame boundary. Since the carrier has no coordinate for another generator or for a value interpretation, an accepted packet can only expose the displayed carry row. □

Theorem 558.3 (Zeckendorf carry NameCert obligations)**.** *The* $\mathsf{NameCert}_{\mathsf{ZCarry}^{\uparrow}}$ *surface has five obligations:*

1. *carrier habitation: the displayed packet* $K = (h, k, G, S, T, B, L, N)$ *is inhabited by* `word_011`*,* `word_100`*, and the generated carry row;*
2. *classifier transport: accepted packets are compared through the generated carry row* G*, not through* $\mathsf{hsame}(h, k)$*;*
3. *source boundary: the source row carries* $\neg\mathsf{ZNormal}(\texttt{word_011})$*;*
4. *target boundary: the target row carries* $\mathsf{ZNormal}(\texttt{word_100})$*;*
5. *ledger boundary: the packet records carry transport, source rejection, target acceptance, and non-*hsame *separation without exporting an arithmetic value or history quotient.*

Proof. Carrier habitation is the displayed packet of Definition 558.1. The source and target words are the two fixed BHist histories of Definition 278.2, and the generator row is the closed ZCarry constructor.

The classifier transport obligation reads the G and B rows together. The G row licenses carry movement from source to target, while B prevents that movement from being read as hsame.

The source and target boundaries are the normal-form rows already exposed by $\mathsf{ZeckendorfNormal}^{\uparrow}$: `word_011` is rejected and `word_100` is accepted. The ledger row packages exactly these witnesses, so no arithmetic value, quotient, or equality row is available to the public surface. □

Theorem 558.4 (Zeckendorf carry non-hsame boundary)**.** *For every accepted* $\mathsf{ZCarry}^{\uparrow}$ *packet* $K = (h, k, G, S, T, B, L, N)$*, the carry classifier separates transport from history sameness:* G *records* $\mathsf{ZCarry}(h, k)$*, while* B *records* $\neg\mathsf{hsame}(h, k)$*. Thus the packet can move a displayed non-normal window to a displayed normal window only as a classifier step, not as a kernel identification of histories.*

Proof. Project the G coordinate of the packet. By Definition 558.2, it is the displayed carry from `word_011` to `word_100`.

Project the boundary coordinate B. It records that the same source and target histories are not related by hsame. Hence carry transport and history sameness occupy distinct rows of the certificate.

The conclusion is a scope statement about the carrier: consumers may read the carry row, but they cannot replace it by a kernel history identification. The ledger L preserves this separation as part of the visible certificate surface. □

Theorem 558.5 (Zeckendorf carry normal-target handoff)**.** *Every downstream consumer of a* $\mathsf{ZCarry}^{\uparrow}$ *packet receives a normal target row only after the generator boundary, source rejection, and non-*hsame *separation have been fixed. The handoff to* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *is the target witness* $\mathsf{ZNormal}(\texttt{word_100})$*; it does not carry a Fibonacci value-preservation claim or a uniqueness-of-value row.*

Proof. Start with an accepted packet and read its generator row. The generator boundary fixes the source as `word_011` and the target as `word_100`.

Next read the source and target normal-form rows. The source row records rejection by the normal-form classifier, while the target row records acceptance by the same structural classifier.

Finally read the non-hsame boundary. Since the source and target are not identified as histories, the downstream $\mathsf{ZeckendorfNormal}^{\uparrow}$ consumer receives only the normal target witness and the ledger explaining how it was reached. Arithmetic value preservation remains outside this certificate surface. □

Theorem 558.6 (Concrete $\mathsf{ZCarry}^{\uparrow}$ packet surface)**.** *The carrier, generator boundary, NameCert obligations, non-*hsame *boundary, and normal-target handoff form the concrete* $\mathsf{ZCarry}^{\uparrow}$ *certificate surface. Its public content is finite carry transport from* `word_011` *to* `word_100` *together with the proof-facing separation between carry classification and history sameness.*

Proof. The carrier fixes the eight displayed rows of the packet. The generator boundary pins the only carry row, and the NameCert obligations state how the source, target, classifier, stability, and ledger fields are read.

The non-hsame boundary prevents the generator from becoming a history equality. The normal-target handoff identifies the only downstream normal-form consumer row.

Together these rows exhaust the concrete certificate surface. There is no carrier coordinate for Fibonacci values, value preservation, uniqueness of arithmetic value, or a quotient of histories, so those claims are not exported by $\mathsf{ZCarry}^{\uparrow}$. □

Corollary 558.7 (Zeckendorf carry strict local obstruction)**.** *Let* $K = (h, k, G, S, T, B, L, N)$ *be an accepted* $\mathsf{ZCarry}^{\uparrow}$ *packet. Suppose a displayed failure, refusal, separation, or countermodel row is attached to a consumer of* K *and is used against a named converse or reuse route. Then the row is a strict local obstruction: it blocks only the route whose read asks to add or replace one of the displayed carry coordinates*

$$\mathsf{ZCarry}(\texttt{word_011}, \texttt{word_100}), \quad S : \neg\mathsf{ZNormal}(\texttt{word_011}), \quad T : \mathsf{ZNormal}(\texttt{word_100}), \quad B : \neg\mathsf{hsame}(h, k), \quad L,$$

Every permitted consumer-facing use factors through these rows, with source `word_011` *and target* `word_100` *fixed. A request for a second carry generator, a hidden target, an* $\mathsf{hsame}(h, k)$ *identification, an arithmetic equality, a Fibonacci value row, a history quotient, a global normalizer, a host theorem, or hidden external validation has no coordinate in the accepted packet.*

Proof. Apply Definition 558.2. It fixes the only generated carry row as

$$\mathsf{ZCarry}(\texttt{word_011}, \texttt{word_100}),$$

forces the source row to `word_011` and the target row to `word_100`, and excludes any second generator, hidden target, or arithmetic equality row from the carrier. Thus a consumer cannot reinterpret a negative row as ranging over arbitrary carry windows or over an ambient arithmetic comparison; the only carry window available to the consumer is the displayed one.

Next apply Definition 558.3. The carrier-habitation obligation supplies the displayed packet K. The classifier-transport obligation routes comparison through G rather than through $\mathsf{hsame}(h, k)$. The source and target boundary obligations expose exactly $S : \neg\mathsf{ZNormal}(\texttt{word_011})$ and $T : \mathsf{ZNormal}(\texttt{word_100})$. The ledger obligation packages carry transport, source rejection, target acceptance, and non-hsame separation without exporting an arithmetic value or history quotient.

Now let the proposed converse or reuse route be consumer-facing. To consume K it must first read the generator, normality, separation, ledger, and local naming rows just listed. If the displayed failure, refusal, separation, or countermodel row denies one of those reads, it blocks that named route at the corresponding packet coordinate. If the route instead asks for a second generator, hidden target, source-target hsame proof, arithmetic equality, value row, quotient, global normalizer, host theorem, or external validation channel, the carrier and obligation theorems give no coordinate through which that request can be read.

Therefore the obstruction is exact and local. It is a negative certificate for the named converse or reuse route inside the displayed $\mathsf{ZCarry}^{\uparrow}$ packet, and it supplies no global impossibility statement, no host-side theorem, and no hidden validation of an unlisted route. □

Chapter 559

A Concrete Naming Certificate for $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$

The $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ packet records the finite handoff from a selected regular-Cauchy tail window to a $\mathsf{Real}^{\uparrow}$ seal. It is the concrete NameCert surface used when a diagonal-limit consumer asks for a rational precision request, a StreamName window, a RegSeqRat row, and the selected finite-tail witness that justifies the real-facing read.

Definition 559.1 (Finite-tail diagonal seal carrier)**.** *A* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (q, s, r, w, e, h, c, p, n)$$

with the following visible coordinates:

1. *q is the rational precision request, read through the displayed* $\mathsf{Rat}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows;*
2. *s is the* $\mathsf{StreamName}^{\uparrow}$ *window selecting the finite diagonal observation interval;*
3. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *row whose regularity ledger supplies the source observations;*
4. *w is the selected finite-tail witness, displaying the bounded tail segment that answers q inside the window s;*
5. *e is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after q, s, r, w have been exposed;*
6. *h records componentwise* hsame *transports for the precision request, StreamName window, RegSeqRat row, finite-tail witness, and real-seal row;*
7. *c records the displayed* Cont *routes by which consumers inspect the rows;*
8. *p is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{FiniteWindowEnvelope}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and selected-tail evidence;*
9. *n is the local* $\mathsf{NameCert}_{\mathsf{FiniteTailDiagonalSeal}^{\uparrow}}$ *row.*

The carrier contains no quotient stream, no host real equality, no unbounded diagonal object, no ambient completeness theorem, and no selected limit outside the finite witness row w.

Theorem 559.2 (Finite-tail diagonal seal NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FiniteTailDiagonalSeal}^{\uparrow}}$ *surface consists exactly of carrier admission for $D = (q, s, r, w, e, h, c, p, n)$, precision routing through q, finite-window routing through s, regular-Cauchy source routing through r, selected-tail*

witness exactness through w, $\mathsf{Real}^{\uparrow}$ *seal handoff through e, componentwise* hsame *transport through h, displayed* Cont *route replay through c, package provenance through p, and local naming through n.*

Proof. Project the carrier of Definition 559.1. The rows $q, s, r, w, e, h, c, p, n$ display the precision request, finite window, regular rational source, selected tail witness, real seal, transports, routes, package provenance, and local naming evidence.

The precision and source obligations are read before the seal. A consumer first reads q, then the selected StreamName window s, and then the RegSeqRat row r whose regularity ledger supplies the observations inside that window.

The selected witness obligation is the row w. It gives the finite tail segment that answers the request and prevents the handoff from appealing to an unbounded diagonal stream or an existential limit choice.

Finally the rows h, c, p, n account for transport, route replay, provenance, and local naming. Since the carrier has no quotient-stream coordinate, no host real equality coordinate, and no ambient-completeness coordinate, the obligation surface is exhausted by the displayed rows. □

Theorem 559.3 (Finite-tail diagonal seal window factorization)**.** *For an accepted* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *carrier $D = (q, s, r, w, e, h, c, p, n)$, every finite-tail read factors through the StreamName window s and the selected witness row w before any* $\mathsf{Real}^{\uparrow}$ *seal row is consumed. The factorization may use the regular-Cauchy source row r, the precision row q, the componentwise transports h, and the displayed routes c, but it has no route through a quotient stream, an infinite diagonal object, or a host real equality.*

Proof. Read the finite-window coordinates from the carrier. The only window coordinate is s, and the only selected tail coordinate is w.

Use the NameCert obligations of Definition 559.2. They force precision routing through q, source routing through r, and selected-tail witness exactness through w before the real-facing row e is reached.

Transport and route replay are then confined to h and c. The package and local certificate rows p, n record that this is a finite packet, so the factorization has no coordinate for quotient streams, infinite diagonal data, or host real equality. □

Theorem 559.4 (Finite-tail diagonal seal window lock)**.** *For an accepted* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *carrier $D = (q, s, r, w, e, h, c, p, n)$, the selected finite-tail witness row w is readable only under the selected* $\mathsf{StreamName}^{\uparrow}$ *window row s and the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row r. Any* $\mathsf{Real}^{\uparrow}$ *seal handoff through e preserves that same window lock through the componentwise transports h, the displayed routes c, the package provenance p, and the local* NameCert *row n.*

Lean4 ✓ `BEDC.Derived.FiniteTailDiagonalSealUp.FiniteTailDiagonalSealCarrier window lock`

Proof. Project the carrier of Definition 559.1. The row w is listed only as the selected finite-tail witness for the window s and the regular-rational source row r.

Apply the NameCert obligation theorem. It routes finite-window exposure through s, regular-Cauchy source exposure through r, and selected-tail witness exactness through w before the seal row e can be consumed.

Use the window factorization theorem to keep every finite-tail read under the same s, r, w boundary. The transports h, routes c, provenance p, and local name n replay that displayed boundary rather than selecting a second window.

Finally apply the non-escape boundary. Since the packet has no quotient stream, unbounded diagonal, host equality, ambient completeness, or external limit coordinate, a Real handoff through e cannot release w from the selected window and source rows. □

Theorem 559.5 (Finite-tail diagonal seal Real handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *carrier receives the seal row* e *only through the displayed chain*

$$q, s, r, w, h, c, p, n.$$

Thus the real-facing handoff consumes a rational precision request, a finite StreamName window, a RegSeqRat source row, a selected finite-tail witness, componentwise transport, route replay, package provenance, and local naming. It does not consume host real equality, quotient-name equality, an ambient completeness principle, or a selected limit outside the finite witness.

Lean4 ✓ `BEDC.Derived.FiniteTailDiagonalSealUp.FiniteTailDiagonalSealCarrier real handoff`

Proof. Start with the carrier row e. It is a $\mathsf{Real}^{\uparrow}$ seal coordinate inside the same finite packet as q, s, r, w, h, c, p, n.

Apply the window factorization theorem. The seal-facing read must pass through the precision, window, source, and witness rows before it reaches e.

The rows h and c then replay the displayed transport and continuation data, while p and n provide provenance and local naming. Because the carrier lists no host equality, quotient equality, ambient completeness, or external limit coordinate, the real-facing handoff is exactly the displayed chain. □

Theorem 559.6 (Finite-tail diagonal seal non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *packet factors through the finite rows*

$$q, s, r, w, e, h, c, p, n.$$

The consumer may read the rational precision request, selected StreamName window, RegSeqRat source, finite-tail witness, $\mathsf{Real}^{\uparrow}$ *seal,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row, and it cannot read quotient streams, host real equality, unbounded diagonal streams, ambient completeness, or a choice-selected limit.*

Proof. Project the accepted carrier and the NameCert obligation surface. The rows $q, s, r, w, e, h, c, p, n$ are the complete displayed packet.

Use the window factorization theorem for all finite-tail observations. It routes tail reads through s and w with the source and precision rows visible.

Use the Real handoff theorem for real-facing consumers. It routes seal reads through q, s, r, w, h, c, p, n before e is consumed.

Since the carrier has no remaining coordinate beyond the displayed rows, no downstream consumer can extract quotient-stream data, host real equality, unbounded diagonal data, ambient completeness, or a choice-selected limit from the packet. □

Theorem 559.7 (Finite-tail diagonal seal selected-tail exactness)**.** *For an accepted* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *carrier*

$$D = (q, s, r, w, e, h, c, p, n),$$

the selected-tail witness row w *is exact for the displayed* $\mathsf{StreamName}^{\uparrow}$ *window* s*. A consumer may read* w *only as the finite tail segment selected under* s *from the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row* r *for the rational precision request* q*. The witness is not a quotient stream, an unbounded diagonal stream, a host real equality, or a selected limit outside the finite packet.*

Lean4 ✓ `BEDC.Derived.FiniteTailDiagonalSealUp.FiniteTailDiagonalSealCarrier selected tail exactness`

Proof. Project the carrier rows. The only selected-tail coordinate is w, and the carrier names it relative to the window row s, source row r, and precision request q.

Use the NameCert obligations and window lock. They force finite-window routing through s, source routing through r, and selected-tail witness exposure through w before the seal row e can be consumed.

Apply non-escape for the negative boundary. Since no quotient stream, unbounded diagonal stream, host equality, ambient completeness, or selected limit is present as a carrier coordinate, w is exact only as the displayed finite witness. □

Theorem 559.8 (Finite-tail diagonal seal RegSeqRat source coverage)**.** *For an accepted* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *carrier*

$$D = (q, s, r, w, e, h, c, p, n),$$

the row r is the only $\mathsf{RegSeqRat}^{\uparrow}$ *source route into the selected finite-tail witness and the* $\mathsf{Real}^{\uparrow}$ *seal. Every seal-facing read passes through the precision row q, the window row s, the source row r, and the selected witness row w before reaching e, with transport, continuation, provenance, and local naming recorded by h, c, p, n.*

Proof. Start with the source coordinate of the carrier. The packet lists one $\mathsf{RegSeqRat}^{\uparrow}$ row, namely r, and no second regular-rational source route.

Apply window factorization and window lock. The selected finite-tail read is confined to s, r, w, while the precision request q fixes the finite observation demand answered by that tail.

Use the Real handoff theorem for the seal-facing step. It routes the consumer through q, s, r, w, h, c, p, n before e is consumed, so r is the only source route available to the seal. □

Theorem 559.9 (Finite-tail diagonal seal obligation package)**.** *The* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *obligation package over*

$$D = (q, s, r, w, e, h, c, p, n)$$

consists exactly of precision routing through q, selected window routing through s, $\mathsf{RegSeqRat}^{\uparrow}$ *source coverage through r, selected-tail witness exactness through w,* $\mathsf{Real}^{\uparrow}$ *seal handoff through e, componentwise transport through h, displayed route replay through c, provenance through p, and the local* NameCert *row n. This package has no quotient-stream, host-real-equality, hidden-limit, or ambient-completeness input.*

Proof. First assemble the displayed carrier rows. The carrier definition and NameCert obligation theorem give the precision, window, source, witness, seal, transport, route, provenance, and local naming coordinates.

Next add the source and witness controls. Selected-tail exactness binds w to the finite window s and source r, while RegSeqRat source coverage makes r the only source route into the witness and seal.

Finally apply Real handoff and non-escape. Real handoff places the seal row e downstream of the displayed finite chain, and non-escape rules out quotient streams, host real equality, unbounded diagonal streams, ambient completeness, and selected limits as additional inputs. □

Lean4 ✓ `BEDC.Derived.FiniteTailDiagonalSealUp.FiniteTailDiagonalSealCarrier obligation package`

Theorem 559.10 (FiniteTailDiagonalSeal obligation closure)**.** *For an accepted* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *carrier* $D = (q, s, r, w, e, h, c, p, n)$*, the obligation surface closes over the same finite packet: carrier admission, precision routing, window routing, witness exactness, seal handoff, transport, route replay, provenance, and local naming are all read through* $q, s, r, w, e, h, c, p, n$*. The closure route is the one consumed by chapter 450, and its upstream rows are the* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows displayed in the carrier.*

Proof. Assemble the carrier and local NameCert rows from Definition 559.1 and Definition 559.2. These rows provide carrier admission, precision routing, finite-window routing, source routing, selected-tail witness exactness, seal handoff, transport, route replay, provenance, and naming.

Use the exactness theorems to fix the route. Definition 559.3, Definition 559.4, Definition 559.7, and Definition 559.8 keep every witness read inside the selected $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{RegSeqRat}^{\uparrow}$ source row, and the precision route supplied through the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance rows.

Finally apply the handoff and boundary theorems. Definition 559.5 sends the selected witness to the $\mathsf{Real}^{\uparrow}$ seal row, while Definition 559.6 blocks quotient streams, host real equality, unbounded diagonal data, ambient completeness, and choice-selected limits. □

Theorem 559.11 (FiniteTailDiagonalSeal RealCompleteness route)**.** *The route from* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *to chapter 450 passes through the same finite-tail seal rows* $q, s, r, w, e, h, c, p, n$*. A RealCompleteness consumer may read the selected* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *precision route, and the* $\mathsf{Real}^{\uparrow}$ *seal row, but it has no route through quotient streams, ambient completeness, host real equality, or an unbounded diagonal object.*

Lean4 ✓ `BEDC.Derived.FiniteTailDiagonalSealUp.FiniteTailDiagonalSealUp StdBridge`

Proof. Start with Definition 559.10. It makes the finite-tail seal packet the entire obligation route available to downstream consumers.

Read the RealCompleteness side through chapter 450. Its finite diagonal-limit packet consumes StreamName windows, RegSeqRat readbacks, DyadicRatCore ledgers, and the final RealUp seal row, which are exactly the rows exposed by s, r, q, e together with the selected witness w.

The route is preserved by h, c, p, n. Componentwise transport, continuation replay, provenance, and local naming keep the consumer on the same finite seal route.

Apply Definition 559.6 for the negative boundary. Since the finite packet lacks quotient streams, ambient completeness, host equality, and unbounded diagonal data, the RealCompleteness route cannot acquire them. □

Theorem 559.12 (FiniteTailDiagonalSeal window obligation package)**.** *The window-specific obligation package inside an accepted* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ *carrier isolates three rows: the* $\mathsf{StreamName}^{\uparrow}$ *window row* s*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row* r*, and the selected finite-tail witness row* w*. Every precision request from the* $\mathsf{DyadicRatCore}^{\uparrow}$ *side reaches the* $\mathsf{Real}^{\uparrow}$ *seal row* e *only after these three rows have been read and transported through* h, c, p, n*.*

Proof. Project the window, source, and witness rows from the carrier. The displayed packet contains one selected window row s, one regular-rational source route r, and one selected finite-tail witness w.

Use Definition 559.4 and Definition 559.7. Together they make w readable only under s and r, with the precision request supplied by q.

Then use Definition 559.5. The seal row e is downstream of q, s, r, w and remains routed by h, c, p, n.

The non-escape theorem supplies the boundary: no quotient stream, host real equality, hidden limit, or ambient completeness row can enter the window package. □

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteTailDiagonalSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$ packet is generated from a rational precision request, selected $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ source row, selected finite-tail witness, $\mathsf{Real}^{\uparrow}$ seal row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FiniteTailDiagonalSeal}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 559.1, Definition 559.9, and Definition 559.11 bind the public finite-tail seal surface over the obligation package and the RealCompleteness route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FiniteTailDiagonalSeal}^{\uparrow}}, \mathsf{bridgeChecked})$

Chapter 560

RegularCauchyTailMeet NameCert construction

The $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ interface packages the finite rows needed when several regular Cauchy consumers must share one dyadic tail threshold. It is a concrete naming certificate for the tail-meet packet used by diagonal real-completion routes; it does not assert quotient equality of streams, a selected limit, trichotomy, or an ambient completeness theorem.

The shared threshold route is the consumer side of the $\mathsf{CauchyModulusMeet}^{\uparrow}$ shared-bound export in chapter 462. It consumes exactly the two $\mathsf{StreamName}^{\uparrow}$ rows, the two source $\mathsf{CauchyModulus}^{\uparrow}$ rows, the shared meet row, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, componentwise hsame transports, displayed Cont routes, package provenance, and the local $\mathsf{NameCert}$ row.

Definition 560.1 (RegularCauchyTailMeet carrier)**.** *A* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N)$$

with the following displayed coordinates:

1. R_0 *and* R_1 *are the two* $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows whose tails must be read through one threshold;*
2. W_0 *and* W_1 *are the paired* $\mathsf{StreamName}^{\uparrow}$ *finite-window schedules exposing the two rational tails;*
3. M_0 *and* M_1 *are the source* $\mathsf{CauchyModulus}^{\uparrow}$ *or dyadic-radius rows attached to the two regular Cauchy names;*
4. τ *is the shared tail threshold row, displayed as a* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger sufficient for both source rows;*
5. Q *is the paired tail comparison row recording the two scheduled observations at the shared threshold;*
6. H *stores componentwise* hsame *transports for the two source names, windows, source moduli, shared threshold, paired comparison, provenance, and local name;*
7. C *stores the displayed* Cont *routes for reading source windows, source modulus rows, the shared threshold, the paired tail comparison, and the real-facing handoff;*
8. L *is the finite ledger over* $\mathsf{RegularCauchyName}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$*;*

9. N is the local $\mathsf{NameCert}_{\mathsf{RegularCauchyTailMeet}^{\uparrow}}$ *row.*
The carrier is only the finite shared-tail packet. It has no coordinate for quotient streams, host real equality, selected limits, trichotomy, or ambient completeness.

Theorem 560.2 (RegularCauchyTailMeet NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTailMeet}^{\uparrow}}$ *surface for the carrier of Definition 560.1 consists exactly of carrier admission, paired* $\mathsf{RegularCauchyName}^{\uparrow}$ *source admission, paired* $\mathsf{StreamName}^{\uparrow}$ *scheduling, source modulus readback, shared dyadic tail-threshold exposure, paired tail comparison, componentwise* hsame *transport, displayed* Cont *routes, finite ledger exactness, package provenance, and the local naming row.*

Proof. Carrier admission is projection from the displayed packet T. Its coordinates list the two regular Cauchy sources, their windows, their source modulus rows, the shared tail threshold, the comparison row, transport, continuation, ledger, and local name.

The shared threshold is finite. The two schedules expose the rational tail windows before τ and Q can be read, and the source modulus rows certify that the same tolerance ledger is sufficient for both sides.

The remaining obligations are provenance and routing obligations. The rows H, C, L, N transport the displayed coordinates, route the reads, record package provenance, and name the packet; none of them introduces quotient equality, a selected limit, trichotomy, host real equality, or completeness. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket namecert obligations`

Theorem 560.3 (RegularCauchyTailMeet classifier stability)**.** *For accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *carriers whose displayed coordinates are related componentwise by the stored* hsame *rows, the paired tail comparison row Q remains readable through the same shared threshold τ. The classifier is stable under transport of the two source names, two window schedules, two source modulus rows, the threshold ledger, and the local certificate rows.*

Proof. Project the two accepted carriers. The only rows that determine the tail classifier are the two source names, their scheduled windows, their source modulus rows, the shared threshold, and the comparison row.

Use the componentwise transport entries in H to move these rows to a common displayed surface. The continuation rows in C then replay the reads from sources to windows, from windows and source bounds to τ, and from τ to Q.

Since the carrier contains no independent classifier coordinate, transported reads must use the same threshold ledger and paired comparison route. Stability follows from the displayed packet itself, not from host real equality or quotient stream equality. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket classifier stability`

Theorem 560.4 (RegularCauchyTailMeet Real seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *diagonal or completion consumer of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *carrier reads tail synchronization only through the paired* $\mathsf{RegularCauchyName}^{\uparrow}$ *sources, paired* $\mathsf{StreamName}^{\uparrow}$ *schedules, source modulus rows, the shared dyadic threshold τ, the paired comparison row Q, displayed* hsame *transports,* Cont *routes, finite ledger, package provenance, and local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTailMeet}^{\uparrow}}$ *row.*

Proof. Start with a real-facing consumer route. The carrier offers no real-facing data except the handoff reached through the displayed schedules, source modulus rows, and shared threshold ledger.

The consumer first reads the paired windows and source bounds. It then reads the common threshold τ and the comparison row Q, with all movement recorded by H and C.

The ledger L and local certificate N record provenance and name the handoff. Because no other coordinate is present, the seal exports tail synchronization without exporting quotient streams, selected limits, trichotomy, host real equality, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket real seal handoff`

Theorem 560.5 (RegularCauchyTailMeet dyadic absolute-value handoff)**.** *Let an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *carrier have shared threshold row* τ*. Suppose the displayed row* τ *is supplied by an accepted* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *endpoint ledger whose nonnegative dyadic endpoint and tolerance ledger are used as the common tail bound. Then the two scheduled regular-Cauchy tails consume only that displayed nonnegative dyadic endpoint, its tolerance ledger, the componentwise* hsame *transports, the displayed* Cont *routes, the finite ledgers, package provenance, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTailMeet}^{\uparrow}}$ *and* $\mathsf{NameCert}_{\mathsf{DyadicAbsoluteValue}^{\uparrow}}$ *rows.*

The handoff exports no quotient streams, selected limits, trichotomy witness, host real equality, ambient completeness, quotient rational, selected real value, or host integer normal form.

Proof. Begin with the $\mathsf{Real}^{\uparrow}$ seal handoff of Definition 560.4. It forces every completion-facing read of the shared tail packet through the paired source rows, paired window schedules, source modulus rows, the shared threshold τ, the comparison row Q, the stored transports, continuations, ledger, package provenance, and local name.

Now read τ through the accepted $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ endpoint ledger. By Definition 293.4, the endpoint offered to $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consumers is the displayed nonnegative dyadic endpoint, reached through the endpoint row, tolerance ledger, transports, continuation routes, package provenance, and local dyadic absolute-value name.

Apply Definition 293.5 to the endpoint source. The finite ledger admits no hidden quotient rational, selected real value, trichotomy proof, host integer normal form, or real-completeness witness. Substituting that endpoint ledger for the shared threshold route leaves the two scheduled tails with exactly the listed finite rows.

Thus the regular-Cauchy tail meet consumes the dyadic absolute-value endpoint as a finite threshold ledger. The route remains a composite of displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, so no quotient stream, selected limit, trichotomy, host real equality, or ambient completeness coordinate enters the handoff. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket dyadic absolute value handoff`

Theorem 560.6 (RegularCauchyTailMeet dyadic endpoint meet)**.** *Let an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *carrier have source rows* R_0, R_1*, schedules* W_0, W_1*, source modulus rows* M_0, M_1*, shared threshold coordinate* τ*, and paired comparison row* Q*. Suppose the two scheduled tails receive displayed nonnegative endpoint and tolerance ledgers from accepted* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *packets. If a displayed dyadic row* τ' *is strong enough for both endpoint tolerance ledgers through the same source modulus rows* M_0 *and* M_1*, then* τ' *is a valid shared threshold for the paired comparison row* Q *and for the* $\mathsf{Real}^{\uparrow}$ *seal handoff of the accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet.*

The meet route uses only the two $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ *endpoint rows, their tolerance ledgers, the paired* $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows, the schedules, the source modulus rows, the displayed threshold row* τ'*, the paired comparison row* Q*, the componentwise* hsame *transports, displayed*

Cont *routes, finite ledgers, package provenance, and the local* NameCert *rows. It exports no quotient stream, selected limit, trichotomy, host real equality, host integer normal form, or ambient completeness witness.*

Proof. First read the two endpoint packets through the dyadic absolute-value bridges. Apply Definition 293.4 to obtain displayed nonnegative dyadic endpoints for the two scheduled tails, and apply Definition 293.5 to keep each endpoint route inside its finite endpoint row, tolerance ledger, transports, continuations, provenance, and local dyadic name.

Next pass each endpoint tolerance ledger to the regular-Cauchy tail surface. Apply Definition 293.8 to make the displayed tolerance rows available to the source modulus reads, and apply Definition 560.7 to identify the only regular-Cauchy rows that can consume them: $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H,$

The displayed row τ' is assumed strong enough for both endpoint tolerance ledgers through the same source modulus rows. Apply Definition 560.8 with τ' in place of the carrier threshold route. The paired comparison row Q and the $\mathsf{Real}^{\uparrow}$ handoff therefore factor through τ' using the already displayed transports, continuations, finite ledger, package provenance, and local name.

All objects used in the construction are named rows in the accepted packets. Since the dyadic endpoint bridges and the tail-meet ledger exactness have no coordinate for quotient streams, selected limits, trichotomy, host real equality, host integer normal forms, or ambient completeness, the finite meet cannot export any such coordinate. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket dyadic endpoint meet`

Theorem 560.7 (RegularCauchyTailMeet ledger exactness)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *carrier, the finite ledger is exact for the route from paired regular Cauchy sources through their windows and source modulus rows to the shared dyadic tail threshold* τ*, the comparison row* Q*, and the* $\mathsf{Real}^{\uparrow}$ *handoff. No ledger entry records an independent tail oracle, quotient stream equality, selected limit, trichotomy row, host real equality, or ambient completeness witness.*

Proof. Inspect the carrier of Definition 560.1. The only tail-threshold data are the two source rows, two scheduled windows, two source modulus rows, the shared threshold row, and the paired comparison row.

Apply the NameCert obligations to bind every accepted read to those rows. Classifier stability then shows that transport cannot replace the shared threshold or comparison row with an external tail oracle.

Finally apply the Real seal handoff. Every real-facing use of the packet factors through the same finite ledger, so the ledger is exact for the displayed route and has no unlisted analytic coordinate. □

Theorem 560.8 (RegularCauchyTailMeet shared-threshold cofinality)**.** *Let an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *carrier have shared threshold row* τ*. If a displayed dyadic threshold row* τ' *is at least as strong as* τ *for both source modulus rows and is transported through the same paired window schedules, then the paired comparison row* Q *and the* $\mathsf{Real}^{\uparrow}$ *handoff factor through* τ' *using the existing* hsame *transports, displayed* Cont *routes, finite ledger,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTailMeet}^{\uparrow}}$ *row.*

This strengthening exports no independent tail oracle, quotient stream, selected limit, host real equality, trichotomy row, or ambient completeness witness.

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket shared threshold cofinality`

Proof. Project the accepted carrier. The two source modulus rows M_0 and M_1 are the only rows that certify threshold sufficiency for the paired tails, and the paired schedules W_0 and W_1 are the only rows that expose the corresponding observations.

Read the displayed strengthening τ' through those same source modulus rows. The hypothesis that τ' is at least as strong as τ for both sources lets each scheduled tail read use τ' without changing the source rows or window schedules.

Replay the paired schedules through the displayed continuation routes. Transport the comparison row through the componentwise hsame entries already stored in H, so the comparison remains the same carrier-facing row Q with the threshold coordinate refined to τ'.

Finally apply ledger exactness and the Real seal handoff. The finite ledger and seal route already contain the required transports, continuations, provenance, and local name, so the strengthened threshold factors through the same public handoff and adds no unlisted analytic coordinate. □

Theorem 560.9 (RegularCauchyTailMeet obligation closure package)**.** *The carrier,* NameCert *obligation surface, classifier stability,* Real$^{\uparrow}$ *seal handoff, dyadic absolute-value endpoint handoff, dyadic endpoint meet, ledger exactness, and shared-threshold cofinality jointly form the complete obligation package for the shared regular-Cauchy tail threshold packet over* RegularCauchyName$^{\uparrow}$*,* StreamName$^{\uparrow}$*,* CauchyModulus$^{\uparrow}$*,* DyadicRatCore$^{\uparrow}$*,* DyadicAbsoluteValue$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*,* Real$^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

The package exports no quotient stream, selected limit, trichotomy coordinate, host equality row, or ambient completeness witness.

Proof. Begin with the finite carrier of Definition 560.1. It displays the paired regular Cauchy sources, paired stream schedules, source modulus rows, shared threshold ledger, paired comparison row, transports, continuations, ledger, package provenance, and local name.

Add the local obligation surface from Definition 560.2. Those obligations certify carrier admission, scheduled source reads, modulus readback, shared-threshold exposure, paired comparison, transport, continuation, ledger exactness, provenance, and naming.

Next use Definition 560.3 and Definition 560.4. They keep the classifier and the real-facing handoff on the same displayed shared threshold and comparison rows.

The dyadic endpoint route is controlled by Definition 560.5. It identifies the shared threshold consumed by the two tails with the displayed nonnegative endpoint and tolerance ledger supplied by the accepted DyadicAbsoluteValue$^{\uparrow}$ packet.

The two-endpoint meet is controlled by Definition 560.6. When two endpoint tolerance ledgers must be served by one displayed dyadic threshold row, the same source modulus rows and schedules route the paired comparison and the real-facing handoff through that shared row.

Finally apply Definition 560.7. The finite ledger exhausts the route from source rows to shared threshold, comparison, and Real$^{\uparrow}$ handoff, so the obligation package has no quotient stream, selected limit, trichotomy, host equality, or ambient completeness coordinate.

Shared-threshold cofinality from Definition 560.8 adds the permitted refinement step. A stronger displayed dyadic threshold can be routed through the same source modulus rows, schedules, transports, continuations, ledger, provenance, and local name without adding an independent tail oracle. □

Theorem 560.10 (RegularCauchyTailMeet diagonal-window threshold handoff)**.** *Let an accepted* RegularCauchyTailMeet$^{\uparrow}$ *packet supply its shared threshold row τ as the selected-window threshold for an accepted* RealDiagonalWindowCoverage$^{\uparrow}$ *packet. Then the paired regular-Cauchy tails route through the same finite threshold τ before the* Real$^{\uparrow}$ *seal of the diagonal-window packet is read.*

The consumer-facing route uses only the paired source rows, scheduled windows, source modulus rows, shared threshold, paired comparison row, componentwise hsame *transports, displayed* Cont *routes, finite ledger,* Pkg *provenance, the selected* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, and the local* NameCert *rows. It exports no independent tail oracle, quotient stream, selected limit, host real equality, trichotomy row, or ambient completeness witness.*

Proof. First apply Definition 560.8. It identifies the shared threshold row consumed by both source tails and keeps the paired comparison and real-facing handoff on the same finite threshold route.

Apply Definition 560.9 to expose the complete shared-tail surface: paired sources, windows, source modulus rows, the threshold ledger, comparison row, transports, continuations, ledger, provenance, and local name.

Finally use Definition 561.8. The diagonal-window packet can read its $\mathsf{Real}^{\uparrow}$ seal only after the selected window and dyadic observation ledger have been displayed, so the shared threshold supplied by the tail-meet packet is consumed before the seal-facing row is available. □

Theorem 560.11 (RegularCauchyTailMeet public shared-threshold certificate)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, the obligation closure package, shared-threshold cofinality theorem, dyadic endpoint meet,* $\mathsf{Real}^{\uparrow}$ *seal handoff, and diagonal-window threshold handoff assemble one public shared-threshold certificate consumed by* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *and by* $\mathsf{Real}^{\uparrow}$*-facing diagonal routes.*

The certificate reads only the paired $\mathsf{RegularCauchyName}^{\uparrow}$ *sources, paired* $\mathsf{StreamName}^{\uparrow}$ *schedules, source modulus rows, shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold ledger, paired comparison row, componentwise* hsame *transports, displayed* Cont *routes, finite ledger,* Pkg *provenance, selected diagonal-window data, and local* NameCert *rows. It exports no quotient stream, selected limit, trichotomy, host equality, hidden tail oracle, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket public shared threshold certificate`

Proof. First collect Definition 560.9. It binds the carrier rows, schedules, source modulus reads, threshold ledger, paired comparison row, transports, continuations, ledger, package provenance, and local name into one obligation surface.

Use Definition 560.8. Cofinal refinement keeps both source tails on the same displayed threshold row and does not introduce an independent tail oracle.

Next apply Definition 560.6 together with Definition 560.4. The dyadic endpoint meet supplies the shared endpoint threshold, and the real-seal handoff keeps the consumer on that finite threshold route.

Finally use Definition 560.10. The selected-window consumer reads the shared threshold before the $\mathsf{Real}^{\uparrow}$ seal route is available, so the assembled rows form the public certificate for $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ and diagonal $\mathsf{Real}^{\uparrow}$ consumers while preserving all listed exclusions. □

Theorem 560.12 (RegularCauchyTailMeet limit-seal threshold route)**.** *Let* $T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H,$ *be an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. Any* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer or diagonal* $\mathsf{Real}^{\uparrow}$ *consumer that reads the public shared threshold of* T *factors through the paired* $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows, paired* $\mathsf{StreamName}^{\uparrow}$ *schedules, source modulus rows, shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold ledger, paired comparison row, visible* BHist *evidence, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The route consumed by chapter 386 and by diagonal $\mathsf{Real}^{\uparrow}$ *readers is therefore the same finite TailMeet certificate route, not a selected limit, quotient stream, host real equality, hidden tail oracle, or ambient completeness row.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket limit seal threshold route`

Proof. First read the accepted carrier through the obligation package. It exposes the paired source rows, scheduled windows, source modulus rows, shared threshold ledger, paired comparison row, componentwise transports, continuations, finite ledger, provenance, and local name as one finite TailMeet surface.

Next compose shared-threshold cofinality with the dyadic endpoint meet. Cofinal refinement keeps stronger precision requests on the displayed source modulus rows, while the endpoint meet supplies the threshold ledger row consumed by the real-facing route.

Use the real-seal handoff, the diagonal-window threshold handoff, and the public shared-threshold certificate. These results make the $\mathsf{CauchyLimitSeal}^{\uparrow}$ and diagonal $\mathsf{Real}^{\uparrow}$ consumers read the threshold only after the same finite route has been displayed.

The exclusion boundary is inherited from consumer exactness. Since the consumer receives only the listed TailMeet rows, there is no coordinate from which to export a quotient stream, selected limit, host real equality, hidden tail oracle, or ambient completeness witness. □

Theorem 560.13 (RegularCauchyTailMeet observation-budget absorption)**.** *Every* $\mathsf{RealObservationBudget}^{\uparrow}$ *request that reads the public shared threshold of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet is absorbed by the same finite TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The observation route of chapter 611 may inspect its own finite request, window, dyadic readback, regular-rational handoff, and seal rows only through that displayed TailMeet entrance. It cannot add a hidden observation budget, host real equality, selected limit, or ambient completeness row to the threshold read.

Proof. Begin with the public shared-threshold certificate. It names τ as the threshold exported to real-facing consumers and keeps the export attached to the paired regular-Cauchy sources, stream schedules, source modulus rows, comparison row, transports, continuations, ledger, provenance, and local name.

Now route the request through the finite observation-budget surface. That sibling chapter admits observation reads through finite request rows, windows, dyadic readbacks, regular-rational handoff rows, and a real-seal boundary, so the TailMeet threshold can enter it only through the displayed finite entrance.

Finally apply the real-seal handoff and consumer exactness. The handoff places the budget read behind the same TailMeet threshold route, and exactness prevents the budget side from appending a host equality row, selected limit, hidden observation budget, or ambient completeness premise. □

Theorem 560.14 (RegularCauchyTailMeet selector-budget public route)**.** *Every* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *route that shares the public threshold of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet reuses the displayed selector-window and* $\mathsf{RegSeqRat}^{\uparrow}$ *route of chapter 678. Its tail-facing threshold entry is the TailMeet row* τ *transported through*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N,$$

and it creates no second selector, hidden threshold, hidden tail oracle, quotient stream, host real equality, selected limit, or ambient completeness row.

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket selector budget public route`

Proof. Start with selector admission and the selector-budget surface. The admitted route supplies the finite selector windows and $\mathsf{RegSeqRat}^{\uparrow}$ readback before any tail-facing threshold is consumed.

Next use the shared-threshold cofinality and route determinacy rows. Cofinality allows stronger displayed thresholds only through M_0 and M_1, and determinacy keeps any shared-threshold read with the same transported source, window, and modulus rows on the same τ.

Attach the public shared-threshold certificate and the diagonal-window threshold handoff. They present the selector-facing threshold as the same public TailMeet row consumed by real-facing routes, with Q, H, C, L, N carried along the displayed package and naming surface.

Thus the selector-budget consumer reuses the existing selector-window and $\mathsf{RegSeqRat}^{\uparrow}$ route. With no second threshold coordinate and no extra selector row in the TailMeet carrier, a hidden tail oracle or ambient completion datum cannot be introduced. □

Theorem 560.15 (RegularCauchyTailMeet triple consumer route factorization)**.** *Any accepted consumer among* $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, *and* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *that reads a* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared threshold factors through the same finite rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

No such consumer may append selected limits, quotient stream equality, host real equality, hidden observation budgets, hidden tail oracles, or ambient completeness rows to that threshold read.

Proof. First use the limit-seal threshold route. It sends every $\mathsf{CauchyLimitSeal}^{\uparrow}$ and diagonal $\mathsf{Real}^{\uparrow}$ threshold read through the paired regular-Cauchy sources, stream schedules, modulus rows, threshold ledger, comparison row, transports, continuations, package, and naming rows.

Next use observation-budget absorption. A $\mathsf{RealObservationBudget}^{\uparrow}$ request may inspect its own finite budget surface only after the same TailMeet entrance has been displayed, so it receives τ with the rows $R_0, R_1, W_0, W_1, M_0, M_1, Q, H, C, L, N$ attached.

Finally use the selector-budget public route. The selector-facing threshold is the same public TailMeet row, transported through the same finite packet and not through a second selector or hidden threshold coordinate.

The three routes therefore share the displayed row list. Since each preceding theorem excludes selected limits, quotient stream equality, host real equality, hidden observation budgets, hidden tail oracles, and ambient completeness rows, their common factorization excludes the same extra coordinates. □

Theorem 560.16 (RegularCauchyTailMeet Real and completion consumer frontier)**.** *Let* $T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N)$ *be an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. Any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer that reads the shared threshold of* T *through* $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, *or* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *must first factor through the single finite TailMeet packet*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

No such consumer may bypass that frontier by using selected limits, quotient stream equality, host real equality, trichotomy rows, hidden observation budgets, hidden tail oracles, or ambient completeness.

Proof. Use the limit-seal threshold route to place every $\mathsf{CauchyLimitSeal}^{\uparrow}$ and diagonal $\mathsf{Real}^{\uparrow}$ read behind the paired source rows, stream schedules, modulus rows, shared threshold ledger, comparison row, transports, continuations, package provenance, and local name.

Next use observation-budget absorption and the selector-budget public route. These results show that the observation and selector surfaces can consume τ only through the same displayed rows; their own budget, selector, window, and readback coordinates do not create another entrance to the threshold.

Apply the triple consumer route factorization. It already identifies the common route for the three downstream consumer surfaces, so a $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer meeting any of them receives the same finite TailMeet packet before any seal-facing or completion-facing read.

The refused objects are not coordinates of that packet. Selected limits, quotient stream equality, host real equality, trichotomy rows, hidden observation budgets, hidden tail oracles, and ambient completeness therefore cannot be exported through the common frontier. □

Theorem 560.17 (RegularCauchyTailMeet Real-completion formal frontier)**.** *Let $T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau,$ be an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *formal target that consumes the shared threshold of T through the real-completion route must use the same finite TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The handoff exposes the threshold only through the paired regular-Cauchy sources, stream schedules, source modulus rows, public dyadic threshold ledger, comparison row, BHist *evidence, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row. It does not permit selected limits, quotient stream equality, host real equality, trichotomy, hidden observation budgets, hidden tail oracles, or ambient completeness.*

Proof. Begin with the limit-seal threshold route. It places every $\mathsf{CauchyLimitSeal}^{\uparrow}$ and diagonal $\mathsf{Real}^{\uparrow}$ threshold read behind the accepted TailMeet packet and keeps the threshold attached to the displayed source, schedule, modulus, comparison, transport, continuation, provenance, and naming rows.

Next apply observation-budget absorption and the selector-budget public route. These results show that budget-facing and selector-facing consumers receive the same τ only after the finite TailMeet entrance has been displayed.

Use the triple consumer route factorization to align the three downstream consumer surfaces. The factorization gives a single row list for limit-seal, observation-budget, and selector-budget reads, so a $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ target using any of them cannot select a different threshold route.

Finally apply the Real and completion consumer frontier. The excluded objects are outside the shared packet; therefore the formal handoff for later $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ work is exactly the finite TailMeet route and not an ambient real, quotient, trichotomy, oracle, or completeness assumption. □

Theorem 560.18 (RegularCauchyTailMeet completion-uniform frontier)**.** *Let $T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q,$ be an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. Every* $\mathsf{Completion}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *or* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *consumer that uses the shared threshold of T must first factor through the common finite TailMeet entrance*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

This entrance is read before any completion seal, real seal, tail row, or uniform-family row is consumed. No such consumer may replace it by selected limits, quotient streams, host real equality, hidden tail oracles, or ambient completeness.

Proof. Start with the limit-seal threshold route. It exposes the shared threshold only through the paired regular-Cauchy source rows, stream schedules, source modulus rows, dyadic threshold ledger, comparison row, transports, continuations, package provenance, and local name.

Next apply the triple consumer route factorization. It aligns the limit-seal, observation-budget, and selector-budget consumers on the displayed TailMeet rows and removes selected limits, quotient stream equality, host real equality, hidden budget rows, hidden tail oracles, and ambient completeness from their threshold reads.

Use the Real-completion formal frontier to pass from those consumer surfaces to later $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ targets. The formal handoff keeps the same row list as the only threshold entrance and does not add trichotomy, quotient, host-equality, oracle, or completeness coordinates.

Finally attach the UniformCauchyCriterion finite-family seal obligation package. Its finite-family surface may read a regular-rational tail or a real seal only through its displayed finite seal route, so when that surface uses the TailMeet shared threshold it receives the same TailMeet rows before any uniform-family row is inspected.

Thus completion-facing, real-facing, and uniform-Cauchy-facing consumers share the displayed finite threshold entrance. Since each component route excludes non-displayed limits, quotient streams, host equality, hidden tail data, and ambient completeness, the common frontier excludes them as well. □

Theorem 560.19 (RegularCauchyTailMeet selector-window-seal consumer totality)**.** *Let* $T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N)$ *be an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. Every consumer route that reaches the shared threshold through* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{RealObservationBudget}^{\uparrow}$*,* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$*, or* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *factors through exactly the displayed TailMeet row list*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

before any real, completion, or uniform-family read. The route is the single selector-window-seal packet determined by Definition 560.12, Definition 560.13, Definition 560.14, Definition 560.15, and Definition 560.18; it admits no selected limit, quotient stream, host real equality, trichotomy row, hidden tail oracle, or ambient completeness coordinate.

Proof. Project the accepted packet T. Its visible rows are the paired $\mathsf{RegularCauchyName}^{\uparrow}$ source certificates, paired $\mathsf{StreamName}^{\uparrow}$ schedules, source modulus rows, shared dyadic threshold ledger, comparison row, BHist evidence, componentwise hsame transports, displayed Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ row.

First use the limit-seal threshold route, the observation-budget absorption route, and the selector-budget public route. These three component results place the $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, and $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ entrances on the same TailMeet threshold row τ, always with the surrounding rows $R_0, R_1, W_0, W_1, M_0, M_1, Q, H, C, L, N$ displayed.

Next apply the triple consumer route factorization. It aligns the three consumer entrances as one finite selector-window-seal route, so a downstream real or completion reader cannot choose a second threshold path after entering through any one of them.

Finally use the completion-uniform frontier. That result places $\mathsf{UniformCauchyCriterion}^{\uparrow}$ consumers on the same entrance before any uniform-family row is inspected, and it keeps completion-facing and real-facing reads behind the displayed packet. Since none of the displayed coordinates is a selected limit, quotient stream, host real equality, trichotomy row, hidden tail oracle, or ambient completeness witness, no such object can enter the consumer route. □

Theorem 560.20 (RegularCauchyTailMeet finite-family threshold absorption)**.** *Let a finite family tail ledger from* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *schedule component tails whose displayed component thresholds share the threshold row supplied by an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. Then the finite-family threshold request factors through the tail-meet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The absorbed route is the same shared-threshold row consumed by $\mathsf{UniformCauchyCriterion}^{\uparrow}$*, and it introduces no independent tail oracle, quotient stream, selected limit, host equality, trichotomy coordinate, or ambient completeness witness.*

Proof. Begin with Definition 560.26 and Definition 560.27. They force every tail-meet threshold read through the displayed source, window, and source-modulus rows before it reaches τ.

Next apply Definition 435.17. The finite-family ledger has no hidden component window outside the scheduled family rows, so a family threshold request whose component tails share the displayed threshold cannot bypass the listed tail-meet route.

Finally use Definition 435.10 together with Definition 560.33. The two transport rows identify the family-facing threshold and the tail-meet threshold as the same transported row, with the exclusions inherited from ledger exactness. □

Theorem 560.21 (RegularCauchyTailMeet limit-seal threshold handoff)**.** *Suppose the public shared-threshold certificate of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet is consumed by a finite-tail diagonal seal route. Then the* $\mathsf{Real}^{\uparrow}$ *seal read passes through the displayed threshold row* τ *before any seal row is available.*

The handoff uses only the paired regular-Cauchy source rows, scheduled windows, source modulus rows, shared threshold, comparison row, componentwise hsame *transports, displayed* Cont *routes, finite ledger,* Pkg *provenance, the finite-tail selected witness row, and the local* $\mathsf{NameCert}$ *rows.*

Proof. First read the shared row through Definition 560.11. The certificate exposes τ as the public threshold consumed by diagonal $\mathsf{Real}^{\uparrow}$ routes while retaining the paired source, window, modulus, comparison, transport, continuation, ledger, package, and naming rows.

Then apply Definition 559.5. The finite-tail diagonal seal can read its $\mathsf{Real}^{\uparrow}$ row only after the precision request, selected window, regular sequence row, and selected finite-tail witness have been fixed.

Combining the two routes places the shared threshold before the seal read. Since neither packet carries quotient streams, host real equality, selected external limits, trichotomy, or ambient completeness, the handoff exports none of those rows. □

Theorem 560.22 (RegularCauchyTailMeet uniform-criterion threshold export)**.** *For every accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet used by* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *and by a* $\mathsf{Real}^{\uparrow}$*-facing diagonal consumer, the exported shared-threshold row is the same row consumed by the finite-family criterion and by the diagonal seal route.*

The export is exactly the row τ *routed through*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N,$$

and it exports no quotient stream, selected limit, trichotomy coordinate, host equality row, or ambient completeness witness.

Proof. Use Definition 560.20 to identify the finite-family $\mathsf{UniformCauchyCriterion}^{\uparrow}$ threshold request with the displayed tail-meet route through τ.

Use Definition 560.21 to identify the diagonal $\mathsf{Real}^{\uparrow}$ consumer route with the same public shared-threshold certificate before any seal row is read.

Finally apply Definition 560.34, Definition 560.35, and Definition 560.7. These rows exhaust the consumer-facing ledger and block every excluded quotient, limit, trichotomy, host-equality, and completeness coordinate, so the export has exactly the shared threshold route stated above. □

Theorem 560.23 (RegularCauchyTailMeet finite-family threshold coverage)**.** *Every finite-family threshold request routed through* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *and accepted by a* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet factors through the displayed rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The coverage is a finite BHist *coverage statement over the paired regular-Cauchy sources, paired stream windows, source modulus rows, shared dyadic threshold, comparison row, componentwise* hsame *transports, displayed* Cont *routes, ledger, and local* $\mathsf{NameCert}$ *row.*

Proof. Begin with Definition 560.22. It identifies the exported row τ as the row shared by the finite-family criterion and the diagonal-facing consumer.

Apply Definition 560.7. The ledger admits only the displayed route from the two source rows through the two windows and source modulus rows to τ and Q.

Finally use Definition 560.11. The public certificate packages exactly the same threshold route for consumers, so the finite-family request is covered by the listed rows and no hidden tail source is available. □

Theorem 560.24 (RegularCauchyTailMeet root-unblock handoff)**.** *Every downstream* $\mathsf{Real}^{\uparrow}$ *diagonal consumer admitted by the root surface of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet receives only the shared threshold row and comparison rows already present in that packet. The handoff does not add a selected limit, quotient stream equality, host real equality, trichotomy row, or ambient completeness witness.*

Proof. First apply Definition 560.8. It keeps any stronger diagonal request on the same displayed shared threshold route.

Next apply Definition 560.11. The consumer-facing package exposes the threshold, comparison row, transports, continuations, ledger, package provenance, and local name already present in the accepted carrier.

The non-escape part is inherited from Definition 560.22. Since that export has no quotient, selected-limit, trichotomy, host-equality, or completeness coordinate, the root handoff supplies only the admitted shared rows. □

Theorem 560.25 (RegularCauchyTailMeet diagonal budget consumer)**.** *Any diagonal budget consumer using an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet consumes the same finite dyadic threshold ledger*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

and cannot obtain a selected limit, trichotomy, quotient stream, or completeness witness from that packet.

Proof. Read the budget request through Definition 560.23. The consumer must pass through the displayed source, window, modulus, threshold, comparison, transport, continuation, ledger, and naming rows.

Use Definition 560.24. The downstream $\mathsf{Real}^{\uparrow}$ diagonal route receives the same shared threshold and comparison data and no additional consumer-specific evidence.

Finally apply Definition 560.7 together with Definition 560.11. The exact ledger and public certificate exhaust the finite dyadic budget surface, so selected limits, trichotomy, quotient streams, and completeness witnesses remain outside the packet. □

Theorem 560.26 (RegularCauchyTailMeet window-source coverage)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet with paired source rows*

$$R_0,\ R_1,$$

paired scheduled windows

$$W_0,\ W_1,$$

and source modulus rows

$$M_0,\ M_1,$$

every displayed threshold read for the shared tail factors through the finite route

$$R_0, R_1 \longrightarrow W_0, W_1 \longrightarrow M_0, M_1 \longrightarrow \tau.$$

The source rows are $\mathsf{RegularCauchyName}^{\uparrow}$ *rows, the windows are* $\mathsf{StreamName}^{\uparrow}$ *rows, the modulus reads are* $\mathsf{DyadicRatCore}^{\uparrow}$ *rows, and the produced threshold* τ *is the same dyadic threshold consumed by the public shared-threshold certificate.*

Proof. Read the carrier coordinates from Definition 560.1. The packet contains the paired regular Cauchy sources, the paired stream schedules, and the paired modulus rows as displayed finite coordinates.

Apply the obligation surface of Definition 560.2. It admits only source reads, scheduled-window reads, and modulus readback through the local $\mathsf{NameCert}$ rows.

Use Definition 560.7. The ledger routes the source and window data to the shared threshold row, so the threshold coordinate τ cannot be read without passing through $R_0, R_1, W_0, W_1, M_0, M_1$. □

Theorem 560.27 (RegularCauchyTailMeet source-modulus exhaustion)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet with displayed rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N,$$

every threshold read factors through exactly the source-window-modulus route

$$R_0, R_1 \longrightarrow W_0, W_1 \longrightarrow M_0, M_1 \longrightarrow \tau.$$

No consumer can read the shared threshold directly from Q*, from a* $\mathsf{Real}^{\uparrow}$ *seal, from a dyadic endpoint row, or from an unlisted tail oracle.*

Proof. Start with the carrier of Definition 560.1. Its only threshold-facing source rows are the paired regular Cauchy names, paired stream windows, paired source modulus rows, and the shared dyadic threshold row.

Apply the local obligations of Definition 560.2. They allow source admission, scheduled-window reads, modulus readback, and shared-threshold exposure only through the displayed packet coordinates.

Use window-source coverage from Definition 560.26. It identifies the mandatory route from R_0, R_1 through W_0, W_1 and M_0, M_1 to τ.

Finally apply ledger exactness and shared-threshold transport, Definition 560.7 and Definition 560.33. The finite ledger records no alternate source for τ, and transport preserves the same displayed threshold row. □

Theorem 560.28 (RegularCauchyTailMeet threshold transport coverage)**.** *Let $T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q,$ be an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. Every transport of the shared threshold row τ to a root-facing or* $\mathsf{Real}^{\uparrow}$*-facing consumer is covered by the displayed componentwise* hsame *row H, the displayed* Cont *route C, the finite ledger L, and the local* NameCert *row N, after the source rows R_0, R_1, window rows W_0, W_1, modulus rows M_0, M_1, and comparison row Q have been read.*

No accepted transport may replace τ by an unlisted tail threshold, quotient-stream equality, selected limit, host real equality, or ambient completeness witness.

Proof. Begin with the carrier of Definition 560.1. It displays exactly the two source rows, two window rows, two modulus rows, shared threshold row, comparison row, transport row, continuation row, ledger row, and local naming row.

Use the NameCert obligations of Definition 560.2. They force every accepted threshold read to pass through $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$ rather than through an external threshold oracle.

Apply classifier stability and ledger exactness. Classifier stability keeps the transported comparison attached to the same shared-threshold coordinate, while ledger exactness rules out an additional threshold entry in L.

Finally use shared-threshold cofinality and the Real seal handoff. They let stronger displayed threshold rows feed the same consumer route, but only through the already named hsame, Cont, Pkg, and NameCert surface. □

Theorem 560.29 (RegularCauchyTailMeet window-pair exhaustion)**.** *Let $T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C$ be an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. The paired window rows W_0 and W_1 exhaust the window evidence for the shared-tail comparison: every accepted comparison read of Q and every downstream handoff to* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ *must factor through both displayed schedules, their source rows R_0, R_1, their source modulus rows M_0, M_1, the shared threshold τ, and the structural rows H, C, L, N.*

The packet has no coordinate for a third scheduled window, an independent tail source, a hidden selector witness, or a host-level stream comparison.

Proof. Read the accepted packet by projection. The carrier exposes two and only two window schedules, namely W_0 and W_1, together with their source rows and modulus rows.

Apply the NameCert obligations and paired-window ledger coverage. The local certificate requires scheduled-window readback before the shared threshold and comparison row can be consumed, and the ledger records both windows before any real-facing handoff is available.

Use source-modulus exhaustion to identify the route to τ. Every threshold read factors through R_0, R_1, then W_0, W_1, then M_0, M_1, so the comparison row Q cannot be read from a smaller or different window family.

Finally apply selector admission and Real seal handoff. Both downstream consumers inherit the same two-window route and cannot add a third window, selected tail, quotient stream, or host comparison outside the displayed packet. □

Theorem 560.30 (RegularCauchyTailMeet Real seal consumer coverage)**.** *Let $T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q,$ be an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. Every* $\mathsf{Real}^{\uparrow}$ *seal consumer, including diagonal and limit-seal consumers, is covered by the same finite handoff route through the paired sources R_0, R_1, paired windows W_0, W_1, source modulus rows M_0, M_1, shared threshold τ, comparison row Q, componentwise transports H, continuations C, ledger L, and local name N.*

Thus Real-facing consumption of the packet never escapes to quotient stream equality, selected limits, independent Cauchy moduli, hidden completeness, host real equality, or an unlisted seal row.

Proof. Start with the Real seal handoff theorem. It presents the completion-facing route as a read through the paired source rows, paired schedules, source modulus rows, shared threshold row, comparison row, transports, continuations, ledger, provenance, and local name.

Use ledger exactness and shared-threshold non-escape. They confine every seal-facing read to $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$ and exclude quotient streams, selected limits, hidden tail oracles, and ambient completeness data.

Apply seal compatibility for $\mathsf{CauchyLimitSeal}^{\uparrow}$ and diagonal $\mathsf{Real}^{\uparrow}$ consumers. The seal receives the same shared threshold and comparison data already carried by the finite packet.

Finally collect threshold transport coverage and window-pair exhaustion. These two obligations show that the transport of τ and the paired-window evidence are already present before the Real seal route is read, so no independent modulus, host equality, or unlisted seal row can enter. □

Theorem 560.31 (RegularCauchyTailMeet threshold-witness determinacy)**.** *Let two accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *presentations have componentwise* hsame *rows on their paired source rows, paired window rows, source modulus rows, shared threshold rows, comparison rows, ledger rows, package rows, and local naming rows. If both presentations transport the source-window-modulus route to the same public shared-threshold certificate, then they determine the same public threshold row under those componentwise transports.*

Proof. Project both accepted presentations through Definition 560.1. Each presentation exposes its threshold only through the displayed source, window, modulus, threshold, comparison, transport, continuation, ledger, provenance, and local naming rows.

Apply source-modulus exhaustion from Definition 560.27. Any threshold witness in either presentation must pass through the same kind of route from paired sources to paired windows, then through paired source modulus rows, and finally to the shared threshold row.

Now use the shared-threshold transport theorem Definition 560.33. The componentwise hsame rows move the source, window, modulus, threshold, comparison, ledger, package, and local naming rows together, so the transported threshold row remains the public row read by the certificate.

The NameCert obligations and ledger exactness rule out a second threshold coordinate. Therefore two accepted transported presentations determine the same public threshold row, with no appeal to quotient streams, selected limits, host real equality, or ambient completeness. □

Theorem 560.32 (RegularCauchyTailMeet paired-window ledger coverage)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, the finite ledger accounts for both scheduled windows W_0 and W_1 before any* $\mathsf{Real}^{\uparrow}$ *seal handoff is available. The ledger must record the paired source rows, paired window schedules, source modulus rows, shared threshold row, paired comparison row, componentwise transports, displayed continuations, package provenance, and local naming row before a seal-facing consumer can read the shared-tail certificate.*

Proof. Begin with Definition 560.26. It requires both scheduled windows to appear on the route from the paired regular Cauchy sources to the common threshold.

Apply Definition 560.7. The ledger is exact for the route from source rows through the two scheduled windows and source modulus rows to τ, Q, and the $\mathsf{Real}^{\uparrow}$ handoff.

Use the NameCert obligation surface to bind the continuation and provenance rows. The packet can replay the route only through H, C, L, N, so the paired windows have already been recorded when a real-facing consumer reaches the comparison row.

Finally apply the Real seal handoff Definition 560.4. The seal-facing read occurs after the shared threshold, comparison row, transports, continuations, ledger, provenance, and local name have been displayed, so it cannot bypass either scheduled window. □

Theorem 560.33 (RegularCauchyTailMeet shared-threshold transport)**.** *Let two accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *presentations have componentwise* hsame *comparisons on the paired source rows, paired window rows, paired modulus rows, shared threshold rows, comparison rows, ledger rows, package rows, and local naming rows. Then any displayed* Cont *route transporting one presentation to the other preserves the public shared-threshold row.*

Thus the row serving the tail threshold in the source presentation is transported to the row serving the tail threshold in the target presentation, and the public certificate still reads the same componentwise route through $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$.

Proof. Begin with the componentwise transport data in the carrier. The hsame rows identify the two source rows, two scheduled windows, two modulus rows, the threshold row, comparison row, ledger row, package row, and local naming row.

Apply Definition 560.3. It keeps the classifier boundary stable under those componentwise comparisons and does not introduce a second threshold coordinate.

Use the displayed Cont route. Since the continuation is attached to the same local packet rows and the public certificate reads its threshold through those rows, the transported certificate consumes the transported threshold row and preserves the shared-threshold route. □

Theorem 560.34 (RegularCauchyTailMeet consumer exactness)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing or diagonal-window consumer of the public* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold reads only*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

Here R_0, R_1 *are the paired* $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows,* W_0, W_1 *are the paired* $\mathsf{StreamName}^{\uparrow}$ *windows,* M_0, M_1 *are the paired* $\mathsf{DyadicRatCore}^{\uparrow}$ *modulus rows,* τ *is the shared dyadic threshold,* Q *is the paired comparison row,* H *gives componentwise* hsame *transport,* C *gives displayed* Cont *continuation,* L *is the finite ledger, and* N *is the local* NameCert *row.*

Proof. For a $\mathsf{Real}^{\uparrow}$-facing consumer, apply Definition 560.4. The real seal is reached only after the shared threshold, comparison row, transports, continuations, ledger, provenance, and naming rows have been displayed.

For a diagonal-window consumer, apply Definition 560.10. The selected window and dyadic observation route read the same threshold before the $\mathsf{Real}^{\uparrow}$ seal can be used.

Finally use Definition 560.26. The threshold itself descends through the paired source rows, window rows, and modulus rows, so every consumer route is exhausted by the listed finite coordinates. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket consumer exactness`

Theorem 560.35 (RegularCauchyTailMeet diagonal consumer non-escape)**.** *No diagonal-window or* $\mathsf{Real}^{\uparrow}$*-facing consumer of the public* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *certificate can export a quotient*

stream, host real equality, hidden limit selection, trichotomy decision, or ambient completeness witness. Every exported datum is routed through the finite rows

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

Proof. Start from consumer exactness in Definition 560.34. A consumer can read only the displayed source, window, modulus, threshold, comparison, transport, continuation, ledger, and naming rows.

Inspect those rows through Definition 560.1. None of them is a quotient-stream coordinate, a host real equality coordinate, a selected-limit coordinate, a trichotomy coordinate, or an ambient completeness coordinate.

The bridge-facing and real-facing routes named by Definition 560.11 therefore preserve the same exclusion boundary. They can move the public threshold to a consumer, but they cannot manufacture any of the excluded host or quotient data. □

Theorem 560.36 (RegularCauchyTailMeet obligation-closure readiness)**.** *The* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet presents the finite obligation package needed by* $\mathsf{Real}^{\uparrow}$ *and completion-facing diagonal consumers. The package consists of the existing* NameCert *obligations, ledger exactness, shared-threshold cofinality, dyadic endpoint meet, public shared-threshold certificate, window-source coverage, shared-threshold transport, consumer exactness, and diagonal consumer non-escape.*

Consequently every downstream read of the shared tail threshold is served by the finite coordinates

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N,$$

with no quotient stream, hidden limit selector, host real equality, trichotomy decision, or ambient completeness premise.

Proof. First collect the carrier and local naming obligations from Definition 560.1 and Definition 560.2. These expose the finite packet rows and the local admission surface.

Next apply Definition 560.7, Definition 560.8, and Definition 560.6. They route the source modulus reads to one shared dyadic threshold and keep endpoint refinement inside the displayed ledger.

Use the public shared-threshold certificate together with window-source coverage and shared-threshold transport. These results identify the consumer-facing threshold row and preserve it under componentwise transport.

Finally apply consumer exactness and diagonal consumer non-escape. The downstream diagonal and $\mathsf{Real}^{\uparrow}$ consumers read exactly the listed finite coordinates, and the excluded quotient, host, selection, trichotomy, and completeness data never appear as carrier coordinates or exported rows. □

Theorem 560.37 (RegularCauchyTailMeet bridge package)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, the public shared-threshold certificate, diagonal-window threshold handoff, dyadic endpoint meet, ledger exactness, and* $\mathsf{Real}^{\uparrow}$ *seal handoff assemble the bridge from the concrete finite packet to the abstract* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *interface consumed by* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, FiniteCauchyApproximat *and diagonal* $\mathsf{Real}^{\uparrow}$ *routes.*

The bridge package reads only the paired $\mathsf{RegularCauchyName}^{\uparrow}$ *sources, paired* $\mathsf{StreamName}^{\uparrow}$ *schedules, source modulus rows, one shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold ledger, paired comparison row, componentwise* hsame *transports, displayed* Cont *routes, finite ledger,* Pkg *provenance, selected diagonal-window data, dyadic endpoint rows, and local* NameCert *evidence. It exports no quotient stream, selected limit, trichotomy row, host equality, independent tail oracle, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetUp StdBridge`

Proof. First apply Definition 560.11. It packages the concrete shared-threshold data as a public object for diagonal-window and diagonal $\mathsf{Real}^{\uparrow}$ consumers.

Use Definition 560.10. The selected-window consumer reads the displayed shared threshold before the $\mathsf{Real}^{\uparrow}$ seal route, so the abstract interface receives the same finite threshold row that the concrete packet exposes.

Next apply Definition 560.6. The endpoint route identifies the paired dyadic tolerance ledgers with the single shared threshold row, which is the row consumed by $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ and by the diagonal routes.

Finally use Definition 560.7 together with the real-seal handoff already named in the public certificate. The finite ledger accounts for every exported route, so the bridge from the concrete packet to the abstract interface carries exactly the listed rows and none of the excluded completeness or quotient data. □

Theorem 560.38 (RegularCauchyTailMeet mature downstream examples)**.** *The shared-tail threshold packet exported by* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *is consumed by* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{FiniteCauchyApproxin}$ *and diagonal* $\mathsf{Real}^{\uparrow}$ *routes through the existing public shared-threshold certificate and bridge package. Each consumer receives the paired source rows, paired schedules, source modulus rows, one shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold ledger, paired comparison row, componentwise* hsame *transports, displayed* Cont *routes, finite ledger,* Pkg *provenance, selected diagonal-window data, dyadic endpoint rows, and local* $\mathsf{NameCert}$ *evidence, with no quotient stream, selected limit, host equality, independent tail oracle, or ambient completeness.*

Proof. Begin with the public shared-threshold certificate Definition 560.11. It presents the shared threshold as a public object for $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ and diagonal $\mathsf{Real}^{\uparrow}$ consumers.

Apply the bridge package Definition 560.37. The bridge names $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ as a consumer of the same shared threshold and keeps the route inside the concrete finite packet.

The three consumer examples therefore use one shared-tail threshold surface. Since the certificate and bridge package both preserve the exclusions on quotient streams, selected limits, host equality, independent tail oracles, and ambient completeness, none of those objects is exported to the downstream examples. □

Theorem 560.39 (RegularCauchyTailMeet selector admission)**.** *An accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet admits a* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ *row exactly through the displayed shared-tail route. The selector precision request, stream window, regularity row, dyadic readback, selected-tail witness, componentwise transports, continuations, package provenance, and local* $\mathsf{NameCert}$ *row must factor through one of the paired source schedules*

$$R_0, W_0, M_0 \qquad \text{or} \qquad R_1, W_1, M_1$$

and then through the common threshold row τ *of the meet packet.*

Conversely, either paired source schedule together with the shared threshold row, comparison row Q*, componentwise* hsame *row* H*, displayed* Cont *row* C*, finite ledger* L*,* Pkg *row, and local naming row* N *supplies the complete selector-facing admission route. No quotient stream, selected limit, host real equality, independent tail oracle, or ambient completeness witness is part of this admission surface.*

Proof. For the forward direction, read the proposed selector row through Definition 560.26. The threshold read must pass through one of the displayed source schedules and then through the shared dyadic threshold τ.

Apply Definition 560.34. It bounds all selector-facing precision, window, readback, transport, continuation, package, and local naming data by the finite rows $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$.

For the reverse direction, choose either paired schedule already displayed in the carrier. The shared-threshold transport theorem keeps the selected schedule attached to the same τ, while the obligation-closure readiness theorem repacks the route as a downstream consumer surface.

The exclusion statement follows from diagonal consumer non-escape. The selector admission has no coordinate for quotient streams, selected limits, host real equality, independent tail oracles, or ambient completeness. □

Theorem 560.40 (RegularCauchyTailMeet source scope)**.** *Every accepted source read of a* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet factors through the paired* $\mathsf{RegularCauchyName}^{\uparrow}$ *rows, paired* $\mathsf{StreamName}^{\uparrow}$ *windows, source modulus rows, and the displayed shared dyadic threshold before any* $\mathsf{Real}^{\uparrow}$ *seal row is available. The source-facing surface is therefore exactly the finite route*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N,$$

with the shared threshold τ serving as the only passage from the two source schedules to the comparison row and the seal-facing handoff.

Proof. Start with the carrier definition and local $\mathsf{NameCert}$ obligations. Definition 560.1 lists the paired source, window, modulus, threshold, comparison, transport, continuation, ledger, package, and local naming rows, while Definition 560.2 makes those rows the admissible source-reading surface.

Next apply ledger exactness and shared-threshold cofinality. By Definition 560.7, an accepted source read reaches τ only through the paired windows and source modulus rows; by Definition 560.8, stronger displayed thresholds remain on the same finite route.

Finally use selector admission and seal compatibility together with the real-seal handoff. Definition 560.39 keeps selector reads on one paired schedule and the shared threshold, and Definition 560.43 keeps every $\mathsf{Real}^{\uparrow}$-facing seal read behind the same displayed rows. Thus no seal row is available before the source schedules, modulus rows, and shared threshold have all been displayed. □

Theorem 560.41 (RegularCauchyTailMeet classifier scope)**.** *The classifier comparison of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet is determined by the shared threshold τ, the paired comparison row Q, the componentwise* hsame *transports in H, and the displayed* Cont *routes in C. It is not determined by quotient stream equality, host real equality, a selected limit, trichotomy, or an ambient completeness coordinate.*

Proof. Read the classifier row through Definition 560.1 and Definition 560.3. The carrier exposes one shared threshold and one paired comparison row, and classifier stability preserves that comparison through the componentwise transports and continuations already stored in the packet.

Use shared-threshold cofinality to compare stronger tail requests. Definition 560.8 allows refinement of the displayed threshold without introducing a second threshold coordinate, independent stream equality test, or host real equality test.

The real-seal handoff and seal compatibility keep the same comparison visible to downstream readers. By Definition 560.4 and Definition 560.43, seal-facing consumers receive the threshold,

comparison, transports, and routes as displayed rows, so the classifier surface has exactly the stated scope. □

Theorem 560.42 (RegularCauchyTailMeet ledger scope)**.** *The finite ledger of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet records only the two source schedules, source modulus rows, shared threshold, paired comparison, componentwise transports, displayed continuation routes, package provenance, and local* $\mathsf{NameCert}$ *row. It records no selected limit, trichotomy row, quotient stream, host real equality, independent tail oracle, or ambient completeness coordinate.*

Proof. Begin with the carrier and ledger exactness. Definition 560.1 identifies L as the finite ledger attached to the displayed rows, and Definition 560.7 exhausts the route from the paired source schedules and modulus rows to τ, Q, and the real-facing handoff.

Add the naming, selector, and seal rows. The local obligations of Definition 560.2, the selector route of Definition 560.39, and the seal route of Definition 560.43 all read the same ledger entries rather than appending hidden completion data.

The exclusion boundary is the one used by classifier stability and the real-seal handoff. Since Definition 560.3 and Definition 560.4 require only the displayed threshold, comparison, transports, continuations, package provenance, and local name, the ledger has no coordinate from which any selected limit, trichotomy, quotient stream, host equality, independent oracle, or ambient completeness witness could be exported. □

Theorem 560.43 (RegularCauchyTailMeet seal compatibility)**.** *Every* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or diagonal* $\mathsf{Real}^{\uparrow}$ *consumer that reads a shared* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold must read it through the paired source rows, the common threshold row, the paired comparison row, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *route of the packet.*

Thus seal-facing consumption is compatible with the same finite rows

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

used by the public shared-threshold certificate and by the bridge package. It introduces no quotient stream, selected limit, host real equality, independent tail oracle, or ambient completeness premise.

Proof. Begin with the public shared-threshold certificate. It identifies the threshold consumed by diagonal $\mathsf{Real}^{\uparrow}$ routes with the displayed common threshold row τ and keeps the consumer on the paired source schedules.

Use the real-seal handoff and the bridge package. The handoff reads the $\mathsf{Real}^{\uparrow}$ seal only through the shared threshold, comparison row, transports, continuations, ledger, provenance, and local naming row; the bridge package preserves those same rows for completion-facing consumers.

For a $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer, follow the same bridge-facing route. The consumer receives the shared threshold and comparison data already carried by the finite packet, and the BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows provide the displayed compatibility path.

Non-escape is inherited from consumer exactness and diagonal consumer non-escape. Since all seal reads are confined to the listed finite rows, no excluded quotient, host, selection, oracle, or completeness datum is available. □

Theorem 560.44 (RegularCauchyTailMeet root consumer package)**.** *The selector admission theorem, seal compatibility theorem, public shared-threshold certificate, and bridge package assemble the downstream root package for* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$*, and diagonal* $\mathsf{Real}^{\uparrow}$ *consumers.*

The package exports one shared threshold route from the paired $\mathsf{RegularCauchyName}^{\uparrow}$ *sources and paired* $\mathsf{StreamName}^{\uparrow}$ *schedules through source modulus rows, the dyadic threshold ledger, comparison row, componentwise* hsame *transports, displayed* Cont *continuations, finite ledger,* Pkg *provenance, and local* NameCert *rows. It exports no quotient stream, selected limit, host real equality, independent tail oracle, or ambient completeness principle.*

Proof. First collect selector admission. It shows that every selector-facing precision and selected-tail read factors through one paired source schedule and the shared threshold row.

Next collect seal compatibility. It shows that $\mathsf{CauchyLimitSeal}^{\uparrow}$ and diagonal $\mathsf{Real}^{\uparrow}$ consumers read the same threshold through the displayed BHist, hsame, Cont, Pkg, and NameCert route.

Add Definition 560.11 and Definition 560.37. The certificate serves $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ and diagonal $\mathsf{Real}^{\uparrow}$ consumers, while the bridge package keeps completion-facing reads inside the same finite shared-tail packet.

The four consumer families therefore share one root package. Its rows are exactly the paired sources, schedules, modulus reads, threshold, comparison, transports, continuations, ledger, provenance, and local name already displayed by the carrier, so the excluded quotient, host, selection, oracle, and completeness data are not exported. □

Theorem 560.45 (RegularCauchyTailMeet root carrier admission)**.** *The root-facing admission surface for an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet is the shared finite threshold row*

$$T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N)$$

of Definition 560.1. A downstream root consumer may admit the packet only after the paired $\mathsf{RegularCauchyName}^{\uparrow}$ *sources, paired* $\mathsf{StreamName}^{\uparrow}$ *windows, paired source modulus rows, shared dyadic threshold, comparison row, componentwise* hsame *transports, displayed* Cont *routes, finite ledger, and local* NameCert *row are visible.*

Proof. Start with the carrier and the local NameCert obligations. They display the two source rows, two scheduled windows, source modulus rows, threshold row, comparison row, transport rows, continuation rows, ledger, and local name.

Use window-source coverage. Every threshold-facing read must pass through the paired sources, paired windows, and paired source modulus rows before it reaches τ.

Apply shared-threshold cofinality to the root-facing threshold. It keeps any strengthened threshold tied to the same paired schedules and source modulus rows, so root admission remains a finite shared-threshold row rather than an independent tail oracle. □

Theorem 560.46 (RegularCauchyTailMeet root classifier stability)**.** *For root-facing paired-window consumers, componentwise* hsame *transport of the rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

preserves the displayed comparison classifier. The transported root surface reads the same paired-window route to τ *and* Q*, and it cannot replace the shared threshold by a quotient-stream, host-limit, selected-subsequence, or ambient-completeness classifier.*

Proof. Project the paired-window route from the carrier. The classifier uses only the paired source rows, schedules, modulus rows, shared threshold, and comparison row.

Apply classifier stability and shared-threshold transport. The componentwise hsame rows move these coordinates together, and the displayed Cont routes replay the same window-to-threshold-to-comparison path.

Use paired-window ledger coverage to keep both scheduled windows recorded before a real-facing or root-facing read can consume the comparison. Since the ledger has no alternate classifier coordinate, the transported root surface preserves exactly the displayed comparison classifier. □

Theorem 560.47 (RegularCauchyTailMeet root ledger exactness)**.** *The root-facing ledger of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet records exactly two input tails and one meet threshold: the rows* R_0, W_0, M_0 *for the first tail, the rows* R_1, W_1, M_1 *for the second tail, the shared dyadic threshold row* τ*, the paired comparison row* Q*, and the structural rows* H, C, L, N*. No root-facing ledger entry records a third tail, an independent threshold, a quotient-stream equality, a selected limit, host real equality, or ambient completeness.*

Proof. Begin with ledger exactness. It confines every accepted read to the route from the paired regular Cauchy sources through their windows and source modulus rows to τ, Q, and the $\mathsf{Real}^{\uparrow}$ handoff.

Use paired-window ledger coverage. Both scheduled windows must be present in L before the shared-tail certificate is available, so the ledger has exactly the two displayed input-tail sides.

Apply real-seal route totality. The real-facing route is already exhausted by the displayed shared threshold and comparison rows, so no additional tail or threshold can be introduced at the root boundary. □

Theorem 560.48 (RegularCauchyTailMeet uniform criterion consumer link)**.** *The root-facing* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *obligation rows supply the shared-tail consumer link required by the* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *root surface of Definition 435.120. A uniform-criterion consumer may read the meet packet only through the admitted shared threshold, the hsame-stable paired-window classifier, and the exact two-tail ledger of the preceding root rows.*

Proof. First collect root carrier admission. It presents the shared finite threshold row required by a uniform Cauchy consumer.

Next collect root classifier stability. The paired-window comparison is preserved under componentwise hsame and displayed Cont replay, so the uniform criterion reads a stable shared-tail classifier.

Finally collect root ledger exactness and apply Definition 435.120. The uniform criterion receives exactly the two input tails and one meet threshold already recorded by the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ ledger, with no quotient, host-limit, selection, oracle, or completeness data available outside that finite route. □

Theorem 560.49 (RegularCauchyTailMeet window-source exhaustion)**.** *Every accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *comparison reads exactly the displayed* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows of the shared-tail carrier. It has no additional window source beyond the paired regular Cauchy names, paired stream schedules, source modulus rows, dyadic threshold ledger, comparison row, componentwise transports, displayed continuations, package provenance, and local naming row.*

Proof. Begin with the carrier and the window-source coverage theorem. They display the two regular Cauchy sources, the two stream schedules, the source modulus rows, the dyadic threshold ledger, and the comparison row.

Apply consumer exactness. It states that comparison-facing reads are confined to the displayed carrier rows and the componentwise hsame transports, displayed Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ row.

Use the root consumer package to repack the route for downstream consumers. The resulting comparison therefore exhausts the listed source rows and exposes no extra window, oracle, quotient stream, host limit, or ambient completeness row. □

Theorem 560.50 (RegularCauchyTailMeet shared-threshold non-escape)**.** *Shared-threshold reads of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet cannot introduce a host limit, quotient stream equality, or choice-selected subsequence. Every such read remains inside the shared dyadic threshold, the paired stream schedules, the source modulus rows, the comparison row, the componentwise* hsame *transports, the displayed* Cont *routes, the* Pkg *provenance, and the local* NameCert *evidence.*

Proof. Start with the shared-threshold transport theorem. It identifies threshold transport with the displayed schedule, modulus, dyadic, comparison, and transport rows.

Next use diagonal consumer non-escape. That theorem rules out quotient stream equality, host real equality, selected subsequences, hidden tail oracles, and ambient completeness data for diagonal consumers of the same packet.

The root package sends shared-threshold consumers through the same route. Hence a shared-threshold read can preserve the finite threshold evidence, but it cannot create any of the excluded host, quotient, or selection data. □

Theorem 560.51 (RegularCauchyTailMeet real-seal route totality)**.** *Any* $\mathsf{Real}^{\uparrow}$ *seal consumer of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet must pass through the same tail-meet window and dyadic endpoint rows before reading the real seal. The route is total for admitted seal reads because the real-seal handoff, dyadic endpoint meet, consumer exactness, diagonal non-escape, and root consumer package share the same* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *boundary.*

Proof. First use the real-seal handoff. It places every $\mathsf{Real}^{\uparrow}$ seal read behind the shared threshold route, comparison row, transport rows, continuations, ledger, provenance, and local name.

Then use the dyadic endpoint meet. The endpoint data consumed by the seal route are the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ threshold and endpoint rows, not a host real limit or quotient stream witness.

Finally combine consumer exactness, diagonal non-escape, and the root consumer package. These theorems keep every admitted seal read inside the same finite tail-meet window, so the route is total for accepted consumers and exports no hidden completion principle. □

Theorem 560.52 (RegularCauchyTailMeet source-window-modulus route)**.** *Every shared-threshold read of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet factors through the paired* $\mathsf{RegularCauchyName}^{\uparrow}$ *source rows, the paired* $\mathsf{StreamName}^{\uparrow}$ *window rows, and the source modulus rows before it reaches the displayed dyadic threshold ledger. The route is a finite* BHist *route recorded by the carrier, the local* NameCert *obligations, ledger exactness, shared-threshold cofinality, and real-seal route totality.*

Proof. Begin with the carrier and NameCert obligations. They expose the paired regular Cauchy source rows, stream windows, source modulus rows, dyadic threshold ledger, comparison row, transports, continuations, provenance, and local name as displayed coordinates.

Use shared-threshold cofinality and ledger exactness next. Any threshold read that refines the common tail must first choose the visible source rows, then the matching window rows, and then the modulus rows that justify the dyadic threshold coordinate.

Finally apply real-seal route totality. It routes admitted seal-facing reads through the same tail-meet window before any real-seal observation is read, so the source-window-modulus factorization is the common route for shared-threshold consumers. □

Theorem 560.53 (RegularCauchyTailMeet formal target envelope)**.** *Every accepted* RegularCauchyTailMeet$^{\uparrow}$ *packet whose source-window-modulus route is read by a* FiniteObservationBudgetSelector$^{\uparrow}$ *or* CauchyLimitSeal$^{\uparrow}$ *consumer factors through the same paired* RegSeqRat$^{\uparrow}$ *sources,* StreamName$^{\uparrow}$ *windows,* DyadicRatCore$^{\uparrow}$ *threshold ledger, comparison row,* hsame *transports,* Cont *routes,* Pkg *provenance, and* NameCert *row before any* Real$^{\uparrow}$ *seal is exposed. The downstream budget-selector and limit-seal reads therefore consume one finite handoff, not a hidden completion route and not a quotient-stream route.*

Proof. Begin with root carrier admission, root classifier stability, and root ledger exactness. These rows identify the accepted packet as the displayed two-source, two-window, one-threshold surface and keep transported comparisons inside the same finite ledger.

Use real-seal route totality and the source-window-modulus route. They place every seal-facing read behind the paired sources, paired windows, source modulus rows, dyadic threshold, comparison, transports, continuations, provenance, and local name before the Real$^{\uparrow}$ seal can be read.

Now read the consumer rows in the FiniteObservationBudgetSelector$^{\uparrow}$ and CauchyLimitSeal$^{\uparrow}$ surfaces. The selector consumes finite window and dyadic-budget rows before its seal handoff, while the limit seal consumes the same shared threshold route before exposing a completion-facing seal.

The two downstream routes therefore meet at the same finite handoff. Since neither consumer receives an additional quotient stream, host-limit equality, selected representative, or ambient completeness coordinate, the formal target envelope is exactly the displayed RegularCauchyTailMeet$^{\uparrow}$ route. □

Theorem 560.54 (RegularCauchyTailMeet formal handoff Lean target)**.** *The root carrier admission, root classifier stability, root ledger exactness, source-window-modulus route, real-seal route totality, and formal target envelope jointly determine the exact finite handoff for a later Lean target over* RegularCauchyTailMeet$^{\uparrow}$*. That handoff consists of paired* RegSeqRat$^{\uparrow}$ *sources, paired* StreamName$^{\uparrow}$ *windows, the* DyadicRatCore$^{\uparrow}$ *threshold row, the comparison row,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert*.*

The target contains no quotient stream, host limit, selected subsequence, or ambient completeness coordinate.

Proof. Begin with root carrier admission, root classifier stability, and root ledger exactness. These rows fix the two source rows, two window rows, threshold ledger, comparison row, transports, continuations, provenance, and local name as one finite carrier surface.

Next apply the source-window-modulus route. It identifies how the paired sources and windows reach the displayed dyadic threshold row before a shared-threshold read can proceed.

Use real-seal route totality and the formal target envelope for the downstream boundary. They require seal-facing consumers and formal consumers to read the same finite handoff before any Real$^{\uparrow}$ seal is exposed.

Thus a later Lean target has an exact object to encode: the paired sources, paired windows, threshold, comparison, transports, routes, provenance, and local name. The excluded quotient, host-limit, subsequence, and completeness data have no coordinate in that object. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetFormalHandoffLeanTarget`

Theorem 560.55 (RegularCauchyTailMeet window-budget exhaustion)**.** *Every budget-selector or* CauchyLimitSeal$^{\uparrow}$ *consumer of an accepted* RegularCauchyTailMeet$^{\uparrow}$ *packet exhausts its read through the two* RegSeqRat$^{\uparrow}$ *source rows, two* StreamName$^{\uparrow}$ *windows, the two source modulus rows, the*

shared DyadicRatCore$^{\uparrow}$ *threshold, comparison row,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row. The consumer receives no further budget window, hidden Cauchy tail, quotient stream equality, selected limit, or ambient completeness coordinate.*

Proof. Begin with the source-window-modulus route, Definition 560.52. It sends every shared-threshold read through the paired regular Cauchy source rows, paired stream windows, and source modulus rows before the dyadic threshold ledger can be read.

Next apply root ledger exactness and real-seal route totality, Definition 560.47 and Definition 560.51. These keep the shared threshold, comparison row, transports, continuations, provenance, and local name on the same finite root surface for every admitted seal-facing read.

Finally use the formal target envelope and handoff target, Definition 560.53 and Definition 560.54. The budget-selector and CauchyLimitSeal$^{\uparrow}$ routes therefore consume exactly the displayed window-budget handoff, and the packet has no remaining coordinate for a second budget window, hidden tail, quotient stream equality, selected limit, or ambient completeness datum. □

Theorem 560.56 (RegularCauchyTailMeet shared-threshold route determinacy)**.** *Two shared-threshold reads of an accepted* RegularCauchyTailMeet$^{\uparrow}$ *packet that use the same transported* RegularCauchyName$^{\uparrow}$ *source rows, the same transported* StreamName$^{\uparrow}$ *window rows, and the same transported source modulus rows reach the same displayed dyadic threshold ledger. The determinacy is internal to the finite* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *surface.*

Proof. Project both reads through the source-window-modulus route. By hypothesis the transported source rows, window rows, and source modulus rows agree componentwise under the displayed hsame transport.

Apply classifier stability and ledger exactness. The paired-window classifier cannot distinguish two reads with the same transported source, window, and modulus coordinates, and the exact ledger has only the displayed dyadic threshold coordinate for that route.

The Cont, Pkg, and NameCert rows then report the same finite ledger entry. Hence both reads reach the same displayed dyadic threshold ledger without invoking quotient stream equality, host limits, or choice-selected subsequences. □

Theorem 560.57 (RegularCauchyTailMeet public tail-meet certificate)**.** *The source-window-modulus route, shared-threshold route determinacy, and the public shared-threshold certificate assemble a public* RegularCauchyTailMeet$^{\uparrow}$ *tail-meet certificate. Any public consumer receives the paired regular Cauchy sources, paired stream windows, source modulus rows, dyadic threshold ledger, comparison row, transports, continuations, provenance, and local NameCert evidence, and receives no quotient stream equality, selected limit, host real equality, or ambient completeness theorem.*

Proof. First use Definition 560.52. It gives the public consumer a finite route from source rows through stream windows and source modulus rows to the displayed dyadic threshold ledger.

Next use Definition 560.56. It makes the displayed threshold ledger independent of duplicate reads that carry the same transported source, window, and modulus coordinates.

Finally combine the public shared-threshold certificate with real-seal route totality. The public certificate exposes the shared threshold as finite NameCert data, while the route-totality boundary keeps seal-facing consumers inside the same tail-meet window and excludes quotient, selection, host-equality, and ambient-completeness data. □

Theorem 560.58 (RegularCauchyTailMeet root threshold source ledger)**.** *Every root-facing threshold read of an accepted* RegularCauchyTailMeet$^{\uparrow}$ *packet factors through*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

before it reaches a downstream root consumer.

Proof. Project the carrier to expose the two source rows R_0, R_1, the two window rows W_0, W_1, the two modulus rows M_0, M_1, the shared threshold τ, comparison row Q, transport H, continuation C, ledger L, and local name N.

Apply the root carrier admission, root classifier stability, and root ledger exactness results. They identify those displayed rows as the root-facing threshold surface and exclude a second root threshold coordinate.

Finally use the uniform-criterion consumer link. It reads the same finite ledger before any UniformCauchyCriterionUp consumer sees the packet, so every root-facing threshold read factors through the listed rows. □

Theorem 560.59 (RegularCauchyTailMeet root shared-threshold coverage)**.** *The shared threshold τ in an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet covers both source modulus rows M_0 and M_1 before any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *consumer reads the packet.*

Proof. Use the carrier and root carrier admission to project the paired sources, windows, modulus rows, and shared threshold.

Apply root classifier stability and root ledger exactness. The threshold row is recorded once in the ledger and is classified against both source modulus rows, so it is not a one-sided witness.

Then apply the uniform-criterion consumer link together with the real-seal route. Both downstream consumers enter through the same displayed threshold ledger, hence the shared threshold covers M_0 and M_1 before either consumer reads the packet. □

Theorem 560.60 (RegularCauchyTailMeet root consumer exhaustion)**.** *Downstream consumers of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet receive only the two-tail, one-threshold finite ledger. They receive no quotient stream, selected limit, host equality, trichotomy, or ambient completeness row.*

Proof. Start with the carrier and the public tail-meet certificate. They expose exactly the paired source rows, paired window rows, source modulus rows, one shared threshold ledger, comparison, transport, continuations, package provenance, and local name.

Apply root ledger exactness and root classifier stability. These results keep root consumers on the displayed two-tail and one-threshold surface rather than on a quotient or selected-limit surface.

Finally use the uniform-criterion consumer link. It reuses the same finite ledger for downstream reads, so quotient stream, selected limit, host equality, trichotomy, and ambient completeness rows are unavailable to those consumers. □

Theorem 560.61 (RegularCauchyTailMeet root threshold provenance)**.** *Every root threshold read of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet is sourced by the displayed rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

and inherits provenance only from the contributing $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{NameCert}$ *rows.*

Proof. Project the carrier and use Definition 560.57. The two source rows, two windows, two modulus rows, shared threshold, comparison, transport, continuation, ledger, and local name are the whole root-facing threshold surface.

Then apply Definition 560.52. It supplies the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ provenance for that surface, while the local $\mathsf{NameCert}$ row names the same finite route. □

Theorem 560.62 (RegularCauchyTailMeet root window-modulus exactness)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, the paired window rows* W_0, W_1 *and source modulus rows* M_0, M_1 *are exactly the route to the shared dyadic threshold* τ*. Any root-facing threshold read reaches* τ *through the source-window-modulus route and the shared-threshold route determinacy.*

Proof. Apply Definition 560.52 to factor a threshold read through the paired window rows and source modulus rows. This gives the displayed route to the dyadic threshold ledger.

Apply Definition 560.56. A second root-facing read with the same transported windows and modulus rows reaches the same threshold ledger, so the paired window and modulus rows are the exact route to τ. □

Theorem 560.63 (RegularCauchyTailMeet root consumer export boundary)**.** *Downstream* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *consumers of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet receive only the finite threshold packet*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

They receive no quotient stream, selected limit, host equality, trichotomy, or ambient completeness row.

Proof. Use Definition 560.60. It confines downstream consumers to the two-tail, one-threshold ledger and excludes quotient, selected-limit, host-equality, trichotomy, and completeness rows.

Then use Definition 560.61 and Definition 560.62. These identify the exported ledger with the displayed finite packet and route both $\mathsf{Real}^{\uparrow}$ and $\mathsf{UniformCauchyCriterion}^{\uparrow}$ reads through the same threshold surface. □

Theorem 560.64 (RegularCauchyTailMeet root seal-budget totality)**.** *Every admitted root-facing* $\mathsf{Real}^{\uparrow}$ *seal-budget read of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet is total on the displayed shared-threshold route*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The read must pass through the paired $\mathsf{RegSeqRat}^{\uparrow}$ *source rows, paired* $\mathsf{StreamName}^{\uparrow}$ *windows, paired source modulus rows, the shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold ledger, and the local* $\mathsf{NameCert}$ *rows before the seal-budget consumer sees the packet.*

Proof. Start with root carrier admission and root threshold source ledger. These results expose the paired sources, windows, modulus rows, shared threshold, comparison row, transports, continuations, ledger, and local name as the whole root-facing route.

Use real-seal route totality. It places every $\mathsf{Real}^{\uparrow}$ seal read behind the same tail-meet window and dyadic endpoint rows, so an admitted seal-budget read has a displayed route whenever the root packet is accepted.

Finally apply root consumer export boundary. The exported data are exactly the finite threshold packet, and no quotient stream, selected limit, host equality, trichotomy, or ambient completeness row is supplied to complete the read elsewhere. □

Theorem 560.65 (RegularCauchyTailMeet root tail-comparison admission)**.** *A root consumer may admit the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *tail comparison only through the paired* $\mathsf{RegSeqRat}^{\uparrow}$ *sources, paired* $\mathsf{StreamName}^{\uparrow}$ *windows, paired source modulus rows, shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold, comparison row* Q*, componentwise* hsame *transports, displayed* Cont *replay, finite ledger, provenance, and local* $\mathsf{NameCert}$ *rows of the carrier.*

The admission surface is stable under the same transported source, window, and modulus rows, and it has no independent tail oracle, selected subsequence, quotient stream equality, or ambient completeness premise.

Proof. Project the comparison through root classifier stability. The classifier uses the displayed paired-window route to τ and Q, and componentwise transport preserves that route.

Apply source-window-modulus route and shared-threshold route determinacy. They force a root comparison read through the paired source, window, and modulus rows before it reaches the dyadic threshold ledger, and duplicate reads with the same transported route reach the same threshold.

Use window-source exhaustion and shared-threshold non-escape. These results exclude additional window sources, independent tail oracles, selected subsequences, quotient stream equality, host limits, and ambient completeness from the admitted comparison surface. □

Theorem 560.66 (RegularCauchyTailMeet root formal handoff surface)**.** *The root consumer package, root seal-budget totality, and root tail-comparison admission assemble the formal handoff surface for downstream* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *consumers. The handoff binds the shared-threshold route to* $\mathsf{Real}^{\uparrow}$ *seal budgets, admits the tail comparison through* Q*, records* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *provenance, and preserves the local* $\mathsf{NameCert}$ *rows of the accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket root formal handoff surface`

Proof. First collect the root consumer package. It assembles selector, seal, public shared-threshold, and bridge-facing consumers around one finite shared-threshold route.

Next add root seal-budget totality. This makes the $\mathsf{Real}^{\uparrow}$ seal-budget side total exactly on the displayed paired-source, paired-window, source-modulus, dyadic-threshold, comparison, transport, continuation, ledger, provenance, and naming rows.

Then add root tail-comparison admission. The comparison side is admitted only through the same Q row and the same transported source, window, modulus, threshold, route, provenance, and local certificate data.

Finally use root consumer export boundary and root threshold provenance. They identify the exported handoff with the finite packet and record its $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{NameCert}$ provenance, while excluding quotient streams, selected limits, host equality, trichotomy, and ambient completeness. □

Theorem 560.67 (RegularCauchyTailMeet selector-budget route lock)**.** *Any* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *read consumed by the root-facing* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *formal handoff of Definition 560.66 must pass through the same paired* $\mathsf{RegSeqRat}^{\uparrow}$ *sources, paired* $\mathsf{StreamName}^{\uparrow}$ *windows, source modulus rows, shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold ledger, comparison row,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row displayed by the accepted TailMeet packet before it reaches any* $\mathsf{Real}^{\uparrow}$ *seal.*

The selector-budget sibling of chapter 678 contributes only finite-window and $\mathsf{RegSeqRat}^{\uparrow}$ *readback along that route. It supplies no second selector, quotient stream, host limit, selected subsequence, or ambient completeness coordinate beyond the root seal-budget and tail-comparison surfaces of Definition 560.64 and Definition 560.65.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket selector budget route lock`

Proof. Begin with the root formal handoff surface. By Definition 560.66, the downstream handoff is already the finite packet whose source, window, modulus, threshold, comparison, transport, route, provenance, and local certificate rows are displayed by the accepted $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ carrier.

Apply Definition 560.64. Any $\mathsf{Real}^{\uparrow}$ seal-budget read behind that handoff is total only on the displayed TailMeet route, so a selector-budget read consumed by the seal side cannot bypass the paired sources, windows, modulus rows, threshold ledger, Q row, transports, continuations, provenance, or local name.

Apply Definition 560.65. The comparison side is admitted through the same transported rows, and the admission excludes an independent tail oracle, selected subsequence, quotient stream equality, and ambient completeness premise.

Finally read the sibling route through chapter 678. That chapter supplies the finite-window and $\mathsf{RegSeqRat}^{\uparrow}$ readback needed by the selector-budget consumer, and the preceding TailMeet rows lock that contribution to the root packet before any $\mathsf{Real}^{\uparrow}$ seal receives it. □

Theorem 560.68 (RegularCauchyTailMeet root formal budget-refusal totality)**.** *Every downstream* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Completion}^{\uparrow}$*,* $\mathsf{UniformCauchyCriterion}^{\uparrow}$*, or* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *consumer that reaches a selector-budget or quotient-stream request from the root formal handoff must first pass through the paired* $\mathsf{RegSeqRat}^{\uparrow}$ *sources, paired* $\mathsf{StreamName}^{\uparrow}$ *windows, source modulus rows, shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold ledger, comparison row,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row of the accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet.*

If the same consumer asks for quotient-stream equality, the request factors through Definition 560.95 and the $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *route of chapter 998. No such consumer receives a selected limit, quotient stream equality, host real equality, trichotomy row, independent tail oracle, or ambient completeness witness outside those displayed routes.*

Proof. First apply Definition 560.66. The handoff presented to downstream $\mathsf{Real}^{\uparrow}$ and $\mathsf{UniformCauchyCriterion}^{\uparrow}$ consumers is already the finite TailMeet packet, with its paired sources, windows, modulus rows, threshold ledger, comparison row, transports, continuations, provenance, and local certificate displayed.

Next apply Definition 560.67. It forces every selector-budget read consumed by that handoff, including the $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ sibling read, through the same accepted TailMeet rows before any $\mathsf{Real}^{\uparrow}$ seal can see the request.

For a quotient-stream request, use Definition 560.95 together with chapter 998. The completion-facing request first traverses the finite TailMeet source-window route and then enters the quotient-refusal route; if either route is absent, the request is recorded by the refusal ledger.

These two consumer routes cover the selector-budget and quotient-stream branches of the root formal handoff. The cited boundaries jointly exclude selected limits, quotient stream equality, host real equality, trichotomy rows, independent tail oracles, and ambient completeness as data exported to downstream consumers. □

Theorem 560.69 (RegularCauchyTailMeet root window threshold coverage)**.** *Every root consumer request for an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet reaches the shared threshold only through*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau$$

together with the displayed hsame*,* Cont*,* Pkg*, and* NameCert *rows. The request has no route to the threshold outside the paired source rows, paired window rows, source-modulus rows, and finite transport/provenance surface.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket root window threshold coverage`

Proof. Start with window-source coverage. The coverage theorem forces every threshold-facing read to expose the two source rows and the two window rows before the shared threshold can be read.

Next use source-modulus exhaustion. It attaches the two modulus rows M_0, M_1 to the same route and leaves no separate modulus source for a root consumer request.

Finally apply shared-threshold non-escape and consumer exactness. The displayed hsame, Cont, Pkg, and NameCert rows are therefore the only structural rows through which the threshold is transported to a root consumer. □

Theorem 560.70 (RegularCauchyTailMeet root modulus route exactness)**.** *For an accepted* RegularCauchyTailMee *packet, the source-modulus rows are the only admissible route into the shared-threshold ledger. A root threshold read is admitted exactly when it factors through the source-window-modulus route, the shared-threshold transport, and the displayed non-escape boundary.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket root modulus route exactness`

Proof. Apply ledger exactness first. The shared threshold ledger has only the displayed dyadic threshold coordinate, so a proposed route cannot enter the ledger through an unlisted analytic row.

Next compose with shared-threshold transport. Transport moves the paired source, window, modulus, threshold, comparison, ledger, package, and local naming rows together, preserving the same threshold row for root reads.

Finally use the non-escape exclusions. Since quotient streams, selected limits, trichotomy rows, host equality, and ambient completeness are absent from the carrier, the source-modulus rows are the exact route into the threshold ledger. □

Theorem 560.71 (RegularCauchyTailMeet root Real seal consumer exhaustion)**.** *Any* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *root consumer of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet reads the finite tail-meet packet before any seal row is consumed. The consumer receives no quotient stream, selected limit, trichotomy row, host equality row, or ambient completeness row.*

↪ variant `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket root downstream seal route`

Proof. First apply root window threshold coverage. It routes the root consumer through $R_0, R_1, W_0, W_1, M_0, M_1, \tau$ and the displayed structural rows before the threshold is available.

Next apply root modulus route exactness. The source-modulus route is the only entrance into the threshold ledger, so a regular-rational or real-facing consumer cannot bypass the finite tail-meet packet.

Finally compose with the Real seal handoff and the public shared-threshold certificate. The handoff places seal consumption after the finite packet, while the public certificate exposes only the shared threshold surface and none of quotient streams, selected limits, trichotomy, host equality, or ambient completeness. □

Theorem 560.72 (RegularCauchyTailMeet root observation-budget entry)**.** *For an accepted* RegularCauchyTailMee *packet, a root threshold read can enter the finite* RealObservationBudget$^{\uparrow}$ *surface of chapter 611 only through the paired source, window, modulus, and threshold rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau$$

together with the displayed comparison, transport, continuation, provenance, ledger, and local NameCert *rows. No budget entry route is supplied outside this finite TailMeet packet.*

Proof. Start with root window threshold coverage. It forces every root-facing read to expose the two source rows, two window rows, source modulus rows, shared threshold, and displayed structural rows before the threshold can be consumed.

Next apply root modulus route exactness. The source-modulus rows are the only admissible route into the shared-threshold ledger, so a budget entry cannot bypass $R_0, R_1, W_0, W_1, M_0, M_1, \tau$.

Finally read the target surface through chapter 611. That chapter admits only finite observation-budget rows, so the TailMeet threshold enters it through the displayed packet and not through quotient streams, host equality, selected limits, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket root observation budget entry`

Theorem 560.73 (RegularCauchyTailMeet root threshold readback determinacy)**.** *For an accepted* RegularCauchyTailMeet$^{\uparrow}$ *packet, any two root threshold readbacks that use the same displayed source-window-modulus route reach the same dyadic threshold row τ. The determinacy is read through*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

and through the finite observation-budget entrance of chapter 611.

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket root threshold readback determinacy`

Proof. First use root window threshold coverage to place both readbacks on the paired source rows, paired window rows, source modulus rows, and shared threshold row.

Next use root modulus route exactness. Since the source-window-modulus route is the exact entrance to the threshold ledger, two readbacks with the same displayed route cannot reach different dyadic threshold rows inside the finite packet.

Now apply root observation-budget entry. When the readback is served to RealObservationBudget$^{\uparrow}$, the budget side receives only the same displayed TailMeet rows, so it cannot split the dyadic readback by adding a quotient stream, selected limit, host equality, or ambient completeness coordinate. □

Theorem 560.74 (RegularCauchyTailMeet root seal consumer boundary)**.** *Every* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *seal consumer of an accepted* RegularCauchyTailMeet$^{\uparrow}$ *packet is bounded by the finite observation-budget surface reached from the root threshold route. The consumer can read only the TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

and the finite RealObservationBudget$^{\uparrow}$ *rows admitted by chapter 611; it receives no quotient stream, host equality, selected limit, trichotomy row, or ambient completeness row.*

Proof. Begin with root Real seal consumer exhaustion. A $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ root consumer must read the finite TailMeet packet before any seal row is consumed.

Apply root observation-budget entry and root threshold readback determinacy. Together they route the threshold through the finite observation-budget entrance and make the dyadic readback determined by the displayed source-window-modulus route.

For a $\mathsf{Completion}^{\uparrow}$ seal consumer, use the same budgeted boundary: it receives the TailMeet threshold only after the observation-budget surface has been displayed. Since both the TailMeet packet and the observation-budget packet are finite NameCert surfaces, no quotient stream, host equality, selected limit, trichotomy row, or ambient completeness row is available to the consumer. □

Theorem 560.75 (RegularCauchyTailMeet root seal budget synchronization)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, any root seal read synchronizes the finite threshold route*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

with the finite $\mathsf{RealObservationBudget}^{\uparrow}$ *entrance before any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal consumer can read the seal. The consumer therefore sees the shared dyadic threshold only through the displayed TailMeet packet and the finite observation-budget rows, with no route through quotient streams, selected limits, host equality, trichotomy, or ambient completeness.*

Proof. First apply root window threshold coverage and root modulus route exactness. These results put every root threshold read on the paired source rows, paired window rows, source-modulus rows, shared threshold row, rational comparison row, transport row, continuation row, ledger row, and local naming row.

Next apply root observation-budget entry. The same finite route is the only entrance into the $\mathsf{RealObservationBudget}^{\uparrow}$ surface, so the seal-side consumer cannot receive τ before the observation-budget packet has been displayed.

Use root threshold readback determinacy to identify all readbacks along that route with the same dyadic threshold row. The budget entrance therefore carries a single determined TailMeet threshold rather than a separate consumer-side threshold.

Finally apply root seal consumer boundary. It places both $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ seal reads after the finite budgeted route and excludes quotient streams, selected limits, host equality, trichotomy rows, and ambient completeness from the seal consumer surface. □

Theorem 560.76 (RegularCauchyTailMeet observation-budget selector handoff)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet whose root threshold route is exported to a* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *consumer, the exported route first factors through the same finite TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

and then through the selector route

$$B \to S \to W \to D \to R \to E.$$

The handoff exports no quotient stream, selected limit, host real equality, trichotomy row, countable-choice row, hidden selector, or ambient completeness theorem.

Proof. First place the exported read on the finite observation-budget surface. By Definition 560.72, the TailMeet route enters the $\mathsf{RealObservationBudget}^{\uparrow}$ side only through $R_0, R_1, W_0, W_1, M_0, M_1, \tau$ and the displayed comparison, transport, continuation, provenance, ledger, and local naming rows.

Next identify the threshold consumed by the selector-facing export. By Definition 560.73, every readback along the displayed route reaches the same dyadic threshold row τ. By Definition 560.75, that determined threshold is synchronized with the finite budget entrance before any $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal read is available.

It remains to describe the selector side of the handoff. By Definition 782.7, an accepted $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ packet with the displayed budget rows determines one finite route $B \to S \to W \to D \to R \to E$. By Definition 782.10, diagonal-limit and Real-completion consumers may use that finite route but receive no independent completion principle from the selector.

Combining the two surfaces gives a single finite export: the TailMeet root threshold is read through $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$ and is then consumed through $B \to S \to W \to D \to R \to E$. None of the excluded analytic rows is present on either side of the handoff, so none can be exported. □

Theorem 560.77 (RegularCauchyTailMeet ObservationBudgetLimiter cap synchronization)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet whose root threshold route is exported through* $\mathsf{RealObservationBudget}^{\uparrow}$ *and then consumed by an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet, the limiter cap row is synchronized with the same finite TailMeet route*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

Every downstream $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, *or* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *read must pass first through the TailMeet source-window-modulus threshold route and then through the limiter triad*

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N).$$

The synchronized handoff exports no quotient stream, selected limit, host real equality, trichotomy row, hidden selector, uncapped schedule, independent $\mathsf{Real}^{\uparrow}$ *carrier, or ambient completeness principle.*

Proof. First fix the TailMeet side of the export. Apply Definition 560.72 to place the root threshold entrance inside $\mathsf{RealObservationBudget}^{\uparrow}$ on the displayed source, window, modulus, threshold, comparison, transport, continuation, ledger, and local naming rows. Then apply Definition 560.73 and Definition 560.75. These identify every readback along that route with the same dyadic threshold row and the same finite budget entrance.

Next read the limiter side through chapter 903. By Definition 903.9, the accepted limiter packet admits a cap row K only after the request and observation-budget rows E, B and before any served window row. By Definition 903.10, the downstream readback rows W, D, R remain tied to that same capped route.

Finally combine this limiter boundary with Definition 560.76 and Definition 903.25. The first theorem shows that selector-facing reads consume the TailMeet threshold only through the finite observation-budget route, while the second identifies the public limiter service as the triad (E, B, K), (W, D, R), and (S, H, C, P, N). Thus each listed downstream consumer must read the TailMeet route before it reads the limiter triad, and the excluded analytic rows have no carrier coordinate or local $\mathsf{NameCert}$ clause from which to be exported. □

Theorem 560.78 (RegularCauchyTailMeet budgeted refinement seal factorization)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, any root threshold route exported to a* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *consumer or to a* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer is read in the following order. The consumer first reads the displayed TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

It then reads the finite observation-budget surface and any limiter cap surface attached to that route. Only after those finite rows have been displayed may a $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer read the seal. The route exports no quotient stream, selected limit, host real equality, trichotomy row, hidden selector, uncapped observation schedule, independent completion carrier, or ambient completeness principle.*

Proof. Start with the root threshold route. By Definition 560.72, every accepted export enters the $\mathsf{RealObservationBudget}^{\uparrow}$ surface only through the displayed TailMeet rows, together with their comparison, transport, continuation, ledger, and local naming coordinates.

The threshold row is then fixed before the seal is visible. Apply Definition 560.73 to identify all readbacks along the route with the same dyadic threshold row τ, and apply Definition 560.75 to place the $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ seal reads after the finite budget entrance.

Now attach the capped budget surface. By Definition 560.77, every downstream $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, or selector-facing read must pass through the TailMeet route and then through the limiter service rows before it can consume a seal.

Finally compare the two named consumers. The refinement chapter chapter 885 reads a Real or Completion route only after its displayed source, selector-budget, window, readback, and seal rows are present, while the Cauchy-limit seal chapter chapter 386 records the finite seal handoff boundary. Composing these chapter surfaces with the TailMeet budget and limiter theorems gives the stated factorization and leaves none of the excluded analytic rows with a carrier coordinate from which to be exported. □

Theorem 560.79 (RegularCauchyTailMeet root budget-limiter factorization)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, any root threshold route exported to* $\mathsf{RealObservationBudget}^{\uparrow}$, ObservationBudgetLim $\mathsf{CauchyModulusRefinement}^{\uparrow}$, *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *factors in one order. The route first reads the displayed TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

It then enters the finite observation-budget surface, then passes through the limiter cap and service triad, before any $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal is read. The route exports no quotient stream, selected limit, host real equality, trichotomy row, hidden selector, uncapped observation schedule, independent completion carrier, or ambient completeness principle.*

Proof. First place the root route on the TailMeet packet. By Definition 560.72, every threshold export reaches $\mathsf{RealObservationBudget}^{\uparrow}$ only through the paired source, window, modulus, threshold, comparison, transport, continuation, ledger, and local naming rows.

Next fix the threshold readback. The determinacy theorem Definition 560.73 identifies all readbacks along that displayed route with the same dyadic threshold row τ, and Definition 560.75 synchronizes that threshold with the finite budget entrance before any $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal is available.

Now attach the limiter stage. By Definition 560.77, the downstream read must pass from the TailMeet route into the limiter cap and service triad (E, B, K), (W, D, R), and (S, H, C, P, N).

Finally apply the budgeted refinement seal factorization, Definition 560.78. It places $\mathsf{CauchyModulusRefinement}^{\uparrow}$ and $\mathsf{CauchyLimitSeal}^{\uparrow}$ after the displayed TailMeet rows, finite observation-budget entrance, and capped limiter service, leaving no excluded analytic coordinate from which a Real or Completion seal can be read earlier. □

Theorem 560.80 (RegularCauchyTailMeet Real tail-agreement factorization)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, any accepted TailMeet root threshold route consumed by* $\mathsf{RealTailAgreementSeal}^{\uparrow}$,

$\mathsf{CauchyLimitSeal}^{\uparrow}$, *or* $\mathsf{Completion}^{\uparrow}$ *factors through one finite order. The route first reads the displayed TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

It then reads the finite $\mathsf{RealObservationBudget}^{\uparrow}$ *surface, then the* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *cap and service triad, and only after those finite rows have been displayed may the consumer read the tail-agreement seal. The route exports no quotient stream, selected limit, host real equality, trichotomy row, hidden selector, uncapped schedule, independent completion carrier, or ambient completeness principle.*

Proof. Start with the root observation-budget entrance. By Definition 560.72, every accepted threshold route enters the budget surface only through the displayed TailMeet source, window, modulus, threshold, comparison, transport, continuation, ledger, and local naming rows.

Next fix the threshold and synchronize the seal side. Apply threshold readback determinacy, Definition 560.73, to identify every readback with the same dyadic threshold row τ. Then apply seal budget synchronization, Definition 560.75, to put the $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ seal reads after that finite budget entrance.

Now attach the limiter and refinement stages. The observation-budget limiter cap synchronization theorem, Definition 560.77, places the cap and service triad after the TailMeet budget entrance, while Definition 560.78 keeps refinement and limit-seal consumers after the same finite rows.

Finally use the root budget-limiter factorization, Definition 560.79. It gives the common route order for $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{CauchyModulusRefinement}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$. Composing this with the $\mathsf{RealTailAgreementSeal}^{\uparrow}$ synchronizer surface keeps the tail-agreement seal behind the displayed TailMeet rows, finite budget surface, and capped limiter service, so none of the excluded analytic or completion-side rows has a coordinate from which to enter earlier. □

Theorem 560.81 (RegularCauchyTailMeet limit seal window pullback)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet whose root threshold route is exported to an accepted* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *packet and an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet over the same finite* $\mathsf{StreamName}^{\uparrow}$ *window, every seal-facing read pulls back to the same displayed TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The same pullback then reaches the $\mathsf{StreamName}^{\uparrow}$ *finite-window lattice meet and the displayed* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows. Conversely, those displayed rows repack into one consumer route for the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *seal row and the* $\mathsf{RealObservationBudget}^{\uparrow}$ *entrance. The route contains no quotient stream, selected limit, host real equality, trichotomy row, hidden selector, unbounded schedule, separate completion carrier, or ambient completeness principle.*

Proof. First place the root route on the TailMeet packet. By Definition 560.79, any route exported toward $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{CauchyModulusRefinement}^{\uparrow}$, or $\mathsf{CauchyLimitSeal}^{\uparrow}$ must read the displayed TailMeet rows, finite observation-budget entrance, and capped limiter service before a seal is available.

Next move from the finite budget route to the seal read. Apply Definition 560.78 and Definition 560.75. These place every $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{RealObservationBudget}^{\uparrow}$ consumer after the same finite threshold route and synchronize the seal-facing read with the finite budget entrance.

Now identify the shared $\mathsf{StreamName}^{\uparrow}$ window. The finite-window lattice dependency of Definition 386.160 forces the seal-facing route through the $\mathsf{StreamName}^{\uparrow}$ finite-window meet, and the tail-budget meet of Definition 386.135 identifies that meet with the displayed regular source, dyadic ledger, real seal, transport, continuation, provenance, and local naming rows.

For the converse direction, start with exactly those displayed TailMeet, stream-window, regular-source, dyadic, real, transport, continuation, package, and naming rows. The cited finite-window and tail-budget meet theorems repack them as the $\mathsf{CauchyLimitSeal}^{\uparrow}$ seal row together with the $\mathsf{RealObservationBudget}^{\uparrow}$ entrance, while the TailMeet budget-limiter factorization supplies the root consumer route.

Finally use Definition 560.73. It identifies all readbacks along the displayed route with the same threshold row τ, so the forward pullback and the reverse repacking describe one deterministic route and none of the excluded analytic rows has a coordinate from which to enter it. □

Theorem 560.82 (RegularCauchyTailMeet observation-budget route uniqueness)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, any two exports into* $\mathsf{RealObservationBudget}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *that use the same displayed rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

reach the same observation-budget entrance and the same seal-facing pullback route. No quotient stream, selected limit, host real equality, trichotomy row, hidden selector, uncapped observation schedule, independent completion carrier, or ambient completeness principle can separate the two exports after those rows are fixed.

Proof. First apply the root observation-budget entry theorem, Definition 560.72. It places any export into $\mathsf{RealObservationBudget}^{\uparrow}$ on the displayed TailMeet rows and their comparison, transport, continuation, ledger, and local naming coordinates.

Next use root threshold readback determinacy, Definition 560.73. Since both exports use the same displayed rows, every readback reaches the same dyadic threshold row τ.

The root seal budget synchronization and root budget-limiter factorization, Definition 560.75 and Definition 560.79, put the finite budget entrance before any seal-facing Real or Completion read.

Finally apply the limit seal window pullback of Definition 560.81. It repacks the fixed TailMeet rows with the shared finite-window and seal rows, so both exports reach one observation-budget entrance and one seal-facing pullback route with none of the excluded analytic coordinates available. □

Theorem 560.83 (RegularCauchyTailMeet RealTailAgreementSeal handoff)**.** *Every* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold exported to* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *is consumed only after the displayed TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

are present, the finite observation-budget entrance is fixed, the limiter cap and service rows are present, the $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row has been inserted, the finite* $\mathsf{StreamName}^{\uparrow}$ *window is selected as a window row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback is exposed, and the agreement row is available. The exported package carries no quotient stream, selected limit, host equality, trichotomy row, or ambient completeness row.*

Proof. First place the exported threshold on the TailMeet packet. The root budget-limiter factorization of Definition 560.79 forces the route through the displayed TailMeet rows, the finite

observation-budget entrance, and the capped limiter service before a downstream seal route can use it.

Next identify the finite window and readback. The limit seal window pullback of Definition 560.81 transports that same threshold route through the shared $\mathsf{StreamName}^{\uparrow}$ finite-window surface and the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ readback, with no separate analytic coordinate available.

Route uniqueness then turns the exported threshold into a single finite package. By Definition 560.82, any consumer using those displayed rows reaches the same observation-budget entrance and the same seal-facing pullback route.

Finally apply the $\mathsf{RealTailAgreementSeal}^{\uparrow}$ budget synchronizer factorization, Definition 699.25. It inserts the synchronizer row before the finite window, dyadic readback, and agreement row are consumed, so the handoff exports one finite threshold package and none of the excluded quotient, selected-limit, host-equality, trichotomy, or ambient-completeness rows. □

Theorem 560.84 (RegularCauchyTailMeet root downstream window exhaustion)**.** *Let $T = (R_0, R_1, W_0, W_1, M_0, M$ be an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. Every downstream* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *root consumer that reads the TailMeet threshold must first exhaust the paired window-source route through the displayed* BHist *rows R_0, R_1, W_0, W_1, the componentwise* hsame *row H, the displayed* Cont *route C, the finite ledger L, the package row* Pkg*, and the local* NameCert *row N. No downstream read can reach τ, Q, or a Real seal handoff before those four source-window rows have been exposed.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket root downstream window exhaustion`

Proof. Start with TailMeet window-source coverage. It forces any threshold-facing read to expose the two regular-Cauchy source rows R_0, R_1 and the two stream-window rows W_0, W_1 before the shared dyadic threshold is available.

Next attach the structural rows. Shared-threshold transport carries the exposed window-source route through the componentwise hsame row H and the displayed Cont route C, while consumer exactness records the same route in L, Pkg, and N.

Finally read the Real seal handoff. The handoff can consume only the already displayed finite TailMeet route, so a root downstream consumer cannot bypass the window-source rows to reach τ, Q, or any completion-facing seal row. □

Theorem 560.85 (RegularCauchyTailMeet root downstream threshold stability)**.** *Let $T = (R_0, R_1, W_0, W_1, M_0, M$ be an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. If a downstream root consumer transports the paired source-window-modulus route through the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows, then the shared threshold row τ and comparison row Q remain the TailMeet rows read by that consumer. The consumer may request a stronger displayed dyadic threshold through M_0 and M_1, but the stabilized route still factors through $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$.*

Proof. Use the shared-threshold transport theorem to move the paired source rows, window rows, modulus rows, threshold row, comparison row, finite ledger, package row, and local name together. The transported route therefore keeps τ and Q attached to the same TailMeet packet.

Now apply shared-threshold cofinality. A stronger displayed dyadic threshold can serve the downstream request only through the same source modulus rows M_0, M_1 and the same paired schedules W_0, W_1.

Consumer exactness and the Real seal handoff close the boundary. They record the transported threshold route in H, C, L, N and prevent the downstream consumer from replacing it by a host equality, quotient stream, selected limit, independent tail oracle, or ambient completeness row. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket root downstream threshold stability`

Theorem 560.86 (RegularCauchyTailMeet root downstream nonescape package)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet* $T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N)$*, downstream root consumers receive exactly the finite TailMeet route certified by Definition 560.84 and Definition 560.85. The package exposes the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows and exports no quotient stream, selected limit, host real equality, trichotomy row, independent tail oracle, or ambient completeness witness.*

Proof. First combine downstream window exhaustion with downstream threshold stability. The first theorem forces each root consumer through R_0, R_1, W_0, W_1 before the threshold is visible, and the second keeps the transported threshold and comparison rows on τ and Q through M_0, M_1, H, C, L, N.

Next compose with consumer exactness. That theorem identifies the listed rows as the complete consumer-facing surface of the accepted TailMeet packet, including the package provenance and local naming evidence.

Finally apply the Real seal handoff rows. Since every Real or Completion consumer reaches the seal through the same TailMeet route, the downstream package has no coordinate from which to export quotient streams, selected limits, host equality, trichotomy, hidden tail data, or ambient completeness. □

Theorem 560.87 (RegularCauchyTailMeet root downstream seal route)**.** *Every downstream* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal consumer of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet* $T = (R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C$ *first factors through the paired source windows* R_0, R_1, W_0, W_1*, then through the modulus rows* M_0, M_1*, then through the shared threshold and comparison rows* τ, Q*, and finally through* H, C, L, Pkg, N*. The route exports no quotient stream, selected limit, host equality, trichotomy row, independent tail oracle, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket root downstream seal route`

Proof. Start with downstream window exhaustion. It forces every seal-facing consumer to read the paired source rows and window rows R_0, R_1, W_0, W_1 before the threshold or seal handoff can be visible.

Next apply downstream threshold stability. Any stronger displayed dyadic request must pass through M_0, M_1 while keeping the shared threshold row τ and the comparison row Q attached to the same TailMeet packet.

Finally use the downstream nonescape package. It repacks the window, modulus, threshold, comparison, transport, continuation, ledger, package, and local naming rows as the complete seal route and excludes quotient streams, selected limits, host equality, trichotomy, independent tail oracles, and ambient completeness. □

Theorem 560.88 (RegularCauchyTailMeet downstream unblock package)**.** *For an accepted* RegularCauchyTailMee *packet, every downstream* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *root consumer receives exactly the combined route certified by window exhaustion, threshold stability, the nonescape package, and the seal route. The public package is the finite tuple* $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, \mathsf{Pkg}, N$*, and it exports no quotient stream, selected limit, host equality, trichotomy row, independent tail oracle, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailMeetUp.RegularCauchyTailMeetPacket downstream unblock package`

Proof. Apply Definition 560.84. Every root consumer first exposes the paired source-window rows R_0, R_1, W_0, W_1 before a threshold-facing or seal-facing read is available.

Apply Definition 560.85. The same route then carries the modulus rows M_0, M_1, preserves the shared threshold row τ, and keeps the comparison row Q attached to the accepted TailMeet packet.

Apply Definition 560.86. This identifies the consumer-facing surface with the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows and excludes every unlisted root resource.

Apply Definition 560.87. The seal consumer therefore factors through the same finite route and cannot bypass the ledger or package evidence.

Ledger exhaustion leaves only $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, \mathsf{Pkg}, N$ in the exported package, while non-escape removes quotient streams, selected limits, host equality, trichotomy, independent tail oracles, and ambient completeness witnesses from the downstream interface. □

Theorem 560.89 (RegularCauchyTailMeet budget-selector handoff)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, every* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *or* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ *consumer must read the paired source windows* R_0, R_1, W_0, W_1*, modulus rows* M_0, M_1*, shared threshold* τ*, comparison row* Q*,* hsame *row* H*,* Cont *row* C*, ledger* L*, package row* Pkg*, and local* $\mathsf{NameCert}$ *row* N *before selecting a downstream budget. The handoff exports no selected limit, quotient stream, host equality, trichotomy row, independent tail oracle, or ambient completeness witness.*

Proof. Start with the downstream unblock package. It identifies the complete public route of an accepted TailMeet packet as the finite tuple $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, \mathsf{Pkg}, N$ and excludes every unlisted root resource.

Apply Definition 560.84 and Definition 560.85. A budget selector must first read the paired source windows and modulus rows, and the shared threshold and comparison row remain attached to the same accepted packet.

Apply Definition 560.86 and Definition 560.87. These route the selector through the displayed hsame, Cont, ledger, package, and local naming rows.

Thus a $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ or $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ consumer can select a downstream budget only after consuming the already displayed finite route. Since that route contains no selected limit, quotient stream, host equality, trichotomy row, independent tail oracle, or ambient completeness witness, none is exported by the handoff. □

Theorem 560.90 (RegularCauchyTailMeet root consumer budget uniqueness)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, any downstream* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *root consumer has exactly the displayed budget route* $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, \mathsf{Pkg}, N$*. The route is the one obtained by the source-window exhaustion, threshold stability, nonescape package, seal route, and budget-selector handoff. No second downstream budget, quotient stream, selected limit, host equality, independent tail oracle, or ambient completeness witness is available to the consumer.*

Proof. Start with the downstream unblock package. It displays the public root route as $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q$ and records that the accepted packet exports only the named rows.

Apply Definition 560.84 and Definition 560.85. The source windows, modulus rows, threshold, and comparison row are forced by the accepted TailMeet packet before a downstream root request can be served.

Apply Definition 560.86 and Definition 560.87. These attach the same request to the displayed hsame, Cont, ledger, package, and local name rows and prevent a $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer from leaving that route.

Finally use Definition 560.89. A downstream budget selector can act only after reading the already displayed route, so any root consumer budget is the route just constructed. The nonescape exclusions remove every alternative carrier for a second budget. □

Theorem 560.91 (RegularCauchyTailMeet root budget route lock)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, any* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Completion}^{\uparrow}$*,* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$*, or* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ *consumer preserving the displayed rows must use the single route*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, \mathsf{Pkg}, N.$$

No selected limit, quotient stream, host equality, trichotomy row, independent tail oracle, or ambient completeness row can supply a second route.

Proof. Start with the downstream window exhaustion and threshold stability theorems. Definition 560.84 fixes the paired source windows and modulus rows, while Definition 560.85 keeps the shared threshold and comparison row on the same accepted packet.

Next apply the nonescape package and seal route. Definition 560.86 removes every unlisted root resource, and Definition 560.87 attaches the consumer to the displayed hsame, Cont, ledger, package, and local naming rows.

Now use the budget-selector handoff together with root consumer budget uniqueness. Definition 560.89 forces $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ and $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ consumers through the displayed route, and Definition 560.90 gives the same route to $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ root consumers.

Thus every listed consumer reads exactly $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, \mathsf{Pkg}, N$. The excluded rows have already been removed from the packet surface, so none can witness a second route. □

Theorem 560.92 (RegularCauchyTailMeet seal consumer tail-fiber factorization)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, every seal-facing consumer that later reads the* $\mathsf{RegularCauchyTailFiber}^{\uparrow}$ *row of chapter 893 must first factor through the TailMeet shared threshold tuple* $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L$ *Only after that finite route is read may the tail-fiber row be made available. The factorization exports no quotient stream, selected limit, host equality, independent tail oracle, or ambient completeness witness.*

Proof. Begin with the root consumer budget uniqueness theorem. A seal-facing downstream consumer has a unique finite TailMeet route, and that route is the displayed tuple $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L$

Use the seal route and the budget-selector handoff. They force the consumer to read the same threshold tuple before any downstream budget or seal-facing read is available.

Now pass to the tail-fiber chapter named in chapter 893. A $\mathsf{RegularCauchyTailFiber}^{\uparrow}$ row can be consumed only as a later row attached to the already routed TailMeet threshold service, because the present packet exports no independent tail oracle and no ambient completeness witness.

The tail-fiber consumer therefore factors through the TailMeet threshold tuple before the tail-fiber row is visible. Since the intermediate route contains no quotient stream, selected limit, host equality, independent tail oracle, or ambient completeness witness, none of those objects can be supplied by the factorization. □

Theorem 560.93 (RegularCauchyTailMeet tail-fiber seal exactness)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet whose seal-facing consumer passes through* $\mathsf{RegularCauchyTailFiber}^{\uparrow}$*, the TailMeet threshold route and the TailFiber paired-window route have the same finite support through the two* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows, the two* $\mathsf{StreamName}^{\uparrow}$ *windows, the two dyadic ledger rows, the shared fiber or threshold row, the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. Conversely, any accepted TailFiber paired-window seal route supplies the same TailMeet seal-consumer entrance. The exactness statement exports no quotient streams, selected limits, host real equality, hidden tail oracles, or ambient completeness.*

Proof. For the forward direction, start with Definition 560.92. It forces the seal-facing consumer through the displayed TailMeet threshold tuple before the $\mathsf{RegularCauchyTailFiber}^{\uparrow}$ row is available.

Apply root consumer budget uniqueness together with the TailMeet root downstream seal route. These identify the source windows, threshold data, continuation rows, package row, and local name row as the only TailMeet entrance for a seal-facing read.

Now use TailFiber paired-window exactness and TailFiber seal-consumer exhaustion. The TailFiber route reads the two regular-rational source rows, two stream windows, two dyadic ledgers, shared fiber row, seal row, componentwise hsame, displayed Cont, Pkg, and local $\mathsf{NameCert}$ rows, and no further consumer coordinate is present.

For the converse direction, begin with an accepted TailFiber paired-window seal route. TailFiber paired-window exactness supplies the common finite support up to the shared fiber row, and seal-consumer exhaustion keeps every listed TailMeet, Real-tail-agreement, and Real-facing consumer inside the same packet.

Re-enter TailMeet through the seal-consumer factorization theorem. The TailFiber route therefore supplies exactly the TailMeet seal-consumer entrance already fixed by root consumer budget uniqueness and the TailMeet seal route. The exclusions in the TailMeet nonescape package and TailFiber ledger exhaustion rule out quotient streams, selected limits, host real equality, hidden tail oracles, and ambient completeness. □

Theorem 560.94 (RegularCauchyTailMeet budget window service lock)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, every* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$*,* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, or* $\mathsf{Completion}^{\uparrow}$ *consumer that requests the TailMeet threshold must first read the paired* $\mathsf{StreamName}^{\uparrow}$ *windows* W_0, W_1*, modulus rows* M_0, M_1*, shared threshold* τ*, comparison row* Q*, transport rows* H, C*, ledger* L*, package row* Pkg*, and local* $\mathsf{NameCert}$ *row* N*. The service is locked to this displayed finite route and cannot be replaced by an uncapped observation request, quotient stream, selected limit, host equality, trichotomy row, independent tail oracle, or ambient completeness witness.*

Proof. Start with window exhaustion. Any threshold-facing consumer must expose the paired StreamName windows W_0, W_1 before τ is available, and the same source-window route keeps the request inside the accepted TailMeet packet.

Apply threshold stability and the downstream unblock package. They attach the modulus rows M_0, M_1, the shared threshold τ, the comparison row Q, the transport rows H, C, the ledger L, the package row Pkg, and the local name row N to the same finite consumer-facing route.

Use the seal route for $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumers and the budget-selector handoff for $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ and $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ consumers. Both routes consume the displayed tuple before a threshold service is available.

The remaining non-escape claim is ledger exhaustion for that tuple. Since the route contains only the displayed windows, modulus rows, threshold, comparison, transport, ledger, package, and local name, no uncapped observation request, quotient stream, selected limit, host equality,

trichotomy row, independent tail oracle, or ambient completeness witness can replace the service. □

Theorem 560.95 (RegularCauchyTailMeet quotient-refusal factorization)**.** *Every completion-facing consumer of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet that requests quotient-stream equality must first pass through the finite TailMeet source-window route and then through the* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *route of chapter 998. If either route is missing, the request is routed to the refusal ledger. The handoff exports no selected limit, quotient stream equality, host real equality, trichotomy, independent tail oracle, or ambient completeness witness.*

Proof. Begin with the downstream unblock package. It exposes the paired source windows R_0, R_1, W_0, W_1, modulus rows M_0, M_1, shared threshold τ, comparison row Q, and structural rows H, C, L, Pkg, N before any completion-facing read is available.

Apply the threshold stability and budget-selector handoff theorems. They keep the selected downstream budget attached to the same finite TailMeet packet and prevent a selector from bypassing the source windows, modulus rows, threshold, comparison, ledger, package, or local name.

Next use the $\mathsf{QuotientStreamRefusal}^{\uparrow}$ non-escape route of chapter 998. A quotient-stream equality request has a route only after it is translated into the displayed StreamName, RegSeqRat, CauchyLimitSeal, and RealUp seal rows; an off-route request is sent to the refusal ledger.

The two routes therefore factor the completion-facing consumer through the TailMeet finite source-window surface and then through the quotient-refusal surface. Since neither packet contains selected limits, quotient stream equality, host real equality, trichotomy, independent tail oracles, or ambient completeness, none of those objects is exported. □

Theorem 560.96 (RegularCauchyTailMeet root downstream budget-seal package)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, every root threshold route exported to* $\mathsf{RealObservationBudget}^{\uparrow}$*,* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$*,* $\mathsf{CauchyModulusRefinement}^{\uparrow}$*, or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *reaches a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal read only after the route has passed through the displayed TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The route then passes through the finite observation-budget surface of chapter 611 and the limiter cap surface of chapter 903. Only after those rows are displayed may refinement or limit-seal consumers read the Real or completion seal surfaces of chapter 885 and chapter 386. The package exports no quotient stream, selected limit, host real equality, trichotomy row, hidden selector, uncapped observation schedule, independent completion carrier, or ambient completeness principle.

Proof. Start with the root budget-limiter factorization. By Definition 560.79, any route to $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{CauchyModulusRefinement}^{\uparrow}$, or $\mathsf{CauchyLimitSeal}^{\uparrow}$ first reads the TailMeet source, window, modulus, threshold, comparison, transport, continuation, ledger, and local naming rows.

Next use the budgeted refinement seal factorization. Definition 560.78 places the finite observation-budget entrance and the capped limiter service before the refinement and limit-seal consumers can reach a Real or completion seal.

The sibling chapter surfaces supply the downstream boundary. The observation-budget and limiter chapters expose only finite budget, window, readback, cap, service, transport, continuation, provenance, and local $\mathsf{NameCert}$ rows, while the refinement and limit-seal chapters read their Real and completion-facing seals through those finite rows.

Finally apply the root window threshold obligations from Definition 560.72, Definition 560.75, and Definition 560.77. These keep every consumer on the displayed route and leave no carrier

coordinate for quotient streams, selected limits, host real equality, trichotomy, hidden selectors, uncapped schedules, independent completion carriers, or ambient completeness. □

Theorem 560.97 (RegularCauchyTailMeet root seal exactness)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal read exported from a root threshold route to a* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer is exact with respect to the displayed route: it must use the same TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

that appear in the root downstream budget-seal package, then the finite observation-budget surface, then the limiter cap surface, before the consumer may read the refinement or limit-seal interface. No downstream consumer may replace those rows by an independent threshold, budget, cap, Real carrier, completion carrier, quotient stream, selected limit, hidden selector, or ambient completeness witness.

Proof. Begin with the package statement Definition 560.96. It already places every exported route to $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{CauchyModulusRefinement}^{\uparrow}$, or $\mathsf{CauchyLimitSeal}^{\uparrow}$ on the displayed TailMeet rows before any $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal read is available.

Next fix the route through the budget and limiter interfaces. The root budget-limiter factorization Definition 560.79 keeps the root threshold route on the TailMeet packet and then passes it through the limiter service, while Definition 560.78 places the refinement and limit-seal consumers after that finite budgeted route.

It remains to identify the rows read by the downstream seal. The observation-budget entry theorem Definition 560.72 supplies the finite budget entrance from the same root rows, and Definition 560.75 synchronizes the $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ seal reads with that entrance.

Finally Definition 560.77 synchronizes the limiter cap with the same route. Hence every downstream seal consumer reads exactly the displayed TailMeet rows, followed by the finite observation-budget and limiter cap surfaces, and there is no remaining coordinate from which an independent analytic or completion-side seal can be obtained. □

Theorem 560.98 (RegularCauchyTailMeet downstream budget source lock)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, every route to* $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{CauchyModulusRefinement}^{\uparrow}$, *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *uses the same displayed TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

No downstream route may substitute a second threshold source, independent budget row, independent limiter cap, quotient stream, selected limit, hidden selector, or ambient completeness witness for those rows.

Proof. Begin with the root downstream budget-seal package of Definition 560.96. It places all four downstream consumers on the same TailMeet source, window, modulus, threshold, comparison, transport, continuation, ledger, and naming rows.

Next use Definition 560.79. The factorization keeps the observation-budget and limiter entrances attached to that same root packet rather than to a second schedule or external completion carrier.

Finally apply the root seal exactness theorem Definition 560.97. Since every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal read is exact with respect to the displayed route, no independent downstream source can replace the listed rows. □

Theorem 560.99 (RegularCauchyTailMeet seal package non-escape)**.** *The downstream budget-seal package for an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet exports no quotient stream, selected limit, uncapped observation schedule, independent completion carrier, host real equality, trichotomy row, hidden selector, or ambient completeness principle. The only seal-facing surface is the displayed TailMeet route followed by the finite observation-budget surface, the limiter cap surface, and the refinement or limit-seal consumer interface.*

Proof. First apply Definition 560.98. It locks every downstream budget, limiter, refinement, and seal route to the displayed TailMeet rows.

Next use Definition 560.78. This places the finite observation budget and capped limiter service before either $\mathsf{CauchyModulusRefinement}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ may expose a Real or completion-facing seal.

The sibling chapters then account for the endpoint rows. The Real observation-budget, observation-budget limiter, Cauchy modulus-refinement, and CauchyLimitSeal surfaces cited in Definition 560.96 provide finite budget, cap, refinement, and seal routes, not quotient streams, selected limits, uncapped schedules, independent completion carriers, or ambient completeness. □

Theorem 560.100 (RegularCauchyTailMeet window threshold totality)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, the threshold row* τ *together with the limiter cap surface exhausts every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$*-facing window request exported through* $\mathsf{RealObservationBudget}^{\uparrow}$*,* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$*,* $\mathsf{CauchyModulusRefinem}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$*. Such a request must pass through the displayed rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

and then through the finite observation-budget and limiter cap rows before any refinement or limit-seal endpoint is read.

Proof. Start with Definition 560.97. It identifies every exported Real or completion seal read with the same TailMeet route, followed by the finite observation-budget and limiter cap surfaces.

Apply the downstream budget source lock of Definition 560.98. This keeps the threshold row τ and comparison row Q attached to the displayed windows, moduli, transport, continuation, ledger, and naming rows.

Finally use the seal package non-escape theorem Definition 560.99. Since no uncapped schedule, independent completion carrier, quotient stream, selected limit, hidden selector, or ambient completeness datum is exported, the threshold row and limiter cap exhaust the whole window request budget. □

Theorem 560.101 (RegularCauchyTailMeet budget-seal finality)**.** *For an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, any downstream route to* $\mathsf{RealObservationBudget}^{\uparrow}$*,* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$*,* $\mathsf{CauchyModulusRefinement}^{\uparrow}$*, or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *is final for a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal consumer exactly when it reads the displayed TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

then the finite observation-budget surface, and then the limiter cap before reaching the refinement or limit-seal endpoint. No route that omits one of those stages is a final budget-seal route, and no final route introduces a quotient stream, selected limit, host real equality, uncapped schedule, independent completion carrier, hidden selector, or ambient completeness principle.

Proof. First compose the package route with seal exactness. Definition 560.96 places the four downstream consumers after the displayed TailMeet packet, and Definition 560.97 identifies every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal read with that same route.

Next lock the source of the budget route. By Definition 560.98, none of the downstream consumers may substitute an independent threshold source, budget row, limiter cap, quotient stream, selected limit, hidden selector, or ambient completeness witness for the listed TailMeet rows.

Now use non-escape and window-threshold totality. Definition 560.99 rules out every off-route seal coordinate, while Definition 560.100 says the threshold row together with the limiter cap exhausts every Real- or completion-facing window request.

The forward direction follows because a final downstream seal route has no remaining coordinate after these displayed stages. Conversely, a route that reads the TailMeet rows, then the observation-budget surface, then the limiter cap, and only then the refinement or limit-seal endpoint has passed every required boundary named above, so it is already final for the budget-seal consumer. □

Theorem 560.102 (RegularCauchyTailMeet observation-budget factorization)**.** *Any* $\mathsf{RealObservationBudget}^{\uparrow}$ *consumer that reads an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold must first factor its observation request through the TailMeet rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

before it reaches the observation-budget rows. Thus the budget consumer sees the paired $\mathsf{RegularCauchyName}^{\uparrow}$ *sources, paired* $\mathsf{StreamName}^{\uparrow}$ *windows, source modulus rows, shared threshold, comparison row, componentwise transports, displayed continuations, finite ledger, provenance, and local* $\mathsf{NameCert}$ *row as the complete entrance to the finite observation-budget surface of chapter 611.*

Proof. Start with the finite observation-budget route of chapter 611. A budget consumer can inspect only the precision request, finite window family, dyadic readbacks, regular-sequence handoff, real-seal boundary, transports, continuations, provenance, and local naming rows supplied by its accepted packet.

Next read the TailMeet threshold through shared-threshold non-escape. By Definition 560.50, every admitted shared-threshold read remains inside the displayed threshold, paired stream schedules, source modulus rows, comparison row, componentwise transports, continuation routes, provenance, and local $\mathsf{NameCert}$ evidence.

Finally apply real-seal route totality. Definition 560.51 places every admitted $\mathsf{Real}^{\uparrow}$ seal read behind the same TailMeet window and dyadic endpoint rows, so the observation-budget consumer cannot reach its budget rows before the TailMeet route has exposed $R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$. □

Theorem 560.103 (RegularCauchyTailMeet selector-budget compatibility)**.** *Any* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *route that shares the accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold consumes that threshold through the selector budget's finite-window and* $\mathsf{RegSeqRat}^{\uparrow}$ *route. It does not introduce a second selector, a hidden threshold, or an independent tail oracle outside the displayed rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

Proof. Read the selector-budget side through chapter 678. Its finite-window and $\mathsf{RegSeqRat}^{\uparrow}$ rows specify the admissible selector request before any downstream tail read is exported.

Now compose with shared-threshold route determinacy. By Definition 560.56, two shared-threshold reads with the same transported source rows, window rows, and source modulus rows reach the same displayed dyadic threshold ledger.

The selector-budget route therefore consumes the TailMeet threshold through the already displayed finite-window and regular-rational route. Since determinacy leaves no second threshold

coordinate and the selector budget supplies no extra selector outside its finite route, the shared threshold cannot be replaced by a hidden threshold or independent tail oracle. □

Theorem 560.104 (RegularCauchyTailMeet real-tail agreement consumer surface)**.** *Every* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet receives exactly the shared threshold* τ*, paired comparison row* Q*, componentwise transports* H*, displayed continuations* C*, package provenance, finite ledger* L*, and local* $\mathsf{NameCert}$ *row* N*, together with the paired source, window, and modulus rows that produce* τ*.*

The consumer surface is therefore the finite TailMeet route

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N,$$

followed by the seal route of chapter 699. It includes no quotient stream, selected limit, host equality, independent tail oracle, or ambient completeness row.

Proof. First use the observation-budget factorization. Definition 560.102 forces every real-facing observation of the TailMeet threshold through the displayed source, window, modulus, threshold, comparison, transport, continuation, ledger, provenance, and local naming rows before any budget-side read is available.

Next use selector-budget compatibility. Definition 560.103 keeps selector-facing reads on the same finite-window and $\mathsf{RegSeqRat}^{\uparrow}$ route to the shared threshold, so the real-tail agreement consumer receives the same τ and Q rather than a second selector or hidden tail threshold.

Finally read the seal side through chapter 699. The agreement seal may consume the shared threshold, paired comparison, transports, continuations, provenance, ledger, and local naming evidence already displayed by the TailMeet packet, but the TailMeet carrier and the two preceding consumer theorems provide no coordinate for quotient streams, selected limits, host equality, independent tail oracles, or ambient completeness. □

Theorem 560.105 (RegularCauchyTailMeet budget-family cofinality)**.** *For any finite family of downstream budget requests accepted through a* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, the shared threshold row remains cofinal. Every requested strengthening factors through the same finite route*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N$$

and a stronger displayed dyadic threshold can be chosen inside that route for all members of the family at once. No request introduces a quotient stream, selected limit, host equality, independent tail oracle, trichotomy row, or ambient completeness coordinate.

Proof. Start with window-source coverage and source-modulus exhaustion. Definition 560.26 and Definition 560.27 force each family request through the two source rows, two window rows, and two source modulus rows before it reaches τ.

Use shared-threshold cofinality for the finite family. Since Definition 560.8 refines the displayed threshold without leaving the carrier route, induction over the finite family yields one stronger displayed threshold row still carried by the same ledger.

Finally apply ledger exactness and the public shared-threshold certificate. Definition 560.7 and Definition 560.11 keep the refined family threshold inside the finite certificate surface, so none of the excluded completion or quotient data can be exported. □

Theorem 560.106 (RegularCauchyTailMeet finite witness induction)**.** *Let a finite list of downstream requests enter through an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet, with each entry either a*

$\mathsf{RealObservationBudget}^{\uparrow}$ *request or a* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *request admitted by the packet. Then the whole list admits one displayed dyadic threshold row inside the same TailMeet route*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The witness is obtained without adding a quotient stream, selected limit, host equality row, independent tail oracle, trichotomy coordinate, or ambient completeness premise.

Proof. For the empty list, use the displayed accepted packet itself. Its public shared-threshold certificate already carries τ together with $R_0, R_1, W_0, W_1, M_0, M_1, Q, H, C, L, N$, so the required witness is the original finite row.

For a nonempty list, assume by induction that the tail of the list has one displayed threshold row inside the same TailMeet route. The head request is either an observation-budget request or a selector-budget request.

In the observation-budget case, apply Definition 560.102; in the selector-budget case, apply Definition 560.109. In both cases the head request reaches the shared threshold only through the displayed source, window, modulus, comparison, transport, continuation, package, ledger, and local naming rows.

Now use Definition 560.105 to refine the induction witness and the head request to one stronger displayed threshold. Source-window-modulus route determinacy, Definition 560.52 and Definition 560.56, keeps that refined row on the same TailMeet route rather than on a second threshold coordinate.

Finally apply ledger exactness and the public shared-threshold certificate. Definition 560.7 and Definition 560.11 exhaust the finite ledger surface for the refined witness, so the induction step has no coordinate from which to export quotient, selected-limit, host-equality, independent-tail, trichotomy, or completeness data. □

Theorem 560.107 (RegularCauchyTailMeet selector-budget absorption)**.** *Every* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *request that enters through an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet is absorbed by the displayed rows*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The selector-budget side may choose finite windows and regular-rational readbacks, but the tail-meet threshold it consumes is still the shared threshold row produced by the paired source schedules, source modulus rows, ledger exactness, public certificate, and seal-compatible handoff.

Proof. Read the selector-budget request through selector admission and selector-budget compatibility. Definition 560.39 supplies the admitted selector route, and Definition 560.103 keeps that route on the selector budget's finite-window and $\mathsf{RegSeqRat}^{\uparrow}$ surface.

Next identify the threshold route. Window-source coverage, source-modulus exhaustion, and shared-threshold route determinacy force the selector-budget read through $R_0, R_1, W_0, W_1, M_0, M_1, \tau$ rather than through a second selector or hidden threshold.

The structural rows are then absorbed by consumer exactness and seal compatibility. Definition 560.34 and Definition 560.43 add exactly Q, H, C, L, N to the route and exclude quotient streams, selected limits, host equality, independent tail oracles, trichotomy, and ambient completeness. □

Theorem 560.108 (RegularCauchyTailMeet diagonal seal-budget exactness)**.** *Every diagonal* $\mathsf{Real}^{\uparrow}$ *seal-budget read of an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet passes through the same finite shared-threshold route used by the public certificate:*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The diagonal seal may read the real-facing handoff only after the paired source schedules, source modulus rows, cofinal shared threshold, exact ledger, public shared-threshold certificate, and seal compatibility rows have all been exposed.

Proof. Begin with the diagonal-facing coverage. Definition 560.10 and Definition 560.49 route the diagonal read through the displayed source schedules and window rows.

Attach the modulus and threshold rows. Source-modulus exhaustion, shared-threshold cofinality, and source-window-modulus route results identify the only admissible path to τ and keep stronger diagonal precision requests cofinal inside the same finite ledger.

Now read the seal side. Definition 560.7, Definition 560.11, and Definition 560.43 make the diagonal seal consume exactly the listed threshold, comparison, transport, continuation, ledger, provenance, and naming rows, with no additional completion premise. □

Theorem 560.109 (RegularCauchyTailMeet selector-budget shared entry)**.** *Every* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *consumer that enters through an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet reads the same shared threshold row* τ *through*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

The selector-budget request may choose its finite selector windows and $\mathsf{RegSeqRat}^{\uparrow}$ *readback, but its tail-facing threshold entry is the TailMeet shared threshold ledger row, transported with the displayed comparison,* hsame *rows, continuations, package provenance, and local* NameCert *evidence.*

Proof. Start from selector-budget compatibility. Definition 560.103 routes the admitted selector request through the finite-window and $\mathsf{RegSeqRat}^{\uparrow}$ surface before any tail threshold is consumed.

Next use selector-budget absorption. Definition 560.107 identifies the absorbed TailMeet route as the displayed source schedules, source modulus rows, shared threshold, comparison row, transports, continuations, ledger, provenance, and local name.

Finally apply shared-threshold route determinacy. Definition 560.56 rules out a second threshold coordinate for the same transported source-window-modulus route, so the selector-budget consumer and the TailMeet packet read the same τ. □

Theorem 560.110 (RegularCauchyTailMeet budget-family row exhaustion)**.** *Let a finite family of downstream observation requests or* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *requests enter through an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. Then every family member factors through the TailMeet carrier and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *surface. No member contributes a row outside*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N.$$

In particular, the family cannot add a quotient stream, selected limit, host equality row, independent tail oracle, trichotomy coordinate, or ambient completeness witness.

Proof. First use budget-family cofinality. Definition 560.105 gives one stronger displayed threshold inside the same TailMeet route for all finite family members.

Observation requests factor through Definition 560.102. Selector-budget requests factor through Definition 560.109. Both routes therefore meet at the same shared threshold row and retain the same comparison, transport, continuation, package, and naming rows.

It remains to exclude extra family rows. Definition 560.7 exhausts the finite ledger surface, so the family has no coordinate from which to export quotient, selected-limit, host-equality, independent-tail, trichotomy, or completeness data. □

Theorem 560.111 (RegularCauchyTailMeet real-tail threshold ledger)**.** *Every* RealTailAgreementSeal$^{\uparrow}$ *read of an accepted* RegularCauchyTailMeet$^{\uparrow}$ *packet consumes exactly the TailMeet shared threshold ledger before the real-tail seal route is available. The consumed rows are*

$$R_0, R_1, W_0, W_1, M_0, M_1, \tau, Q, H, C, L, N,$$

with τ supplied by the public shared-threshold certificate and transported through the displayed hsame*,* Cont*,* Pkg*, and* NameCert *surface.*

Proof. Begin with the real-tail agreement consumer surface. Definition 560.104 lists exactly the TailMeet rows visible to the RealTailAgreementSeal$^{\uparrow}$ side and gives no separate threshold oracle.

Next apply diagonal seal-budget exactness. Definition 560.108 forces a real-facing seal-budget read through the displayed source schedules, source modulus rows, shared threshold, comparison, transports, continuations, ledger, provenance, and local name before the seal route is read.

Finally use the public shared-threshold certificate. Definition 560.11 identifies the real-tail threshold with the same public τ, so the agreement seal consumes exactly the TailMeet ledger and cannot introduce an additional real-tail threshold row. □

Closure status for NameCert$_{\text{RegularCauchyTailMeet}^{\uparrow}}$.

Constructive story: A RegularCauchyTailMeet$^{\uparrow}$ packet is generated from two RegularCauchyName$^{\uparrow}$ source rows, paired StreamName$^{\uparrow}$ schedules, source modulus rows, one shared DyadicRatCore$^{\uparrow}$ tail-threshold ledger, a paired comparison row, componentwise hsame transports, displayed Cont routes, finite ledger, package provenance, and local NameCert evidence.

Not claimed: This chapter does not close quotient streams, selected limits, trichotomy, host real equality, ambient completeness, or public bridge checking.

Upgrade path: No further formal-axis bridge step remains for this shared-tail packet.

Chapter 561

A Concrete Naming Certificate for $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$

The $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ interface records the finite selected-window route used when Real completeness arguments pass from a precision request to a visible diagonal observation and then to a $\mathsf{Real}^{\uparrow}$ seal. It sits over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert, and it exposes only the rows needed by the diagonal-window consumer.

This packet consumes the finite-window schedule of chapter 126, the regular-rational readback of chapter 301, the dyadic observation ledger of chapter 291, and the seal boundary of chapter 38 before exposing its diagonal-window coverage row.

Definition 561.1 (Real diagonal-window coverage carrier)**.** *A* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (q, w, r, d, e, h, c, p, n)$$

with the following visible coordinates:

1. *q is the rational precision request, read through the displayed* $\mathsf{Rat}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows;*
2. *w is the selected* $\mathsf{StreamName}^{\uparrow}$ *window that exposes the finite diagonal observation interval requested by q;*
3. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row naming the rational observation selected by w;*
4. *d is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger recording the endpoint, radius, comparison, and precision rows used by the readback;*
5. *e is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after q, w, r, d have been exposed;*
6. *h stores componentwise* hsame *transports for the precision request, selected window, readback row, dyadic ledger, seal row, provenance, and local name;*
7. *c stores the displayed* Cont *routes from q to w, from w to r, from r to d, and from d to the seal row e;*
8. *p is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
9. *n is the local* $\mathsf{NameCert}_{\mathsf{RealDiagonalWindowCoverage}^{\uparrow}}$ *row.*

The carrier contains no quotient stream, no host real equality, no unbounded diagonal stream, no ambient completeness theorem, and no selected limit outside the displayed seal row.

Lean4 ✓ `BEDC.Derived.RealDiagonalWindowCoverageUp.RealDiagonalWindowCoverageTasteGate single carrier alignment`

Definition 561.2 (Real diagonal-window coverage classifier)**.** *For accepted carriers*

$$G = (q, w, r, d, e, h, c, p, n) \quad \textit{and} \quad G' = (q', w', r', d', e', h', c', p', n'),$$

the classifier $\mathsf{RealDiagonalWindowCoverageClassifier}(G, G')$ *compares only the displayed precision request, selected* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger,* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row. It never compares host streams extensionally and never identifies completed reals by quotient equality.*

Theorem 561.3 (Real diagonal-window coverage NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RealDiagonalWindowCovera}}$ *surface for Definition 561.1 consists exactly of carrier admission for* G*, precision-request exposure through* q*, selected-window coverage through* w*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback through* r*, dyadic observation-ledger exactness through* d*,* $\mathsf{Real}^{\uparrow}$ *seal handoff through* e*, componentwise* hsame *transport through* h*, displayed* Cont *route replay through* c*,* Pkg *provenance through* p*, and local naming through* n*.*

Proof. Carrier admission is projection from the displayed packet G. The rows $q, w, r, d, e, h, c, p, n$ list the precision request, selected window, regular rational readback, dyadic observation ledger, real seal, transports, routes, package provenance, and local name.

The selected-window obligation is finite. A consumer reads q first, then uses w to inspect the requested diagonal interval, and then reads the rational observation through r and the dyadic ledger through d.

The remaining rows account for transport, route replay, provenance, and naming. Since no coordinate records quotient streams, host real equality, an unbounded diagonal stream, ambient completeness, or a selected external limit, the local NameCert obligation surface is exhausted by the displayed packet. □

Theorem 561.4 (Real diagonal-window coverage carrier admission)**.** *An accepted* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *packet exposes exactly the carrier rows*

$$q, w, r, d, e, h, c, p, n.$$

These rows are, respectively, the precision request, selected $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger,* $\mathsf{Real}^{\uparrow}$ *seal row, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row.*

Proof. Read Definition 561.1. Carrier admission is projection from the displayed tuple $G = (q, w, r, d, e, h, c, p, n)$.

Apply the NameCert obligations of Definition 561.3. They name each coordinate as part of the local certificate surface and provide no additional row beyond the displayed tuple.

The carrier definition excludes quotient streams, host real equality, unbounded diagonal streams, ambient completeness, and selected external limits, so the accepted packet exposes exactly the nine listed rows. □

Lean4 ✓ `BEDC.Derived.RealDiagonalWindowCoverageUp.RealDiagonalWindowCoverageCarrier carrier admission`

Theorem 561.5 (Real diagonal-window coverage induction)**.** *Every seal-facing consumer of an accepted* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *carrier* $G = (q, w, r, d, e, h, c, p, n)$ *is generated by finite induction along* q*, then* w*, then* r*, then* d*, then* e*, with* h, c, p, n *preserving the same displayed route.*

Proof. Use Definition 561.4 to expose the nine carrier rows. The base read is the precision request q, which has no access to a stream quotient, host real equality, selected limit, or completeness principle.

Induct over the finite selected-window observation ledger. A successor step either advances from the precision request q to the selected $\mathsf{StreamName}^{\uparrow}$ window w, from w to the $\mathsf{RegSeqRat}^{\uparrow}$ readback row r, from r to the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger d, or from d to the $\mathsf{Real}^{\uparrow}$ seal e.

The remaining rows h, c, p, n do not create a second consumer path. They transport, replay, record provenance, and name the same route, so no quotient stream, host real equality, unbounded diagonal stream, selected limit, or ambient completeness can appear. □

Theorem 561.6 (Real diagonal-window coverage classifier stability)**.** *For accepted* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *packets, classifier comparison is stable under componentwise* hsame *transport of the precision request, selected* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger,* $\mathsf{Real}^{\uparrow}$ *seal row, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row.*

Proof. Unfold the classifier in Definition 561.2. Its comparison fields are exactly the displayed precision request, window, readback, dyadic ledger, seal row, transports, routes, provenance, and local name.

Use the h coordinate of the carrier to transport each component. The same rows are the rows exposed by carrier admission, so no comparison field is lost or replaced during transport.

The RealUp handoff theorem keeps seal-facing comparisons on the displayed route through q, w, r, d, h, c, p, n. Hence classifier stability never appeals to host stream equality, quotient equality of completed reals, or an undisplayed completeness principle. □

Theorem 561.7 (Real diagonal-window coverage selected-window coverage)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing read of an accepted* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *packet reaches the seal row* e *only after the selected* $\mathsf{StreamName}^{\uparrow}$ *window* w *and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger* d *have been displayed.*

Proof. Start from the carrier definition. The $\mathsf{Real}^{\uparrow}$ seal row e is listed after the precision request q, selected window w, $\mathsf{RegSeqRat}^{\uparrow}$ readback r, and dyadic ledger d.

Apply Definition 561.3. The selected-window and dyadic observation-ledger obligations are part of the local certificate surface before any seal-facing consumer is exported.

Now use Definition 561.8. It routes every $\mathsf{Real}^{\uparrow}$ completion or continuous-map consumer through the displayed selected-window and dyadic-ledger rows before the seal row is read. □

Theorem 561.8 (Real diagonal-window coverage RealUp handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *completion or continuous-map consumer of an accepted* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *carrier receives the seal row* e *only through the displayed route*

$$q, w, r, d, h, c, p, n.$$

Thus the handoff consumes a rational precision request, a selected $\mathsf{StreamName}^{\uparrow}$ *window, a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, componentwise transport, route replay, package provenance, and local naming before the* $\mathsf{Real}^{\uparrow}$ *seal is read.*

Lean4 ✓ `BEDC.Derived.RealDiagonalWindowCoverageUp.RealDiagonalWindowCoverageCarrier realup handoff`

Proof. Start with the carrier row e. It is the only $\mathsf{Real}^{\uparrow}$ seal coordinate in the finite packet.

Apply the NameCert obligations. They force a seal-facing read to pass through the precision request q, the selected window w, the readback row r, and the dyadic ledger d before the seal is consumed.

The rows h and c replay the displayed transport and continuation data, while p and n provide provenance and local naming. Because the carrier lists no host equality, quotient equality, ambient completeness, or external limit coordinate, the real-facing handoff is exactly the displayed route. □

Theorem 561.9 (Real diagonal-window coverage non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *packet factors through the finite rows*

$$q, w, r, d, e, h, c, p, n.$$

The consumer may read the rational precision request, selected $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *source observation,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row, and it cannot read quotient streams, host real equality, unbounded diagonal streams, ambient completeness, or a choice-selected limit.*

Proof. Project the accepted carrier and the local NameCert surface. The rows $q, w, r, d, e, h, c, p, n$ are the complete displayed packet.

Use the classifier of Definition 561.2. It compares only those rows under the stored transport and route data, so a transported consumer remains on the same finite window-read route.

Use the RealUp handoff theorem for seal-facing consumers. It routes every completion or continuous-map read through q, w, r, d, h, c, p, n before e is consumed.

Since the carrier has no remaining coordinate beyond the displayed rows, no downstream consumer can extract quotient-stream data, host real equality, unbounded diagonal data, ambient completeness, or a choice-selected limit from the packet. □

Theorem 561.10 (Real diagonal-window tail-meet triangle handoff)**.** *Let* $G = (q, w, r, d, e, h, c, p, n)$ *be an accepted* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *packet. Suppose its selected window row* w *is supplied by an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold packet, and suppose its dyadic observation ledger* d *is supplied by an accepted* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *three-leg estimate. Then every* $\mathsf{Real}^{\uparrow}$ *seal-facing consumer of* G *factors through the finite route*

$$q \to w \to r \to d \to e$$

together with the tail-meet shared threshold, the triangle-bound tolerance ledger, componentwise hsame *rows, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}$ *rows of the three packets.*

The handoff exports no quotient stream, selected limit, host real equality, ambient completeness principle, or hidden tail oracle.

Proof. Begin with the RealUp handoff of Definition 561.8. It forces every seal-facing read of G through the displayed precision request, selected window, readback row, dyadic ledger, transport rows, continuation routes, provenance, and local name before e is consumed.

Next read the selected window through the shared tail packet. Apply Definition 560.9; its shared-threshold surface supplies the paired regular-Cauchy tails, source schedules, source modulus

rows, threshold ledger, comparison row, transports, continuations, provenance, and local tail-meet name.

Now read the dyadic observation ledger through the triangle-bound packet. Apply Definition 466.8 for the three-leg estimate and Definition 466.7 for its consumer boundary.

Composing the displayed Cont routes gives the route $q \to w \to r \to d \to e$. Each leg is already guarded by componentwise hsame, Pkg provenance, and a local NameCert row, and the cited non-escape boundaries leave no coordinate for quotient streams, selected limits, host real equality, ambient completeness, or a hidden tail oracle. □

Theorem 561.11 (Real diagonal-window coverage kernel scope)**.** *The carrier, classifier, local* $\mathsf{NameCert}_{\mathsf{RealDiagonalWindowCoverage}^{\uparrow}}$ *obligations, selected-window coverage,* $\mathsf{Real}^{\uparrow}$ *handoff, non-escape boundary, and tail-meet triangle handoff for an accepted* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *packet are all routed through exactly the displayed* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. No step in this kernel scope adds a quotient-stream coordinate, host real equality, unbounded diagonal stream, selected limit, or ambient completeness coordinate.*

Proof. Start from Definition 561.1 and Definition 561.2. They display the packet $G = (q, w, r, d, e, h, c, p, n)$ and restrict classifier comparison to the same precision request, selected window, readback row, dyadic ledger, seal row, transports, continuations, provenance, and local name.

Apply Definition 561.3 for the local certificate surface. The selected-window coverage theorem then forces every seal-facing read to display w and d before the $\mathsf{Real}^{\uparrow}$ row e is consumed.

Use Definition 561.8 and Definition 561.9. They keep completion and downstream consumers on the finite route through $q, w, r, d, e, h, c, p, n$ and exclude every undisplayed real or stream coordinate.

Finally, Definition 561.10 composes this route with the cited $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ and $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ packets. Those packets are consumed through their displayed threshold and estimate rows, so the full kernel dependency scope is precisely the listed BEDC rows. □

Theorem 561.12 (Real diagonal-window coverage selected-window source lock)**.** *For an accepted* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *packet* $G = (q, w, r, d, e, h, c, p, n)$*, the selected window* w *and dyadic ledger* d *determine the only source-lock route from the rational precision request* q *to the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* r *and the* $\mathsf{Real}^{\uparrow}$ *seal row* e*. The source lock has no quotient stream, host equality, unbounded diagonal stream, selected limit, or ambient completeness coordinate.*

Proof. Project the carrier in Definition 561.1. The route from q to r passes through the selected $\mathsf{StreamName}^{\uparrow}$ window w, and the route from r to e passes through the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger d.

Apply Definition 561.3 to identify the certificate rows that expose w, r, d, and e. Then apply Definition 561.7, which prevents a $\mathsf{Real}^{\uparrow}$-facing read from reaching e before the selected window and dyadic ledger have been displayed.

The handoff theorem Definition 561.8 supplies the same route for completion and continuous-map consumers. The non-escape theorem Definition 561.9 removes every other source coordinate, so w and d are the only source-lock route to r and e. □

Theorem 561.13 (Real diagonal-window coverage tail-meet triangle scope)**.** *The tail-meet and triangle-bound handoff cited by Definition 561.10 consumes only the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold packet, the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *estimate packet, and the local* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *route*

$$q, w, r, d, e, h, c, p, n.$$

It exports no extra source stream, no selected limit, no host equality, no ambient completeness row, and no hidden tail oracle.

Proof. Begin with Definition 561.10. Its hypotheses name exactly one accepted selected-window packet from $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ and one accepted dyadic-ledger packet from $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$.

The local $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ contribution is fixed by Definition 561.1 and Definition 561.3. These give only the rows $q, w, r, d, e, h, c, p, n$ and the corresponding local certificate surface.

The $\mathsf{Real}^{\uparrow}$ handoff and non-escape theorems keep the seal-facing consumer on the displayed route through those rows. Therefore the tail-meet and triangle-bound packets are consumed as threshold and estimate witnesses for w and d, not as a new stream, limit, host-equality, completeness, or tail-oracle coordinate. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealDiagonalWindowCoverage}^{\uparrow}}$.

Constructive story: A $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ packet is generated from a rational precision request, a selected $\mathsf{StreamName}^{\uparrow}$ window, a $\mathsf{RegSeqRat}^{\uparrow}$ readback row, a $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, a $\mathsf{Real}^{\uparrow}$ seal row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RealDiagonalWindowCoverage}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 561.1, Definition 561.2, Definition 561.3, Definition 561.7, Definition 561.8, Definition 561.9, Definition 561.10, Definition 561.11, Definition 561.12, and Definition 561.13 bind the finite selected-window route from precision request through $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ readback to $\mathsf{DyadicRatCore}^{\uparrow}$ observations, the $\mathsf{Real}^{\uparrow}$ seal, the selected-window source lock, and the tail-meet triangle scope for downstream consumers.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RealDiagonalWindowCoverage}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.RealDiagonalWindowCoverageUp.RealDiagonalWindowCoverageCarrier\_realup\_handoff`

Bridge status: none

Origin: human

Not claimed: This chapter does not close RealUp completeness, uniqueness of completed limits, quotient equality of streams, host real equality, continuous-map theorems, Lean verification, or bridge checking.

Upgrade path: Bridge checking requires a checked standard bridge for the selected-window $\mathsf{Real}^{\uparrow}$ seal handoff.

Chapter 562

A Concrete Naming Certificate for $\mathsf{TypedReductionNormalForm}^{\uparrow}$

The $\mathsf{TypedReductionNormalForm}^{\uparrow}$ surface binds typed reduction to the terminal normal-form boundary as finite BEDC data. It refines the type-checking packet by recording the source membership, the visible reduction route, the target membership, and the normal-form row in one local $\mathsf{NameCert}$ object, so consumers can use the endpoint without importing host conversion or a normalization oracle.

Definition 562.1 (Typed reduction normal-form packet)**.** *A* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *packet is a finite* BHist *carrier*

$$Q = (T, J, E, R, F, H, C, P, N)$$

with the following displayed rows:

1. *T is the displayed term row containing the source window, the target window, and the terminal normal-form window;*
2. *J is the finite judgment ledger for the typing assumptions, source judgment, target judgment, and terminal judgment consumed by the packet;*
3. *E is the* Ext *membership row that records the accepted source membership and the target membership read exposed by subject reduction;*
4. *R is the* Cont *reduction route from the source term row to the terminal target row, with every intermediate step named by the packet;*
5. *F is the normal-form boundary row, stating that the terminal target has no further packet-visible typed reduction route;*
6. *H records the componentwise* hsame *transports for term rows, judgment rows, membership rows, reduction routes, normal-form rows, package rows, and local certificate rows;*
7. *C records the continuation reads for source membership, typed reduction, target membership, normal-form boundary access, and replay of the terminal packet;*
8. *P is the* Pkg *provenance over* BHist, Ext, Cont, hsame, *the judgment ledger, the normal-form boundary, and the surrounding* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{TypedReductionNormalForm}^{\uparrow}}$ *row.*

The carrier has no coordinate for host conversion, semantic equality of terms, a global normalization theorem, an erased typing derivation, or a normalization oracle.

Lean4 (definition) `BEDC.Derived.TypedReductionNormalFormUp.TypedReductionNormalFormPacket`

Theorem 562.2 (TypedReductionNormalForm NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{TypedReductionNormalForm}^{\uparrow}}$ *surface for Definition 562.1 consists of five obligations:*

1. *carrier exposure for the finite packet* $Q = (T, J, E, R, F, H, C, P, N)$*;*
2. *reduction-route exactness, saying that every typed reduction read is the displayed route* R *and its named intermediate* Cont *rows;*
3. *subject-reduction seal, saying that the target membership reached after the typed reduction is read only through* E*,* R*,* H*,* C*,* P*, and* N*;*
4. *normal-form boundary, saying that the terminal target is accepted only at the boundary row* F *and no further typed reduction route can be consumed unless it is a displayed packet row;*
5. *non-escape from host conversion, semantic equality of terms, global normalization, erased derivation semantics, or any normalization oracle not named by the packet.*

Lean4 ✓ `BEDC.Derived.TypedReductionNormalFormUp.TypedReductionNormalFormPacket namecert obligations`

Proof. Carrier exposure is the packet inventory of Definition 562.1. The rows name the term windows, judgment ledger, membership row, reduction route, normal-form boundary, transports, continuation reads, package provenance, and local certificate.

Reduction-route exactness follows by projecting R and C. A consumer can replay the typed route only through the named Cont rows, while H supplies the permitted componentwise transports.

The subject-reduction seal uses the same rows. The source membership is read from E, the route is read from R, and the target membership is the membership coordinate exposed by the local certificate after the displayed transport and package provenance have been checked.

The normal-form boundary is the row F. Since no coordinate names a host conversion relation, semantic equality, erased derivation, global normalization theorem, or normalization oracle, the terminal boundary cannot be replaced by data outside Q. □

Theorem 562.3 (TypedReductionNormalForm subject-reduction seal)**.** *Let* $Q = (T, J, E, R, F, H, C, P, N)$ *be an accepted* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *packet. Every public target-membership read after a typed reduction reaches the normal-form boundary only through the displayed* Ext *row* E*, the* Cont *route* R*, the componentwise* hsame *transports* H*, the continuation reads* C*, the* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{TypedReductionNormalForm}^{\uparrow}}$ *row* N*. The read does not use host conversion, semantic equality of terms, a global normalization theorem, or a normalization oracle.*

Lean4 ✓ `BEDC.Derived.TypedReductionNormalFormUp.TypedReductionNormalFormPacket subject reduction seal`

Proof. Project the accepted packet. The source and target term windows are in T, the judgment context is in J, the membership data are in E, and the typed reduction route is in R.

Replay the route through C and transport the visible rows through H. The package row P records the dependencies on BHist, Ext, Cont, hsame, the ledger, the boundary row, and the local certificate, so the target membership read is still the displayed BEDC packet.

Finally read the terminal boundary from F and authenticate it through N. The carrier inventory has no row for host conversion, semantic equality, global normalization, erased derivation semantics, or a normalization oracle, so none of those objects can participate in the public read. □

Theorem 562.4 (TypedReductionNormalForm route exactness)**.** *Let $Q = (T, J, E, R, F, H, C, P, N)$ be an accepted* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *packet. Every packet-visible typed reduction read is the displayed route R together with the named continuation reads in C. The read may use the term row T, judgment ledger J, membership row E, componentwise transports H, provenance row P, and local naming row N, but it has no route through host conversion, semantic equality of terms, erased derivation semantics, a global normalization theorem, or a normalization oracle.*

Proof. Project the packet using Definition 562.1. The only row that stores typed reduction is R, and the only row that replays it for consumers is C.

Apply the NameCert obligation surface of Definition 562.2. It names reduction-route exactness as a local obligation and binds every intermediate step to the displayed Cont rows.

The subject-reduction seal of Definition 562.3 keeps target membership reads on the same route. Since the carrier contains no host conversion, semantic equality, erased derivation, global normalization, or oracle coordinate, the displayed route is exact. □

Lean4 ✓ `BEDC.Derived.TypedReductionNormalFormUp.TypedReductionNormalFormPacket route exactness`

Theorem 562.5 (TypedReductionNormalForm terminal-boundary non-escape)**.** *For an accepted* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *packet $Q = (T, J, E, R, F, H, C, P, N)$, every normal-form access is bound to the terminal boundary row F. A consumer may authenticate the boundary through H, C, P, N and may read the surrounding typed route through T, J, E, R, but it cannot replace F by host conversion, semantic equality of terms, erased derivation semantics, a global normalization theorem, or a normalization oracle.*

Proof. Begin with the carrier inventory. The terminal normal-form boundary is represented by the row F, while the source, target, judgment, membership, and route data are represented by T, J, E, R.

Use the NameCert obligations to expose the boundary row. They state that terminal access is accepted only at F and that further typed-reduction consumption must be a displayed packet row.

Finally combine this with the subject-reduction seal. Target membership arrives through E and R, then the terminal boundary is read from F and authenticated through H, C, P, N; no hidden conversion, semantic equality, erased derivation, global normalization, or oracle row is available. □

Lean4 ✓ `BEDC.Derived.TypedReductionNormalFormUp.TypedReductionNormalFormPacket terminal boundary nonescape`

Theorem 562.6 (TypedReductionNormalForm transport stability)**.** *Accepted* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *packets preserve their finite route and terminal-boundary surface under the componentwise transports H and continuation reads C. If the rows T, J, E, R, F, P, N are transported componentwise, then the source membership, typed reduction route, target membership, and normal-form boundary remain the same packet surface over $Q = (T, J, E, R, F, H, C, P, N)$.*

Proof. Read the transport rows from the packet definition. The row H records componentwise hsame transports for terms, judgments, memberships, reduction routes, normal-form boundaries, package rows, and certificate rows, while C records the corresponding continuation reads.

Apply the NameCert obligations. Carrier exposure, route exactness, the subject-reduction seal, and the normal-form boundary all refer to the same displayed rows, so transporting one component cannot introduce a new route or boundary object.

The subject-reduction seal then repacks the transported source membership, typed reduction route, target membership, and terminal boundary through E, R, F, H, C, P, N. Thus transport stability preserves exactly the finite packet surface and excludes host conversion, semantic equality, global normalization, erased derivation semantics, and normalization oracles. □

Lean4 ✓ `BEDC.Derived.TypedReductionNormalFormUp.TypedReductionNormalFormPacket transport stability`

Theorem 562.7 (TypedReductionNormalForm terminal readback bridge)**.** *The checked transport-stable* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *packet bridges the public terminal normal-form boundary to the standard readback surface only through the displayed rows* $T, J, E, R, F, H, C, P, N$*. The bridge reads source membership, the finite typed-reduction route, target membership, terminal normal-form boundary, componentwise transports, continuation replay, provenance, and the local* NameCert *row. It excludes host conversion, semantic equality of terms, erased derivation semantics, normalization oracles, and any host normalization procedure outside the packet.*

Proof. Start with the transport-stable packet of Definition 562.6. It preserves the same finite surface $Q = (T, J, E, R, F, H, C, P, N)$ under componentwise transports and continuation reads.

The terminal readback surface is reached by reading F after the route R and membership row E have been replayed through C and transported through H. The judgment ledger J, provenance row P, and local naming row N keep that read inside the displayed packet.

Because the carrier has no coordinate for host conversion, semantic equality, erased derivation semantics, global normalization, or a normalization oracle, the bridge cannot use any of those routes. It is therefore exactly the public terminal boundary read through $T, J, E, R, F, H, C, P, N$. □

Closure status for $\mathsf{NameCert}_{\mathsf{TypedReductionNormalForm}^{\uparrow}}$.

Constructive story: A $\mathsf{TypedReductionNormalForm}^{\uparrow}$ packet is generated from a term-window row, a finite typing-judgment ledger, source and target membership rows, a displayed typed-reduction route, a terminal normal-form boundary, componentwise transports, continuation reads, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{TypedReductionNormalForm}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 562.1, Definition 562.2, Definition 562.3, Definition 562.4, Definition 562.5, Definition 562.6, and Definition 562.7 bind the BHist, Ext, Cont, hsame, Pkg, and NameCert scope for the typed route, source membership, target membership, terminal normal-form boundary, and standard readback bridge, with chapter 683 as the representative downstream consumer of the finite terminal readback bridge.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{TypedReductionNormalForm}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.TypedReductionNormalFormUp.TypedReductionNormalFormPacket\_transport\_stability`

Bridge status: none

Origin: human

Not claimed: This chapter does not close host conversion, semantic equality of terms, global normalization, erased derivation semantics, normalization oracles, or bridge checking.

Upgrade path: No further theory-axis upgrade remains; bridge checking is governed only by the verification axis.

Chapter 563

A Concrete Naming Certificate for $\mathsf{TasteGateCompilerWitness}^{\uparrow}$

The $\mathsf{TasteGateCompilerWitness}^{\uparrow}$ packet is the finite compiler-facing NameCert surface for a chapter-level taste gate. It records the candidate chapter token, the ChapterTasteGate row, the displayed event-flow conservativity row, the no-hidden-input, round-trip, and layer-separation rows, the dependency ledger, the audit result row, transport and replay routes, package provenance, and local naming data in one visible certificate.

The $\mathsf{TasteGateCompilerWitness}^{\uparrow}$ packet consumes the candidate-admission packet of chapter 545 and the endpoint and route packaging discipline of chapter 473. The witness is narrower than either sibling: it certifies only the displayed compiler-facing TasteGate evidence row and audit-result route, not arbitrary admission or compiler correctness.

Definition 563.1 (TasteGateCompilerWitness carrier)**.** *A* $\mathsf{TasteGateCompilerWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (X, T, E, N, R, L, D, A, H, C, P, Z)$$

with the following displayed rows:

1. *X is the candidate chapter token, recording the chapter label, declared carrier name, and paper site whose taste-gate status is being certified;*
2. *T is the* ChapterTasteGate *row, exposing the four chapter-level obligations used by the admission check;*
3. *E is the event-flow conservativity row, recording the finite* GroundCompiler *event-flow image through which the candidate text and generated declaration surface are read;*
4. *N is the no-hidden-input row, stating that every accepted input channel for the candidate is named in the event-flow image and dependency ledger;*
5. *R is the round-trip row, recording that the displayed compiler witness can be replayed from the named source tokens to the named certificate rows;*
6. *L is the layer-separation row, keeping paper prose, compiler events, Lean declarations, and package provenance in their displayed layers;*
7. *D is the dependency ledger, listing the local BEDC rows, ground-compiler theorem references, candidate NameCert rows, and refusal-side gaps used by the witness;*
8. *A is the audit result row, recording acceptance or refusal of the witness surface against T, E, N, R, L, D;*

9. *H stores componentwise* hsame *transports for $X, T, E, N, R, L, D, A, C, P, Z$;*
10. *C records the displayed* Cont *routes by which a reader accesses the taste-gate rows, compiler witness rows, dependency ledger, and audit result;*
11. *P is the* Pkg *provenance over* BHist, NameCert, ChapterTasteGate, GroundCompiler, *compiler event-flow rows, dependency ledgers, audit results,* hsame, Cont, *and local naming;*
12. *Z is the local* $\mathsf{NameCert}_{\mathsf{TasteGateCompilerWitness}^{\uparrow}}$ *row.*

The carrier has no coordinate for hidden prompt state, oracle taste, unlisted compiler facts, host-side chapter approval, or a dependency outside D.

Lean4 (definition) `BEDC.Derived.TasteGateCompilerWitnessUp.TasteGateCompilerWitnessUp`
Lean4 ✓ `BEDC.Derived.TasteGateCompilerWitnessUp.TasteGateCompilerWitnessTasteGate single carrier alignment`

Theorem 563.2 (TasteGateCompilerWitness NameCert obligations)**.** *For every accepted* TasteGateCompilerWitnes *carrier*

$$W = (X, T, E, N, R, L, D, A, H, C, P, Z),$$

the local $\mathsf{NameCert}_{\mathsf{TasteGateCompilerWitness}^{\uparrow}}$ *surface consists exactly of carrier exposure for W, candidate-token exposure through X,* ChapterTasteGate *exposure through T, compiler event-flow exposure through E, no-hidden-input exposure through N, round-trip exposure through R, layer-separation exposure through L, dependency-ledger exposure through D, audit-result exposure through A, componentwise transport through H, replay routes through C, package provenance through P, and local naming through Z.*

Proof. Carrier exposure is projection from Definition 563.1. The tuple lists every row available to a reader of the compiler witness.

The candidate and taste-gate obligations are X and T. They identify the chapter token and expose the chapter-level conservativity, no-hidden-input, round-trip, and layer-separation obligations without importing an unnamed chapter object.

The compiler-facing obligations are E, N, R, L, D, A. These rows record the displayed event-flow image, the input-channel boundary, replay route, layer boundary, dependency ledger, and audit result as finite data.

The structural obligations are H, C, P, Z. Transport, continuation, provenance, and local naming preserve the same witness surface and add no hidden approval channel. Hence the listed rows exhaust the local NameCert surface. □

Theorem 563.3 (TasteGateCompilerWitness ground compiler route)**.** *Every accepted* $\mathsf{TasteGateCompilerWitness}^{\uparrow}$ *packet reads the* ChapterTasteGate *row only through the ground-compiler route*

$$X \longmapsto E \longmapsto (N, R, L) \longmapsto D \longmapsto A.$$

Thus conservativity, no-hidden-input, round-trip, and layer-separation claims are accepted only when the displayed event-flow row, compiler replay row, dependency ledger, and audit result row are all present in the same packet.

Proof. Begin with the carrier of Definition 563.1. The only candidate token is X, and the only taste-gate row is T.

The event-flow row E is the compiler-facing entrance to the witness. A reader cannot inspect T as an ambient judgment; the route to the obligations passes through the displayed compiler image.

The rows N, R, L split the compiler evidence into input-channel, replay, and layer-separation checks. The dependency ledger D then records the named BEDC rows and ground-compiler theorem references used by those checks.

Finally A records the audit result for the same rows. Since transport and replay are componentwise through H and C, the accepted route cannot replace the displayed compiler evidence with an unlisted theorem or host-side approval. □

Theorem 563.4 (TasteGateCompilerWitness non-escape)**.** *Every exported read of an accepted* $\mathsf{TasteGateCompilerWitness}^{\uparrow}$ *packet factors through*

$$(X, T, E, N, R, L, D, A, H, C, P, Z).$$

The read may export the candidate chapter token, $\mathsf{ChapterTasteGate}$ *obligations, ground-compiler event-flow evidence, no-hidden-input row, round-trip row, layer-separation row, dependency ledger, audit result, transport routes, package provenance, and local NameCert. It cannot export hidden prompt state, oracle taste, unlisted compiler facts, selected host semantics, or a dependency not named by* D*.*

Proof. Project the exported read through the accepted carrier. The tuple gives exactly the rows $X, T, E, N, R, L, D, A, H, C, P, Z$.

Use Definition 563.2 to account for the local naming surface, candidate token, taste-gate row, compiler evidence, ledger, audit result, transport, continuation, and provenance.

Use Definition 563.3 for the route from the candidate token to the audit result. Every compiler-facing claim is tied to the displayed event-flow and dependency rows.

The carrier has no coordinate for hidden prompt state, oracle taste, unlisted compiler facts, selected host semantics, or a dependency outside D. No exported read can therefore supply one. □

Theorem 563.5 (TasteGateCompilerWitness public package)**.** *The public package exported by an accepted* $\mathsf{TasteGateCompilerWitness}^{\uparrow}$ *carrier is the finite surface*

$$\mathsf{Pub}(W) = (X, T, E, N, R, L, D, A, H, C, P, Z).$$

It is a concrete NameCert packet tying $\mathsf{ChapterTasteGate}$ *obligations to ground-compiler witness rows, dependency-ledger rows, and audit-result rows. Any AI-origin chapter promotion that cites this package obtains only that finite witness surface and no external admission principle.*

Proof. Start with the carrier and NameCert obligations. They provide the exact public row list and identify the local certificate surface as finite BHist data.

Apply Definition 563.3. This binds the taste-gate obligations to the compiler event-flow row, replay row, layer-separation row, dependency ledger, and audit result.

Apply Definition 563.4. The exported package cannot exceed the displayed rows, so it cannot become an external admission principle or host-side taste judgment.

Thus $\mathsf{Pub}(W)$ is precisely the concrete compiler-witness NameCert packet available to downstream chapter-promotion checks. □

Theorem 563.6 (TasteGateCompilerWitness mature downstream package)**.** *For every accepted* $\mathsf{TasteGateCompilerWitness}^{\uparrow}$ *carrier*

$$W = (X, T, E, N, R, L, D, A, H, C, P, Z),$$

every downstream AI-origin promotion, conservativity-audit consumer, or compiler-witness audit consumer of the accepted packet factors through

$$\mathsf{Pub}(W) = (X, T, E, N, R, L, D, A, H, C, P, Z).$$

The consumer receives the displayed candidate token, ChapterTasteGate *row, ground-compiler event-flow row, no-hidden-input row, round-trip row, layer-separation row, dependency ledger, audit result, componentwise transports, replay routes, package provenance, and local NameCert, and receives no hidden prompt state, oracle taste, unlisted compiler fact, host-side approval, or dependency outside D.*

Proof. Start with the carrier definition. The accepted packet has exactly the rows $X, T, E, N, R, L, D, A, H, C, P, Z$, with no carrier coordinate for hidden prompt state, oracle taste, unlisted compiler facts, host-side approval, or dependencies outside D.

Use Definition 563.2 to identify the local NameCert obligations exposed by those rows. The downstream consumer can name the candidate token, taste-gate row, compiler evidence, ledger, audit result, transports, replay routes, provenance, and local certificate only through that displayed surface.

Use Definition 563.3 to force every taste-gate and compiler-witness read through the ground-compiler event-flow, replay, layer-separation, dependency-ledger, and audit-result rows. This prevents the consumer from replacing the public route with an unlisted compiler fact or host-side approval.

Finally apply Definition 563.4 and Definition 563.5. The exported package is precisely $\mathsf{Pub}(W)$, so the downstream promotion or audit consumer factors through the same public package and obtains no additional state. □

Closure status for $\mathsf{NameCert}_{\mathsf{TasteGateCompilerWitness}^{\uparrow}}$.

Constructive story: A $\mathsf{TasteGateCompilerWitness}^{\uparrow}$ packet is generated from a candidate chapter token, ChapterTasteGate row, compiler event-flow row, no-hidden-input row, round-trip row, layer-separation row, dependency ledger, audit result row, componentwise transports, displayed continuations, package provenance, and local NameCert row.

Upgrade path: No further paper-axis theory step remains for this packet; verification-axis bridge checking is a separate closure task.

Chapter 564

A Concrete Naming Certificate for TasteGateStability$^{\uparrow}$

The TasteGateStability$^{\uparrow}$ packet turns the TasteGate discipline of chapter 9459 into a finite NameCert carrier. It records the proposed chapter site, displayed carrier surface, ChapterTasteGate obligations, ground-compiler witness rows, admission ledger, componentwise transports, replay routes, package provenance, and the local boundary that prevents a TasteGate pass from becoming hidden semantic approval.

The stability packet consumes the candidate-admission surface of chapter 545 and the compiler-witness route of chapter 563: admission supplies the candidate row being tested, while the compiler witness supplies the ground-compiler evidence read by W and replayed through C.

Definition 564.1 (TasteGateStability carrier)**.** *A* TasteGateStability$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (X, K, T, W, A, H, C, P, N)$$

with the following displayed rows:

1. *X is the candidate chapter identity row, recording the chapter label, origin row, and concrete-instance site;*
2. *K is the candidate NameCert carrier row, exposing the finite source, classifier, pattern, ledger, and non-escape surface proposed by the chapter;*
3. *T is the* ChapterTasteGate *row, displaying conservativity, no-hidden-input, round-trip, and layer-separation obligations for the same candidate;*
4. *W is the ground-compiler witness row, listing the finite event-flow image and named compiler facts used to read the no-hidden-input, round-trip, and source-channel separation gates;*
5. *A is the admission ledger, recording accepted and refused TasteGate reads for the displayed candidate surface;*
6. *H stores componentwise* hsame *transports for X, K, T, W, A, C, P, N;*
7. *C records the displayed* Cont *routes that replay the candidate carrier, TasteGate row, ground-compiler witnesses, and admission ledger;*
8. *P is the* Pkg *provenance over* BHist*,* NameCert*,* ChapterTasteGate*, ground-compiler witnesses, admission ledgers,* hsame*,* Cont*, and local naming;*

9. N is the local $\mathsf{NameCert}_{\mathsf{TasteGateStability}^{\uparrow}}$ *row.*
The packet contains no hidden prompt state, no host-side theory approval, no oracle classifier, no unlisted compiler theorem, and no global horizon admission rule outside the displayed rows.

Lean4 (definition) `BEDC.Derived.TasteGateStabilityUp.TasteGateStabilityUp`
Lean4 ✓ `BEDC.Derived.TasteGateStabilityUp.TasteGateStabilityTasteGate single carrier alignment`

Theorem 564.2 (TasteGateStability NameCert obligations)**.** *For every accepted* $\mathsf{TasteGateStability}^{\uparrow}$ *carrier*

$$S = (X, K, T, W, A, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{TasteGateStability}^{\uparrow}}$ *surface consists exactly of carrier admission for S, candidate identity through X, candidate NameCert exposure through K,* $\mathsf{ChapterTasteGate}$ *exposure through T, ground-compiler witness exposure through W, admission-ledger accounting through A, componentwise transport through H, replay routes through C, package provenance through P, and the local naming row N.*

Proof. Carrier admission is projection from Definition 564.1. The packet exposes exactly the candidate identity, candidate carrier, TasteGate obligations, ground-compiler witness rows, admission ledger, transport rows, replay routes, provenance, and local naming row.

The internal NameCert surface is the row K. It is read as a displayed candidate carrier, classifier, pattern, ledger, and non-escape surface, not as an ambient guarantee that the candidate has already joined the horizon.

The TasteGate surface is the row T, while the compiler-facing evidence is the row W. These rows keep chapter-level stability claims tied to the finite compiler witnesses that display no-hidden-input, round-trip, and layer-separation checks.

Finally A, H, C, P, N account for accepted and refused reads, transport the same rows, replay them for consumers, record provenance, and name the packet locally. No other NameCert obligation is exposed by the carrier. □

Theorem 564.3 (TasteGateStability ground-compiler witness route)**.** *Every accepted* $\mathsf{TasteGateStability}^{\uparrow}$ *route that reads the* $\mathsf{ChapterTasteGate}$ *row T must pass through the ground-compiler witness row W and the replay routes in C. The route may report the displayed no-hidden-input, round-trip, and layer-separation gates for the candidate, but it cannot cite an unlisted compiler theorem or an external semantic judgment.*

Proof. Project the carrier of Definition 564.1. The only row that carries chapter-level TasteGate obligations is T, and the only row that records compiler evidence for those obligations is W.

The replay routes in C bind the read of T to the displayed witness row W. Thus a consumer cannot detach a no-hidden-input, round-trip, or layer-separation claim from the finite event-flow image and named compiler facts that support it.

Since the carrier has no coordinate for an unlisted compiler theorem or external semantic judgment, every accepted TasteGate route remains inside the displayed witness rows. □

Theorem 564.4 (TasteGateStability non-escape boundary)**.** *No consumer of an accepted* $\mathsf{TasteGateStability}^{\uparrow}$ *packet can extract hidden prompt state, host-side theory approval, an oracle classifier, an unlisted compiler theorem, or a global horizon admission rule. Every consumer read factors through*

$$(X, K, T, W, A, H, C, P, N).$$

Proof. Inspect the carrier inventory. Its coordinates are the candidate identity row, candidate NameCert carrier row, TasteGate row, ground-compiler witness row, admission ledger, transport rows, replay routes, package provenance, and local naming row.

The transport and continuation rows preserve exactly those coordinates. They can replay a displayed candidate surface and its TasteGate evidence, but they do not introduce host approval, hidden prompt state, oracle classification, or an additional compiler fact.

Therefore the forbidden objects have no projection target in the packet. Any consumer read seeking one of them has to leave the displayed rows, so it is not a read of the accepted $\mathsf{TasteGateStability}^{\uparrow}$ carrier. □

Theorem 564.5 (TasteGateStability carrier field obligation)**.** *Every accepted* $\mathsf{TasteGateStability}^{\uparrow}$ *packet exposes candidate identity, candidate* NameCert *carrier,* ChapterTasteGate *row, ground-compiler witness row, admission ledger, componentwise transports, replay routes, package provenance, and local naming as fields of the same finite carrier*

$$S = (X, K, T, W, A, H, C, P, N).$$

The TasteGate carrier-alignment marker applies to this single carrier surface; it does not authorize a separate prompt state, host-side approval channel, oracle classifier, unlisted compiler theorem, or global horizon-admission row.

Proof. Project the carrier of Definition 564.1. Its coordinates are exactly $X, K, T, W, A, H, C, P, N$, with X carrying candidate identity, K carrying the candidate NameCert surface, T carrying ChapterTasteGate, W carrying ground-compiler witnesses, A carrying the admission ledger, and H, C, P, N carrying transport, replay, provenance, and naming.

Apply Definition 564.2. The local NameCert surface reads those coordinates as one accepted packet rather than as independent chapter-side records.

The ground-compiler witness route of Definition 564.3 binds the TasteGate row T to the witness row W and the replay routes C. The checked TasteGate carrier-alignment marker records the same single-carrier alignment for the displayed surface.

Finally use Definition 564.4. Since the carrier has no coordinate for hidden prompt state, host approval, oracle classification, unlisted compiler facts, or global horizon admission, the listed fields are the full carrier-field obligation surface. □

Theorem 564.6 (TasteGateStability admission ledger obligation)**.** *For every accepted* $\mathsf{TasteGateStability}^{\uparrow}$ *packet* $S = (X, K, T, W, A, H, C, P, N)$*, the admission ledger row* A *records accepted and refused* ChapterTasteGate *reads for the displayed candidate surface. The ledger is read through the same carrier, witness, transport, replay, provenance, and naming rows, and it never becomes host-side theory approval, semantic certification of the candidate chapter, bridge checking, or global horizon admission.*

Proof. Begin with the carrier definition. The row A is one field of the accepted packet, and its role is admission-ledger accounting for the same candidate identity X, candidate carrier K, TasteGate row T, and compiler witness row W.

Apply Definition 564.2. It includes admission-ledger accounting through A in the local NameCert surface, together with the transports H, replay routes C, provenance P, and local naming row N.

Next use Definition 564.3. Accepted or refused reads of T are tied to the ground-compiler witness row W and to the displayed replay routes, so the ledger records TasteGate access to that finite evidence rather than a host semantic judgment.

The checked TasteGate carrier-alignment marker and Definition 564.4 close the boundary. The marker aligns TasteGate with the same finite carrier, and the non-escape theorem blocks host approval, hidden prompt state, oracle classifiers, unlisted compiler theorems, and global horizon admission from entering through A. □

Theorem 564.7 (TasteGateStability scoped dependency boundary)**.** *Every accepted read of a* $\mathsf{TasteGateStability}^{\uparrow}$ *packet*

$$S = (X, K, T, W, A, H, C, P, N)$$

is scoped by the displayed BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* ChapterTasteGate*, and ground-compiler witness rows. The read cannot be replaced by host approval, hidden prompt state, oracle classification, or unlisted compiler facts.*

Proof. First project the packet through Definition 564.2. The local certificate reads candidate identity, candidate carrier, TasteGate exposure, ground-compiler witnesses, admission ledger, transport, replay, provenance, and naming through the displayed carrier.

Next use Definition 564.3. It binds the TasteGate row T to the witness row W and the replay routes C, so compiler-facing evidence is finite packet data rather than an ambient semantic judgment.

Apply Definition 564.4, Definition 564.5, and Definition 564.6. These rows keep the carrier fields and ledger reads inside S and exclude host approval, hidden prompt state, oracle classification, unlisted compiler facts, bridge checking, and global horizon admission. □

Closure status for $\mathsf{NameCert}_{\mathsf{TasteGateStability}^{\uparrow}}$**.**

Upgrade path: No paper-side closure upgrade remains; bridge checking remains the formal bridge-axis task.

Chapter 565

A Concrete Naming Certificate for $\mathsf{GeneratorInductionBoundary}^{\uparrow}$

The $\mathsf{GeneratorInductionBoundary}^{\uparrow}$ packet is the concrete NameCert surface for separating authorized generator-internal induction from free-floating induction. It packages the generator signature, closure witness, continuation route, GAP socket, transport row, package provenance, and local naming row into one finite carrier, so that every induction read remains attached to the generator that licenses it.

Definition 565.1 (GeneratorInductionBoundary carrier)**.** *A* $\mathsf{GeneratorInductionBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (S, W, C, G, H, P, N)$$

with the following displayed rows:

1. *S is the authorized generator signature row, recording the generator name, its closed constructor list, and the local induction pattern licensed by that constructor list;*
2. *W is the closure witness row, recording that the displayed induction step ranges only over the closure generated by S;*
3. *C is the continuation route row, recording the* Cont *paths by which a consumer may replay the generator-internal induction step and transport its conclusion to later finite histories;*
4. *G is the GAP socket row, recording attempted reads that would move from the generator closure to a free-floating universal induction principle;*
5. *H stores componentwise* hsame *transport for S, W, C, G, P, N;*
6. *P is the* Pkg *provenance over* BHist*, authorized generator signatures, closure witnesses, continuation routes, GAP sockets,* hsame*, and local naming;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{GeneratorInductionBoundary}^{\uparrow}}$ *row.*

The carrier has no coordinate for a universal induction rule, an unbounded object domain, a hidden host-CIC evaluator, an oracle continuation, or an induction conclusion detached from the authorized generator signature.

Theorem 565.2 (GeneratorInductionBoundary NameCert obligations)**.** *For every accepted* $\mathsf{GeneratorInductionBou}$ *carrier*

$$B = (S, W, C, G, H, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{GeneratorInductionBoundary}^{\uparrow}}$ *surface consists exactly of carrier admission for* B*, authorized generator exposure through* S*, closure-witness exposure through* W*, continuation routing through* C*, GAP socket accounting through* G*, componentwise transport through* H*, package provenance through* P*, and local naming through* N*.*

Proof. Carrier admission is projection from Definition 565.1. The packet displays the authorized generator signature, closure witness, continuation route, GAP socket, transport, provenance, and naming rows as finite coordinates.

The generator and closure obligations are the rows S and W. They identify the constructor list being used and bind the induction read to the closure generated by that list.

The continuation obligation is the row C. Every replay of the induction step must pass through the displayed route, so the consumer receives a generator-internal conclusion rather than a detached induction rule.

Finally G, H, P, N preserve the same boundary object under socket accounting, transport, provenance, and naming. Since the carrier contains no coordinate for universal induction or hidden host evaluation, the local $\mathsf{NameCert}_{\mathsf{GeneratorInductionBoundary}^{\uparrow}}$ surface is exactly the displayed finite packet. □

Theorem 565.3 (GeneratorInductionBoundary GAP non-escape)**.** *Every accepted* $\mathsf{GeneratorInductionBoundary}^{\uparrow}$ *continuation route factors through the finite rows*

$$(S, W, C, G, H, P, N).$$

The route may export that an induction step is authorized inside the generator named by S*, carried by the closure witness* W*, replayed through* C*, transported by* H*, packaged by* P*, named by* N*, and separated from free-floating induction by the GAP socket* G*. It cannot export a universal induction principle, a conclusion over an unbounded object domain, or a host-CIC delegation that has no displayed row in the packet.*

Proof. Project the route through the carrier. The only available coordinates are S, W, C, G, H, P, N.

Use Definition 565.2 to account for the authorized generator signature, closure witness, continuation route, GAP socket, transport, provenance, and local naming rows.

The row G records attempted movement from generator-internal induction to a free-floating induction rule. Because such movement is represented only as a socket row and not as an exported conclusion, it cannot become a new induction coordinate.

Thus any exported route remains inside the displayed generator boundary. A universal induction principle, an unbounded object domain, or an unrecorded host-CIC delegation would require an extra row outside B, and the carrier has no such row. □

Theorem 565.4 (GeneratorInductionBoundary generator closure dependency)**.** *For every accepted* $\mathsf{GeneratorInductionBoundary}^{\uparrow}$ *carrier*

$$B = (S, W, C, G, H, P, N),$$

the authorized generator signature row S *and closure witness row* W *are consumed through the generator-closure surface of chapter 486. The GAP socket row* G *is compatible with the finite socket discipline of chapter 498: it records the attempted move from generator-internal induction to a free-floating induction principle without exporting such a principle.*

Proof. Project the carrier in Definition 565.1. The row S records the authorized generator signature, and W records that the displayed induction step ranges only over the closure generated by S.

Use the local obligations of Definition 565.2. They make S and W mandatory exposure rows before the continuation route C can be read, so the boundary consumes the same generator-closure data recorded by chapter 486.

Finally apply Definition 565.3. The row G remains a socket accounting row and does not become an exported induction coordinate. This is the same finite GAP discipline enforced by chapter 498, so the boundary packet links generator closure to the socket without adding universal induction. □

Closure status for $\mathsf{NameCert}_{\mathsf{GeneratorInductionBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{GeneratorInductionBoundary}^{\uparrow}$ packet is generated from an authorized generator signature, closure witness, continuation route, GAP socket, componentwise hsame transport, Pkg provenance, and local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{GeneratorInductionBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 565.1, Definition 565.2, and Definition 565.3 bind the finite carrier, local NameCert obligations, continuation boundary, and GAP non-escape surface for generator-internal induction.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{GeneratorInductionBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not prove a universal induction principle, close host-CIC soundness, certify arbitrary generator signatures, or provide Lean verification for the boundary packet.

Upgrade path: Obligation closure requires checked carrier admission, generator-signature exposure, closure-witness exposure, continuation routing, GAP socket accounting, and non-escape theorems for the same finite boundary packet.

Chapter 566

A Concrete Naming Certificate for $\mathsf{PropextTransportBoundary}^{\uparrow}$

The $\mathsf{PropextTransportBoundary}^{\uparrow}$ surface records the constructive replacement for proposition-stratum identification. It accepts bidirectional implication evidence between propositions only as direction-indexed transport data, then records how contexts, history sameness, package provenance, continuation replay, and the local naming row consume that transport without producing an equality token $P = Q$.

This proposition-stratum boundary is the directed-implication sibling of chapter 515. UnwitnessedExistenceClosu handles the term, type, and proposition closure family, while $\mathsf{PropextTransportBoundary}^{\uparrow}$ isolates the proposition-level transport row and refuses to collapse it into proposition equality.

Definition 566.1 (PropextTransportBoundary carrier)**.** *A* $\mathsf{PropextTransportBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (B, D, R, H, C, P, N)$$

with the following displayed coordinates:

1. *B is the bidirectional implication evidence for the proposition pair under comparison, recorded as the two directed rows $P \Rightarrow Q$ and $Q \Rightarrow P$;*
2. *D records the chosen direction rows through which each consumer reads the implication evidence;*
3. *R records context-read replacement routes for the admitted consumers, with no coordinate for equality tokens, global rewrite, or transport through $P = Q$;*
4. *H records the* hsame *and* psame *transport rows that move the proposition labels, implication rows, direction choices, context reads, continuation replay, provenance, and local naming row componentwise;*
5. *C records the* Cont *replay routes by which a consumer may request the forward read, the reverse read, the selected direction, and the returned context row;*
6. *P records* Pkg *provenance over the ThreeAxiomsOneClosure schema, the core* NameCert *discipline,* hsame, psame, *and* Cont*;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{PropextTransportBoundary}^{\uparrow}}$ *row.*

The carrier has no hidden coordinate for proposition equality, propositional extensionality, host rewrite through $P = Q$, or arbitrary proposition-valued context transport.

Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryTasteGate single carrier alignment`

Theorem 566.2 (PropextTransportBoundary NameCert obligations)**.** *For every* $\mathsf{PropextTransportBoundary}^{\uparrow}$ *carrier*

$$T = (B, D, R, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{PropextTransportBoundary}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier exposure for the displayed bidirectional implication, chosen direction, context-read replacement, transport, continuation, provenance, and naming rows;*
2. *direction discipline, requiring each consumer to name a row in D before using either implication row in B;*
3. *transport discipline, requiring every comparison of boundary packets to move only through the componentwise* hsame *and* psame *rows in H;*
4. *replay discipline, requiring every context read to pass through one of the displayed* Cont *routes in C and one of the replacement routes in R;*
5. *non-escape, excluding proposition equality, propositional extensionality, host rewrite through $P = Q$, and arbitrary proposition-valued context transport.*

Proof. Carrier exposure is projection from Definition 566.1. The packet lists the implication evidence, direction rows, context-read routes, transport rows, replay routes, provenance, and local naming row as finite coordinates.

Direction discipline is local because the only way to consume B is through a row in D. A forward consumer reads the $P \Rightarrow Q$ row together with its chosen direction; a reverse consumer reads the $Q \Rightarrow P$ row together with its chosen direction. No consumer obtains an undirected identification from the pair.

Transport discipline follows by reading equality-sensitive movement through H. The hsame and psame rows preserve the displayed coordinates componentwise, so comparison of two boundary packets can move proposition labels and classifier rows only along the named transport rows.

Replay discipline is then forced by C and R. The continuation row selects one of the admitted requests, and the replacement row returns the corresponding context-read output without invoking a global rewrite rule.

The non-escape clause is inspection of the carrier inventory. Since no coordinate names $P = Q$, propext, host rewrite, or arbitrary context transport, the local naming surface cannot export any of them. □

Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryNameCertObligations`

Theorem 566.3 (PropextTransportBoundary direction determinacy)**.** *For every* $\mathsf{PropextTransportBoundary}^{\uparrow}$ *carrier*

$$T = (B, D, R, H, C, P, N),$$

any consumer of an implication row in B must first select a direction row in D. If two accepted packets agree on D, H, C, P, N, then the exposed read is determined directionwise: a forward selection exposes the same $P \Rightarrow Q$ read, and a reverse selection exposes the same $Q \Rightarrow P$ read. No unordered identification of the two implication rows, witness of $P = Q$, invocation of propext*, host rewrite, or arbitrary proposition-valued context transport is exported by this agreement.*

Proof. Project the carrier coordinates from Definition 566.1. The implication evidence is stored in B, but Definition 566.2 makes each use pass through a chosen row of D before either implication row can be read.

Now compare two accepted packets whose D, H, C, P, N coordinates agree. The common D row fixes whether the consumer asks for the forward or reverse implication read. The common H rows move proposition labels and packet coordinates componentwise, while the common C routes replay the selected request through the displayed continuation surface.

The common provenance row P and local naming row N ensure that this replay is still the same named boundary consumption, not a host-side rewrite. Thus a forward request remains the directed $P \Rightarrow Q$ read, and a reverse request remains the directed $Q \Rightarrow P$ read.

Finally inspect the carrier inventory. Since the packet has no coordinate for unordered proposition equality, propext, host rewrite through $P = Q$, or arbitrary proposition-valued context transport, direction agreement cannot export any of these operations. □

Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryDirectionDeterminacy`

Theorem 566.4 (PropextTransportBoundary non-escape)**.** *For every* PropextTransportBoundary$^{\uparrow}$ *carrier*

$$T = (B, D, R, H, C, P, N),$$

the exported proposition-stratum replacement surface is exactly the finite packet T together with its displayed projection routes. In particular, reading the boundary cannot construct a witness of $P = Q$, cannot invoke propext*, cannot perform host rewrite through $P = Q$, and cannot transport an arbitrary proposition-valued context outside the routes recorded in R and C.*

Proof. Read the exported surface by projections from T. The only implication data are the two directed rows in B, and the only permitted uses of those rows are the choices recorded in D.

The context side is likewise explicit. A consumer must use a replacement route in R and replay it through C; those rows return only the named context-read outputs.

If a witness of $P = Q$, a propext invocation, a host rewrite, or an arbitrary context transport were exported, it would have to be a coordinate of the finite packet or the output of one of its routes. The carrier contains no such coordinate, and R and C are defined only for displayed replacement reads. Hence none of the excluded operations escapes the boundary. □

Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryNonEscapeReadback`
Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryNonEscape`

Theorem 566.5 (PropextTransportBoundary ledger exactness)**.** *For every* PropextTransportBoundary$^{\uparrow}$ *carrier*

$$T = (B, D, R, H, C, P, N),$$

the provenance ledger of the boundary is exactly the displayed Pkg *row P together with the local naming row N and the transport and replay rows H, C. Its dependency surface is over ThreeAxiomsOneClosure, core* NameCert*,* hsame*,* psame*, and* Cont*, and it contains no proposition-equality, propositional-extensionality, or host-rewrite dependency row.*

Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryLedgerExactness`

Proof. The ledger-bearing coordinates are displayed in the carrier: P records package provenance, N records the local name, H records transport, and C records replay. These rows are finite coordinates of T.

Inspect the support named by P. It ranges over the ThreeAxiomsOneClosure schema, the core NameCert discipline, hsame, psame, and Cont. These are exactly the rows needed to explain the replacement of proposition equality by directed implication transport.

No further ledger row is present. Therefore any proposition-equality, propositional-extensionality, or host-rewrite dependency would require an additional coordinate outside the packet, contradicting the displayed carrier inventory. □

Theorem 566.6 (PropextTransportBoundary three-axioms sibling link)**.** *The* PropextTransportBoundary$^{\uparrow}$ *ledger is the proposition-stratum projection of the three-stratum no-escape surface of chapter 515. It keeps only the displayed bidirectional implication, direction, replacement, transport, replay, provenance, and naming rows, and it introduces no witness of $P = Q$, no* propext *row, no host rewrite, and no arbitrary context transport.*

Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryThreeAxiomsSiblingLink`

Proof. Read the local carrier inventory from Definition 566.1. The packet contains only B, D, R, H, C, P, N, so the proposition-stratum boundary is represented by directed implication evidence, chosen direction rows, local replacement routes, componentwise transport, continuation replay, provenance, and local naming.

Apply Definition 566.5. The ledger surface is exactly P together with N, H, C, over the ThreeAxiomsOneClosure schema, core NameCert rows, hsame, psame, and Cont.

The sibling chapter chapter 515 supplies the broader term, type, and proposition no-escape surface. Taking the proposition-stratum projection leaves the displayed directed transport rows here and adds no proposition equality token.

Therefore the local ledger is linked to that sibling surface without introducing $P = Q$, propext, host rewrite, or arbitrary context transport. □

Theorem 566.7 (PropextTransportBoundary TasteGate handoff)**.** *Every accepted* PropextTransportBoundary$^{\uparrow}$ *packet gives a finite handoff object for a* ChapterTasteGate *consumer: the gate may inspect B, D, R, H, C, P, N, accept the directed replacement reads recorded there, and reject any request whose consumption path requires proposition equality,* propext*, host rewrite through $P = Q$, or arbitrary proposition-valued context transport.*

Proof. Build the handoff object by projecting the seven coordinates of the carrier. The gate receives the bidirectional implication rows, the chosen direction rows, the replacement routes, the componentwise transport rows, the replay routes, provenance, and the local naming row.

Acceptance is finite because every permitted read is named by a coordinate of T. A request that follows D, R, H, and C is a directed replacement read and can be checked against the displayed provenance in P and the local name in N.

Rejection is the complement of this displayed surface. A request requiring $P = Q$, propext, host rewrite, or arbitrary proposition-valued context transport asks for a coordinate absent from T, so the ChapterTasteGate has a concrete reason to refuse it. □

Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryTasteGateHandoff`

Theorem 566.8 (PropextTransportBoundary context replacement locality)**.** *For every accepted* PropextTransportBoundary$^{\uparrow}$ *carrier*

$$T = (B, D, R, H, C, P, N),$$

each context read exported by the boundary is local to the displayed replacement row R and the displayed Cont *row C. A consumer may replay only a named replacement route through C, and the replay returns only the context-read output recorded in R; it does not create a host rewrite, a witness of $P = Q$, or arbitrary transport for proposition-valued contexts.*

Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryContextReplacementLocality`

Proof. Project the carrier from Definition 566.1. The replacement coordinate is R, and the replay coordinate is C; no other coordinate is assigned to context transport.

Apply Definition 566.2 to force every context read through the replay discipline. The obligation surface requires a displayed Cont route and one of the replacement routes in R before any context-read output can be returned.

The direction and non-escape theorems then keep the read local. By Definition 566.3, implication consumption remains directionwise, and by Definition 566.4, the packet has no coordinate for equality, propext, host rewrite, or arbitrary proposition-valued transport. □

Theorem 566.9 (PropextTransportBoundary direction ledger coverage)**.** *For every accepted* PropextTransportBoun *carrier*

$$T = (B, D, R, H, C, P, N),$$

every accepted implication read is covered by one of the directed rows in D. The ledger never records the two implication rows in B as an unordered proposition equality, and no public read of the packet can replace this directed coverage by $P = Q$ or propext*.*

Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryDirectionLedgerCoverage`

Proof. The carrier exposes implication evidence only through B together with direction rows D. The NameCert obligations of Definition 566.2 require a consumer to name a row in D before using either implication row.

The coverage statement is therefore exactly Definition 566.3 read as a ledger condition. A forward request is covered by the forward row, and a reverse request is covered by the reverse row; there is no third unordered row.

Finally use Definition 566.5 and Definition 566.4. The provenance ledger contains only the displayed package, naming, transport, and replay rows, and the carrier inventory excludes proposition equality and propext. □

Theorem 566.10 (PropextTransportBoundary TasteGate refusal exactness)**.** *For every accepted* PropextTransportBoundary$^{\uparrow}$ *packet, the* ChapterTasteGate *refusal is exact for requests whose consumption path requires a witness of $P = Q$,* propext*, host rewrite through $P = Q$, or arbitrary proposition-valued context transport. Such a request is refused precisely because no displayed row of B, D, R, H, C, P, N supplies the requested operation, while requests following the directed rows in D, replacement row R, transport row H, replay row C, provenance row P, and naming row N remain admissible.*

Lean4 ✓ `BEDC.Derived.PropextTransportBoundaryUp.PropextTransportBoundaryTasteGateRefusalExactness`

Proof. Start from the handoff theorem Definition 566.7. The gate receives exactly the displayed carrier coordinates and accepts directed replacement reads recorded by those coordinates.

For an admitted request, Definition 566.8 supplies the local context route through R and C, while Definition 566.9 supplies the directed implication row in D. Transport and provenance are then read through H, P, N.

For a refused request, inspect the same inventory. By Definition 566.4 and Definition 566.5, the packet has no equality row, propext row, host-rewrite row, or arbitrary context-transport row. The gate therefore refuses exactly those requests whose path needs one of the absent operations. □

Theorem 566.11 (PropextTransportBoundary standard bridge route)**.** *Every accepted* PropextTransportBoundary$^{\uparrow}$ *packet exports its public boundary only through the displayed ThreeAxiomsOneClosure,* NameCert*,* hsame*,* psame*,* Cont*,* Pkg*, and* ChapterTasteGate *rows. This route gives a paper bridge to the standard refusal of proposition-extensional transport without importing proposition equality, host rewrite through $P = Q$, or arbitrary proposition-valued context transport.*

Proof. Start with the carrier of Definition 566.1 and the NameCert obligations of Definition 566.2. They force every accepted read through the displayed rows B, D, R, H, C, P, N before any public boundary can be exported.

Direction determinacy and ledger exactness then identify the bridge boundary. Apply Definition 566.3 to keep implication use direction-indexed, and Definition 566.5 to source the public ledger only from the ThreeAxiomsOneClosure, naming, transport, replay, and provenance rows.

The sibling link and gate handoff supply the standard bridge face. By Definition 566.6, the boundary is the proposition-stratum route of the three-axioms closure surface; by Definition 566.7, a ChapterTasteGate consumer receives exactly this finite handoff.

Finally use context replacement locality and refusal exactness. Theorems Definition 566.8 and Definition 566.10 keep the context route local to R, C and refuse equality, propext, host rewrite, and arbitrary proposition-valued transport. This is the stated paper bridge route. □

Closure status for NameCert$_{\text{PropextTransportBoundary}^{\uparrow}}$**.**

Constructive story: A PropextTransportBoundary$^{\uparrow}$ packet is generated from bidirectional implication evidence, chosen direction rows, context-read replacement routes, componentwise hsame and psame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{PropextTransportBoundary}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 566.1 and the theorem rows of this chapter bind the displayed carrier $T = (B, D, R, H, C, P, N)$ to the ThreeAxiomsOneClosure provenance surface, core NameCert, hsame, psame, Cont, Pkg, ChapterTasteGate handoff routes, and the paper bridge of Definition 566.11, with proposition equality, propositional extensionality, host rewrite, and arbitrary proposition-valued context transport excluded from the scoped primitive boundary.

Formal verification: FormalStatus(NameCert$_{\text{PropextTransportBoundary}^{\uparrow}}$, unformalized)

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not claim proposition equality, propositional extensionality, host rewrite through $P = Q$, arbitrary proposition-valued context transport, Lean verification, or bridge checking.

Upgrade path: No stronger paper-side closure is claimed beyond the directed implication transport boundary and its bridge discipline.

Chapter 567

A Zeckendorf Classifier Surface for $\mathsf{ZCarry}^{\uparrow}$

This chapter realizes the zero-marker Zeckendorf carry classifier as a finite BHist naming packet. The packet separates carry-relatedness from hsame: it records the local carry window, the normal-form target window, the non-normal source window, and the displayed transports by which consumers inspect those rows.

The classifier depends horizontally on the normal-form sibling chapter 278: the carrier rows s and t read source rejection and target admission from that surface. The downstream carry packet of chapter 544 then consumes this classifier boundary when it packages the finite carry row for $\mathsf{ZCarry}^{\uparrow}$.

Definition 567.1 (Zeckendorf carry-classifier carrier)**.** *A* $\mathsf{ZCarry}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (u, v, c, s, t, h, r, p, n)$$

with the following visible coordinates:

1. *u is the displayed source carry window, with public shape* `word_011`*;*
2. *v is the displayed target carry window, with public shape* `word_100`*;*
3. *c is the local carry row witnessing* $\mathsf{ZCarry}(u, v)$*;*
4. *s is the source-normality boundary row, witnessing that u is rejected by the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *normal-form classifier;*
5. *t is the target-normality row, witnessing that v is accepted by the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *normal-form classifier;*
6. *h is the negative history-sameness row, witnessing that the carry relation is not* $\mathsf{hsame}(u, v)$*;*
7. *r is the finite carry-window readback ledger, exposing only u, v, c, s, t, h to downstream consumers;*
8. *p is the* Pkg *provenance over* BHist, hsame, $\mathsf{ZeckendorfNormal}^{\uparrow}$, $\mathsf{ZCarry}^{\uparrow}$, *and the local carry generator;*
9. *n is the local* $\mathsf{NameCert}_{\mathsf{ZCarry}^{\uparrow}}$ *row.*

The carrier has no coordinate for Fibonacci value preservation, arithmetic equality, kernel rewriting, host numeric interpretation, or global replacement of hsame*.*

Lean4 (definition) `BEDC.Derived.ZeckendorfCarryClassifierUp.ZeckendorfCarryClassifierUp`
Lean4 ✓ `BEDC.Derived.ZeckendorfCarryClassifierUp.TasteGate.ZeckendorfCarryClassifierTasteGate single carrier alignment`

Definition 567.2 (Zeckendorf carry-classifier sameness)**.** *For accepted* $\mathsf{ZCarry}^{\uparrow}$ *carriers*

$$K = (u, v, c, s, t, h, r, p, n) \quad \text{and} \quad K' = (u', v', c', s', t', h', r', p', n'),$$

the classifier sameness judgment $\mathsf{ZCarrySame}(K, K')$ *holds exactly when the source windows are connected by displayed* $\mathsf{hsame}(u, u')$*, the target windows are connected by displayed* $\mathsf{hsame}(v, v')$*, and the carry rows* c, c' *read the same local generator from* `word_011` *to* `word_100`*. The judgment does not identify* u *with* v *inside either carrier.*

Theorem 567.3 (Zeckendorf carry-classifier NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ZCarry}^{\uparrow}}$ *surface for the carrier of Definition 567.1 consists exactly of five finite rows:*

1. *carrier admission for the displayed packet* K*;*
2. *source-window rejection by the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *normal-form classifier;*
3. *target-window admission by the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *normal-form classifier;*
4. *carry-not-*hsame *separation for the displayed source and target windows;*
5. *ledger exactness, stating that every public read of* $\mathsf{ZCarry}^{\uparrow}$ *factors through* $u, v, c, s, t, h, r, p, n$*.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryClassifierUp.ZeckendorfCarryClassifierCarrier namecert obligations`

Proof. Carrier admission is projection of the finite packet in Definition 567.1. The packet displays the source window, target window, carry row, normality rows, negative hsame row, readback ledger, package provenance, and local naming row.

The source and target normality rows are read from s and t. The source row records rejection of the adjacent-one window, while the target row records acceptance of the zero-zero-one window under the normal-form classifier.

The separation row is h. It states that the carry relation is a classifier edge between the two windows, not a history-sameness proof from the source to the target.

Finally, ledger exactness is read from r, p, n. Since no arithmetic equality, Fibonacci value row, host numeric interpretation, or kernel rewrite appears as a coordinate, the public NameCert surface is exhausted by the displayed finite rows. □

Theorem 567.4 (Zeckendorf carry-window determinacy)**.** *For an accepted* $\mathsf{ZCarry}^{\uparrow}$ *carrier*

$$K = (u, v, c, s, t, h, r, p, n),$$

the displayed carry row c *determines the local source and target windows up to the carrier's external* hsame *transports:* u *is the rejected* `word_011` *window and* v *is the accepted* `word_100` *window. Any consumer that asks for the carried window reads the same finite pair through* r *and cannot choose a second target window inside the packet.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryClassifierUp.ZeckendorfCarryClassifier window determinacy`

Proof. Inspect the carry row c. The $\mathsf{ZCarry}^{\uparrow}$ carrier admits only the local generator from the source window `word_011` to the target window `word_100`.

The source-normality and target-normality rows then fix the orientation. The row s rejects the source as a normal form, while t accepts the target as a normal form; reversing the pair would contradict those displayed roles.

Transport can only occur through the external hsame comparisons named in Definition 567.2. These comparisons preserve each side of the window pair separately and never identify the source with the target. Therefore the finite window readback has a single displayed target inside the packet. □

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryClassifierUp.ZeckendorfCarryClassifierCarrier window determinacy`

Theorem 567.5 (Zeckendorf carry non-escape boundary)**.** *Every public read exported by an accepted* $\mathsf{ZCarry}^{\uparrow}$ *carrier factors through* $u, v, c, s, t, h, r, p, n$*. In particular, the carrier cannot be used as a kernel rewrite rule, an* $\mathsf{hsame}(u, v)$ *witness, a Fibonacci value-preservation theorem, an arithmetic equality, or a global normalization procedure.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryClassifierUp.ZeckendorfCarryClassifierCarrier nonescape boundary`

Proof. Start with the carrier inventory. The packet contains exactly the source and target windows, the local carry row, the source and target normality rows, the negative hsame row, the readback ledger, package provenance, and the local naming row.

The public classifier read is routed through c and r. The normal-form evidence is routed through s and t, and the separation from history-sameness is routed through h.

None of the excluded objects appears as a packet coordinate. Hence no consumer can extract a kernel rewrite, source-target hsame proof, Fibonacci value row, host arithmetic equality, or global normalizer from the $\mathsf{ZCarry}^{\uparrow}$ NameCert surface. □

Theorem 567.6 (Zeckendorf carry-classifier scoped kernel route)**.** *Every accepted* $\mathsf{ZeckendorfCarryClassifier}^{\uparrow}$ *carrier read factors through the displayed* BHist *windows* u, v*, the side transports named by* hsame*, the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *source-rejection and target-admission rows* s, t*, the local* $\mathsf{ZCarry}^{\uparrow}$ *generator row* c*, the finite readback ledger* r*, the* Pkg *provenance row* p*, and the local* NameCert *naming row* n*. The scoped kernel route contains no coordinate for Fibonacci value preservation, global normalization, kernel rewriting, source-target* hsame*, or host arithmetic equality.*

Proof. Project the accepted packet of Definition 567.1. Its carrier rows are exactly the displayed windows, the local carry row, the source and target normal-form rows, the separation row, the readback ledger, provenance, and local naming.

The source and target reads then factor through the normal-form sibling. The row s records the $\mathsf{ZeckendorfNormal}^{\uparrow}$ rejection of the source window, while t records the corresponding target admission; any side comparison is transported only through the external hsame rows of Definition 567.2.

Finally apply the non-escape boundary of Definition 567.5. The readback ledger r, provenance p, and local name n preserve the finite route, and the absent global arithmetic or kernel-rewrite objects cannot be exported from the packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{ZeckendorfCarryClassifier}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ZeckendorfCarryClassifier}^{\uparrow}$ packet is generated from a finite carry-classifier carrier, source and target normal-form rows, sameness separation, package provenance, and local naming.

Theory closure: TheoryGate(NameCert$_{\mathsf{ZeckendorfCarryClassifier}^{\uparrow}}$, publicClosed)

Scope closed: The public finite carry-classifier export binds the carrier, sameness rule, NameCert-obligation rows, window determinacy, normal-form dependency, and non-escape boundary over BHist, hsame, ZeckendorfNormal$^{\uparrow}$, Pkg, and NameCert.

Formal verification: FormalStatus(NameCert$_{\mathsf{ZeckendorfCarryClassifier}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This classifier block does not prove Fibonacci value preservation, global normalization, source-target hsame, or a Lean implementation.

Upgrade path: Obligation closure requires checked carrier and classifier obligation rows for the finite carry-classifier packet.

Chapter 568

A Concrete Naming Certificate for EffectiveReplacementLedger$^{\uparrow}$

The EffectiveReplacementLedger$^{\uparrow}$ interface records the finite certificate packet that realizes the three replacement directions of section 9387.3. It gathers explicit choice witnesses, classifier-respecting quotient transport, direction-indexed proposition transport, and the axiom-purity refusal row into one local NameCert surface, so later purity and boundary arguments can consume a concrete ledger rather than a schematic discipline statement.

When a replacement row is used as a finite refusal witness, EffectiveReplacementLedger$^{\uparrow}$ consumes the bounded finite-refutation boundary of chapter 579. When a proposed replacement would become a truth-total or validation-as-row query, it consumes the reflection-limit boundary of chapter 586. These sibling links are dependency rows only; they add no proof search, truth principle, quotient principle, choice principle, or propext principle beyond the displayed ledger.

Definition 568.1 (EffectiveReplacementLedger carrier)**.** *An* EffectiveReplacementLedger$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (W, Q, T, A, H, C, P, N)$$

with the following visible coordinates:

1. *W is the choice-witness row, recording countable witness functions, dependent-step witnesses along displayed* Cont *chains, and finite-recursion witnesses over closed inductive lists;*
2. *Q is the quotient-transport row, recording classifier-respecting transport through typed* NameCert *data without choosing a canonical representative;*
3. *T is the propext-transport row, recording bidirectional implication as direction-indexed* hsame *and* psame *transport rather than as a proposition-equality token;*
4. *A is the axiom-purity refusal row, recording that no consumer may request* Classical.choice*,* Quot.sound*,* propext*, or a host rewrite through those operations;*
5. *H stores componentwise* hsame *and* psame *transports for the witness, quotient, proposition, refusal, provenance, and naming rows;*
6. *C stores the finite* Cont *routes by which consumers read each replacement row and receive only its displayed output;*
7. *P records* Pkg *provenance over the ThreeAxiomsOneClosure schema, typed* NameCert*,* BHist*,* hsame*,* psame*,* Cont*, and the axiom-purity audit surface;*

8. N is the local $\mathsf{NameCert}_{\mathsf{EffectiveReplacementLedger}^{\uparrow}}$ *row.*
The carrier contains no hidden coordinate for an unwitnessed selector, a quotient representative section, a proposition equality $P = Q$, or an ignored axiom-purity gate.

Lean4 (definition) `BEDC.Derived.EffectiveReplacementLedgerUp.EffectiveReplacementLedgerCarrier`

Theorem 568.2 (EffectiveReplacementLedger choice row)**.** *For every accepted carrier $E = (W, Q, T, A, H, C, P, N$ the choice replacement surface is exactly the witness row W together with the continuation routes in C that expose its entries. Countable choice is read as an explicit witness function over a displayed $\mathbb{N}$-indexed family, dependent choice is read as displayed step data along a* Cont *chain, and finite choice is read as primitive recursion over a closed inductive list.*

Proof. Project the carrier to W and C. The witness row names the three admitted forms of choice replacement, and the continuation row gives the only routes by which a consumer may read them.

Each route returns a displayed witness: a function for the countable case, a step witness for the dependent case, or a finite recursive witness for the closed-list case. None of these reads supplies an oracle body outside the carrier.

The refusal row A blocks any request for an unwitnessed selector. Therefore the choice surface of the packet is exhausted by W and its displayed routes in C. □

Lean4 ✓ `BEDC.Derived.EffectiveReplacementLedgerUp.EffectiveReplacementLedgerChoiceRow`

Theorem 568.3 (EffectiveReplacementLedger quotient transport row)**.** *For every accepted carrier $E = (W, Q, T, A, H, C, P, N)$, the quotient replacement surface is exactly the classifier-respecting transport row Q together with the* hsame *and* psame *transport data in H. A consumer may move certified content across the displayed classifier, but it may not extract a canonical representative, a quotient section, or a host-side collapse of carrier elements.*

Proof. Read Q as the quotient-facing coordinate of the packet. It names classifier-respecting transport through typed NameCert data and has no field for a representative-selection function.

The transport row H supplies the componentwise movement required to compare two certified presentations. It moves witness rows, classifier rows, provenance rows, and naming rows through displayed sameness data.

If a consumer asks for a quotient representative or a type-level collapse, the request is not routed through Q or H and is therefore refused by A. Thus quotient use remains transport-only inside the finite packet. □

Lean4 ✓ `BEDC.Derived.EffectiveReplacementLedgerUp.EffectiveReplacementLedgerQuotTransportRow`

Theorem 568.4 (EffectiveReplacementLedger propext transport row)**.** *For every accepted carrier $E = (W, Q, T, A, H, C, P, N)$, the proposition-stratum replacement surface is exactly the direction-indexed transport row T together with the continuation routes in C and the componentwise* hsame *and* psame *rows in H. Bidirectional implication may be consumed in a named direction, but the carrier exports no proposition equality and no host rewrite through $P = Q$.*

Proof. Project the packet to T. This row records bidirectional implication as directed transport data, so a consumer must name which direction it reads before using the implication evidence.

The route row C exposes only those directed reads, and the transport row H preserves them componentwise across certified presentations. Together they provide exactly the replacement behavior named in Definition 9387.8.

The refusal row A excludes proposition equality, propositional extensionality, and host rewrite. Since none of these is a coordinate of E, they cannot be exported by certificate projection. □

Lean4 ✓ `BEDC.Derived.EffectiveReplacementLedgerUp.EffectiveReplacementLedgerPropextTransportRow`

Theorem 568.5 (EffectiveReplacementLedger axiom-purity boundary)**.** *For every accepted carrier $E = (W, Q, T, A, H, C, P, N)$, the axiom-purity refusal row A is a boundary on the whole packet: any requested read that requires* Classical.choice*,* Quot.sound*,* propext*, an unwitnessed selector, a quotient representative section, or proposition equality is rejected rather than transported through W, Q, T, H, or C.*

Proof. Inspect the carrier inventory. The positive replacement rows are W, Q, and T, while H and C only transport and replay those displayed rows.

The refusal row A is attached to the same package provenance P and local name N. It therefore constrains every public read of the packet, not merely one replacement direction.

A request for one of the excluded operations has no coordinate to project and no continuation route to replay. The only available response is the refusal recorded in A, so the finite ledger preserves the axiom-purity boundary. □

Lean4 ✓ `BEDC.Derived.EffectiveReplacementLedgerUp.EffectiveReplacementLedgerAxiomPurityBoundary`

Theorem 568.6 (EffectiveReplacementLedger NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{EffectiveReplacementLedger}^{\uparrow}}$ *surface for Definition 568.1 consists of five finite obligations: carrier exposure for E, choice-witness exactness for W, quotient-transport exactness for Q, propext-transport exactness for T, and axiom-purity non-escape for A over the shared transport, continuation, provenance, and naming rows H, C, P, N.*

Proof. Carrier exposure is projection of the displayed tuple $E = (W, Q, T, A, H, C, P, N)$. The packet lists every replacement, transport, continuation, provenance, and naming row as a finite coordinate.

The three exactness obligations are supplied by the row theorems above. Definition 568.2 binds W to explicit witnesses, Definition 568.3 binds Q to classifier-respecting transport, and Definition 568.4 binds T to direction-indexed proposition transport.

The final obligation is the non-escape boundary of Definition 568.5. Repacking these rows with H, C, P, N gives one finite NameCert packet whose public surface contains replacement data and refusal data, but no classical axiom dependency. □

Lean4 ✓ `BEDC.Derived.EffectiveReplacementLedgerUp.EffectiveReplacementLedgerTasteGate single carrier alignment`

Closure status for $\mathsf{NameCert}_{\mathsf{EffectiveReplacementLedger}^{\uparrow}}$.

Constructive story: An $\mathsf{EffectiveReplacementLedger}^{\uparrow}$ packet is generated from explicit choice witnesses, classifier-respecting quotient transport, direction-indexed proposition transport, an axiom-purity refusal row, componentwise hsame and psame transports, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{EffectiveReplacementLedger}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 568.1, Definition 568.2, Definition 568.3, Definition 568.4, Definition 568.5, Definition 568.6, and the TasteGate target bind the mature paper scope of finite BHist packet rows, hsame and psame transport, displayed Cont replay, Pkg provenance, local NameCert, refusal of Classical.choice, Quot.sound, and propext, and the public replacement-ledger surface aligned with the standard bridge schema.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{EffectiveReplacementLedger}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not claim Lean verification, machine bridge checking, general quotient construction, proposition equality, classical choice, or an executable audit implementation.

Upgrade path: A machine bridge target would move only the verification axis; the present chapter already records the mature paper surface while the formal axis remains unformalized.

Chapter 569

A Concrete Naming Certificate for $\mathsf{AnalyticContinuationSocket}^{\uparrow}$

The $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ interface turns the analytic-continuation operation of chapter 9341 into a finite operation-socket certificate. It does not assert a global monodromy theorem or a host analytic continuation principle. It names the local source rows, overlap witnesses, continuation output rows, transport routes, and branch-obstruction ledger that a downstream $\mathsf{Holomorphic}^{\uparrow}$ or Riemann-hypothesis-facing consumer may inspect.

Definition 569.1 (AnalyticContinuationSocket carrier)**.** *An* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (F, G, U, A, O, B, H, C, P, N)$$

with the following displayed rows:

1. *F is the source* $\mathsf{Holomorphic}^{\uparrow}$ *row on the first* $\mathsf{Complex}^{\uparrow}$ *domain;*
2. *G is the overlapping* $\mathsf{Holomorphic}^{\uparrow}$ *row on the second* $\mathsf{Complex}^{\uparrow}$ *domain;*
3. *U is the finite overlap witness row, including the displayed nontrivial overlap and agreement evidence needed by the local identity route;*
4. *A is the analytic-continuation operation row that reads F, G, U and proposes an output continuation;*
5. *O is the output* $\mathsf{Holomorphic}^{\uparrow}$ *row on the displayed union domain;*
6. *B is the branch-obstruction ledger, recording every requested continuation route that leaves the displayed overlap-and-output packet as a* GAP *boundary;*
7. *H stores componentwise* hsame *transports for F, G, U, A, O, B and the local naming rows;*
8. *C stores the finite* Cont *routes by which consumers read the source rows, overlap witness, output row, branch ledger, package provenance, and local naming row;*
9. *P is the* Pkg *provenance over the same finite operation-socket packet;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{AnalyticContinuationSocket}^{\uparrow}}$ *row.*

The carrier exposes exactly this local socket. It contains no unrestricted analytic-continuation operator, no global branch selector, no quotient of germs, and no host complex-analysis theorem.

Lean4 (definition) `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier`

Theorem 569.2 (AnalyticContinuationSocket NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{AnalyticContinuationSocket}^{\uparrow}}$ *surface for Definition 569.1 consists of five finite rows: carrier admission for S; classifier stability for the two holomorphic source rows, the overlap witness, the operation row, and the output row; ledger exactness for the branch-obstruction coordinate B;* Pkg *provenance over F, G, U, A, O, B, H, C; and local naming exactness for N.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier namecert obligations`

Proof. Carrier admission is projection of the finite tuple S. The source, overlap, operation, output, obstruction, transport, continuation, package, and local naming rows are all visible coordinates of the same BHist packet.

Classifier stability is componentwise. Transport of F, G, U preserves the two source rows and the overlap agreement evidence, transport of A, O preserves the proposed continuation output, and transport of B preserves the recorded non-escape boundary.

The package and local naming rows repack these coordinates without adding a host continuation principle. Thus the socket certificate consists exactly of the five displayed obligation rows. □

Theorem 569.3 (AnalyticContinuationSocket overlap transport)**.** *For an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier $S = (F, G, U, A, O, B, H, C, P, N)$, the local overlap witness U transports only along the displayed* hsame *row H and the displayed* Cont *routes C. The transported read preserves the two* $\mathsf{Holomorphic}^{\uparrow}$ *source rows F, G, the* $\mathsf{Complex}^{\uparrow}$ *overlap boundary named by U, the analytic-continuation operation row A, the output row O, the package row P, and the local* NameCert *row N; it does not create a monodromy theorem, global continuation operator, quotient of germs, or branch selector.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketPacket overlap transport`

Proof. Project the carrier. The overlap witness U is displayed in the same finite packet as the two source rows, operation row, output row, transport row, continuation routes, package provenance, and local naming row.

Apply the classifier-stability part of Definition 569.2. It allows the overlap evidence to move only through componentwise hsame transport and the corresponding Cont reads.

The carrier definition contains no row for monodromy, global continuation, quotient-of-germs equality, or branch selection. The transported overlap read therefore remains a local overlap-boundary read. □

Theorem 569.4 (AnalyticContinuationSocket branch ledger exhaustion)**.** *Every branch-sensitive read of an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier is exhausted by the rows $F, G, U, A, O, B, H, C, P, N$. If the read is not a source-row read, overlap-witness read, operation-row read, output-row read, transport read, continuation-route read, package read, or local naming read, then it is recorded in the branch-obstruction ledger B and is not exported as analytic-continuation evidence.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier branch ledger exhaustion`

Proof. Read the request through the finite continuation routes C. The positive cases are exactly the displayed source, overlap, operation, output, transport, package, and naming coordinates.

For a request outside those coordinates, use the branch-obstruction coordinate B. The ledger non-escape theorem records such a request as a GAP boundary rather than as another continuation row.

Since the packet has no hidden analytic bridge or host continuation principle, the two cases exhaust the carrier-visible branch reads. □

Theorem 569.5 (AnalyticContinuationSocket local output handoff)**.** *Every downstream* Holomorphic$^{\uparrow}$ *consumer of the output row O from an accepted* AnalyticContinuationSocket$^{\uparrow}$ *carrier receives the local handoff packet $F, G, U, A, O, H, C, P, N$ together with the branch-obstruction ledger B. The handoff states that O is the displayed local operation output over the two source rows and overlap witness; it does not state global analytic continuation, monodromy invariance, branch selection, or any Riemann-hypothesis-facing zero-location consequence.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier local output handoff`

Proof. Start with the operation row A and output row O. The carrier places O as the displayed output of the local operation over F, G, U.

Transport and consumer access are supplied only by H and C, then repacked by P and N. Thus a downstream Holomorphic$^{\uparrow}$ consumer receives the same local packet rather than an ambient continuation operator.

The branch ledger B handles every request outside that packet. By branch-ledger exhaustion, such requests stay in the ledger and cannot become monodromy, branch-choice, or zero-location data. □

Theorem 569.6 (AnalyticContinuationSocket ledger non-escape)**.** *Every consumer read exported by an accepted* AnalyticContinuationSocket$^{\uparrow}$ *carrier factors through the displayed rows $F, G, U, A, O, B, H, C, P, N$. If a read asks for continuation data outside the source rows, overlap witness, proposed output, and displayed transport routes, the request is recorded in B as a* GAP *boundary and is not exported as a holomorphic continuation row.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier ledger nonescape`

Proof. Read the consumer request through the displayed Cont route C. If the request lands in the two source rows, the overlap witness, the operation row, the output row, or the package and naming rows, the carrier supplies exactly that coordinate.

If the request leaves those coordinates, no row of S can supply a continuation witness. The branch-obstruction ledger B is the only remaining classifier-visible coordinate for such a request, so the read is recorded as non-escape evidence rather than as an output continuation. □

Theorem 569.7 (AnalyticContinuationSocket holomorphic handoff)**.** *For an accepted* AnalyticContinuationSocket$^{\uparrow}$ *carrier $S = (F, G, U, A, O, B, H, C, P, N)$, every downstream* Holomorphic$^{\uparrow}$ *consumer of the output row O also reads the source rows F, G, the overlap witness U, the operation row A, and the transport, continuation, package, and local naming rows H, C, P, N. The handoff exposes no standalone continuation function and no branch choice outside the displayed packet.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier holomorphic handoff`

Proof. Begin with the output row O. In the carrier definition it appears only as the result coordinate of the operation row A over the displayed source rows F, G and overlap witness U.

Transport through H preserves the same source-overlap-output boundary, and the continuation routes in C expose the output only through that boundary. The package and local naming rows P, N then identify the same finite packet for downstream consumers.

The branch ledger B rules out the remaining escape case. A consumer that asks for a branch choice or continuation function outside the displayed packet reaches B, not another $\mathsf{Holomorphic}^{\uparrow}$ row. □

Theorem 569.8 (AnalyticContinuationSocket overlap classifier stability)**.** *Let $S = (F, G, U, A, O, B, H, C, P, N)$ be an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier. Transported reads of the source rows F, G and the overlap witness U preserve the local overlap-agreement classifier through the displayed componentwise* hsame *rows in H, the* Cont *routes in C, the package provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{AnalyticContinuationSocket}^{\uparrow}}$ *row N. A transported overlap read may replay the named agreement boundary, but it cannot replace that boundary by a global identity theorem, monodromy theorem, quotient-of-germs equality, or branch selector.*

Proof. Start with the carrier of Definition 569.1. The rows F, G, U are named coordinates of the same finite socket packet, and H stores their componentwise hsame transport.

Apply the classifier-stability row of Definition 569.2. Transport of F, G, U preserves the source rows and the local overlap agreement evidence rather than introducing a new continuation object.

Now read the transported overlap through C, P, N. The ledger non-escape theorem Definition 569.6 and the holomorphic handoff theorem Definition 569.7 keep downstream consumers inside the displayed packet, so the overlap classifier remains the named local classifier. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier overlap classifier stability`

Theorem 569.9 (AnalyticContinuationSocket operation-output factorization)**.** *For an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier $S = (F, G, U, A, O, B, H, C, P, N)$, every exported operation-output row O factors through the finite rows F, G, U, A, H, C, P, N. The branch ledger B records exactly the attempted reads that do not factor through those rows. Thus O is a local operation output of the displayed socket, not the value of an unrestricted analytic-continuation operator and not the result of a hidden branch-choice rule.*

Proof. Project the output coordinate O from the carrier in Definition 569.1. By definition it is paired with the operation row A, which reads only the two source rows F, G and the overlap witness U.

Use Definition 569.2 to attach the finite hsame, Cont, Pkg, and local naming rows. These rows provide the only certified route by which a consumer can identify the operation output.

The non-factorizing case is handled by Definition 569.6. Any read outside F, G, U, A, H, C, P, N is recorded in B, and Definition 569.7 prevents that ledger entry from becoming an additional $\mathsf{Holomorphic}^{\uparrow}$ output. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier operation output factorization`

Theorem 569.10 (AnalyticContinuationSocket RH handoff boundary)**.** *Every Riemann-hypothesis-facing zeta-continuation consumer of an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier receives only the finite local operation socket*

$$F, G, U, A, O, H, C, P, N$$

together with the branch-obstruction ledger B. The handoff supplies no monodromy theorem, no global analytic-continuation principle, no quotient of germs, no branch selector, and no zero-location consequence.

Proof. Begin with the holomorphic handoff of Definition 569.7. It exposes O only through the source rows, overlap witness, operation row, transport, continuation, package, and local naming rows.

Add the local NameCert surface from Definition 569.2. The Riemann-hypothesis-facing consumer can inspect carrier admission, classifier stability, branch-ledger exactness, package provenance, and local naming, all within the same finite carrier of Definition 569.1.

Finally apply Definition 569.6. Requests for monodromy, branch selection, global continuation, or zero-location consequences leave the displayed packet and are therefore recorded only as branch-obstruction data in B. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier rh handoff boundary`

Theorem 569.11 (AnalyticContinuationSocket root source overlap)**.** *For an accepted* AnalyticContinuationSocket$^{\uparrow}$ *carrier $S = (F, G, U, A, O, B, H, C, P, N)$, every source-overlap read used by a root continuation consumer factors through the displayed source rows F, G, the finite overlap witness U, the componentwise transport row H, the displayed continuation routes C, the package provenance P, and the local* NameCert *row N. The read may reach the operation row A and output row O only through that source-overlap packet.*

Proof. Project the carrier and the local NameCert obligations. They list F, G, U as the only source-overlap coordinates and place H, C, P, N as the only transport, route, provenance, and naming rows available to a consumer.

Apply overlap classifier stability. Transported source and overlap reads preserve the local agreement boundary through H and are replayed only through the displayed routes in C.

Finally use holomorphic handoff and the RH handoff boundary. A downstream consumer can inspect A and O only after the same source-overlap packet has been displayed, so no hidden continuation source is introduced. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier root source overlap`

Theorem 569.12 (AnalyticContinuationSocket root branch ledger)**.** *Every nonlocal continuation request made against an accepted* AnalyticContinuationSocket$^{\uparrow}$ *carrier lands in the branch-obstruction ledger B. Such a request may be transported, replayed, packaged, and named through H, C, P, N, but it is not exported as a source row, overlap witness, operation row, output row, holomorphic continuation row, branch selector, or zero-location datum.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier root branch ledger`

Proof. Start with ledger non-escape. It sends every request outside the displayed source, overlap, operation, output, transport, route, provenance, and naming coordinates to the branch-obstruction row B.

Use the ledger obligation and zeta branch-obstruction exactness. These theorems keep branch-sensitive and Riemann-hypothesis-facing requests in B rather than exporting them as continuation or zero-location evidence.

The RH handoff boundary then removes the remaining escape paths. Monodromy, branch selection, global continuation, and zero-location conclusions are not consumer-visible coordinates of the root socket. □

Theorem 569.13 (AnalyticContinuationSocket branch-obstruction consumer lock)**.** *Every nonlocal continuation request made by a downstream consumer of an accepted* AnalyticContinuationSocket$^{\uparrow}$ *carrier is locked to the branch-obstruction row B. The request may be transported and named through H, C, P, N, but it cannot be exported as a holomorphic continuation row, source row, overlap witness, operation row, output row, branch selector, monodromy datum, or zero-location consequence.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier branch obstruction consumer lock`

Proof. Start with the root branch ledger. It sends every nonlocal continuation request to B and denies export as source, overlap, operation, output, holomorphic continuation, branch-selection, or zero-location data.

Apply branch-ledger exhaustion and ledger non-escape. They identify the positive carrier-visible routes and record every request outside those routes as branch-obstruction data rather than as continuation evidence.

Finally use overlap transport and the RH handoff boundary. Transport through H, C, P, N preserves the same ledger coordinate, and Riemann-hypothesis-facing consumers receive no zero-location or global-continuation consequence from that coordinate. □

Theorem 569.14 (AnalyticContinuationSocket zeta locality boundary)**.** *Every zeta-facing consumer of an accepted* AnalyticContinuationSocket$^{\uparrow}$ *carrier receives only the local socket rows*

$$F, G, U, A, O, H, C, P, N$$

together with the branch ledger B. The consumer receives no monodromy theorem, global analytic-continuation principle, branch selector, quotient-of-germs equality, or zero-location consequence.

Proof. Read the RH handoff boundary first. It exposes the finite local operation socket and the branch-obstruction ledger, while excluding monodromy, global continuation, quotient-of-germs equality, branch selection, and zero-location conclusions.

Use the root source-overlap theorem and local output handoff. They force the output row O to pass through F, G, U, A, H, C, P, N before any downstream consumer can inspect it.

Now apply the root branch ledger. A zeta-facing request outside that local socket is routed to B, where it remains branch-obstruction data rather than a zero-location consequence. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier zeta locality boundary`

Theorem 569.15 (AnalyticContinuationSocket output-branch separation)**.** *For an accepted* AnalyticContinuationS *carrier, the output row O factors through*

$$F, G, U, A, H, C, P, N,$$

while branch-sensitive requests factor through B. These two routes do not collapse into a global analytic-continuation principle, branch selector, monodromy theorem, quotient-of-germs equality, or zero-location theorem.

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier output branch separation`

Proof. Project the operation-output factorization. The output coordinate O is a local operation result over F, G, U, A and is certified only through H, C, P, N.

Next apply branch-ledger exhaustion, ledger non-escape, and the root branch ledger. Requests that do not factor through the source-overlap-output route are recorded in B.

Finally combine holomorphic handoff with the RH handoff boundary. The output route supplies a local $\mathsf{Holomorphic}^{\uparrow}$ handoff, while the branch route remains obstruction data; the two routes therefore do not yield a global continuation or zero-location principle. □

Theorem 569.16 (AnalyticContinuationSocket root downstream unblock)**.** *The finite root surface exported by an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier to* $\mathsf{Holomorphic}^{\uparrow}$ *and zeta-continuation consumers is exactly*

$$F, G, U, A, O, B, H, C, P, N.$$

The package combines the source rows, overlap witness, operation row, output row, branch ledger, componentwise transports, continuation routes, package provenance, and local naming row, and it excludes global monodromy, branch selection, quotient-of-germs equality, and zero-location consequences.

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier root downstream unblock`

Proof. First combine the root source-overlap theorem with holomorphic handoff. The consumer-visible output row O is reached only through F, G, U, A, H, C, P, N.

Next apply the root branch-ledger theorem. Every request outside that source-overlap-output path lands in B and remains obstruction data.

Finally repack the two paths with the RH handoff boundary. The downstream consumer receives one finite surface, $F, G, U, A, O, B, H, C, P, N$, and no unlisted analytic-continuation principle. □

Theorem 569.17 (AnalyticContinuationSocket vision concretization)**.** *The analytic-continuation operation surface of chapter 9341 is concretized by* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *as a finite* BHist *operation-socket packet over holomorphic source rows, overlap witnesses, continuation outputs, componentwise transport, continuation routes, package provenance, local naming, and branch-obstruction non-escape.*

Proof. The carrier of Definition 569.1 supplies the finite operation-socket packet. The NameCert obligations of Definition 569.2 bind carrier admission, classifier stability, branch-ledger exactness, package provenance, and local naming.

The ledger non-escape theorem prevents undisplayed continuation routes from becoming output rows, and the holomorphic handoff theorem shows how downstream $\mathsf{Holomorphic}^{\uparrow}$ consumers read the displayed continuation output. These clauses are exactly the finite BEDC concretization of the operation surface. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier vision concretization`

Theorem 569.18 (AnalyticContinuationSocket carrier source obligation)**.** *Carrier admission for an accepted* AnalyticContinuationSocket$^{\uparrow}$ *packet projects the finite rows*

$$F, G, U, A, O, B, H, C, P, N.$$

These rows expose the two Holomorphic$^{\uparrow}$ *source rows, the finite overlap witness, the operation row, the output row, the branch-obstruction ledger, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *row. They do not expose a global continuation operator, branch selector, quotient of germs, or host complex-analysis theorem.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier carrier source obligation`

Proof. Project the carrier of Definition 569.1. The finite tuple lists exactly the source, overlap, operation, output, obstruction, transport, continuation, package, and local naming rows.

Apply the NameCert obligations of Definition 569.2. Carrier admission is one of the displayed obligations, and the remaining obligation rows are read only through the same finite packet.

The ledger non-escape theorem Definition 569.6 rules out any continuation read outside these rows. Therefore the admitted carrier supplies the stated source surface and no host analytic-continuation principle. □

Theorem 569.19 (AnalyticContinuationSocket classifier stability obligation)**.** *Componentwise* hsame *transport for accepted* AnalyticContinuationSocket$^{\uparrow}$ *packets preserves the source rows F, G, the overlap witness U, the operation row A, the output row O, and the branch-obstruction ledger B. Under this transport the classifier may replay the displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row, but it cannot replace them with an ambient analytic-continuation theorem or a hidden branch choice.*

Proof. Start with the transport row H in Definition 569.1. It stores the componentwise hsame data for the source, overlap, operation, output, obstruction, and local naming rows.

Use the classifier-stability clause of Definition 569.2. Transport of F, G, U preserves the source and overlap evidence, transport of A, O preserves the operation-output boundary, and transport of B preserves the recorded obstruction ledger.

The holomorphic handoff of Definition 569.7 then keeps downstream Holomorphic$^{\uparrow}$ consumers on the same displayed packet. Since the carrier has no branch selector or host continuation theorem, the transported classifier cannot export one. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier classifier stability obligation`

Theorem 569.20 (AnalyticContinuationSocket ledger exactness obligation)**.** *Every branch-obstruction read of an accepted* AnalyticContinuationSocket$^{\uparrow}$ *packet is recorded in the ledger row B. Such a read may be transported by H, replayed by C, named by P and N, and compared with the source, overlap, operation, and output rows, but it cannot become a new* Holomorphic$^{\uparrow}$ *output row or a continuation output outside O.*

Proof. Project the branch-obstruction coordinate B from Definition 569.1. It is the only displayed row assigned to continuation requests that leave the source, overlap, operation, and output packet.

Apply the ledger non-escape theorem Definition 569.6. Reads outside the displayed continuation packet are recorded as GAP boundary data in B rather than exported as holomorphic continuation rows.

Finally use the holomorphic handoff of Definition 569.7. Downstream $\mathsf{Holomorphic}^{\uparrow}$ consumers receive O only through F, G, U, A, H, C, P, N, so a branch-obstruction read remains ledger data and cannot turn into another output row. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier ledger exactness obligation`

Theorem 569.21 (AnalyticContinuationSocket operation landing exactness)**.** *For an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *packet* $S = (F, G, U, A, O, B, H, C, P, N)$*, every exported operation landing at the output row* O *factors through the finite rows* F, G, U, A, H, C, P, N*. The row* O *may be transported, replayed, packaged, and locally named by those rows, but it cannot be replaced by a global analytic-continuation operator, hidden branch rule, monodromy theorem, or quotient-of-germs equality.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier operation landing exactness`

Proof. Project the carrier of Definition 569.1. The only output coordinate is O, and it is displayed beside the source rows F, G, overlap witness U, operation row A, transport row H, continuation routes C, package provenance P, and local naming row N.

Apply the local NameCert obligations of Definition 569.2. Carrier admission, classifier stability, package provenance, and local naming all read the same finite socket packet.

Use overlap transport and holomorphic handoff, Definition 569.3 and Definition 569.7, to keep every downstream read of O on the displayed source-overlap-operation route. The ledger exactness obligation Definition 569.20 and ledger non-escape theorem Definition 569.6 send every non-factorizing continuation request to B rather than to another output row. □

Theorem 569.22 (AnalyticContinuationSocket overlap classifier route)**.** *For an accepted* AnalyticContinuationSock *packet* $S = (F, G, U, A, O, B, H, C, P, N)$*, every accepted overlap classifier read factors through* F, G, U, H, C, P, N*. The read may identify the operation row* A *and output row* O *only after the displayed source-overlap classifier has been transported through* H*, replayed through* C*, packaged by* P*, and named by* N*.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier overlap classifier route`

Proof. Start with the carrier definition and the local NameCert obligations. They place the source rows F, G and overlap witness U in the same finite packet as the transport, route, package, and naming rows H, C, P, N.

Apply overlap transport Definition 569.3. It keeps the overlap witness on the displayed hsame and Cont paths and forbids replacement by monodromy, quotient-of-germs equality, or a branch selector.

Finally use holomorphic handoff together with ledger exactness and ledger non-escape. Reads that reach A or O do so through the same overlap route, while reads outside F, G, U, H, C, P, N are recorded in B and are not accepted as overlap-classifier output. □

Theorem 569.23 (AnalyticContinuationSocket branch obstruction nonexport)**.** *For an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *packet* $S = (F, G, U, A, O, B, H, C, P, N)$*, every nonlocal continuation request is recorded in the branch-obstruction ledger* B*. Such a request may be transported by* H*, replayed by* C*, packaged by* P*, and locally named by* N*, but it cannot export a* $\mathsf{Holomorphic}^{\uparrow}$ *output, branch selector, quotient-of-germs equality, monodromy theorem, or zero-location datum.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier branch obstruction nonexport`

Proof. Project the branch-obstruction coordinate from Definition 569.1. The carrier assigns nonlocal continuation requests to B and lists no separate coordinate for branch selection, monodromy, quotient-of-germs equality, or zero-location data.

Use the local NameCert obligations and overlap transport to identify the permitted finite reads. The source rows, overlap witness, operation row, output row, transport routes, package provenance, and local naming are all read from $F, G, U, A, O, H, C, P, N$.

Apply ledger non-escape and the ledger exactness obligation. A request outside those rows remains branch-obstruction data in B rather than an exported continuation witness.

The holomorphic handoff then rules out the remaining export path: downstream $\mathsf{Holomorphic}^{\uparrow}$ consumers receive the displayed local output O only through F, G, U, A, H, C, P, N, so a nonlocal branch request cannot become a holomorphic output or a zero-location datum. □

Theorem 569.24 (AnalyticContinuationSocket carrier obligation)**.** *For an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *packet*

$$S = (F, G, U, A, O, B, H, C, P, N),$$

carrier admission is exactly the projection of the source rows F, G, the overlap witness U, the operation row A, the output row O, the branch-obstruction ledger B, the componentwise transport row H, the continuation-route row C, the provenance row P, and the local naming row N.

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier carrier obligation`

Proof. Project the carrier definition Definition 569.1. It lists precisely the source, overlap, operation, output, obstruction, transport, continuation, provenance, and naming rows of the finite socket.

Apply the NameCert obligations of Definition 569.2. Carrier admission is one of the five displayed obligation rows, and the remaining rows are read from the same packet.

The ledger non-escape theorem blocks any hidden continuation operator, branch selector, quotient of germs, or host complex-analysis theorem. Thus the carrier obligation is exactly the displayed finite projection. □

Theorem 569.25 (AnalyticContinuationSocket classifier obligation)**.** *Let $S = (F, G, U, A, O, B, H, C, P, N)$ and $S' = (F', G', U', A', O', B', H', C', P', N')$ be accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *packets. Classifier preservation is componentwise: the source rows F, G compare with F', G', the overlap witnesses U, U' compare through the displayed agreement boundary, the operation and output rows A, O compare with A', O' through the stored* hsame *and* Cont *routes, and the branch ledgers B, B' compare only as obstruction ledger rows.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier classifier obligation`

Proof. Use the classifier-stability row of Definition 569.2. It preserves the two source rows, the overlap witness, the operation row, the output row, and the obstruction ledger by componentwise transport.

The overlap classifier stability theorem keeps the F, G, U comparison on the local overlap-agreement boundary. The operation-output factorization theorem keeps the A, O comparison on the displayed operation output rather than on an unrestricted continuation operator.

Finally, ledger non-escape and the holomorphic handoff prevent an obstruction comparison from becoming another $\mathsf{Holomorphic}^{\uparrow}$ output. Hence the classifier obligation preserves overlap and output through hsame and Cont only. □

Theorem 569.26 (AnalyticContinuationSocket ledger obligation)**.** *Every branch-sensitive consumer read of an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *packet factors through the finite rows*

$$F, G, U, A, O, B, H, C, P, N.$$

If the read asks for a continuation output not displayed by O through the source, overlap, operation, transport, route, provenance, and naming rows, the request remains in the branch-obstruction ledger B and is not exported as a continuation output.

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier ledger obligation`

Proof. Start from the ledger exactness obligation Definition 569.20. It assigns branch-obstruction reads to B and keeps them from becoming output rows outside O.

Apply ledger non-escape to exhaust the carrier-visible rows. The holomorphic handoff then shows that downstream $\mathsf{Holomorphic}^{\uparrow}$ consumers obtain the displayed output only through F, G, U, A, H, C, P, N.

Use overlap classifier stability and operation-output factorization for the two positive paths through the socket. All remaining branch-sensitive reads are ledger entries, so no undisplayed continuation output escapes the packet. □

Theorem 569.27 (AnalyticContinuationSocket zeta branch-obstruction exactness)**.** *Let $S = (F, G, U, A, O, B, H, C, P, N)$ be an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier. Every zeta-continuation or Riemann-hypothesis-facing request that asks for nontrivial zero-location data, monodromy data, a branch selector, or continuation data beyond the displayed local socket is recorded in the branch-obstruction ledger B. Such a request is not exported as continuation evidence, zero-location evidence, or a new* $\mathsf{Holomorphic}^{\uparrow}$ *output row.*

Proof. Project the carrier of Definition 569.1. Its consumer-readable coordinates are exactly $F, G, U, A, O, B, H, C, P, N$, with B assigned to branch-obstruction accounting.

Apply Definition 569.6 and Definition 569.26. A request outside the source rows, overlap witness, local operation output, displayed transports, routes, provenance, and naming rows has no output coordinate other than the ledger row B.

Finally use Definition 569.10. The Riemann-hypothesis-facing handoff excludes monodromy, branch selection, global continuation, and zero-location consequences, so the branch-sensitive request remains a ledger entry rather than exported continuation evidence. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier zeta branch obstruction exactness`

Theorem 569.28 (AnalyticContinuationSocket overlap-to-zeta handoff)**.** *Let $S = (F, G, U, A, O, B, H, C, P, N)$ be an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier. Every zeta-continuation consumer that reads the socket output receives only the overlap-and-output handoff*

$$F, G, U, A, O, H, C, P, N$$

together with the ledger row B. The handoff may certify that O is the displayed local output over the overlap witness U, but it supplies no nontrivial zero-location datum, monodromy theorem, branch selector, or continuation evidence outside O.

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier overlap to zeta handoff`

Proof. Start from Definition 569.7. The output row O is exposed only through the source rows F, G, the overlap witness U, the operation row A, and the transport, route, provenance, and local naming rows H, C, P, N.

Use the carrier inventory in Definition 569.1. It contains no separate coordinate for a zeta branch selector, monodromy theorem, zero-location conclusion, or continuation object beyond the displayed operation output.

Apply Definition 569.10 and Definition 569.26. The zeta-facing consumer therefore reads the local overlap/output socket, while any request outside that socket is recorded in B and not exported as continuation evidence. □

Theorem 569.29 (AnalyticContinuationSocket zero-location non-read)**.** *Let $S = (F, G, U, A, O, B, H, C, P, N)$ be an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier. No Riemann-hypothesis-facing consumer can read a nontrivial zero-location conclusion from S. The consumer can read only the local overlap/output socket, and every zero-location, monodromy, branch-selector, or global-continuation request is recorded in B rather than exported as continuation evidence.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier no zero location read`

Proof. The carrier definition Definition 569.1 lists no zero-location coordinate. Its output coordinate is the local $\mathsf{Holomorphic}^{\uparrow}$ row O, read through the finite overlap and operation packet.

Apply Definition 569.7 and Definition 569.10. These results give the Riemann-hypothesis-facing consumer only the local socket $F, G, U, A, O, H, C, P, N$ and the branch-obstruction ledger B.

The remaining cases are exactly the requests covered by Definition 569.6 and Definition 569.26. They stay in B, so no zero-location read can be exported by the socket. □

Theorem 569.30 (AnalyticContinuationSocket carrier admission)**.** *For every accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier*

$$S = (F, G, U, A, O, B, H, C, P, N),$$

the carrier admitted over BHist *is exactly the finite socket packet with* $\mathsf{Complex}^{\uparrow}$*-based* $\mathsf{Holomorphic}^{\uparrow}$ *source rows F, G, overlap witness U, local operation row A, output* $\mathsf{Holomorphic}^{\uparrow}$ *row O, branch ledger B, componentwise* hsame *transports H, finite* Cont *routes C,* Pkg *provenance P, and local* $\mathsf{NameCert}_{\mathsf{AnalyticContinuationSocket}^{\uparrow}}$ *row N. No admitted carrier supplies a quotient of germs, selected analytic continuation, global branch selector, or ambient complex-analysis theorem outside those rows.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier carrier admission`

Proof. Project the displayed carrier Definition 569.1. Its rows are already indexed by BHist and expose the two $\mathsf{Complex}^{\uparrow}$-based $\mathsf{Holomorphic}^{\uparrow}$ sources, the overlap witness, operation, output, branch ledger, transports, routes, package provenance, and local name.

Use the carrier obligation Definition 569.24. It identifies carrier admission with the same finite projection and leaves no coordinate from which an external continuation theorem can be read.

Finally apply ledger non-escape and the holomorphic handoff. The admitted carrier is therefore the local socket packet itself; any branch-sensitive request outside the displayed output remains ledger data rather than carrier data. □

Theorem 569.31 (AnalyticContinuationSocket classifier transport)**.** *Let*

$$S = (F, G, U, A, O, B, H, C, P, N)$$

be an accepted $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier. Classifier transport through* S *is componentwise over the* BHist *socket rows: the* $\mathsf{Complex}^{\uparrow}$*-based* $\mathsf{Holomorphic}^{\uparrow}$ *source rows* F, G*, overlap witness* U*, local operation row* A*, output row* O*, and branch ledger* B *are transported only through the displayed* hsame *row* H*, the finite* Cont *routes* C*, the* Pkg *provenance* P*, and the local* $\mathsf{NameCert}$ *row* N*.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier classifier transport`

Proof. Start with the classifier obligation Definition 569.25. It compares the source rows, overlap witness, operation row, output row, and branch ledger only componentwise.

The overlap classifier stability theorem keeps the F, G, U comparison on the displayed overlap boundary, while the operation-output factorization theorem keeps A and O attached to the same local socket route. The stored hsame and Cont rows are the only transport surfaces used in those comparisons.

The branch ledger is transported as ledger data. By the ledger non-escape and holomorphic handoff theorems, transport of B cannot become a new $\mathsf{Holomorphic}^{\uparrow}$ output, a global branch choice, or an external analytic-continuation result. □

Theorem 569.32 (AnalyticContinuationSocket branch-ledger exactness)**.** *For an accepted* AnalyticContinuationSoc *carrier*

$$S = (F, G, U, A, O, B, H, C, P, N),$$

every branch-sensitive $\mathsf{Complex}^{\uparrow}$*,* $\mathsf{Holomorphic}^{\uparrow}$*, or downstream socket consumer read is routed through the displayed ledger* B *unless it is already the local output row* O *transported from the source rows* F, G *across* U *by* A, H, C, P, N*. Thus the branch ledger is exact for the packet: it records precisely the requests not exported by the local holomorphic output, and it asserts no completed analytic-continuation theorem outside the finite socket.*

Proof. Begin with the ledger obligation Definition 569.26. It places every branch-sensitive read either in the displayed local output route or in the ledger row B.

Use carrier admission and classifier transport to keep this split inside the same BHist packet. The rows $F, G, U, A, O, H, C, P, N$ define the positive local-output route, while B records requests whose branch data is not displayed by that route.

Finally apply the zeta branch-obstruction exactness and overlap-to-zeta handoff theorems. They show that zero-location, monodromy, branch-selector, and global-continuation requests remain ledger entries, so the exactness claim does not assert analytic continuation as a completed external theorem. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier branch ledger exactness`

Theorem 569.33 (AnalyticContinuationSocket overlap source obligation)**.** *Let*

$$S = (F, G, U, A, O, B, H, C, P, N)$$

be an accepted $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier. Every accepted socket source overlap is read only through the* $\mathsf{Complex}^{\uparrow}$ *and* $\mathsf{Holomorphic}^{\uparrow}$ *source rows* F, G*, the overlap classifier row* U*, componentwise* hsame *transport* H*, displayed* Cont *route* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{AnalyticContinuationSocket}^{\uparrow}}$

row N. No overlap source read supplies a quotient of germs, selected branch, global continuation, or analytic-continuation oracle outside those rows.

Proof. Start with carrier admission. The carrier of Definition 569.1 exposes the source rows F, G and the overlap row U before any operation output is read.

Use the NameCert obligations and classifier transport. They keep the overlap classifier attached to the displayed $\mathsf{Complex}^{\uparrow}$ and $\mathsf{Holomorphic}^{\uparrow}$ source rows through H, C, P, N.

Finally apply branch ledger exactness and overlap-to-zeta handoff. Requests outside the displayed overlap source route are recorded in B rather than exported as source-overlap evidence, so the listed rows exhaust the obligation. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier overlap source obligation`

Theorem 569.34 (AnalyticContinuationSocket branch ledger obligation)**.** *For an accepted* AnalyticContinuationSo *carrier*

$$S = (F, G, U, A, O, B, H, C, P, N),$$

branch-ledger reads are exact for the displayed overlap row U, branch tag or obstruction row B, local operation row A, and local output row O. The ledger exports only the recorded split between local output and obstruction; it exports no analytic-continuation oracle, global monodromy theorem, branch selector, or zero-location datum.

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier branch ledger obligation`

Proof. Begin with Definition 569.32. It states that branch-sensitive reads are routed either to the local output path through O or to the ledger row B.

Use ledger exhaustion and local output handoff to identify the positive route. The rows $F, G, U, A, O, H, C, P, N$ are exactly the displayed overlap, operation, output, transport, route, provenance, and naming rows.

Now use zeta branch-obstruction exactness. Zero-location, monodromy, branch-selector, and global-continuation requests remain obstruction entries in B, so the ledger does not export an analytic-continuation oracle. □

Theorem 569.35 (AnalyticContinuationSocket operation handoff obligation)**.** *Every* AnalyticContinuationOperatic *or* $\mathsf{ZetaContinuationApplication}^{\uparrow}$ *consumer of an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier*

$$S = (F, G, U, A, O, B, H, C, P, N)$$

must factor through the source-overlap ledger F, G, U, H, C, P, N and the branch ledger B before reading the operation output O. Such a consumer may receive the local operation handoff A, O over the displayed overlap, but it cannot bypass the source and branch ledgers to obtain global analytic continuation, monodromy, branch selection, or zero-location information.

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier operation handoff obligation`

Proof. First apply the overlap source obligation. It makes every accepted source-overlap read pass through F, G, U, H, C, P, N.

Next apply the branch ledger obligation. It accounts for every branch-sensitive request before the operation output is consumed, assigning nonlocal requests to B.

Finally use the holomorphic handoff and overlap-to-zeta handoff. They route the local operation output through A, O after the source and branch ledgers have been read, while zeta-facing obstruction exactness blocks any bypass to global continuation or zero-location data. □

Theorem 569.36 (AnalyticContinuationSocket public export)**.** *The public* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *export of an accepted carrier*

$$S = (F, G, U, A, O, B, H, C, P, N)$$

is exactly the finite socket packet consisting of the source rows F, G*, overlap witness* U*, operation row* A*, output row* O*, branch ledger* B*, componentwise* hsame *transport* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{AnalyticContinuationSocket}^{\uparrow}}$ *row* N*. The export contains no monodromy theorem, quotient-of-germs object, branch selector, or zero-location consequence beyond those rows.*

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier public export`

Proof. Start with the NameCert obligations for Definition 569.1. They expose the accepted socket as the displayed tuple $S = (F, G, U, A, O, B, H, C, P, N)$ and require classifier stability for the source, overlap, operation, output, branch, transport, route, provenance, and naming rows.

Use branch-ledger exactness together with holomorphic handoff and overlap classifier stability. These results keep every source-overlap read inside F, G, U, H, C, P, N and keep every branch-sensitive request either in the local output route through A, O or in the branch ledger B.

Next apply operation-output factorization, the RH handoff boundary, and the operation handoff obligation. They show that downstream operation and zeta-facing consumers must pass through the same finite rows before receiving the output, so the exported object is the packet itself.

The exclusions follow from the same routing boundary. Monodromy, quotient-of-germs data, branch selection, and zero-location conclusions are not coordinates of S and therefore cannot be projected from the public socket export. □

Theorem 569.37 (AnalyticContinuationSocket bridge route)**.** *The public export of Definition 569.36, the operation-output factorization of Definition 569.9, the RH handoff boundary of Definition 569.10, and the branch-ledger exhaustion of Definition 569.4 assemble the finite bridge route from local* $\mathsf{Holomorphic}^{\uparrow}$ *overlap data to zeta-facing continuation consumers. For an accepted carrier*

$$S = (F, G, U, A, O, B, H, C, P, N),$$

every such consumer must pass through the source rows, overlap witness, operation row, output row, branch ledger, componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{AnalyticContinuationSocket}^{\uparrow}}$ *row before receiving continuation-facing output. The route exports no monodromy theorem, branch choice, quotient-of-germs object, or zero-location claim.*

Proof. Begin with the public export. It identifies the socket surface with the displayed rows $F, G, U, A, O, B, H, C, P, N$.

Next use operation-output factorization and the RH handoff boundary. They force every zeta-facing consumer to read the operation output only after the local overlap and branch rows have been exposed.

Finally apply branch-ledger exhaustion. It routes every branch-sensitive request either through the displayed output row or through the obstruction ledger, so the bridge route remains finite and contains no monodromy, branch selector, quotient germ, or zero-location coordinate. □

Lean4 ✓ `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier bridge route`

↪ variant `BEDC.Derived.AnalyticContinuationSocketUp.AnalyticContinuationSocketCarrier bridge route certificate`

The sibling dependency lattice is part of the socket surface: chapter 68 supplies the two Holomorphic$^{\uparrow}$ source rows and output row read by the branch and overlap ledger, while chapter 588 consumes the same finite continuation-facing route as zeta-facing operation data. Thus the dependency is the branch/overlap ledger together with the continuation operation route, not a detached bibliographic citation.

Closure status for $\mathsf{NameCert}_{\mathsf{AnalyticContinuationSocket}\uparrow}$.

Constructive story: An AnalyticContinuationSocket$^{\uparrow}$ packet is generated from two Holomorphic$^{\uparrow}$ source rows, a finite overlap witness, an analytic-continuation operation row, an output Holomorphic$^{\uparrow}$ row, a branch-obstruction ledger, displayed hsame transports, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AnalyticContinuationSocket}\uparrow}$, maturePackageClosed)

Scope closed: The mature finite socket packet is the carrier $S = (F, G, U, A, O, B, H, C, P, N)$ together with the public bridge route, branch ledger exactness, source-overlap and operation handoffs, hsame transport, Cont replay, Pkg provenance, local NameCert rows, and the sibling dependency lattice through Holomorphic$^{\uparrow}$ and ZetaContinuationApplication$^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AnalyticContinuationSocket}\uparrow}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close global monodromy, quotient-of-germs construction, branch selection, RH zero-location consequences, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, classifier stability, branch-ledger exactness, package provenance, and local naming for the same finite socket packet.

Chapter 570

A Concrete Naming Certificate for $\mathsf{ZetaContinuationSocket}^{\uparrow}$

The $\mathsf{ZetaContinuationSocket}^{\uparrow}$ packet turns the Riemann-zeta continuation narrative into a finite local certificate. It reads the already displayed $\mathsf{ZetaBasic}^{\uparrow}$ source, the eta half-plane handoff, the $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ operation boundary, the pole and functional-equation ledgers, the $\mathsf{Gamma}^{\uparrow}$ factor interface, and the trivial-zero ledger as named rows of one BHist packet. It does not assert RH, global zero classification, a complete constructive Gamma chapter, or a branch selector outside the displayed continuation routes.

The witness-facing handoff is the sibling packet of chapter 580, while this socket chapter supplies the boundary rows before the witness adds its package-provenance coordinate.

Definition 570.1 (ZetaContinuationSocket carrier)**.** *A* $\mathsf{ZetaContinuationSocket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (B, E, A, P, F, T, G, H, C, N)$$

with the following displayed rows:

1. *B is the* $\mathsf{ZetaBasic}^{\uparrow}$ *source row on the half-plane $\Re(s) > 1$;*
2. *E is the eta half-plane row, including the eta-series value, the denominator boundary $1 - 2^{1-s}$, and the overlap agreement with B where both rows are defined;*
3. *A is the* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *handoff row that reads B, E and the finite overlap evidence as a local continuation socket;*
4. *P is the pole-residue row at $s = 1$, recording the simple-pole boundary and residue* $\mathsf{E1(e)}$ *without exporting a regular value there;*
5. *F is the finite functional-equation factor ledger, containing the rows for 2^s, π^{s-1}, $\sin(\pi s/2)$, the reflected zeta input $1 - s$, and their displayed product route;*
6. *T is the trivial-zero ledger, recording the negative-even inputs whose sine factor is zero and the companion rows that remain finite at those inputs;*
7. *G is the* $\mathsf{Gamma}^{\uparrow}$ *factor interface row, naming the input boundary for $\Gamma(1 - s)$ and recording poles as ledger entries rather than as zeta values;*
8. *H stores the displayed* hsame *transports among the zeta-basic source, eta row, analytic-continuation socket row, pole row, functional-equation factor rows, trivial-zero ledger, Gamma factor interface, and local naming row;*

9. *C stores the finite* Cont *routes by which consumers read the source half-plane, eta handoff, pole boundary, functional-equation factorization, Gamma interface, trivial-zero ledger, package provenance, and local naming row;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{ZetaContinuationSocket}^{\uparrow}}$ *row.*

The carrier exposes exactly this finite socket. It contains no unrestricted meromorphic-continuation principle, no proof that all nontrivial zeros lie on the critical line, no complete $\mathsf{Gamma}^{\uparrow}$ *construction, and no hidden analytic branch choice.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationSocketUp.ZetaContinuationSocketTasteGate single carrier alignment`

Theorem 570.2 (ZetaContinuationSocket NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ZetaContinuationSocket}^{\uparrow}}$ *surface for Definition 570.1 consists of five finite rows: carrier admission for Z; classifier stability for B, E, A, P, F, T, G under the displayed* hsame *transports in H; ledger exactness for the pole, branch, Gamma-boundary, and trivial-zero coordinates;* Pkg *provenance through the continuation routes in C; and local naming exactness for N.*

Proof. Carrier admission is projection of the tuple Z. Each analytic ingredient named by the socket is a visible coordinate, so the certificate never reads an unlisted continuation object.

Classifier stability is componentwise. The displayed hsame transports in H preserve the zeta-basic source, the eta handoff, the analytic-continuation socket boundary, the pole-residue row, the functional-equation factor rows, the trivial-zero ledger, and the Gamma-boundary row.

Ledger exactness is also coordinatewise. Requests at $s = 1$ land in P, Gamma inputs at a pole land in G, negative-even zero requests land in T, and branch requests outside the finite routes land in the obstruction part of the analytic-continuation socket row A.

The continuation routes in C and the local naming row N then repack the same coordinates as a finite NameCert surface. No row introduces a global continuation theorem or an RH-facing zero-location conclusion. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationSocketUp.ZetaContinuationSocketNameCertObligations`

Theorem 570.3 (ZetaContinuationSocket ledger non-escape)**.** *Every consumer read exported by an accepted* $\mathsf{ZetaContinuationSocket}^{\uparrow}$ *carrier factors through the displayed rows $B, E, A, P, F, T, G, H, C, N$. A read that asks for a zeta value at the pole, a Gamma value at a Gamma pole, a continuation route outside the displayed eta and functional-equation routes, or a nontrivial-zero location claim is recorded in the corresponding ledger coordinate and is not exported as a zeta-continuation value.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationSocketUp.ZetaContinuationSocketLedger nonescape`

Proof. Read the consumer request through the finite routes in C. If it lands in the half-plane source row, eta handoff, analytic-continuation socket row, pole row, functional-equation factor ledger, trivial-zero ledger, Gamma-boundary row, transport row, or local naming row, the carrier returns that coordinate.

It remains to inspect requests outside those coordinates. A value at $s = 1$ is blocked by P, a Gamma-pole request is blocked by G, a branch request outside the displayed continuation routes is blocked by A, and a nontrivial-zero location assertion has no carrier coordinate. Each case is therefore a ledger read rather than an exported zeta value. □

Theorem 570.4 (ZetaContinuationSocket analytic handoff)**.** *For an accepted* ZetaContinuationSocket$^{\uparrow}$ *carrier* $Z = (B, E, A, P, F, T, G, H, C, N)$*, every downstream consumer of the continued zeta row also reads the* ZetaBasic$^{\uparrow}$ *source row* B*, the eta half-plane row* E*, the* AnalyticContinuationSocket$^{\uparrow}$ *handoff row* A*, the pole-residue row* P*, the functional-equation factor ledger* F*, the trivial-zero ledger* T*, the* Gamma$^{\uparrow}$ *interface* G*, and the transport, continuation, and naming rows* H, C, N*.*

Proof. Begin with a downstream continued-zeta read. By the carrier definition, such a read reaches the output only through the continuation socket coordinate A and its finite route in C.

The source side of A is the pair of rows B, E together with their overlap evidence. Transport through H preserves this source boundary, so the downstream read keeps the zeta-basic and eta inputs visible.

The remaining analytic boundary is supplied by P, F, T, G. These coordinates record the pole at 1, the functional-equation factors, the trivial-zero sine cancellations, and the Gamma-boundary interface. Thus the handoff exports a finite packet, not a standalone meromorphic function or a hidden branch choice. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationSocketUp.ZetaContinuationSocketCarrier analytic handoff`

Theorem 570.5 (ZetaContinuationSocket vision concretization)**.** *The zeta continuation application is concretized by* ZetaContinuationSocket$^{\uparrow}$ *as a finite* BHist *socket packet over the* ZetaBasic$^{\uparrow}$ *source, eta half-plane handoff,* AnalyticContinuationSocket$^{\uparrow}$ *route, pole-residue row, functional-equation factor ledger,* Gamma$^{\uparrow}$ *interface, trivial-zero ledger, displayed* hsame *transports, finite* Cont *routes, and local* NameCert *row.*

Proof. The carrier of Definition 570.1 supplies the finite packet. The NameCert obligations of Definition 570.2 bind its carrier, classifier, ledger, route, and naming rows.

The non-escape theorem prevents pole, Gamma-boundary, branch, and nontrivial-zero-location requests from becoming continuation values. The analytic handoff theorem identifies the exact rows a downstream zeta-continuation consumer must read. These clauses realize the zeta continuation application as a finite BEDC socket certificate. □

Closure status for NameCert$_{\text{ZetaContinuationSocket}^{\uparrow}}$**.**

Constructive story: A ZetaContinuationSocket$^{\uparrow}$ packet is generated from the ZetaBasic$^{\uparrow}$ source row, eta half-plane row, AnalyticContinuationSocket$^{\uparrow}$ handoff, pole-residue row at 1, functional-equation factor ledger, Gamma$^{\uparrow}$ boundary interface, trivial-zero ledger, displayed hsame transports, finite Cont routes, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ZetaContinuationSocket}^{\uparrow}}$, seed)

Scope closed: Definition 570.1, Definition 570.2, Definition 570.3, and Definition 570.4 define the local socket carrier, obligation rows, non-escape ledger, and downstream analytic handoff.

Formal verification: FormalStatus(NameCert$_{\text{ZetaContinuationSocket}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close RH, nontrivial-zero classification, global meromorphic uniqueness, complete Gamma$^{\uparrow}$ construction, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, classifier stability, pole and Gamma ledger exactness, functional-equation route provenance, trivial-zero ledger exactness, and local naming for the same finite socket packet.

Theorem 570.6 (ZetaContinuationSocket witness carrier bridge)**.** *Let* $Z = (B, E, A, P, F, T, G, H, C, N)$ *be an accepted* ZetaContinuationSocket$^{\uparrow}$ *carrier as in Definition 570.1. Suppose* R *is a displayed* Pkg *provenance row over the same zeta source, eta handoff, pole ledger, functional-equation ledger,*

trivial-zero ledger, Gamma-boundary row, transport row, route row, and local naming row, with package scope

$$\mathsf{ZetaBasic}^{\uparrow},\ \mathsf{ZetaCont}^{\uparrow},\ \mathsf{AnaCont}^{\uparrow},\ \mathsf{Holomorphic}^{\uparrow},\ \mathsf{Complex}^{\uparrow},\ \mathsf{BHist},\ \mathsf{hsame},\ \mathsf{Cont},\ \mathsf{NameCert}.$$

Then

$$W = (B, E, A, P, F, T, G, H, C, R, N)$$

is an accepted $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *carrier as in Definition 580.1. Its downstream non-escape boundary is the same as the boundary of Z: pole requests land in P, negative-even trivial-zero requests land in T, Gamma-dependent requests outside the displayed functional-equation factors land in G, branch requests outside the displayed continuation routes land in A, and RH or non-trivial-zero-location requests have no exported carrier coordinate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationSocketUp.ZetaContinuationSocketWitnessCarrierBridge`

Proof. Unpack the socket carrier. The accepted packet Z already supplies the source row B, eta row E, analytic-continuation socket row A, pole row P, functional-equation factor ledger F, trivial-zero ledger T, Gamma interface G, componentwise transports H, finite continuation routes C, and local naming row N.

The only coordinate required by Definition 580.1 and not already present in the socket tuple is the package-provenance coordinate R. By hypothesis, R is displayed over exactly the same zeta, eta, pole, functional-equation, trivial-zero, Gamma-boundary, transport, route, and naming coordinates, and its package scope is the witness scope listed in Definition 580.1. Inserting this row between C and N therefore gives the witness tuple $W = (B, E, A, P, F, T, G, H, C, R, N)$ with every required coordinate visible.

It remains to compare the exported boundaries. The provenance row R is a package row; it records how the already displayed coordinates are named through Pkg, and it is not an analytic continuation row, a Gamma completion row, a pole-regularization row, or a zero-location row. Thus adding R cannot create a route that bypasses A, P, T, G, H or C.

Now apply the socket non-escape statement of Definition 570.3. The pole boundary is still the coordinate P, the negative-even trivial-zero ledger is still T, Gamma escape is still absorbed by G, and branch escape is still absorbed by A. The witness handoff statement of Definition 580.37 reads these same coordinates through W and exports no RH conclusion and no zero-location classifier. Hence the constructed witness has the same downstream non-escape boundary as the original socket carrier. □

Theorem 570.7 (ZetaContinuationSocket functional-equation boundary)**.** *Let $Z = (B, E, A, P, F, T, G, H, C, N)$ be an accepted* $\mathsf{ZetaContinuationSocket}^{\uparrow}$ *carrier as in Definition 570.1. Any accepted route that reads eta data, pole data,* $\mathsf{Gamma}^{\uparrow}$ *boundary data, branch data, trivial-zero data, transport data, continuation-route data, or local naming data into the witness-facing packet must factor through the displayed functional-equation ledger F together with the visible socket rows $B, E, A, P, T, G, H, C, N$.*

The route exports no RH verdict, no nontrivial-zero classifier, no global meromorphic uniqueness principle, and no completed $\mathsf{Gamma}^{\uparrow}$ *construction. Those endpoints are not coordinates of the carrier and are not added by the witness carrier bridge.*

Proof. Project the carrier from Definition 570.1. The eta row is E, the pole row is P, the functional-equation factor ledger is F, the trivial-zero ledger is T, the $\mathsf{Gamma}^{\uparrow}$ boundary interface is G, and the structural rows are H, C, N.

Apply Definition 570.3. Reads asking for a pole value, a Gamma-pole value, a branch outside the displayed continuation routes, or a nontrivial-zero location are recorded in the corresponding ledger coordinates instead of being exported as continuation values.

Apply Definition 570.4. Every downstream continued-zeta read keeps the source, eta, socket, pole, functional-equation, trivial-zero, Gamma-boundary, transport, continuation, and naming rows visible. Thus the functional-equation boundary is a displayed ledger route, not a hidden analytic theorem.

Finally apply Definition 570.6. Passing to the witness packet only inserts the package-provenance row over the same displayed coordinates. Since RH verdicts, nontrivial-zero classifiers, global meromorphic uniqueness, and completed Gamma constructions are absent from the socket carrier, no witness-facing route can export them. □

Theorem 570.8 (ZetaContinuationSocket boundary exhaustion)**.** *Every accepted* $\mathsf{ZetaContinuationSocket}^{\uparrow}$ *socket read factors through the analytic-continuation socket rows* B, E, A*, the pole row* P*, the functional-equation ledger* F*, the trivial-zero ledger* T*, the* $\mathsf{Gamma}^{\uparrow}$ *boundary row* G*, the witness-carrier bridge, the functional-equation boundary, the visible ledger rows, the displayed* hsame *transport, the* Cont *replay, package provenance, and the local* $\mathsf{NameCert}$ *row before any downstream witness may consume it. The exhausted boundary exports no RH verdict, no global meromorphic uniqueness principle, no nontrivial-zero classification, and no complete* $\mathsf{Gamma}^{\uparrow}$ *construction.*

Proof. Start with the NameCert obligations of Definition 570.2. They bind carrier admission, classifier stability, ledger exactness, provenance, and local naming to the visible rows of the socket packet.

Apply ledger non-escape, Definition 570.3, and analytic handoff, Definition 570.4. These force every consumer read through the source, eta, continuation socket, pole, functional-equation, trivial-zero, Gamma-boundary, transport, replay, and naming rows.

Now apply the witness carrier bridge and the functional-equation boundary, Definition 570.6 and Definition 570.7. Passing to a witness only adds package provenance over the same displayed rows, and the functional-equation route keeps the factor ledger visible.

The listed rows therefore exhaust the socket boundary. Since RH, global meromorphic uniqueness, nontrivial-zero classification, and a complete Gamma construction are absent from the carrier and from the bridge row, no downstream witness can consume them through this socket read. □

Chapter 571

A Concrete Naming Certificate for $\mathsf{DimLiftBoundary}^{\uparrow}$

The $\mathsf{DimLiftBoundary}^{\uparrow}$ packet turns the AxisZeckendorf dimension-lift refusal into a finite boundary certificate. It records the carry rows, normal-address rows, cannot-claim rows, full-axis context, real-facing refusal, transport routes, package provenance, and local naming row that a later dimension-lift acceptance flow must inspect before it may claim any primitive dimension reading.

The boundary packet consumes the refusal surface of chapter 554, the carry row of chapter 544, the finite normal-address surface of chapter 278, and the $\mathsf{Real}^{\uparrow}$ handoff of chapter 38. These sibling chapters supply displayed dependency rows for the boundary packet, not primitive dimension data.

It is also read downstream of the zero-spine AxisNat carrier in chapter 276 and the standard-boundary comparison in chapter 530. Those sibling rows explain why the ZCarry and normal-address evidence remains refusal evidence rather than a primitive dimension row.

Definition 571.1 (DimLiftBoundary carrier)**.** *A* $\mathsf{DimLiftBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (Z, N, A, F, R, H, C, P, Q)$$

with the following displayed rows:

1. *Z is the* $\mathsf{ZCarry}^{\uparrow}$ *carry-classifier ledger over the relevant AxisZeckendorf histories;*
2. *N is the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *normal-address row for the same finite histories;*
3. *A is the* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *refusal row containing the dimension-lift non-claim;*
4. *F is the* $\mathsf{FullAxis}^{\uparrow}$ *context row through which the carry and normal-address data are read;*
5. *R is the* $\mathsf{Real}^{\uparrow}$ *refusal boundary, recording that no real, metric, topological, vector-space, homological, projective, or geometric dimension row is exported;*
6. *H stores componentwise* hsame *transports for the carry row, normal-address row, cannot-claim row, full-axis context, real-facing boundary, and local naming row;*
7. *C stores the finite* Cont *routes by which consumers read the displayed rows from the packet boundary;*
8. *P is the* Pkg *provenance over* $\mathsf{ZCarry}^{\uparrow}$, $\mathsf{ZeckendorfNormal}^{\uparrow}$, $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$, $\mathsf{FullAxis}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *Q is the local* $\mathsf{NameCert}_{\mathsf{DimLiftBoundary}^{\uparrow}}$ *row.*

The carrier is a boundary packet, not a dimension object. It exposes the finite rows that explain why a dimension-lift reading is blocked, while leaving any accepted dimension interface to a separate certificate.

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryPacket single carrier alignment`

Definition 571.2 (DimLiftBoundary classifier)**.** *For accepted packets $D = (Z, N, A, F, R, H, C, P, Q)$ and $D' = (Z', N', A', F', R', H', C', P', Q')$, the classifier* $\mathsf{DimLiftBoundaryClassifier}(D, D')$ *holds exactly when the displayed* hsame *and* Cont *rows transport Z to Z', N to N', A to A', F to F', R to R', P to P', and Q to Q' componentwise. The classifier preserves carry and normal-address rows while blocking any read that treats those rows as a primitive dimension.*

Theorem 571.3 (DimLiftBoundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DimLiftBoundary}^{\uparrow}}$ *surface for Definition 571.1 consists of five finite rows: carrier admission for D; classifier stability for Z, N, A, F, R under the displayed transports H; route exactness for the consumer reads in C; package provenance through P; and local naming exactness for Q. These rows preserve the carry and normal-address evidence while keeping primitive dimension readings outside the certificate.*

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryCarrier namecert obligations`

Proof. Carrier admission is projection of the finite tuple D. Each dependency row named in the statement is a visible coordinate of the same BHist packet.

Classifier stability is componentwise. The hsame table H and the routes C transport the carry ledger, normal-address row, cannot-claim row, full-axis context, and real-facing refusal boundary without adding a dimension coordinate.

The package and naming rows then repack exactly those coordinates. Since the carrier has no row for geometric, topological, vector-space, homological, projective, metric, or real dimension data, the NameCert surface is exhausted by the boundary packet. □

Theorem 571.4 (DimLiftBoundary non-escape)**.** *Every consumer read exported by an accepted* $\mathsf{DimLiftBoundary}^{\uparrow}$ *carrier factors through the displayed rows $Z, N, A, F, R, H, C, P, Q$. A read that asks to interpret the carry classifier or normal-address row as a primitive dimension lands in the refusal boundary A and R, not in a dimension-valued row.*

Proof. Read the consumer request through the finite routes in C. If it asks for carry evidence, normal-address data, the cannot-claim row, the full-axis context, transport, provenance, or local naming, the corresponding coordinate of D supplies that read.

If the request asks for a primitive dimension interpretation, no coordinate of D has that type. The only visible rows governing the request are the cannot-claim row A and the real-facing refusal boundary R.

Thus the request is recorded as boundary evidence. It cannot escape as a geometric, topological, vector-space, homological, projective, metric, or real dimension object. □

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryNonEscape`

Theorem 571.5 (DimLiftBoundary public export)**.** *The carrier of Definition 571.1, the classifier of Definition 571.2, and the local obligations of Definition 571.3 export a public boundary packet for later* $\mathsf{DimLift}^{\uparrow}$ *acceptance-flow work. Downstream consumers may read the displayed* $\mathsf{ZCarry}^{\uparrow}$, $\mathsf{ZeckendorfNormal}^{\uparrow}$, $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$, $\mathsf{FullAxis}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert *rows, but they receive no primitive dimension interface from this chapter.*

Proof. The carrier supplies the public rows $Z, N, A, F, R, H, C, P, Q$. The classifier preserves those rows componentwise, so a downstream consumer can transport the boundary packet without changing its visible dependency surface.

The NameCert obligations identify the exact admission, transport, route, provenance, and naming rows. The non-escape theorem then blocks every request that would turn the carry or normal-address evidence into a primitive dimension object.

Therefore the public export is a boundary carrier for future acceptance-flow chapters. It supplies the refusal surface that such chapters must consume before supplying any separate dimension certificate. □

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryPublicExport`

Theorem 571.6 (DimLiftBoundary axis refusal obligations)**.** *For an accepted* $\mathsf{DimLiftBoundary}^{\uparrow}$ *carrier* $D = (Z, N, A, F, R, H, C, P, Q)$*, the AxisZeckendorf-facing refusal surface consists exactly of the* $\mathsf{ZCarry}^{\uparrow}$ *carry rows in* Z*, the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *normal-address rows in* N*, the* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ *cannot-claim rows in* A*, the* $\mathsf{FullAxis}^{\uparrow}$ *context row in* F*, and the transport, route, provenance, and local naming rows* H, C, P, Q*. The surface refuses any export that reads* Z *or* N *as a primitive geometric, topological, vector-space, homological, projective, metric, or real dimension.*

Proof. Project the carrier and read the AxisZeckendorf coordinates Z, N, A, F. The carry and normal-address rows are visible only inside the full-axis context, and the cannot-claim row records the refusal attached to that context.

The remaining rows H, C, P, Q transport, route, package, and name this same boundary. None of them supplies a dimension-valued coordinate or a classifier into one.

Therefore every axis-facing consumer receives the carry and normal-address evidence as refusal evidence. It cannot repack the same rows as a primitive dimension interface. □

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryAxisRefusalObligations`

Theorem 571.7 (DimLiftBoundary Real handoff non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing read of an accepted* $\mathsf{DimLiftBoundary}^{\uparrow}$ *carrier factors through the displayed refusal boundary* R *together with* Z, N, A, F, H, C, P, Q*. The handoff may report that the AxisZeckendorf carry and normal-address rows have no real-dimension export, but it may not produce a real coordinate, real metric dimension, host-real equality row, or completion-facing dimension object.*

Proof. Start with the real-facing coordinate R. By definition of the carrier, R is reached only after the carry rows, normal-address rows, cannot-claim rows, and full-axis context have already been displayed.

The continuation routes in C and transports in H replay the same refusal packet for a real-facing consumer. Package provenance P and local naming Q record the dependency surface without adding any real-valued coordinate.

Thus the real handoff is a non-escape boundary. It can expose refusal of a real dimension reading, but it cannot export a real dimension object or any host-real comparison datum. □

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryRealHandoffNonescape`

Theorem 571.8 (DimLiftBoundary Zeckendorf carrier scope)**.** *The Zeckendorf scope of an accepted* $\mathsf{DimLiftBoundary}^{\uparrow}$ *carrier is the finite packet* Z, N, A, F, H, C, P, Q *together with the real-facing refusal row* R*. It is closed under the displayed* hsame *transports and* Cont *routes for AxisZeckendorf carry rows, normal-address rows, cannot-claim rows, full-axis context, RealUp refusal, package provenance, and NameCert rows, and it contains no primitive geometric, topological, vector-space, homological, projective, metric, or real dimension carrier.*

Proof. Read the finite packet componentwise. The Zeckendorf data are exactly Z, N, A, F, and the only consumer-visible extensions are the transport, route, provenance, local naming, and real-facing refusal rows.

Closure under the displayed transports follows because H names the componentwise hsame rows for the same coordinates. Closure under consumer access follows because C lists the only continuation routes out of the packet.

Since no coordinate of D is a primitive dimension carrier, the Zeckendorf scope remains a carrier for refusal evidence. The scope ends at the listed boundary rows. □

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryZeckendorfCarrierScope`

Theorem 571.9 (DimLiftBoundary route-exactness refusal)**.** *For an accepted* DimLiftBoundary$^{\uparrow}$ *carrier $D = (Z, N, A, F, R, H, C, P, Q)$, every consumer request that tries to read Z or N as a primitive dimension must pass through the cannot-claim row A and the real-facing refusal row R. The route table C and transport table H may expose carry evidence, normal-address evidence, full-axis context, provenance, and local naming, but they do not expose a dimension-valued row.*

Thus route exactness for primitive-dimension requests is a refusal route. The exact target of such a request is the displayed pair A, R, not a geometric, topological, vector-space, homological, projective, metric, or real dimension object.

Proof. Read the request through the continuation table C. If it asks for carry, normal-address, full-axis, transport, package, or naming evidence, the corresponding coordinate of the carrier supplies that displayed row.

If the same request asks for a primitive dimension interpretation of Z or N, no carrier coordinate has that type. The only displayed rows governing that request are the cannot-claim row A and the real-facing refusal boundary R.

Transport through H preserves this boundary componentwise. It can move the refusal packet along accepted presentations, but it cannot add a new dimension row to the carrier. □

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryCarrier cannot claim route exactness`

Theorem 571.10 (DimLiftBoundary axis normal-address lock)**.** *For an accepted* DimLiftBoundary$^{\uparrow}$ *carrier $D = (Z, N, A, F, R, H, C, P, Q)$, the rows Z and N are locked to AxisZeckendorf carry and normal-address evidence only after four sibling routes are displayed: the* Real$^{\uparrow}$ *handoff row R of Definition 571.7, the* ZeckendorfNormal$^{\uparrow}$ *scope row of Definition 571.8, the* ZCarry$^{\uparrow}$ *carry row inside the full-axis context F, and the* AxisZeckendorfCannotClaim$^{\uparrow}$ *refusal route of Definition 571.9. Any accepted normal-address read must preserve this route through F, H, C, P, Q and cannot reinterpret Z or N as a primitive dimension carrier.*

The lock is local to the displayed packet. It records a boundary address, not a full dimensional lift, host equality of addresses, RealUp completeness, or completeness of the axis.

Proof. Project the carrier rows. The carry coordinate Z and normal-address coordinate N occur together with the full-axis context F, so each read of either row is already addressed inside the AxisZeckendorf packet rather than inside an ambient dimension object.

Use the Zeckendorf carrier scope of Definition 571.8. It closes the displayed packet under the hsame transports and Cont routes while keeping primitive dimension carriers outside the scope.

Use the Real handoff non-escape theorem Definition 571.7. It places the row R downstream of the carry, normal-address, cannot-claim, and full-axis rows, so an accepted normal-address read cannot bypass the real-facing refusal boundary.

Finally apply the cannot-claim route exactness of Definition 571.9. The request may expose Z, N, F, H, C, P, Q, but a primitive-dimension request is routed to A and R.

The package row P and local naming row Q therefore record the same dependency boundary. They name the axis-normal evidence already present; they do not provide a separate dimension row, host address equality, or completeness principle. □

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryAxisNormalAddressLock`

Theorem 571.11 (DimLiftBoundary downstream acceptance boundary)**.** *Any later* $\mathsf{DimLift}^{\uparrow}$ *acceptance certificate that exports a dimension row must first consume the displayed* $\mathsf{DimLiftBoundary}^{\uparrow}$ *refusal packet* $Z, N, A, F, R, H, C, P, Q$*. In particular, the later certificate must account for the cannot-claim row* A*, the real-facing refusal row* R*, the axis-normal lock on* Z, N*, and the transport, route, provenance, and naming boundary* H, C, P, Q *before it exports any separate dimension evidence.*

Consequently $\mathsf{DimLiftBoundary}^{\uparrow}$ *is a required refusal boundary for downstream acceptance work, not an acceptance certificate and not a primitive dimension source.*

Proof. Begin with Definition 571.9. It forces primitive-dimension requests against the boundary carrier through the refusal rows A and R.

Next use Definition 571.10. It fixes Z and N as AxisZeckendorf carry and normal-address evidence under F, H, C, P, Q rather than as dimension-valued rows.

A later acceptance certificate may add a separate dimension row only after this packet has been consumed as refusal evidence. Without that consumption, the later certificate would be reading through a row that the present carrier explicitly does not export. □

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryDownstreamAcceptanceBoundary`

Theorem 571.12 (DimLiftBoundary carrier admission obligation)**.** *For every displayed packet*

$$D = (Z, N, A, F, R, H, C, P, Q)$$

accepted as a $\mathsf{DimLiftBoundary}^{\uparrow}$ *carrier, carrier admission is exactly the admission of the nine rows* $Z, N, A, F, R, H, C, P, Q$ *in Definition 571.1. The row* Z *admits AxisZeckendorf carry evidence,* N *admits normal-address evidence,* A *admits the cannot-claim refusal,* F *admits the full-axis context,* R *admits the real-facing refusal boundary,* H *admits componentwise transport,* C *admits consumer routes,* P *admits package provenance, and* Q *admits the local NameCert name. No admitted row is a primitive dimension carrier.*

Proof. Project the carrier definition. The displayed tuple has exactly the rows $Z, N, A, F, R, H, C, P, Q$, and each row is named in the carrier inventory.

Apply Definition 571.3. Its carrier-admission clause is the first local NameCert row and it ranges over the same displayed packet.

Finally apply Definition 571.4. Since primitive dimension reads land in A and R rather than in a dimension-valued coordinate, carrier admission does not add any primitive dimension carrier. □

Lean4 ✓ `BEDC.Derived.DimLiftBoundaryUp.DimLiftBoundaryCarrier admission obligation`

Theorem 571.13 (DimLiftBoundary classifier stability obligation)**.** *For accepted packets* $D = (Z, N, A, F, R, H, C, P, Q)$ *and* $D' = (Z', N', A', F', R', H', C', P', Q')$*, the* $\mathsf{DimLiftBoundary}^{\uparrow}$ *classifier is stable exactly when the displayed* hsame *and* Cont *rows transport the carry, normal-address, cannot-claim, full-axis, real-facing refusal, provenance, and local naming coordinates componentwise. This stability preserves the refusal interpretation of* Z, N, A, F, R *and does not create a geometric, topological, vector-space, homological, projective, metric, or real dimension row.*

Proof. Start with Definition 571.2. It defines classifier comparison by componentwise hsame and Cont transport across Z, N, A, F, R, P, Q and their primed counterparts.

The transport table H and route table C are visible coordinates of both accepted packets. Thus classifier stability is checked inside the same finite carrier surface, not by an external dimension semantics.

Use Definition 571.8 and Definition 571.10. They keep Z and N locked to AxisZeckendorf carry and normal-address evidence under F, H, C, P, Q, so stable transport preserves the refusal interpretation. □

Theorem 571.14 (DimLiftBoundary ledger obligation)**.** *For every accepted* $\mathsf{DimLiftBoundary}^{\uparrow}$ *carrier* $D = (Z, N, A, F, R, H, C, P, Q)$*, the ledger obligations are route exactness through* C*, package provenance through* P*, local naming exactness through* Q*, and non-escape through* A *and* R*. Any consumer route that asks for carry, normal-address, full-axis, transport, provenance, or naming data receives the corresponding displayed row; any route that asks for primitive dimension data is refused by the cannot-claim and real-facing boundary rows.*

Proof. Route exactness is supplied by the continuation table C. By Definition 571.9, a request for primitive dimension data is routed to A and R, while ordinary carrier requests remain on the displayed rows.

Package provenance and local naming are the rows P and Q of Definition 571.1. The NameCert obligations of Definition 571.3 identify these rows as part of the same finite boundary packet.

Non-escape is then Definition 571.4. Together with the public boundary statement of Definition 571.5, it ensures that the ledger exports refusal evidence for downstream acceptance work and no primitive dimension interface. □

Closure status for $\mathsf{NameCert}_{\mathsf{DimLiftBoundary}^{\uparrow}}$**.**

Constructive story: A $\mathsf{DimLiftBoundary}^{\uparrow}$ packet is generated from $\mathsf{ZCarry}^{\uparrow}$ carry rows, $\mathsf{ZeckendorfNormal}^{\uparrow}$ normal-address rows, the $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ refusal row, $\mathsf{FullAxis}^{\uparrow}$ context, $\mathsf{Real}^{\uparrow}$ refusal boundary, componentwise hsame transports, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DimLiftBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 571.1, Definition 571.2, Definition 571.3, Definition 571.4, and Definition 571.5 bind the finite boundary carrier, classifier, obligation rows, non-escape rule, and public export for AxisZeckendorf dimension-lift refusal.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DimLiftBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close a primitive geometric dimension, topological dimension, vector-space dimension, homological dimension, projective dimension, metric dimension, real dimension, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, classifier stability, route exactness, package provenance, local naming exactness, and non-escape for the same finite boundary packet.

Chapter 572

A Concrete Naming Certificate for $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$

The $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$ interface records the finite BEDC packet by which the standard-boundary comparison between nonempty unary histories and nonempty zero-spine histories is made inspectable. It refines the displayed boundary row of $\mathsf{UnaryDirectionBridge}^{\uparrow}$ into a local NameCert target while preserving the kernel distinction between the $\mathsf{Nat}^{\uparrow}$ unary carrier and the $\mathsf{AxisNat}^{\uparrow}$ zero-spine carrier.

The dependency anchors are $\mathsf{Nat}^{\uparrow}$, $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{Add}^{\uparrow}$, $\mathsf{AxisAdd}^{\uparrow}$, $\mathsf{UnaryDirectionBridge}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert. The $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$ packet consumes the source-boundary row of chapter 9344 before exposing its forward and backward standard-boundary routes; it exposes a standard-interface handoff, but it does not identify unary and zero-spine histories inside the finite kernel.

Definition 572.1 (Unary-zero-spine standard-isomorphism carrier)**.** *A* $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (U, A, L, F, R, H, C, P, N)$$

with the following visible rows:

1. *U is the nonempty* $\mathsf{Nat}^{\uparrow}$ *unary-spine row, read as a displayed* Unary *history with at least one* E1 *step;*
2. *A is the nonempty* $\mathsf{AxisNat}^{\uparrow}$ *zero-spine row, read as a displayed* ZeroSpine *history with at least one* E0 *step;*
3. *L is the length-match row stating that U and A have the same finite successor count at the standard boundary;*
4. *F is the forward finite continuation route from the unary row through L to the corresponding zero-spine row;*
5. *R is the backward finite continuation route from the zero-spine row through L to the corresponding unary row;*
6. *H stores componentwise* hsame *transports for U, A, L, F, R and the local naming row;*
7. *C stores displayed* Cont *routes for unary inspection, zero-spine inspection, length comparison, forward readback, backward readback, additive-interface handoff, and NameCert audit;*

8. *P is the* Pkg *provenance row naming* $\mathsf{Nat}^{\uparrow}$, $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{Add}^{\uparrow}$, $\mathsf{AxisAdd}^{\uparrow}$, $\mathsf{UnaryDirectionBridge}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}}$ *row.*

The displayed length-match row is

$$\begin{aligned} \mathsf{len}_{\mathsf{Unary}}(U) &= \mathsf{len}_{\mathsf{ZeroSpine}}(A), \\ \mathsf{len}_{\mathsf{Unary}}(U) &> 0, \\ \mathsf{len}_{\mathsf{ZeroSpine}}(A) &> 0. \end{aligned}$$

The classifier accepts only packets whose forward and backward routes are both finite continuations over the displayed rows and whose additive-interface handoff is read through C after L, H, P, N are present. It has no coordinate for host equality of histories, quotienting the two carriers, or replacing the displayed routes by an ambient standard-model function.

Lean4 ✓ `BEDC.Derived.UnaryZeroSpineStandardIsoUp.UnaryZeroSpineStandardIsoTasteGate single carrier alignment`

Theorem 572.2 (Unary-zero-spine standard-isomorphism NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{UnaryZeroSpine}}$ *surface for Definition 572.1 consists of five BEDC-native rows:*

1. *carrier exposure for the finite packet $Z = (U, A, L, F, R, H, C, P, N)$;*

2. *classifier stability under componentwise* hsame *transport of the unary row, zero-spine row, length-match row, forward route, backward route, continuation ledger, package provenance, and local naming row;*

3. *route-ledger exactness stating that every accepted forward or backward comparison is one of the displayed finite routes F or R through C and L;*

4. *standard-interface handoff stating that* $\mathsf{Add}^{\uparrow}/\mathsf{AxisAdd}^{\uparrow}$ *consumers may read the comparison only through the transported length-match and route rows;*

5. *nonidentification boundary stating that the packet does not turn nonempty unary and zero-spine histories into* hsame*-identical kernel histories.*

Lean4 ✓ `BEDC.Derived.UnaryZeroSpineStandardIsoUp.UnaryZeroSpineStandardIsoCarrier namecert obligations`

Proof. Carrier exposure is projection from the finite packet in Definition 572.1. The source rows, length-match row, forward and backward routes, transports, continuations, package provenance, and local naming row are all displayed before the classifier accepts the packet.

Classifier stability is componentwise. Transport through H preserves the two source rows, the length-match row, and both finite routes, while C, P, N repack the same public read surface.

Route-ledger exactness follows because F and R are the only comparison routes in the carrier. Any standard-interface handoff to $\mathsf{Add}^{\uparrow}$ or $\mathsf{AxisAdd}^{\uparrow}$ must pass through C after the length and route rows have been read.

The nonidentification row is inherited from the kernel-distinct bridge discipline of $\mathsf{UnaryDirectionBridge}^{\uparrow}$. Since the carrier contains no equality coordinate identifying U and A as histories, the NameCert surface exposes a standard-boundary comparison rather than a kernel identification. □

Theorem 572.3 (Unary-zero-spine standard-isomorphism nonidentification boundary)**.** *For any accepted* $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$ *packet* $Z = (U, A, L, F, R, H, C, P, N)$*, the displayed standard-boundary comparison preserves the existing kernel distinction between the nonempty* Unary *row* U *and the nonempty* ZeroSpine *row* A*. In particular, transporting the packet through* H *and reading the forward or backward routes through* C *does not produce an* hsame *row identifying the underlying unary and zero-spine histories as the same kernel history.*

Lean4 ✓ `BEDC.Derived.UnaryZeroSpineStandardIsoUp.UnaryZeroSpineStandardIsoCarrier nonidentification boundary`

Proof. Read the packet through its displayed coordinates. The length-match row L relates only the finite successor counts of U and A at the standard boundary; it is not a history equality row.

The forward route F and backward route R are continuation routes over the displayed rows. They witness public readback in opposite directions, but neither route contains a coordinate whose target is an hsame identification of the two underlying histories.

Transport through H is componentwise over U, A, L, F, R, N. It can rename each displayed coordinate inside its own classifier, but it cannot merge the unary and zero-spine carriers because no such merge row is present in the packet.

Thus the standard-boundary comparison remains compatible with the kernel-distinct bridge discipline. The packet makes the standard-interface handoff inspectable while leaving the unary and zero-spine histories nonidentified inside BHist. □

Theorem 572.4 (Unary-zero-spine standard-isomorphism route totality)**.** *For every accepted* $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$ *packet* $Z = (U, A, L, F, R, H, C, P, N)$*, every accepted forward or backward comparison route is one of the displayed finite routes* F *or* R *through the length-match row* L*, the componentwise transport row* H*, the continuation ledger* C*, the package row* P*, and the local naming row* N*. No comparison route can be read from a host equality of histories, a quotient identifying* $\mathsf{Nat}^{\uparrow}$ *with* $\mathsf{AxisNat}^{\uparrow}$*, or an ambient standard-model function outside the packet.*

Proof. Project the carrier of Definition 572.1. Its only route coordinates are the forward route F and the backward route R, both listed before any standard-interface consumer can inspect the packet.

Apply the route-ledger exactness row in Definition 572.2. It forces every accepted comparison to pass through L, H, C, P, N together with exactly one of the displayed routes.

The nonidentification boundary of Definition 572.3 excludes a hidden kernel identification. Therefore a downstream route has no source other than F or R. □

Lean4 ✓ `BEDC.Derived.UnaryZeroSpineStandardIsoUp.UnaryZeroSpineStandardIsoRoute unary closure`

Theorem 572.5 (Unary-zero-spine standard-isomorphism axis-nat handoff)**.** *Every* $\mathsf{Nat}^{\uparrow}$, $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{Add}^{\uparrow}$*, or* $\mathsf{AxisAdd}^{\uparrow}$ *consumer of an accepted* $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$ *packet reads only the nonempty source rows* U, A*, the length-match row* L*, the displayed finite routes* F, R*, the componentwise* hsame *transports, the* Cont *routes,* Pkg *provenance, and local* NameCert *row. Such a consumer receives a standard-boundary handoff, not a kernel identification of unary and zero-spine histories.*

Proof. Begin with the standard-interface handoff clause in Definition 572.2. It allows additive-interface consumers to read the comparison only after the length-match and route rows are present.

Use route totality from Definition 572.4. Any forward or backward read available to $\mathsf{Nat}^{\uparrow}$, $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{Add}^{\uparrow}$, or $\mathsf{AxisAdd}^{\uparrow}$ is therefore one of the displayed finite routes through L, H, C, P, N.

Finally apply Definition 572.3. Since no hsame row identifies the underlying histories, the consumer handoff is a standard-boundary route and not a kernel equality. □

Lean4 ✓ `BEDC.Derived.UnaryZeroSpineStandardIsoUp.UnaryZeroSpineStandardIsoAxisNatHandoff`

Theorem 572.6 (Unary-zero-spine standard-isomorphism downstream unblock)**.** *The NameCert obligations, route totality, axis-nat handoff, and nonidentification boundary for* $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$ *form a finite downstream standard-boundary package. A consumer may cite the package to inspect the nonempty* $\mathsf{Nat}^{\uparrow}$ *row, the nonempty* $\mathsf{AxisNat}^{\uparrow}$ *row, the length-match row, the displayed forward and backward routes,* BHist, hsame, Cont, Pkg, *and* NameCert *support, while receiving no host equality of histories, no quotient between the two carriers, and no ambient standard-model isomorphism row.*

Lean4 ✓ `BEDC.Derived.UnaryZeroSpineStandardIsoUp.UnaryZeroSpineStandardIsoDownstreamUnblock`

Proof. First assemble the local obligation surface from Definition 572.2. It supplies carrier exposure, classifier stability, route-ledger exactness, standard-interface handoff, and the nonidentification row.

Next add route totality from Definition 572.4. This makes F and R the only comparison routes available to the downstream consumer.

Then use the axis-nat handoff theorem above. It records that $\mathsf{Nat}^{\uparrow}$, $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{Add}^{\uparrow}$, and $\mathsf{AxisAdd}^{\uparrow}$ consumers read the length and route rows rather than a kernel identification.

The existing nonidentification boundary closes the package by excluding host equality, quotienting of the two carriers, and ambient standard-model replacement. The downstream consumer therefore receives exactly the displayed finite standard-boundary route. □

Closure status for $\mathsf{NameCert}_{\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}}$.

Constructive story: A $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$ packet is generated by nonempty unary and zero-spine source rows, a displayed length-match row, forward and backward finite continuation routes, componentwise hsame transports, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 572.1, Definition 572.2, Definition 572.4, Definition 572.3, Definition 572.5, and Definition 572.6 bind the carrier, obligation, route, axis-nat handoff, boundary, and downstream unblock surface for the unary-zero-spine standard-boundary packet.

Bridge status: none

Origin: human

Not claimed: This chapter does not close a full standard-model isomorphism theorem or identify $\mathsf{Nat}^{\uparrow}$ with $\mathsf{AxisNat}^{\uparrow}$ inside the kernel.

Upgrade path: Public closure requires a public consumer surface beyond the finite standard-boundary package displayed here.

Chapter 573

A Concrete Naming Certificate for $\mathsf{RiemannZeroCountLedger}^{\uparrow}$

The $\mathsf{RiemannZeroCountLedger}^{\uparrow}$ interface records the finite height-window packet needed by the zero-count witness direction of Definition 9239.15. It packages a requested imaginary-height bound, the visible critical-strip zero packets below that height, a unary count row, a Riemann-von Mangoldt comparison ledger, an explicit error row, transport and continuation routes, package provenance, and local naming data. The packet is a counting witness surface only: it does not prove RH, does not assert zero-set completeness, and does not supply analytic continuation.

The ledger consumes its zero-side inputs through existing concrete-instance surfaces. The critical-line route is supplied by chapter 548, while the zero packet source is supplied by chapter 73; the count ledger therefore records a dependency route already visible in its carrier rows rather than a standalone RH-side object.

Definition 573.1 (RiemannZeroCountLedger carrier)**.** *A* $\mathsf{RiemannZeroCountLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (T, Z, U, M, E, H, C, P, N)$$

with the following displayed rows:

1. *T is the* $\mathsf{Nat}^{\uparrow}$ *height request row naming the imaginary-height window $|\Im(s)| \leq T$;*
2. *Z is the finite packet list of* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *rows whose zero and critical-strip coordinates are displayed inside the requested height window;*
3. *U is the* $\mathsf{UnaryHistory}$ *count row assigned to the visible list Z;*
4. *M is the Riemann-von Mangoldt comparison ledger, recording the main-term row, logarithmic row, normalization row, and comparison route used for the same height request;*
5. *E is the explicit error row bounding the gap between the unary count U and the comparison ledger M;*
6. *H stores componentwise* hsame *transports for the height request, zero packet list, unary count row, comparison ledger, error row, package provenance, and local naming row;*
7. *C stores the displayed* Cont *routes for reading the height request, filtering the finite zero packet list, counting the list, comparing against M, exposing the error row, and handing the result to an RH-facing consumer;*

8. *P is the* Pkg *provenance over* $\mathsf{Nat}^{\uparrow}$, UnaryHistory, $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$, $\mathsf{ZetaZeros}^{\uparrow}$, $\mathsf{CritStrip}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{RiemannZeroCountLedger}^{\uparrow}}$ *row.*

The carrier exposes only a finite height-window count ledger. It contains no completed zero-set quotient, no proof that the listed packets exhaust all analytic zeros below the height, no analytic-continuation constructor, and no proof of RH*.*

Theorem 573.2 (RiemannZeroCountLedger NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RiemannZeroCountLedger}^{\uparrow}}$ *surface for the carrier of Definition 573.1 consists of six finite obligations:*

1. *carrier admission: the accepted object is the displayed* BHist *packet* $L = (T, Z, U, M, E, H, C, P, N)$*;*

2. *height-window binding: the height request row T is the only row used to filter the critical-strip zero packets in Z;*

3. *zero-list visibility: every counted entry is a displayed* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *packet with its* $\mathsf{ZetaZeros}^{\uparrow}$ *and* $\mathsf{CritStrip}^{\uparrow}$ *coordinates still visible;*

4. *unary-count exactness: the count row U is the* UnaryHistory *count of the displayed finite list Z and not a cardinality of an ambient zero set;*

5. *comparison-error ledger: the Riemann-von Mangoldt comparison row M and explicit error row E are both read before the count is exported;*

6. *non-escape: every downstream zero-count read factors through $T, Z, U, M, E, H, C, P, N$ and has no route to zero-set completeness, analytic continuation, host cardinality, or a proof of* RH*.*

Lean4 ✓ `BEDC.Derived.RiemannZeroCountLedgerUp.RiemannZeroCountLedgerCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 573.1. The height request, zero packet list, unary count, comparison ledger, error row, transports, continuations, provenance, and local naming row are explicit coordinates.

Height-window binding and zero-list visibility are componentwise reads. The route first reads T, then filters the visible $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ rows in Z, while each listed zero keeps its $\mathsf{ZetaZeros}^{\uparrow}$ and $\mathsf{CritStrip}^{\uparrow}$ coordinates visible through the stored transport and continuation rows.

The count and comparison obligations are the rows U, M, E. The count is the unary count of the displayed list, and the comparison is only the finite Riemann-von Mangoldt ledger with its explicit error row.

Since the carrier has no coordinate for an ambient zero set, analytic continuation, host cardinality, zero-set completeness, or an RH proof, every downstream read is exhausted by the displayed rows. □

Theorem 573.3 (RiemannZeroCountLedger window exhaustion)**.** *Every RH-facing zero-count read exported by an accepted* $\mathsf{RiemannZeroCountLedger}^{\uparrow}$ *carrier can inspect only*

$$T, Z, U, M, E, H, C, P, N.$$

It may read the requested height, the displayed finite list of critical-strip zero packets, the unary count, the Riemann-von Mangoldt comparison ledger, the explicit error row, componentwise hsame *transports, displayed* Cont *routes, package provenance, and local* NameCert *row. It cannot infer that the finite list contains all analytic zeros below the height, cannot construct analytic continuation, cannot read a host zero-set cardinality, and cannot close* RH*.*

Lean4 ✓ `BEDC.Derived.RiemannZeroCountLedgerUp.RiemannZeroCountLedgerCarrier window exhaustion`

Proof. Start with an RH-facing zero-count request. By the carrier definition, the only height input is T, and the only zero data available at that height is the finite packet list Z.

Apply the zero-list and unary-count obligations of Definition 573.2. They force the count read to pass through displayed $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ packets and then through the unary count row U.

Next read the comparison surface. The rows M and E record the Riemann-von Mangoldt comparison and the explicit constructive error before the result is exported.

The remaining rows H, C, P, N provide transport, replay, provenance, and local naming only. Therefore the height-window surface is exhausted by the displayed packet and has no route to zero-set completeness, analytic continuation, host cardinality, or a proof of the RH predicate. □

Theorem 573.4 (RiemannZeroCountLedger height-filter stability)**.** *For every accepted* $\mathsf{RiemannZeroCountLedger}^{\uparrow}$ *carrier* $L = (T, Z, U, M, E, H, C, P, N)$*, a transported zero-count read preserves the displayed height request row* T *before the finite zero packet list* Z *is filtered. The componentwise* hsame *row* H *and displayed* Cont *replay row* C *may transport and replay the height request, but they cannot replace* T *by a new height window, a host real bound, or an untracked zero-set predicate.*

Proof. Project the carrier of Definition 573.1. The height request is the coordinate T, and the zero packet list Z is filtered only after that coordinate is read.

Apply the height-window binding obligation of Definition 573.2. It makes T the unique displayed row used by the finite filter, so a downstream read cannot introduce a second height source.

Now read the transport and replay rows. The componentwise hsame entries in H preserve the height row as the same displayed coordinate, while the Cont route in C replays the read of T before the filter on Z.

Therefore the transported packet still filters Z under the original displayed height row. Since no carrier coordinate stores a host real bound or ambient zero-set predicate, those endpoints cannot be inferred by transport. □

Theorem 573.5 (RiemannZeroCountLedger comparison-error nonescape)**.** *Every RH-facing export of an accepted* $\mathsf{RiemannZeroCountLedger}^{\uparrow}$ *carrier must read the Riemann-von Mangoldt comparison ledger* M *and explicit error row* E *before the unary count row* U *is handed to a consumer. The export is only a finite comparison-error ledger for the displayed height window; it cannot imply* RH*, analytic continuation, zero-set completeness, host cardinality, or completeness of the analytic zero list.*

Lean4 ✓ `BEDC.Derived.RiemannZeroCountLedgerUp.RiemannZeroCountLedgerCarrier comparison error nonescape`

Proof. Start with the exported zero-count read of Definition 573.3. That theorem exhausts the read by the displayed rows $T, Z, U, M, E, H, C, P, N$.

Use the comparison-error ledger obligation in Definition 573.2. It requires both M and E to be opened before the count is exported, so the consumer receives a comparison row together with its explicit error boundary.

The rows M and E compare the unary count against the finite Riemann-von Mangoldt ledger for the same displayed height request. They do not add a coordinate for analytic continuation, all zeros below the height, host cardinality, or a proof of the RH predicate.

Thus the export is non-escaping: it records the comparison-error surface for the finite packet and refuses each analytic endpoint named in the statement. □

Theorem 573.6 (RiemannZeroCountLedger zero-list count transport)**.** *Let* $L = (T, Z, U, M, E, H, C, P, N)$ *and* $L' = (T', Z', U', M', E', H', C', P', N')$ *be accepted* $\mathsf{RiemannZeroCountLedger}^{\uparrow}$ *carriers connected by the componentwise* hsame *transport and displayed* Cont *replay rows of their local packets. If the transported read identifies the height request, zero-list row, and unary-count row with the displayed* T, Z, U *rows of* L*, then the transported packet preserves the same finite zero list* Z *and the same unary count* U *before any comparison-error export is consumed.*

Proof. Project both accepted carriers. In each packet, the zero-list row and unary-count row are displayed coordinates, not ambient zero-set or host-cardinality data.

Apply zero-list visibility and unary-count exactness from Definition 573.2. These obligations force the count to be the UnaryHistory count of the displayed finite list and force every counted entry to remain a visible $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ packet.

Now use the hypothesis on the componentwise transport and replay rows. The hsame entries identify the transported height, zero-list, and count rows with T, Z, U, and the Cont entries replay those reads before the comparison rows are consumed.

Consequently the transported export preserves the displayed finite list and its unary count. Any attempt to read a different finite list, host cardinality, zero-set completeness theorem, or analytic continuation would bypass the named coordinates and would no longer be a transported read of the accepted packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{RiemannZeroCountLedger}^{\uparrow}}$**.**

Constructive story: A $\mathsf{RiemannZeroCountLedger}^{\uparrow}$ packet is generated from a $\mathsf{Nat}^{\uparrow}$ height request, a finite list of $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ packets, a UnaryHistory count row, a Riemann-von Mangoldt comparison ledger, an explicit error row, displayed hsame transports, Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RiemannZeroCountLedger}^{\uparrow}}, \mathsf{seed})$

Scope closed: The seed scope records the finite height-window zero-count carrier, local naming obligations, unary-count exactness, comparison-error ledger, and RH-facing readback boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RiemannZeroCountLedger}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not prove RH, construct analytic continuation, enumerate all analytic zeros, close zero-set completeness, assert host cardinality, or provide bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, height-window binding, zero-list visibility, unary-count exactness, comparison-error ledger exactness, and non-escape for the displayed zero-count packet.

Chapter 574

A Concrete Naming Certificate for $\mathsf{CertificatePipelineStageBoundary}^{\uparrow}$

The $\mathsf{CertificatePipelineStageBoundary}^{\uparrow}$ interface names the finite boundary between two adjacent certificate compiler stages. It keeps both compiler packets visible, records the shared middle-stage compatibility row, and exposes only the classifier, continuation, package, and local naming rows needed by downstream compiler-pipeline consumers.

The boundary is a consumer of chapter 473 because the adjacent packets K_{SM} and K_{MT} are accepted $\mathsf{CertificateCompiler}^{\uparrow}$ routes. This chapter adds only the displayed middle-row compatibility ledger J between those two compiler packets.

Definition 574.1 (CertificatePipelineStageBoundary carrier)**.** *A* $\mathsf{CertificatePipelineStageBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (S, M, T, K_{SM}, K_{MT}, J, H, C, P, N)$$

with the following visible rows:

1. *S is the source* NameCert *row for the first compiler stage;*
2. *M is the middle* NameCert *row that receives the first stage and supplies the second stage;*
3. *T is the target* NameCert *row for the second compiler stage;*
4. *K_{SM} is an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet from S to M;*
5. *K_{MT} is an accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet from M to T;*
6. *J is the middle-stage compatibility row asserting that the target row read by K_{SM} is the source row read by K_{MT};*
7. *H records componentwise* hsame *transports for the source, middle, target, adjacent compiler packets, compatibility row, package row, and local naming row;*
8. *C records the displayed* Cont *routes for the first compiler stage, the middle-stage handoff, the second compiler stage, and the composed boundary read;*
9. *P names* BHist, hsame, Cont, Pkg, NameCert, $\mathsf{CertificateCompiler}^{\uparrow}$, *and the adjacent compiler-stage boundary shape;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{CertificatePipelineStageBoundary}^{\uparrow}}$ *row.*

The packet contains no host compiler semantics, program equivalence theorem, global optimisation proof, or unrecorded intermediate-representation interpretation.

Theorem 574.2 (CertificatePipelineStageBoundary NameCert obligations)**.** *For the carrier of Definition 574.1, the local* $\mathsf{NameCert}_{\mathsf{CertificatePipelineStageBoundary}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission for the displayed packet* $B = (S, M, T, K_{SM}, K_{MT}, J, H, C, P, N)$*;*
2. *middle landing and source compatibility, requiring the target certificate row consumed by* K_{SM} *to be the same displayed middle row* M *used as the source certificate row of* K_{MT}*;*
3. *classifier transport across the boundary, first through* K_{SM} *and then through* K_{MT}*, with no classifier row outside* S, M, T*;*
4. *continuation composition, composing the first-stage route, middle-stage handoff, and second-stage route through the displayed* C *row;*
5. *non-escape from host compiler semantics, excluding program equality, semantic models, global optimisation correctness, and unrecorded target behavior.*

Proof. Carrier admission is projection of Definition 574.1. The rows $S, M, T, K_{SM}, K_{MT}, J, H, C, P, N$ are visible coordinates of one finite BHist packet.

The middle compatibility obligation is the row J. It states that the first accepted $\mathsf{CertificateCompiler}^{\uparrow}$ packet lands in the same middle naming certificate that the second accepted compiler packet reads as its source.

Classifier transport is read stage by stage. The first packet transports source classifier rows from S to M, the second transports those middle rows from M to T, and the componentwise transports in H preserve the same displayed boundary rows.

Continuation composition is the corresponding route in C. It concatenates the first-stage continuation route, the middle-stage handoff route, and the second-stage continuation route before the package row P and local naming row N expose the boundary to consumers.

No further coordinate remains in the carrier. Hence host compiler semantics, program equality, global optimisation correctness, and unrecorded target behavior cannot witness the adjacent-stage boundary. □

Theorem 574.3 (CertificatePipelineStageBoundary middle-row determinacy)**.** *Let*

$$B = (S, M, T, K_{SM}, K_{MT}, J, H, C, P, N)$$

and

$$B' = (S', M', T', K_{SM}, K_{MT}, J', H', C', P', N')$$

be accepted $\mathsf{CertificatePipelineStageBoundary}^{\uparrow}$ *carriers in the sense of Definition 574.1 and Definition 574.2. Assume that both displayed compatibility rows identify the target* $\mathsf{NameCert}$ *row read by the shared first compiler packet* K_{SM} *with the source* $\mathsf{NameCert}$ *row read by the shared second compiler packet* K_{MT}*. Then the displayed middle rows* M *and* M' *are classifier-same as the common middle* $\mathsf{NameCert}$ *row of the adjacent compiler pair, and every composed boundary read exported by either* B *or* B' *factors through that common middle row before it reaches the target row.*

Proof. Project the shared first compiler packet as

$$K_{SM} = (S_0, M_0, G_{SM}, E_{SM}, C_{SM}, H_{SM}, P_{SM}, N_{SM}).$$

By Definition 473.3, every accepted read of K_{SM} exposes its endpoint NameCert rows before any landing or classifier comparison is consumed. Since the same packet K_{SM} occurs in both boundary carriers, the target endpoint available to both boundary reads is the single displayed row M_0.

Project the shared second compiler packet as

$$K_{MT} = (M_1, T_0, G_{MT}, E_{MT}, C_{MT}, H_{MT}, P_{MT}, N_{MT}).$$

The same endpoint-availability result says that the source endpoint available to every accepted read of K_{MT} is the single displayed row M_1.

Now read the two compatibility rows. In B, the row J asserts that the target row read from K_{SM} is the source row read from K_{MT}. Hence J identifies M_0 and M_1 as the displayed middle certificate used by the boundary carrier, so M is classified with that common middle row. The same argument with J' shows that M' is classified with the same common middle row. By transitivity of the local NameCert classifier comparison, M and M' are classifier-same.

It remains to identify the route used by a composed boundary read. The boundary obligation theorem makes the composed read the continuation row in C obtained by replaying the first compiler route, the middle-stage handoff, and the second compiler route. The first route reaches the target endpoint of K_{SM}, the second route starts from the source endpoint of K_{MT}, and the compatibility row is exactly the displayed identification between those two endpoint reads. Thus the composed read in B factors through the common middle row before any target read in T is available.

The same reasoning applies to B' with C' and T'. No alternative middle row can be inserted, because Definition 473.18 forces a composite of the two accepted compiler packets to hand off only through their displayed middle NameCert row, and Definition 473.10 makes classifier transport pass through the displayed landing, hsame, and Cont rows of those same packets. Since the boundary carrier has no coordinate for an independent middle certificate, host compiler semantics, program equivalence theorem, or unrecorded target behavior, every composed boundary read of either accepted packet factors through that common middle row. □

Closure status for $\mathsf{NameCert}_{\mathsf{CertificatePipelineStageBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{CertificatePipelineStageBoundary}^{\uparrow}$ packet is generated from finite BHist rows for source, middle, and target certificate stages, two compiler-edge packets, compatibility rows at the shared middle endpoint, and the composed boundary read. The pipeline boundary is built by replaying the first compiler route, the middle-stage handoff, and the second compiler route through Cont before any target-facing row is available. Componentwise hsame transports source, middle, target, landing, and classifier rows, while Pkg records the certificate-compiler dependencies. The common middle row is therefore a displayed boundary coordinate, not an inferred host compiler equivalence.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CertificatePipelineStageBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the stage-boundary carrier, middle-row handoff, edge-classifier exactness, and composed-boundary factorization for $\mathsf{CertificatePipelineStageBoundary}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CertificatePipelineStageBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim host compiler semantics, program equivalence, an independent hidden middle certificate, or unrecorded target behavior.

Upgrade path: Obligation closure requires Lean encodings of the boundary carrier, middle compatibility row, edge classifier transport, and composed-read factorization.

Chapter 575

AspectChain NameCert Construction

The $\mathsf{AspectChain}^{\uparrow}$ interface packages the mind-matter double-aspect reading of Definition 9415.12 as one finite certificate. The records-side rows expose the public material record surface of the chain, while the inscription-event-side rows expose the accepted event surface by which the same chain point is written, checked, and handed to local consumers. The inscription-event coordinate is the concrete sibling surface of chapter 519, while the locality rows are consumer boundaries only and do not collapse $\mathsf{AspectChain}^{\uparrow}$ into a global observer frame. The packet does not identify private mental states with host physical objects, and it does not add a metaphysical identity relation outside the displayed BHist data.

Definition 575.1 (AspectChain carrier)**.** *An* $\mathsf{AspectChain}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (R, I, G, L, O, H, C, P, N)$$

with the following displayed rows:

1. *R is the records-side* BHist *row read as the material record surface of the chain point;*
2. *I is the inscription-event-side* $\mathsf{InscriptionEvent}^{\uparrow}$ *row for the same accepted chain point;*
3. *G is the public* GAP *provenance row recording the open commitment carried by the double-aspect reading;*
4. *L is the local* $\mathsf{LocalityCell}^{\uparrow}$ *or* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *row through which nearby observers may read the public record without receiving an all-observer frame;*
5. *O is the optional* $\mathsf{OtherMindsCommitment}^{\uparrow}$ *row by which a consumer may treat another inscription event as another conscious observational system;*
6. *H stores componentwise* hsame *transports for the records row, inscription-event row,* GAP *provenance, locality row, other-minds row, package row, and local name;*
7. *C stores the displayed* Cont *routes by which a consumer reads R, I, G, L, O without leaving the finite packet;*
8. *P is the* Pkg *provenance over* BHist, hsame, Cont, GAP *provenance,* $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{LocalityCell}^{\uparrow}$, $\mathsf{ObserverLocalityCell}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, *and* NameCert*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{AspectChain}^{\uparrow}}$ *row.*

The classifier compares accepted packets only through the displayed rows and their stored transports. It has no coordinate for a host mental substance, a host physical substance, a private phenomenal object, or an external identity predicate between mind and matter.

Lean4 ✓ `BEDC.Derived.AspectChainUp.AspectChainTasteGate single carrier alignment`

Theorem 575.2 (AspectChain NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{AspectChain}^{\uparrow}}$ *surface for the carrier of Definition 575.1 consists of five finite obligations:*

1. *carrier admission for the displayed packet* $A = (R, I, G, L, O, H, C, P, N)$*;*
2. *records-side exactness: the material reading is exactly the* BHist *row* R *together with its displayed transports and consumer routes;*
3. *inscription-event exactness: the phenomenological-first-person reading is exactly the* $\mathsf{InscriptionEvent}^{\uparrow}$ *row* I *together with its public checker, consumer, and* GAP *ledger surface;*
4. *locality and other-minds accountability: every cross-observer read factors through* L *and, when present, through* O*;*
5. *non-collapse: the packet records two readings of one accepted chain point, but it exports neither a host mental state, nor a host physical object, nor a metaphysical identity relation between them.*

Lean4 ✓ `BEDC.Derived.AspectChainUp.AspectChainNameCertObligations`

Proof. Carrier admission is projection from Definition 575.1. The rows $R, I, G, L, O, H, C, P, N$ are all displayed coordinates of one finite BHist packet.

The records-side obligation reads only R and the attached rows in H and C. Thus the material reading is a public record surface rather than an additional host object.

The inscription-event obligation reads I by applying the public carrier and downstream-handoff surface of $\mathsf{InscriptionEvent}^{\uparrow}$. Its checker, consumer, and GAP ledger data remain rows inside the same packet.

For locality and other-minds accountability, a consumer must route through L before treating the record as a shared local cell, and through O before treating another inscription event as another conscious observational system. The remaining rows H, C, P, N only transport, route, record provenance, and name this finite packet. □

Theorem 575.3 (AspectChain consumer boundary)**.** *Every consumer of an accepted* $\mathsf{AspectChain}^{\uparrow}$ *carrier may read only the records-side* BHist *row, the* $\mathsf{InscriptionEvent}^{\uparrow}$ *row, the* GAP *provenance row, the locality-cell row, the other-minds commitment row, the componentwise* hsame *transports, the displayed* Cont *routes, the* Pkg *provenance, and the local* NameCert *row.*

In particular, a consumer may use the packet to compare the records-side and inscription-event-side readings of one chain point, but it receives no hidden mental state, no host physical substrate object, no all-observer locality frame, and no unrecorded cross-aspect bridge.

Lean4 ✓ `BEDC.Derived.AspectChainUp.AspectChainConsumerBoundary`

Proof. Start with a consumer route into A. By the carrier definition, the only visible rows are $R, I, G, L, O, H, C, P, N$.

The records read is routed through R. The inscription-event read is routed through I, and Definition 519.5 bounds that read by the public source, name, route, check, consumer, ledger, transport, continuation, package, and naming rows of the inscription event.

The locality and other-minds reads are bounded by their displayed rows. The locality row prevents the consumer from importing a global observer frame, while the other-minds row records a commitment surface rather than direct access to another private state.

Consequently the consumer boundary is exactly the finite packet surface. The comparison of the two aspects is an internal two-reading relation over A, not an exported host-level identity or bridge object. □

Theorem 575.4 (AspectChain non-collapse)**.** *An accepted* $\mathsf{AspectChain}^{\uparrow}$ *carrier realizes the mind-matter double-aspect reading as one finite* BHist *packet with records-side and inscription-event-side rows. This realization does not collapse the records-side row into the inscription-event row, does not collapse the inscription-event row into the records-side row, and does not export host mental-state identity, host physical-object identity, private phenomenal access, or ambient metaphysical identity.*

Lean4 ✓ `BEDC.Derived.AspectChainUp.AspectChainCarrier non collapse`

Proof. Project the carrier $A = (R, I, G, L, O, H, C, P, N)$. The records-side coordinate R and the inscription-event coordinate I are distinct displayed rows of the same finite packet.

Definition 575.2 fixes the two exactness obligations separately. The records-side reading is exhausted by R and its routes, while the inscription-event reading is exhausted by I and its public inscription-event surface.

Definition 575.3 then bounds every public consumer by the same finite rows. Since the packet contains no coordinate for private phenomenal access, host physical-object identity, or an external identity predicate, no consumer can collapse either aspect into the other or export a metaphysical identity claim. □

Theorem 575.5 (AspectChain public export)**.** *The public export of an accepted* $\mathsf{AspectChain}^{\uparrow}$ *carrier is exactly the records-side row R, inscription-event row I,* GAP *provenance row G, locality row L, other-minds row O, componentwise* hsame *transport row H, displayed* Cont *replay row C,* Pkg *provenance row P, and local* $\mathsf{NameCert}_{\mathsf{AspectChain}^{\uparrow}}$ *row N. It exports no host mind–matter identity, private phenomenal object, host physical substrate object, all-observer locality frame, or global observer frame.*

Lean4 ✓ `BEDC.Derived.AspectChainUp.AspectChainPublicExport`

Proof. Project the accepted carrier through Definition 575.1. The only displayed rows are $R, I, G, L, O, H, C, P, N$, and the classifier has no coordinate outside those rows.

Apply Definition 575.2. The records-side, inscription-event, locality, other-minds, and non-collapse obligations identify the public object surface and exclude host mental or physical identities.

Finally use Definition 575.3 and Definition 575.4. Every consumer read is bounded by the same finite packet, so the public export is the listed row surface and not a global observer frame or ambient mind–matter bridge. □

Theorem 575.6 (AspectChain bridge-status boundary)**.** *The public export rows of Definition 575.5 and the non-collapse rows of Definition 575.4 do not constitute a standard bridge, host mind–matter identity, or bridge-checked interpretation. Any bridge consumer for* $\mathsf{AspectChain}^{\uparrow}$ *must add a separate bridge row beyond*

$$R, I, G, L, O, H, C, P, N.$$

Lean4 ✓ `BEDC.Derived.AspectChainUp.AspectChain bridge status boundary`

Proof. Project the accepted carrier through Definition 575.1. The rows $R, I, G, L, O, H, C, P, N$ are records, inscription, GAP provenance, locality, other-minds, transport, replay, provenance, and naming rows.

Apply Definition 575.5 to identify the public surface, and apply Definition 575.4 to keep the records-side and inscription-event-side readings from becoming host identities. These theorems bound what the packet exports; they do not add an external interpretation row.

The closure block records bridge status none. Thus no standard bridge, host mind–matter identity, or bridge-checked interpretation is named by the displayed packet, and any bridge consumer must supply an additional bridge row outside the listed carrier. □

Theorem 575.7 (AspectChain bridge handoff)**.** *Every bridge-facing consumer of an accepted* $\mathsf{AspectChain}^{\uparrow}$ *packet must read the public export of Definition 575.5 and the non-collapse boundary of Definition 575.4 before it adds any separate bridge row. The handoff is a paper-side bridge boundary: it orders the public records-side, inscription-event-side, locality, other-minds, transport, replay, provenance, and naming rows for later bridge use, but it does not itself certify a standard bridge, host mind–matter identity, or machine-checked bridge interpretation.*

Lean4 ✓ `BEDC.Derived.AspectChainUp.AspectChain bridge handoff`

Proof. Project the accepted carrier $A = (R, I, G, L, O, H, C, P, N)$. The only bridge-facing input available from the chapter is the same finite packet surface already named by the public export theorem.

Apply Definition 575.4. The records-side and inscription-event-side readings remain two displayed rows of one packet, so a later bridge row cannot treat either reading as an already exported host identity.

Apply Definition 575.6. Any standard bridge must be supplied as a separate row beyond the displayed carrier. Thus the handoff records the paper boundary for bridge consumers while leaving bridge verification outside this chapter. □

Theorem 575.8 (AspectChain mature consumer completeness)**.** *The mature consumer surface of an accepted* $\mathsf{AspectChain}^{\uparrow}$ *packet is exhausted by the public export of Definition 575.5, the non-collapse boundary of Definition 575.4, the bridge-status boundary of Definition 575.6, and the bridge handoff of Definition 575.7. In particular, every mature consumer either reads the displayed packet rows*

$$R, I, G, L, O, H, C, P, N$$

or asks for a bridge row whose absence is already recorded by the boundary and handoff theorems; no further consumer class receives private phenomenal access, host mental-state identity, host physical-object identity, global observer locality, or a bridge-checked interpretation from this packet.

Proof. Start with the public export theorem. It identifies the only rows exported by an accepted carrier: records, inscription-event, GAP provenance, locality, other-minds, transport, replay, provenance, and local naming.

Apply the non-collapse theorem to the same rows. It prevents a mature consumer from turning the records-side and inscription-event-side readings into host identities, private phenomenal access, or an ambient mind–matter identity predicate.

For bridge-facing reads, use the bridge-status boundary and then the bridge handoff. The boundary states that the displayed rows do not themselves constitute a standard bridge, and the handoff orders exactly what a later bridge consumer must read before supplying any separate bridge row.

These four surfaces cover the public, non-collapse, bridge-boundary, and bridge-handoff consumers of the packet. Since the carrier has no coordinate outside $R, I, G, L, O, H, C, P, N$ and the bridge row is explicitly external to the chapter, there is no remaining mature consumer class to close. □

Closure status for $\mathsf{NameCert}_{\mathsf{AspectChain}\uparrow}$.

Constructive story: An $\mathsf{AspectChain}^{\uparrow}$ packet is generated from one records-side BHist row, one $\mathsf{InscriptionEvent}^{\uparrow}$ row, public GAP provenance, a locality-cell row, an optional other-minds commitment row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.AspectChainUp.taste gate`

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AspectChain}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 575.1, Definition 575.2, Definition 575.3, Definition 575.4, Definition 575.5, Definition 575.6, Definition 575.7, and Definition 575.8 bind the public records-side row, inscription-event row, GAP provenance, locality and other-minds rows, hsame transport, Cont routes, Pkg provenance, local NameCert rows, bridge-facing boundary, and mature consumer completeness already listed by the packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{AspectChain}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a Lean implementation, bridge checking, private phenomenal access, host mental-state identity, host physical-object identity, global observer frame, or ambient metaphysical identity.

Upgrade path: Bridge verification requires a separate standard bridge row over the already listed packet rows.

Chapter 576

A Concrete Naming Certificate for $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$

The $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$ interface records a causal-commitment failure as a finite contrary-record packet. It turns the causality reading of section 9415.1 into a concrete naming surface: an observed regularity ledger, a forward-binding Gap commitment, a contrary record, and the GAP non-escape ledger through which downstream consumers may inspect the failure. The finite contrary-record row specializes the witness-row discipline of chapter 503 and is consumed by bounded-search refutation through chapter 579 as a finite branch surface.

Definition 576.1 (Finite witnessed refutation carrier)**.** *A* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (R, G, K, V, D, H, C, P, N)$$

with the following visible rows:

1. *R is the finite observed-regularity ledger that supported the causal commitment;*
2. *G is the* Gap*-tagged forward-binding commitment asserting that the recorded regularity persists beyond the currently observed history;*
3. *K is the finite commitment key naming the prediction, tolerance, domain cell, and record shape against which a contrary record is checked;*
4. *V is the contrary-record witness, displayed as a finite observation row whose classifier conflicts with the commitment key;*
5. *D is the decision ledger recording the local comparison between K and V;*
6. *H stores the displayed* hsame *transports for the regularity ledger, commitment row, commitment key, contrary witness, and decision ledger;*
7. *C stores the* Cont *routes by which consumers inspect the support record, commitment, witness, and decision row;*
8. *P is the* Pkg *provenance row over* BHist, hsame, Cont, Gap, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteWitnessedRefutation}^{\uparrow}}$ *registration row.*

The local classifier compares two carriers only through these rows. It does not decide universal causality, does not choose a host law, and does not erase the Gap *commitment; it records that the named finite witness conflicts with the named finite commitment key.*

Lean4 ✓ `BEDC.Derived.FiniteWitnessedRefutationUp.FiniteWitnessedRefutationCarrier single carrier alignment`

Theorem 576.2 (Finite witnessed refutation NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FiniteWitnessedRefutation}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier formation for the finite packet of Definition 576.1;*
2. *classifier stability for the transported support ledger R, commitment row G, key K, contrary witness V, and decision ledger D;*
3. *witness exactness, requiring the contrary record consumed by the refutation to be exactly the displayed row V;*
4. *decision exactness, requiring the conflict claim to be read only through the comparison row D between K and V;*
5. *package closure, requiring the* hsame, Cont, Pkg, *and* NameCert *rows to contain exactly the provenance used by downstream causal-commitment consumers.*

Lean4 ✓ `BEDC.Derived.FiniteWitnessedRefutationUp.FiniteWitnessedRefutationCarrier namecert obligations`

Proof. Carrier formation is the tuple assembly of Definition 576.1. The support ledger, commitment, key, contrary witness, decision row, transport rows, continuation routes, package provenance, and naming row are all visible coordinates of F.

Classifier stability is componentwise. Transport the support ledger and commitment first, then transport the key and contrary witness, and finally transport the decision ledger that compares them.

Witness exactness and decision exactness are projections of the same finite packet. A consumer may cite a refutation only by reading V against K through D.

Package closure follows by projecting H, C, P, and N. No host causal law, all-future causal closure, or external failure oracle occurs as a coordinate of the carrier. □

Theorem 576.3 (Finite witnessed refutation ledger exactness)**.** *For every accepted packet*

$$F = (R, G, K, V, D, H, C, P, N),$$

the public refutation read is exactly the finite route from the support ledger R and forward-binding commitment G to the key K, contrary witness V, and comparison ledger D, transported by H, routed by C, packaged by P, and named by N. No refutation read may use a witness, comparison, or support record absent from the packet.

Lean4 ✓ `BEDC.Derived.FiniteWitnessedRefutationUp.FiniteWitnessedRefutationLedgerExactness`

Proof. Begin with Definition 576.2. Its witness exactness clause binds every contrary record to V, and its decision exactness clause binds the conflict claim to D.

The support side is also finite. The rows R and G state which observed regularity and which forward-binding Gap commitment are under inspection, while K states the finite prediction cell tested by V.

The remaining rows H, C, P, N carry transport, continuation, provenance, and local naming. Hence the refutation route is exactly the displayed finite ledger, not a hidden appeal to an ambient theory of causation. □

Theorem 576.4 (Finite witnessed refutation non-escape)**.** *The public boundary of* FiniteWitnessedRefutation$^{\uparrow}$ *exports only the finite contrary-record packet over* BHist*,* Gap*,* hsame*,* Cont*,* Pkg*, and* NameCert*. It exports no host causal law, no global falsification principle, no all-future causal closure, no external observation selector, and no erasure of the original* Gap *commitment.*

Lean4 ✓ `BEDC.Derived.FiniteWitnessedRefutationUp.FiniteWitnessedRefutationCarrier non escape`

Proof. Inspect the carrier coordinates of Definition 576.1. The only failure-facing rows are the support ledger, commitment row, key, contrary witness, and decision ledger.

Apply Definition 576.3. Every public refutation read passes through those rows and their displayed transport, continuation, package, and naming data.

The excluded objects are absent from the tuple. The packet therefore records a finite witnessed conflict with a causal commitment, while the wider question of universal causal closure remains outside the exported boundary. □

Theorem 576.5 (Finite witnessed refutation public packet)**.** *An accepted* FiniteWitnessedRefutation$^{\uparrow}$ *packet is a public causal-commitment failure surface for downstream BEDC consumers. Such a consumer may inspect the supporting observations, the forward-binding* Gap *row, the commitment key, the contrary witness, and the decision ledger, but every read must factor through the same* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows displayed by the carrier.*

Lean4 ✓ `BEDC.Derived.FiniteWitnessedRefutationUp.FiniteWitnessedRefutationCarrier public packet`

Proof. Use Definition 576.2 to obtain the carrier, stability, witness, decision, and package clauses. These clauses identify the rows available to a public consumer.

Next apply Definition 576.3. It forces the refutation read through $R, G, K, V, D, H, C, P, N$ and rules out any absent witness or comparison row.

Finally apply Definition 576.4. Since the carrier has no coordinate for a host law, global falsification principle, external observation selector, or erased Gap, the exported object is exactly the finite public packet. □

Theorem 576.6 (Finite witnessed refutation public consumer export)**.** *Every downstream consumer reading an accepted* FiniteWitnessedRefutation$^{\uparrow}$ *packet through*

$$R, G, K, V, D, H, C, P, N$$

must also expose the GapClosureBoundary$^{\uparrow}$ *and* BoundedSearchRefutation$^{\uparrow}$ *sibling routes before treating the contrary record as public refutation data. The exported surface contains only the finite carrier rows, local* NameCert *obligations, ledger exactness, non-escape, public packet route, and Gap boundary crosslink; it contains no universal causality law, host-law selector, global falsification principle, all-future causal closure, or erased* Gap *commitment.*

Proof. Begin with Definition 576.2. It identifies the carrier, local naming, stability, witness, decision, transport, continuation, and package rows available to a refutation consumer.

Apply Definition 576.3 and Definition 576.4. These force every read through the displayed rows $R, G, K, V, D, H, C, P, N$ and rule out host laws, external selectors, erased commitments, and global falsification data.

Finally combine Definition 576.5 with Definition 576.7. The public packet supplies the finite export surface, while the Gap boundary and bounded-search sibling route keep the contrary record local to the displayed branch rather than promoting it to universal causal closure. □

Lean4 ✓ `BEDC.Derived.FiniteWitnessedRefutationUp.FiniteWitnessedRefutationCarrier public export`

Theorem 576.7 (Finite witnessed refutation Gap boundary crosslink)**.** *For an accepted* FiniteWitnessedRefutation$^{\uparrow}$ *packet*

$$F = (R, G, K, V, D, H, C, P, N),$$

the forward-binding Gap *row G and the refusal/non-escape reading of the refutation are governed by the common boundary of chapter 1006. The finite witnessed refutation supplies the contrary record V and decision ledger D, while* GapClosureBoundary$^{\uparrow}$ *supplies the rule that unsupported closure requests route to refusal rather than to internal universal closure.*

The same finite contrary-record row V and decision ledger D are also the branch surface consumed by chapter 579: bounded-search refutation reads the displayed finite branch witness, while GapClosureBoundary$^{\uparrow}$ *supplies the refusal boundary that prevents the branch from becoming universal causal closure.*

Lean4 ✓ `BEDC.Derived.FiniteWitnessedRefutationUp.FiniteWitnessedRefutationCarrier gap boundary crosslink`

Proof. Project the finite refutation carrier. The rows $R, G, K, V, D, H, C, P, N$ display the support ledger, forward-binding Gap commitment, commitment key, contrary witness, decision ledger, transport, continuation, provenance, and local name.

Apply the public packet theorem above. It lets downstream consumers inspect R, G, K, V, D only through the same structural rows H, C, P, N and does not erase the original Gap commitment.

Now use the GapClosureBoundary source and refusal surface of Definition 1006.2 and Definition 1006.3. That common carrier routes unsupported attempts to turn a Gap request into internal closure to the refusal ledger, so the finite witnessed refutation remains a contrary-record packet rather than a universal closure principle. □

Theorem 576.8 (Finite witnessed refutation mature budget)**.** *The* FiniteWitnessedRefutation$^{\uparrow}$ *packet is a mature contrary-record branch surface for downstream bounded-refutation consumers. Its carrier, NameCert obligations, ledger exactness, non-escape theorem, public packet theorem, public consumer export, and Gap boundary crosslink give* GapClosureBoundary$^{\uparrow}$ *and* BoundedSearchRefutation$^{\uparrow}$ *exactly the finite support ledger, forward-binding* Gap *commitment, commitment key, contrary witness, decision ledger, transport, replay, provenance, and local naming rows they consume. The mature surface still refuses universal causality, global falsification, all-future causal closure, host-law selection, Lean verification, and standard bridge checking.*

Proof. Use Definition 576.1 and Definition 576.2. They expose the finite contrary-record branch as $R, G, K, V, D, H, C, P, N$ and bind every public read to those coordinates.

Apply Definition 576.3, Definition 576.4, and Definition 576.5. These results identify the reusable public packet while ruling out host causal laws, external selectors, erased Gap commitments, and global falsification data.

Finally combine Definition 576.6 with Definition 576.7. The downstream routes receive exactly the contrary-record branch consumed by GapClosureBoundary and bounded-search refutation, so no further paper-side theory grade remains for the finite branch surface itself. □

Lean4 ✓ `BEDC.Derived.FiniteWitnessedRefutationUp.FiniteWitnessedRefutationCarrier mature budget`

Closure status for NameCert$_{\text{FiniteWitnessedRefutation}^{\uparrow}}$**.**

Constructive story: A FiniteWitnessedRefutation$^{\uparrow}$ packet is generated from a finite support ledger, a forward-binding Gap row, a commitment key, a contrary witness, a decision ledger, displayed transports, continuation routes, provenance, and local naming.

Theory closure: TheoryGate(NameCert$_{\mathsf{FiniteWitnessedRefutation}\uparrow}$, maturePackageClosed)

Scope closed: The mature surface over BHist, Gap, hsame, Cont, Pkg, and NameCert is exactly Definition 576.1, Definition 576.2, Definition 576.3, Definition 576.4, Definition 576.5, Definition 576.6, Definition 576.7, and Definition 576.8.

Formal verification: FormalStatus(NameCert$_{\mathsf{FiniteWitnessedRefutation}\uparrow}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close universal causality, global falsification, all-future causal closure, host-law selection, bridge checking, or Lean verification.

Upgrade path: No further theory-axis upgrade remains for this finite contrary-record surface; Lean verification and bridge checking remain outside the claim.

Chapter 577

A Concrete Naming Certificate for $\mathsf{AnalyticContinuationOperation}^{\uparrow}$

The $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ interface turns the operation surface of chapter 9341 into a concrete BEDC operation packet. It names the holomorphic input rows, complex-domain rows, overlap evidence, continuation predicate, output row, branch-obstruction ledger, transport rows, package provenance, and local naming row that a downstream consumer can inspect without appealing to host quotient equality or an undisplayed branch selector.

Definition 577.1 (Analytic continuation operation carrier)**.** *An* $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (D_1, D_2, F, G, U, A, O, L, H, C, P, N)$$

with the following displayed rows:

1. D_1, D_2 *are the two* $\mathsf{Complex}^{\uparrow}$ *domain rows;*
2. F *is the* $\mathsf{Holomorphic}^{\uparrow}$ *input row over* D_1*;*
3. G *is the* $\mathsf{Holomorphic}^{\uparrow}$ *input row over* D_2*;*
4. U *is the finite overlap row carrying the displayed domain-compatibility and pointwise* hsame *agreement evidence;*
5. A *is the analytic-continuation operation row, read as the* $\mathsf{AnaCont}^{\uparrow}$ *predicate over* F, G, U*;*
6. O *is the output* $\mathsf{Holomorphic}^{\uparrow}$ *row over the displayed union domain;*
7. L *is the continuation ledger, including the uniqueness row, domain-read rows, and the branch-obstruction row;*
8. H *stores componentwise* hsame *transports for* $D_1, D_2, F, G, U, A, O, L$*;*
9. C *stores the finite* Cont *routes by which consumers read the inputs, overlap evidence, output row, ledger rows, package provenance, and local naming row;*
10. P *is the* Pkg *provenance over the same finite operation packet;*
11. N *is the local* $\mathsf{NameCert}_{\mathsf{AnalyticContinuationOperation}^{\uparrow}}$ *row.*

The branch-obstruction row in L *is a recorded boundary. It is not a closed general decision procedure for monodromy, branch selection, or path-dependent continuation.*

Lean4 ✓ BEDC.Derived.AnalyticContinuationOperationUp.AnalyticContinuationOperationTasteGate single carrier alignment

Theorem 577.2 (Analytic continuation operation NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{AnalyticContinuationOpera}}$ *surface for Definition 577.1 consists of five finite rows: carrier admission for Q; classifier stability for the* $\mathsf{Complex}^{\uparrow}$ *domain rows, the* $\mathsf{Holomorphic}^{\uparrow}$ *input rows, the overlap row, the* $\mathsf{AnaCont}^{\uparrow}$ *operation row, and the output row; continuation-ledger exactness for L;* Pkg *provenance over $D_1, D_2, F, G, U, A, O, L, H, C$; and local naming exactness for N.*

Proof. Carrier admission is projection of the finite tuple Q. Each domain, input, overlap, operation, output, ledger, transport, continuation, package, and naming coordinate is displayed as a row of the same BHist packet.

Classifier stability is componentwise. The $\mathsf{Complex}^{\uparrow}$ rows are transported through their displayed domain classifier, the $\mathsf{Holomorphic}^{\uparrow}$ rows through their holomorphic classifier, and the overlap row through the stored pointwise hsame agreement evidence. The operation row A is stable because the $\mathsf{AnaCont}^{\uparrow}$ predicate is read only through the transported inputs, overlap evidence, and output row.

The package and naming rows do not add analytic content. They repack the same finite rows as Pkg provenance and local NameCert exactness, so the obligation surface is exactly the five displayed rows. □

Lean4 ✓ BEDC.Derived.AnalyticContinuationOperationUp.AnalyticContinuationOperationCarrier namecert obligations

Theorem 577.3 (Analytic continuation operation stability)**.** *Let $Q = (D_1, D_2, F, G, U, A, O, L, H, C, P, N)$ be an accepted* $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ *carrier. Any componentwise* hsame *transport of the two* $\mathsf{Complex}^{\uparrow}$ *domain rows, the two* $\mathsf{Holomorphic}^{\uparrow}$ *input rows, the overlap evidence, and the output row preserves carrier admission, the* $\mathsf{AnaCont}^{\uparrow}$ *operation row, the continuation ledger L, the* Pkg *row P, and the local* NameCert *row N.*

Proof. Begin with the transports stored in H. They identify the two domain rows, the two holomorphic input rows, the overlap row, the operation row, the output row, and the ledger row component by component.

The $\mathsf{AnaCont}^{\uparrow}$ predicate has no hidden carrier outside those coordinates. After transporting D_1, D_2, F, G, U and O, the restriction clauses and overlap-agreement clause remain the same clauses under hsame.

The ledger row is transported by exact coordinate equality in H. The uniqueness and domain-read rows therefore remain attached to the same operation packet, and the branch-obstruction row remains a boundary row rather than an exported continuation witness.

Finally, Pkg provenance and local naming read the transported packet through C. Thus P and N classify the transported operation packet without changing the operation surface. □

Theorem 577.4 (Analytic continuation operation ledger exactness)**.** *For an accepted* AnalyticContinuationOperatio *carrier $Q = (D_1, D_2, F, G, U, A, O, L, H, C, P, N)$, every exported continuation fact factors through the displayed rows $D_1, D_2, F, G, U, A, O, L, H, C, P, N$. Requests for branch choice, quotient-of-germs equality, or continuation data outside the displayed overlap and output rows are recorded only in the branch-obstruction coordinate of L and are not exported as* $\mathsf{Holomorphic}^{\uparrow}$ *rows.*

Proof. Read an exported fact through the continuation routes stored in C. If the route lands in the two domain rows, input rows, overlap row, operation row, output row, transport row, package row, or local naming row, exactness is immediate because the coordinate is part of Q.

If the route asks for a continuation object beyond those coordinates, no displayed row of Q carries such an object. The ledger L is then the only classifier-visible destination for the request.

Inside L, the branch-obstruction coordinate records the boundary. It is a ledger entry saying that this route is outside the closed packet, not a constructive decision procedure for all branch behaviour and not a hidden source of a new holomorphic output row. □

Theorem 577.5 (Analytic continuation operation public export)**.** *The public surface of an accepted* $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ *carrier exports exactly the finite operation packet: two* $\mathsf{Complex}^{\uparrow}$ *domain rows, two* $\mathsf{Holomorphic}^{\uparrow}$ *input rows, the overlap and pointwise* hsame *evidence, the* $\mathsf{AnaCont}^{\uparrow}$ *operation row, the output* $\mathsf{Holomorphic}^{\uparrow}$ *row, the continuation ledger, componentwise* hsame *transports, finite* Cont *read routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *exactness.*

Proof. The carrier definition lists every row available to public consumers. The NameCert obligations identify carrier admission, classifier stability, ledger exactness, package provenance, and local naming for precisely those rows.

Stability ensures that changing representatives inside the displayed hsame classifiers does not change the exported operation packet. Ledger exactness prevents undisplayed branch data, quotient equality, or host continuation principles from entering the export.

Therefore the public export is exactly the finite BEDC operation packet over the holomorphic inputs, overlap evidence, output row, continuation ledger, transport routes, package provenance, and local naming row. □

Definition 577.6 (Analytic continuation operation socket extraction)**.** *Let* $Q = (D_1, D_2, F, G, U, A, O, L, H, C, P, N)$ *be an accepted* $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ *carrier, and suppose that the branch-obstruction coordinate of the continuation ledger* L *is displayed as* B*. The socket extracted from* Q *along* B *is the finite packet*

$$\mathrm{Sock}(Q, B) = (F, G, U, A, O, B, H, C, P, N).$$

It is read by retaining the two holomorphic source rows, the finite overlap row, the analytic-continuation operation row, the output row, the displayed branch-obstruction coordinate, the componentwise transports, the continuation routes, the package provenance, and the local naming row, while forgetting the two explicit domain rows and the non-obstruction ledger coordinates of L*.*

Theorem 577.7 (Analytic continuation operation socket extraction)**.** *Let* $Q = (D_1, D_2, F, G, U, A, O, L, H, C, P, N)$ *be an accepted* $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ *carrier. If the branch-obstruction coordinate of* L *is displayed as* B*, then the extracted packet*

$$\mathrm{Sock}(Q, B) = (F, G, U, A, O, B, H, C, P, N)$$

is an accepted $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *carrier. Every* $\mathsf{Holomorphic}^{\uparrow}$ *output read exported through the operation packet factors through this socket: the read reaches* O *only through the source rows* F, G*, the overlap witness* U*, the operation row* A*, and the visible* H, C, P, N *routes, while every branch-sensitive request outside that source-overlap-output path is recorded in* B *and is not exported as another* $\mathsf{Holomorphic}^{\uparrow}$ *row.*

Proof. Project the accepted operation carrier using Definition 577.1. The rows F, G, U, A, O are displayed coordinates of Q: F and G are the two $\mathsf{Holomorphic}^{\uparrow}$ source rows, U is the finite overlap row, A is the $\mathsf{AnaCont}^{\uparrow}$ operation row over F, G, U, and O is the output $\mathsf{Holomorphic}^{\uparrow}$ row. The ledger row L contains the displayed branch-obstruction coordinate B by hypothesis.

The domain rows D_1, D_2 are not independent socket coordinates. In the socket carrier of Definition 569.1, the domains are read through the source rows F, G and the overlap witness

U. Thus forgetting D_1, D_2 does not remove a socket field; it leaves exactly the source-overlap-operation-output surface F, G, U, A, O.

The remaining socket rows are inherited from the same finite operation packet. The transport row H already stores componentwise hsame transport for F, G, U, A, O and for the ledger containing B. The continuation row C already stores the finite Cont routes by which consumers read the inputs, overlap evidence, output row, ledger rows, package provenance, and local naming row. The package row P and the naming row N repack these retained coordinates as the local socket surface. Therefore the tuple $\mathrm{Sock}(Q, B)$ has exactly the carrier coordinates required by Definition 569.1.

Carrier admission and classifier stability are supplied by the operation NameCert obligations of Definition 577.2: they apply componentwise to the holomorphic source rows, overlap row, operation row, and output row. Ledger exactness for L restricts to ledger exactness for the displayed branch-obstruction coordinate B. These are precisely the socket obligation rows listed in Definition 569.2, so the extracted packet is accepted as an $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ carrier.

It remains to check the output read. By operation ledger exactness in Definition 577.4, every exported continuation fact from Q factors through the displayed operation rows, and every request for branch choice, quotient-of-germs equality, or continuation data outside the displayed overlap and output rows is recorded only in the branch-obstruction coordinate of L. Under the extraction, that coordinate is B.

Now apply the socket output factorization theorem Definition 569.9 to $\mathrm{Sock}(Q, B)$. The output row O factors through F, G, U, A, H, C, P, N, and the branch ledger B records exactly the attempted reads that do not factor through those rows. The holomorphic handoff theorem Definition 569.7 then prevents a ledger entry from becoming a second output row. Hence every $\mathsf{Holomorphic}^{\uparrow}$ output read through the operation packet factors through the extracted socket and no hidden branch selector or unrestricted analytic-continuation operator is exported. □

Theorem 577.8 (Analytic continuation operation socket ledger consumer)**.** *Let $Q = (D_1, D_2, F, G, U, A, O, L, H, C$ be an accepted $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ carrier, and let B be the displayed branch-obstruction coordinate of L. Every socket consumer of the operation output reads O only through the finite packet*

$$F, G, U, A, O, B, H, C, P, N.$$

The consumer may inspect the BHist ledger, componentwise hsame transports, Cont routes, Pkg provenance, and local $\mathsf{NameCert}$ row, but it cannot read a second $\mathsf{Holomorphic}^{\uparrow}$ output or a branch-sensitive continuation object outside the socket ledger.

Proof. Begin with socket extraction, Definition 577.7. It identifies the operation socket as $\mathrm{Sock}(Q, B) = (F, G, U, A, O, B, H, C, P, N)$ and proves that the output read factors through this packet.

Now apply ledger exactness and public export. Ledger exactness confines branch-sensitive requests to L, and public export lists no output row beyond the displayed $\mathsf{Holomorphic}^{\uparrow}$ row O.

Since B is the branch-obstruction coordinate of L, a socket consumer can inspect it only as ledger data. It cannot reclassify that ledger row as another output, so every operation-output read remains inside $F, G, U, A, O, B, H, C, P, N$. □

Theorem 577.9 (Analytic continuation operation domain-overlap boundary)**.** *For an accepted $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ carrier $Q = (D_1, D_2, F, G, U, A, O, L, H, C, P, N)$, the $\mathsf{Complex}^{\uparrow}$ domain rows D_1, D_2 and the overlap row U must be displayed before any $\mathsf{Holomorphic}^{\uparrow}$ output row is exported. A consumer can reach O only after reading the source rows F, G, the domain-overlap evidence D_1, D_2, U, the $\mathsf{AnaCont}^{\uparrow}$ operation row A, and the structural rows H, C, P, N; branch-sensitive requests remain in the ledger and cannot become a second output.*

Lean4 ✓ BEDC.Derived.AnalyticContinuationOperationUp.AnalyticContinuationOperation domain overlap boundary

Proof. Project the operation carrier. The output row O is listed after the two domain rows, the two holomorphic source rows, the overlap row, and the operation row.

Use overlap classifier exactness for the domain-overlap side. It forces every overlap-classifier read through D_1, D_2, F, G, U, A and through the structural rows H, C, P, N before any output-facing read is available.

Finally apply the socket ledger consumer theorem. After the output route reaches the socket surface, the branch-obstruction coordinate remains ledger data. Thus no branch-sensitive request can bypass the displayed domain-overlap rows or become a second $\mathsf{Holomorphic}^{\uparrow}$ output. □

Theorem 577.10 (Analytic continuation operation overlap classifier exactness)**.** *Let $Q = (D_1, D_2, F, G, U, A, O, L,$ be an accepted $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ carrier. Every overlap-classifier read of Q factors through the displayed domain rows D_1, D_2, source rows F, G, finite overlap row U, operation row A, and structural rows H, C, P, N. The classifier cannot replace the local overlap evidence by monodromy, quotient-of-germs equality, a branch selector, or an undisplayed continuation object.*

Proof. Project the carrier of Definition 577.1. The rows $D_1, D_2, F, G, U, A, O, L, H, C, P, N$ are the complete operation packet, and U is the only displayed overlap row.

Use the NameCert obligations and stability, Definition 577.2 and Definition 577.3. They preserve the two domain rows, the two holomorphic source rows, the overlap row, the operation row, and the output row componentwise under hsame transport.

Finally apply public export and socket extraction, Definition 577.5 and Definition 577.7. Downstream overlap reads pass to the socket only through $F, G, U, A, O, H, C, P, N$, while the domain rows are read through those source and overlap coordinates. No separate branch selector or quotient continuation row is available. □

Theorem 577.11 (Analytic continuation operation branch-ledger non-escape)**.** *Let $Q = (D_1, D_2, F, G, U, A, O, L,$ be an accepted $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ carrier. Branch-sensitive reads of Q remain ledger entries in L unless they factor through the displayed source-overlap-operation-output route $F, G, U, A, O, H, C, P, N$. The branch obstruction is therefore a ledger boundary, not a hidden selector, host continuation oracle, quotient-of-germs equality, global monodromy decision, or second $\mathsf{Holomorphic}^{\uparrow}$ output.*

Proof. Begin with ledger exactness, Definition 577.4. It sends every continuation request outside the displayed overlap and output rows to the branch-obstruction coordinate of L.

Use public export to bound the available rows. The exported packet lists the two domains, two sources, overlap evidence, operation row, output row, ledger, transports, routes, package provenance, and local naming; it does not list a selector, oracle, quotient equality, global monodromy decision, or additional output row.

Apply socket extraction. When a displayed branch-obstruction coordinate is retained as B, the socket can hand off only the source-overlap-operation-output route, and branch-sensitive requests outside that route remain in B. Since B is a coordinate of L, the original operation packet also keeps those requests as ledger data. □

Theorem 577.12 (Analytic continuation operation socket handoff exactness)**.** *Let $Q = (D_1, D_2, F, G, U, A, O, L, H$ be an accepted $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ carrier, and let B be the displayed branch-obstruction coordinate of L. The handoff from Q to $\mathrm{Sock}(Q, B)$ preserves exactly the source rows F, G, overlap row U, operation row A, output row O, branch ledger B, transports H, routes C, provenance P,*

and local name N. It forgets only the explicit domain coordinates D_1, D_2 after they have been consumed by the source and overlap rows.

Proof. Start from the socket extraction theorem Definition 577.7. It defines the extracted packet as $\mathrm{Sock}(Q, B) = (F, G, U, A, O, B, H, C, P, N)$ and proves that this packet is accepted by the socket carrier.

Use overlap classifier exactness. The domain rows D_1, D_2 have already been consumed through F, G, U before the socket read reaches A or O, so forgetting them as separate socket coordinates does not lose a public operation row.

Finally use branch-ledger non-escape. The branch coordinate B remains a ledger boundary and cannot become a hidden selector or another $\mathsf{Holomorphic}^{\uparrow}$ output. Therefore the handoff preserves exactly the displayed socket coordinates and no additional continuation data. □

Theorem 577.13 (Analytic continuation operation contour socket handoff)**.** *Let $Q = (D_1, D_2, F, G, U, A, O, L, H,$ be an accepted* $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ *carrier, and let B be the displayed branch-obstruction coordinate of L. Any* $\mathsf{ContourIntegralOperation}^{\uparrow}$ *consumer of this operation must read the extracted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *packet*

$$\mathrm{Sock}(Q, B) = (F, G, U, A, O, B, H, C, P, N)$$

together with the two $\mathsf{Holomorphic}^{\uparrow}$ *source rows F, G, the overlap row U, the operation row A, the output row O, and the branch ledger B before a contour-facing route is exposed. No contour-facing read bypasses $D_1, D_2, F, G, U, A, O, L, H, C, P, N$.*

Proof. Begin with socket extraction and handoff exactness. By Definition 577.7 and Definition 577.12, the operation exports the socket only as $\mathrm{Sock}(Q, B)$, with $F, G, U, A, O, B, H, C, P, N$ as its visible coordinates.

Next apply the domain-overlap boundary. The contour-facing consumer cannot reach the output row O until the rows $D_1, D_2, F, G, U, A, H, C, P, N$ have been read, so the two holomorphic source rows and the overlap row are already part of the route before contour data can be exposed.

Finally use branch-ledger non-escape. Branch-sensitive requests remain in L, and the displayed coordinate B is retained by the socket as ledger data. Thus every contour-facing handoff passes through the finite operation packet and no hidden branch selector, quotient-of-germs equality, or second holomorphic output is available to the consumer. □

Theorem 577.14 (Analytic continuation operation holomorphic route non-escape)**.** *For an accepted* $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ *carrier $Q = (D_1, D_2, F, G, U, A, O, L, H, C, P, N)$, every holomorphic output route remains inside the displayed coordinates $D_1, D_2, F, G, U, A, O, L, H, C, P, N$. Such a route cannot become quotient-of-germs equality, a branch selection, a monodromy decision, or a second* $\mathsf{Holomorphic}^{\uparrow}$ *row.*

Proof. Use ledger exactness and public export. The ledger theorem confines every exported continuation fact to the displayed rows of Q, while public export lists exactly the two domain rows, two holomorphic source rows, overlap evidence, operation row, output row, ledger, transports, routes, package provenance, and local naming row.

Now apply the socket ledger consumer theorem. Once a holomorphic output route is read through the extracted socket, the only output coordinate is O, and the branch-obstruction coordinate is still ledger data.

The excluded alternatives have no coordinate in the packet. Quotient-of-germs equality, branch selection, monodromy decision, and an additional $\mathsf{Holomorphic}^{\uparrow}$ output are therefore not reachable from a holomorphic output route inside Q. □

Theorem 577.15 (Analytic continuation operation zeta consumer boundary)**.** *Any* ZetaContinuationWitness$^{\uparrow}$ *consumer that reads an* AnalyticContinuationOperation$^{\uparrow}$ *carrier* $Q = (D_1, D_2, F, G, U, A, O, L, H, C, P, N)$ *must first factor through chapter 569, chapter 521, and the displayed operation packet* $D_1, D_2, F, G, U, A, O, L, H, C,$ *Only after those rows have been exposed may the consumer read a zeta-continuation witness packet, and the route exports no RH zero-location consequence.*

Proof. First apply the contour socket handoff theorem. It forces every contour-facing route from the operation to pass through the extracted AnalyticContinuationSocket$^{\uparrow}$ packet, the two holomorphic source rows, the overlap row, the operation row, the output row, and the branch ledger.

Next apply holomorphic route non-escape. The route remains inside $D_1, D_2, F, G, U, A, O, L, H, C, P, N$ and cannot turn into quotient-of-germs equality, branch selection, monodromy decision, or an additional holomorphic row.

The zeta witness is then read only after the socket and contour chapters have consumed this finite operation packet. Since neither the operation packet nor the contour-facing handoff contains an RH predicate or a zero-location coordinate, the zeta consumer receives continuation data without any RH zero-location consequence. □

Theorem 577.16 (AnalyticContinuationOperation bridge consumption)**.** *Every bridge consumer of an accepted* AnalyticContinuationOperation$^{\uparrow}$ *packet must read the displayed source rows, the domain-overlap row, the operation row, the output row, the branch ledger, the socket handoff, the contour-integral consumer route, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and the local* NameCert *row before using the operation. Such a consumer cannot use quotient-of-germs equality, global monodromy, a branch selector, or an RH zero-location consequence.*

Proof. Start with public export, Definition 577.5. It exposes exactly the finite operation surface over $D_1, D_2, F, G, U, A, O, L, H, C, P, N$.

Next use socket extraction and socket handoff exactness, Definition 577.7 and Definition 577.12. They force every bridge-facing operation read through the source rows, overlap row, operation row, output row, branch ledger, transports, routes, provenance, and local name.

Finally apply the contour socket handoff and zeta consumer boundary, Definition 577.13 and Definition 577.15. The contour consumer route receives only the displayed operation packet, while the zeta-facing route carries no RH zero-location coordinate. Ledger exactness keeps quotient-of-germs equality, global monodromy, and branch selection outside the exported bridge consumption surface. □

Closure status for NameCert$_{\text{AnalyticContinuationOperation}^{\uparrow}}$**.**

Constructive story: An AnalyticContinuationOperation$^{\uparrow}$ packet is generated from two Complex$^{\uparrow}$ domain rows, two Holomorphic$^{\uparrow}$ input rows, finite overlap and pointwise hsame evidence, an AnaCont$^{\uparrow}$ operation row, an output Holomorphic$^{\uparrow}$ row, a continuation ledger, componentwise hsame transports, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{AnalyticContinuationOperation}^{\uparrow}}$, bridgedClosed)

Scope closed: Definition 577.1, Definition 577.2, Definition 577.5, and Definition 577.16 define the local operation carrier, obligation rows, exported operation certificate, and bridge-consumption route.

Formal verification: FormalStatus(NameCert$_{\text{AnalyticContinuationOperation}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.AnalyticContinuationOperationUp.AnalyticContinuationOperationCarrier\_namecert\_obligat`

Bridge status: none

Origin: human

Not claimed: This chapter does not close global monodromy, quotient-of-germs construction, general branch selection, RH zero-location consequences, or bridge checking.

Upgrade path: Mature closure requires examples or completeness-style consumer coverage; machine bridge checking remains a separate verification target.

Chapter 578

A Concrete Naming Certificate for $\mathsf{ConsciousObserverState}^{\uparrow}$

The $\mathsf{ConsciousObserverState}^{\uparrow}$ interface turns the current-state side of the consciousness, universe, and observer frame into a finite naming surface. It records the present observer state, the self-recognition row attached to that state, the observation ledger visible at that state, a Gap acknowledgement for what remains unfulfilled, the displayed consumer routes, package provenance, and a local $\mathsf{NameCert}$ row. The packet is local: it depends on observer-history and locality-cell certificates but does not export a global observer, a shared universe, an external time scalar, a spacetime manifold, or a host-level self object.

Definition 578.1 (Conscious observer-state carrier)**.** *A* $\mathsf{ConsciousObserverState}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (O, s, R, L, G, H, C, P, N)$$

with the following visible rows:

1. *O is the observer-history row from which the present state is read;*
2. *s is the current-state row inside O;*
3. *R is the self-recognition row, recording that the observer at s recognizes the same identity carried by the inspected history prefix;*
4. *L is the observation ledger row containing the finite records available at s;*
5. *G is the* Gap *acknowledgement row for commitments named at s whose witness rows are not yet present in L;*
6. *H records componentwise* hsame *transport for the observer history, current state, self-recognition row, observation ledger, gap acknowledgement, continuation routes, package row, and local name row;*
7. *C records the displayed* Cont *routes by which a consumer reads O, then s, then R, L, and G;*
8. *P is the* Pkg *provenance over* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{ObserverLocalityCell}^{\uparrow}$, BHist, Gap, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *source certificates: the observer-history row is the packet certified in chapter 477, and the locality-cell row is the finite local-cell packet of chapter 513;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ConsciousObserverState}^{\uparrow}}$ *row.*

The carrier has no coordinate for a detached self, a global universe object, an external clock, a manifold point, an all-observer frame, host psychological content, or an instantaneous remote observation.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier present route package`

Theorem 578.2 (Conscious observer-state NameCert obligations)**.** *For the carrier of Definition 578.1, the local* $\mathsf{NameCert}_{\mathsf{ConsciousObserverState}^{\uparrow}}$ *surface consists exactly of five obligations:*

1. *carrier admission for the finite packet* $S = (O, s, R, L, G, H, C, P, N)$*;*
2. *current-state recognition, requiring* R *to name the identity read from* O *at* s*;*
3. *observation-ledger exposure, requiring every present observation read to pass through* L*;*
4. Gap *acknowledgement exactness, requiring* G *to name only commitments attached to* s *whose witness rows are absent from* L*;*
5. *stability and non-escape under the componentwise* hsame *row* H*, displayed* Cont *routes in* C*, package provenance* P*, and local name row* N*.*

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 578.1. The packet displays the observer history, present state, self-recognition row, observation ledger, acknowledgement row, transport, routes, provenance, and local naming row.

The current-state recognition clause reads O before s and reads R only as the recognition row attached to that same state. The observation-ledger clause then exposes exactly the records in L as the universe-for-the-observer at s.

The acknowledgement clause reads G after L. Thus the gap row can name only commitments not witnessed by the current ledger, while remaining attached to the same present state.

Finally, H transports the displayed rows componentwise and C replays only their listed routes. Since no detached self, global universe, external clock, manifold coordinate, or all-observer frame occurs among the coordinates, the local certificate cannot export one. □

Theorem 578.3 (Conscious observer-state recognition exactness)**.** *For every accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

the self-recognition row R *is readable only after the observer-history row* O *and the current-state row* s *have been displayed. Thus self-recognition cannot detach from the observer-history row that supplies the present state.*

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier recognition exactness`

Proof. Project the carrier of Definition 578.1. Its visible order exposes O as the observer-history row, then s as the current-state row inside that history, and only then R as the recognition row attached to that state.

Apply Definition 578.2. The NameCert surface requires current-state recognition to name the identity read from O at s, while the same carrier excludes a detached self, a global observer, an external clock, a manifold point, and host psychological content.

The structural rows H, C, P, N transport, route, package, and name that same displayed packet. They do not add a second recognition source, so R remains exact for the observer-history row already displayed by O and s. □

Theorem 578.4 (Conscious observer-state GAP acknowledgement exactness)**.** *For every accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

the Gap *acknowledgement row* G *names only commitments attached to the current state* s *whose witness rows are absent from the present ledger* L*. It cannot supply remote records or witness rows outside that ledger boundary.*

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier gap acknowledgement exactness`

Proof. Project the same carrier. The acknowledgement row G occurs after the observer history O, current state s, recognition row R, and ledger row L, so it is not an independent source of observation data.

Use Definition 578.2. Its acknowledgement clause states that G names only commitments attached to s whose witness rows are absent from L.

The exclusions in Definition 578.1 remove every route to an instantaneous remote observation, global universe, external clock, manifold point, or detached self. Hence the acknowledgement is exact for the local ledger boundary and cannot provide a remote record. □

Theorem 578.5 (Conscious observer-state locality provenance exactness)**.** *For every accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

the package row P *routes the current-state read through the* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *and* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *sibling certificates. The transport row* H *and continuation row* C *replay exactly those observer-history, current-state, recognition, ledger, and acknowledgement rows.*

Proof. Project the provenance coordinate in Definition 578.1. It names the observer-history row certified by chapter 477 and the finite local-cell packet certified by chapter 513.

Apply Definition 578.2. The accepted packet reads O, then s, then R, L, G, with stability and non-escape supplied only by H, C, P, N.

The row H transports the displayed coordinates componentwise, and C replays the same displayed routes. Since the carrier excludes a global observer, shared universe, external time scalar, spacetime manifold, host psychological content, and instantaneous remote observation, provenance exactness is exhausted by the two sibling certificates named in P and replayed by H and C. □

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier locality provenance exactness`

Theorem 578.6 (Conscious observer-state classifier stability)**.** *Let*

$$S = (O, s, R, L, G, H, C, P, N)$$

be an accepted $\mathsf{ConsciousObserverState}^{\uparrow}$ *carrier. Any classifier comparison of* S *with another accepted carrier is stable only after both packets expose the same finite observer-history surface, current-state row, self-recognition row, observation ledger row,* Gap *acknowledgement row, componentwise transport, displayed routes, package provenance, and local naming row. The classifier does not compare detached selves, global universes, host mental states, manifold coordinates, or instantaneous remote records.*

Proof. Project the accepted carriers. The classifier can inspect only the rows listed in Definition 578.1.

Transport by H moves the observer history, current state, self-recognition row, observation ledger, and acknowledgement row together. The routes in C then replay the same finite reads on the transported surface.

The provenance row P and the local name row N bind the compared rows to the same package shape. Because the carrier contains no detached self, global universe, host mental-state, manifold-coordinate, or instantaneous-remote-record coordinate, classifier stability is exhausted by the displayed packet. □

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier classifier stability`

Theorem 578.7 (Conscious observer-state ledger exactness)**.** *For every accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet, the ledger visible at the current state is exactly the observation row L together with the* Gap *acknowledgement row G, read through O, s, R, H, C, P, N. A consumer can therefore read the present observer-state surface as*

$$O \quad \textit{then} \quad s \quad \textit{then} \quad R, L, G \quad \textit{then} \quad H, C, P, N.$$

No additional row records a hidden universe, a separate self-substance, a global clock, a spacetime point, an all-observer synchronization map, or a remote record available without acknowledgement.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateTasteGate single carrier alignment`

Proof. Read the carrier in order. The history row O supplies the finite observer-history surface, and s selects the present row within that surface.

The self-recognition row R is read at s. The observation ledger L then supplies the present records, and the acknowledgement row G supplies the named gaps attached to that same state.

The remaining rows H, C, P, N account for transport, continuation, provenance, and local naming. They do not add observational content. Hence the ledger is exact for the displayed current-state packet and contains no hidden global or host-level coordinate. □

Theorem 578.8 (Conscious observer-state current ledger route)**.** *For an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

every current-state consumer reads the observer-history row O, the current-state row s, the self-recognition row R, and the present ledger row L before it can read the Gap *acknowledgement row G, the componentwise transport row H, the displayed* Cont *routes C, the package provenance P, or the local* $\mathsf{NameCert}_{\mathsf{ConsciousObserverState}^{\uparrow}}$ *row N.*

The route cannot begin from a detached self, a remote observation, a global observer, an external clock, a spacetime point, or host psychological content.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier current ledger route`

Proof. Project the carrier of Definition 578.1. Its row order displays O, s, R, L before the acknowledgement and route-support rows.

Apply the NameCert obligations of Definition 578.2. They attach recognition, ledger exposure, transport, continuation, provenance, and local naming to that same finite packet.

Use ledger exactness from Definition 578.7 and locality provenance from Definition 578.5. These results keep the current-state consumer on O, s, R, L before G, H, C, P, N can be consumed, and the carrier excludes every detached, remote, global, external, manifold, or host row. □

Theorem 578.9 (Conscious observer-state GAP ledger route)**.** *For an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

the Gap *row G is only a continuation of the present ledger route through O, s, R, L. It may acknowledge commitments whose witness rows are absent from L, but it cannot supply a remote observation, a hidden universe row, a detached self, an external clock, a spacetime point, or a host-state observation.*

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier gap ledger route`

Proof. Read the carrier and NameCert obligations first. The acknowledgement row G is listed after the observer-history, current-state, recognition, and present-ledger rows.

Apply ledger exactness from Definition 578.7. The visible present surface is L together with G, both read at the current state s in the observer-history row O.

Finally use locality provenance from Definition 578.5. The rows H, C, P, N replay and name the same local route; they do not turn the acknowledgement into a remote observation or any excluded global, external, manifold, detached, or host coordinate. □

Theorem 578.10 (Conscious observer-state locality-cell handoff)**.** *For an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

the observer-history certificate of chapter 477 and the observer-locality-cell certificate of chapter 513 are the only provenance channels for the current-state packet. Every handoff to a current-state consumer must pass through $O, s, R, L, G, H, C, P, N$ with P naming exactly those sibling certificate channels.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier locality cell handoff`

Proof. Project P from the carrier of Definition 578.1. The provenance coordinate names the observer-history and observer-locality-cell sibling certificates and no third provenance source.

Apply Definition 578.2. The local certificate requires the current-state row, recognition row, ledger row, and acknowledgement row to remain attached to the same displayed observer-history packet.

Use ledger exactness and locality provenance exactness. The present ledger is read through O, s, R, L, G, while H and C transport and replay only that route. Thus the locality-cell handoff is exhausted by the two sibling certificate channels named in P. □

Theorem 578.11 (Conscious observer-state GAP-ledger non-escape)**.** *For an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

the Gap *acknowledgement row G is attached only to the present ledger L at the current state s read from O. A consumer may read acknowledged commitments only by first routing through O, s, R, L and then through the displayed transport, continuation, provenance, and naming rows H, C, P, N.*

The packet cannot export a detached self, a global universe, an external clock, a spacetime point, or a remote record not present in L or acknowledged by G.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier gap ledger nonescape`

Proof. Project the carrier and read O before any acknowledgement. The current row s is selected inside that observer-history surface, and R records the recognition row attached to the same present state.

The ledger step is then local. The row L supplies the present records, and G names only commitments attached to s whose witness rows are not present in that ledger.

Transport through H and consumer access through C preserve this order. With P and N binding provenance and local naming, no coordinate remains for a detached self, global universe, external clock, spacetime point, or remote record outside the ledger-and-gap pair. □

Theorem 578.12 (Conscious observer-state route locality)**.** *For an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

every public route to the current observer-state surface is one of the displayed Cont *routes in* C*. Such a route reads* O*, then* s*, then the local rows* R, L, G*, and then the stabilizing rows* H, P, N*; it does not bypass the present-state ledger.*

Consequently route locality excludes detached self rows, shared-universe rows, external-clock rows, spacetime-point rows, and all-observer synchronization rows.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier route locality`

Proof. Start with the displayed route row C. By the carrier definition, C is the public continuation surface for reading O, then s, then R, L, G.

Componentwise transport through H preserves those route endpoints. A transported consumer still reaches the same observer-history row, current-state row, recognition row, observation ledger, and acknowledgement row rather than a detached host object.

The package and naming rows P, N bind the route to the local certificate. Because no coordinate in S stores a shared universe, external time scalar, manifold point, or all-observer synchronization map, no displayed continuation can route to one. □

Theorem 578.13 (Conscious observer-state dependency handoff)**.** *For an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

the dependency handoff to observer-history and observer-locality consumers is exactly the pair of local reads recorded by O, s, R, L, G *and routed through* C*. Componentwise transport in* H *preserves the observer-history anchor, current-state row, self-recognition row, observation ledger, and* Gap *acknowledgement as one packet.*

The handoff supplies no global observer, no global universe, no external clock, no spacetime point, and no remote record outside the finite current-state ledger.

Proof. Project the packet and read the dependency anchors from O and s. The self-recognition row R and ledger row L are attached to that same present state, with G recording only the named gaps at that state.

Use H for componentwise transport. The observer-history anchor, current-state row, self-recognition row, ledger, and gap acknowledgement move together, so the dependency handoff cannot split off a free-standing self or global frame.

Replay the handoff through C and record provenance through P, N. The non-escape boundary is then the carrier inventory: detached self, global universe, external clock, spacetime point, and remote record rows are absent from S. □

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier dependency handoff`

Theorem 578.14 (Conscious observer-state locality-cell readback)**.** *For an accepted* ConsciousObserverState$^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

every accepted present-state packet reads its current state through the ObserverLocalityCell$^{\uparrow}$ *row named by the provenance coordinate P. After $O, s, R, L, G, H, C, P, N$ have been displayed, the current-state read is the locality-cell readback already certified by the same local route; it is not a free read from a global observer, shared universe, external clock, manifold point, host-state coordinate, or remote record.*

Proof. Project the carrier of Definition 578.1. The current-state row s is read only after the observer-history row O, and the provenance row P names the sibling observer-history and locality-cell certificates used by that read.

Use the route-locality result of Definition 578.12. The displayed continuation row C is the only public route to O, s, R, L, G, while H preserves the route endpoints componentwise.

The locality-cell reference in the provenance row therefore supplies the readback boundary. Since S has no coordinate for a global observer, shared universe, external clock, manifold point, host-state coordinate, or remote record, the accepted packet reads the current state only through the displayed locality-cell route. □

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier locality cell readback`

Theorem 578.15 (Conscious observer-state present ledger boundary)**.** *For an accepted* ConsciousObserverState$^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

a present-state consumer may read only the present ledger row L and the Gap *acknowledgement row G after it has read O and s. The consumer may use R, H, C, P, N only to recognize, transport, route, package, and name that same local surface; it cannot export a global universe, external clock, remote record, detached self, or manifold point.*

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier present ledger boundary`

Proof. Start with ledger exactness from Definition 578.7. The consumer reaches the present observation surface by reading O, then s, then R, L, G.

Apply GAP-ledger non-escape from Definition 578.11. The acknowledgement row G remains attached to commitments at the current state whose witness rows are absent from L.

Route locality from Definition 578.12 supplies the consumer boundary through C, with H, P, N preserving, packaging, and naming the same route. Because the carrier has no global-universe, external-clock, remote-record, detached-self, or manifold-point coordinate, the present ledger boundary is exactly L and G after O and s. □

Theorem 578.16 (Conscious observer-state GAP locality exhaustion)**.** *For an accepted* ConsciousObserverState$^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

every acknowledged commitment in G remains attached to the same current state s and the same locality-cell route named by P and replayed by C. Any consumer that bypasses the present ledger row L or the acknowledgement row G is outside the displayed carrier surface.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier gap locality exhaustion`

Proof. Use GAP-ledger non-escape from Definition 578.11. It binds every acknowledged commitment in G to the current state s and to witness rows absent from the present ledger L.

Use dependency handoff from Definition 578.13 together with the locality-cell readback of Definition 578.14. The observer-history anchor, current-state row, ledger row, acknowledgement row, and locality-cell route remain one packet under H, C, P, N.

Finally apply the present ledger boundary of Definition 578.15. A consumer route that does not pass through L and G has no displayed coordinate in S, so it is not a consumer of the accepted carrier. □

Theorem 578.17 (Conscious observer-state present route exhaustion)**.** *For an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

every public route to the present observer-state surface factors through the displayed rows $O, s, R, L, G, H, C, P, N$*. In particular, a route first reads the observer-history row* O*, then the current-state row* s*, then the self-recognition row* R*, the present ledger row* L*, and the* Gap *acknowledgement row* G*, and only then uses componentwise transport, continuation replay, package provenance, and local naming.*

No public route bypasses the present-state ledger or exits to a global observer, shared universe, external time scalar, spacetime manifold, host psychological-content row, or remote observation row.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier present route exhaustion`

Proof. Start from the carrier of Definition 578.1. Its visible inventory is exactly $O, s, R, L, G, H, C, P, N$, and Definition 578.2 makes that inventory the local naming surface.

Use ledger exactness from Definition 578.7 and GAP non-escape from Definition 578.11. These results force the present route to pass through L before any acknowledged commitment in G can be read.

Use route locality from Definition 578.12 and the dependency handoff of Definition 578.13. The displayed continuation row C replays the same present-state dependency path, while H, P, N transport, package, and name that path without adding a global or host-level coordinate. □

Theorem 578.18 (Conscious observer-state GAP consumer exactness)**.** *For an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

a Gap*-facing consumer can read only commitments attached to the current state* s *whose witness rows are absent from the present ledger* L*. The consumer reaches those commitments through* O, s, R, L, G *and the stabilizing rows* H, C, P, N*, and it reads no additional observer, universe, time, manifold, host-subject, or remote-record surface.*

Proof. Read the present state through O and s. The carrier and NameCert obligations attach R, L, G to that same state, so the consumer has no independent Gap source.

Apply ledger exactness and GAP-ledger non-escape. The ledger row L supplies the available witness rows at s, and G names only commitments whose witnesses are absent from that ledger.

Finally use route locality and dependency handoff. The continuation row C makes the consumer route explicit, while H, P, N preserve, package, and name the same route. Since the carrier has no coordinate for a global observer, shared universe, external time, spacetime manifold, host

psychological content, or remote record, the Gap consumer is exact for the current-state ledger boundary. □

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier gap consumer exactness`

Theorem 578.19 (Conscious observer-state current ledger handoff)**.** *For every accepted* ConsciousObserverState$^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

each present-state consumer handoff reads the rows in the order $O, s, R, L, G, H, C, P, N$*. The handoff then passes only the present ledger row* L *and the* Gap *acknowledgement row* G*, transported and named through* H, C, P, N*, to observer-history and locality consumers.*

No detached observer, external clock, spacetime point, host content row, or remote record is handed across this boundary.

Proof. Start with the carrier of Definition 578.1 and the NameCert obligations of Definition 578.2. They display the ordered packet $O, s, R, L, G, H, C, P, N$ and require the recognition, ledger, and acknowledgement rows to be read after the observer-history row and current state row.

Apply ledger exactness from Definition 578.7 together with GAP-ledger non-escape from Definition 578.11. These theorems make L the visible present ledger at s and make G only an acknowledgement of commitments whose witness rows are absent from that ledger.

Finally use route locality, dependency handoff, and GAP consumer exactness from Definition 578.12, Definition 578.13, and Definition 578.18. They keep the consumer-facing handoff inside H, C, P, N and exclude every route not carried by the displayed current-state packet. □

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier current ledger handoff`

Theorem 578.20 (Conscious observer-state local GAP coverage)**.** *For every accepted* ConsciousObserverState$^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

each acknowledged commitment in G *is either witnessed by the visible present ledger* L *at the current state* s *or remains explicitly named as a local* Gap *at* s*. The coverage adds no remote record, global universe row, external time coordinate, or host-level observer surface.*

Proof. Read the carrier and the NameCert obligations first. The only available commitment surface is the displayed current-state packet $O, s, R, L, G, H, C, P, N$.

Use ledger exactness to identify the visible witness rows at s with L. Then apply GAP-ledger non-escape and GAP consumer exactness. These results say that every acknowledged commitment read through G is scoped by the same current state and can be consumed only as a local absence from the present ledger.

Route locality and dependency handoff close the coverage. Since every route is replayed through C and packaged by P, N with componentwise transport in H, no global universe, remote record, or host-level observer row can appear as a second coverage source. □

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier local gap coverage`

Theorem 578.21 (Conscious observer-state route package exactness)**.** *For every accepted* ConsciousObserverState$^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

the rows H, C, P, N package exactly the same current-state route from O through s, R, L, G. They may transport, replay, prove provenance for, and name that route, but they cannot add a detached self, external clock, spacetime point, all-observer synchronization row, host content row, or remote record.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier route package exactness`

Proof. The carrier and NameCert obligations determine the route inventory. The rows H, C, P, N are displayed only as transport, continuation replay, package provenance, and local naming for the same O, s, R, L, G packet.

Apply route locality and dependency handoff. They identify C as the current-state continuation route and ensure that H, P, N preserve, package, and name the route rather than widening it.

Ledger exactness, GAP non-escape, and GAP consumer exactness show that the only observer-facing data on the route are the present ledger and local acknowledgement at s. Therefore the route package is exact and contains none of the excluded detached, external, global, host, or remote rows. □

Theorem 578.22 (Conscious observer-state primitive scope)**.** *For every accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

the rows $O, s, R, L, G, H, C, P, N$ are scoped only by the BEDC primitive sources they display: O is a BHist *observer-history row, s is a current-state row inside that history, R is the self-recognition row read at s, L is the present ledger row, G is the* Gap *acknowledgement row, H is componentwise* hsame *transport, C is displayed* Cont *routing, P is* Pkg *provenance, and N is the local* $\mathsf{NameCert}_{\mathsf{ConsciousObserverState}^{\uparrow}}$ *row.*

Proof. Use the carrier of Definition 578.1. Its coordinates already name the observer-history, current-state, recognition, ledger, acknowledgement, transport, route, package, and naming rows.

Apply the NameCert obligations of Definition 578.2. They read R, L, G only after O and s, and they route all stability through H, C, P, N.

Ledger exactness in Definition 578.7 and GAP non-escape in Definition 578.11 bind the observational and acknowledgement rows to the same present state. Route locality and present route exhaustion from Definition 578.12 and Definition 578.17 then exclude any primitive source outside BHist, Gap, hsame, Cont, Pkg, and $\mathsf{NameCert}$. □

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier primitive scope`

Theorem 578.23 (Conscious observer-state GAP scope binding)**.** *For an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

the Gap *row G is scoped by the present ledger L and the current state s alone. A public read of G must first expose O, s, R, L and then replay the displayed transport, continuation, package, and naming rows H, C, P, N.*

Proof. Start with GAP-ledger non-escape from Definition 578.11. It attaches G to commitments at the current state s whose witness rows are absent from L.

Use ledger exactness from Definition 578.7. The present observational surface is L together with G, both read after the observer-history row O and the self-recognition row R attached to s.

Finally apply route locality and present route exhaustion. The only public path to G is through the displayed continuation row C with componentwise transport H, package provenance P, and local naming N; no global observer, shared universe, remote record, or host-level state can widen the Gap scope. □

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier gap scope binding`

Theorem 578.24 (Conscious observer-state route-scope package)**.** *For an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

every public route to the observer-state surface factors through the displayed Cont *routes in* C *and the package provenance row* P*. The route may expose* O, s, R, L, G *only through the componentwise* hsame *transport* H *and the local* $\mathsf{NameCert}_{\mathsf{ConsciousObserverState}^{\uparrow}}$ *row* N*.*

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier route scope package`

Proof. Apply route locality from Definition 578.12. It makes C the public continuation surface for O, then s, then R, L, G.

Use dependency handoff from Definition 578.13. The handoff keeps the observer-history anchor, current-state row, recognition row, ledger, and Gap acknowledgement in one packet under H.

Present route exhaustion in Definition 578.17 supplies the route coverage, and GAP consumer exactness in Definition 578.18 supplies the consumer boundary. The provenance row P and local name row N therefore bind every public route to the displayed package rather than to an external observer, universe, clock, manifold, host content, or remote-record surface. □

Theorem 578.25 (Conscious observer-state public export)**.** *The public* $\mathsf{ConsciousObserverState}^{\uparrow}$ *export is exactly the finite current-state observer packet*

$$S = (O, s, R, L, G, H, C, P, N),$$

together with the carrier, NameCert obligations, ledger exactness, GAP non-escape, route locality, dependency handoff, locality-cell readback, present ledger boundary, GAP locality exhaustion, route exhaustion, GAP consumer surface, current-ledger handoff, local GAP coverage, route package exactness, primitive scope, GAP scope binding, and route-scope package already established in this chapter.

The export supplies no detached self, global observer, shared universe, external clock, spacetime point, host psychological content, or remote record.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier public export`

Proof. First assemble the finite packet from the carrier and NameCert obligations. The rows $O, s, R, L, G, H, C, P, N$ are the only observer-history, current-state, recognition, ledger, acknowledgement, transport, route, provenance, and naming coordinates available to the export.

Next use ledger exactness and GAP non-escape. The ledger rows bind the present observational surface to s, while the GAP row records only local acknowledgement of absent witness rows and cannot export a remote record or external observer state.

The route-locality chain then supplies the public access path. Apply route locality, dependency handoff, locality-cell readback, present route exhaustion, GAP consumer exactness, current-ledger handoff, local GAP coverage, route package exactness, primitive scope, GAP scope binding, and

the route-scope package to keep every public read inside the same displayed continuation and package surface.

Therefore the public export is the assembled packet itself. Since no theorem in the chain introduces coordinates for a detached self, global observer, shared universe, external clock, spacetime point, host psychological content, or remote record, none of those objects is supplied by the export. □

Theorem 578.26 (Conscious observer-state bridge route)**.** *Every public* $\mathsf{ConsciousObserverState}^{\uparrow}$ *export supplied by Definition 578.25 bridges only through the finite packet*

$$S = (O, s, R, L, G, H, C, P, N).$$

The observer-history provenance is the row governed by chapter 477, and the locality-cell provenance is the row governed by chapter 513. The bridge route has no coordinate for a global observer, shared universe, external clock, spacetime point, host psychological-content row, or remote observation.

Lean4 ✓ `BEDC.Derived.ConsciousObserverStateUp.ConsciousObserverStateCarrier bridge route`

Proof. Start with the public export theorem. It identifies the exported surface with the displayed packet S and excludes any detached self, global observer, shared universe, external clock, spacetime point, host psychological content, or remote record.

Apply route package exactness from Definition 578.21. The public route is therefore mediated by the displayed Pkg provenance P, the local NameCert row N, and the componentwise hsame transport H, rather than by an ambient observer object.

Next use locality-cell handoff from Definition 578.10. This pins the locality component of the route to the local cell provenance described in chapter 513, while the observer-history row remains the one described in chapter 477.

Finally apply present route exhaustion from Definition 578.17. Since every present route is exhausted by the displayed continuation and package rows of S, the bridge route cannot introduce a global observer, shared universe, external clock, spacetime point, host psychological-content row, or remote observation. □

Closure status for $\mathsf{NameCert}_{\mathsf{ConsciousObserverState}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ConsciousObserverState}^{\uparrow}$ packet is generated from an observer-history row, a current-state row, a self-recognition row, an observation ledger, a Gap acknowledgement, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ConsciousObserverState}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 578.1, Definition 578.2, Definition 578.6, Definition 578.7, Definition 578.8, Definition 578.9, Definition 578.10, Definition 578.11, Definition 578.12, Definition 578.13, Definition 578.14, Definition 578.15, Definition 578.16, Definition 578.17, Definition 578.18, Definition 578.19, Definition 578.20, Definition 578.21, Definition 578.25, and Definition 578.26 bind the finite current-state observer packet, GAP ledger, locality-cell readback, present ledger boundary, route locality, dependency handoff, route exhaustion, GAP consumer surface, current-ledger handoff, local GAP coverage, route package exactness, public packet export, and bridge route.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ConsciousObserverState}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close a global observer, a shared universe, external time, manifold spacetime, host psychological content, checked Lean verification, or bridge checking.

Upgrade path: No further paper-side closure grade remains; Lean verification and bridge checking remain on the verification axis.

Chapter 579

A Concrete Naming Certificate for $\mathsf{BoundedSearchRefutation}^{\uparrow}$

The $\mathsf{BoundedSearchRefutation}^{\uparrow}$ surface packages a finite refutation search as BEDC naming data. It records the proposition being inspected, a displayed depth budget, the finite frontier reached by that budget, a refutation witness when one is found or a Gap row when the budget is exhausted, and the provenance rows through which a consumer may replay the bounded search. The packet is not a global proof-search oracle: every accepted read is bounded by the displayed depth row and remains inside BHist, hsame, Cont, Pkg, and NameCert.

It consumes the finite contrary-record surface of chapter 576 when a bounded frontier displays an explicit witness row: the bounded search packet supplies the depth and frontier ledger, while the witnessed-refutation packet supplies the contrary record and decision ledger consumed by the refutation branch.

Definition 579.1 (BoundedSearchRefutation carrier)**.** *A* $\mathsf{BoundedSearchRefutation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (A, K, F, R, G, H, C, P, N)$$

with the following displayed rows:

1. *A is the proposition row being searched for a certificate-level refutation;*
2. *K is the finite depth budget row, including the displayed start depth, successor ledger, and final bounded depth inspected by the packet;*
3. *F is the search frontier row, listing exactly the finite proof states reached within the budget K and the local edges by which each frontier entry was generated;*
4. *R is the displayed refutation witness row, present only when the frontier contains a route from an assumed witness of A to $\bot$;*
5. *G is the* Gap *row, present exactly when the bounded frontier ends without a displayed refutation witness and recording that the packet makes no truth claim beyond the budget;*
6. *H stores componentwise* hsame *transports for proposition rows, depth rows, frontier rows, refutation-witness rows,* Gap *rows, provenance, and local naming rows;*
7. *C stores the displayed* Cont *routes for reading the proposition row, advancing the bounded frontier, replaying a displayed refutation witness, or exposing the* Gap *row;*

8. *P is the* Pkg *provenance over* BHist, msame, hsame, Cont, Gap, *bounded frontier rows, displayed refutation witnesses, and the surrounding* NameCert *rows;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{BoundedSearchRefutation}^{\uparrow}}$ *row.*

The carrier contains no host-level proof search, no unbounded recursion principle, no truth predicate for all naming certificates, no excluded-middle branch, and no witness selected outside the displayed frontier.

Lean4 (definition) `BEDC.Derived.BoundedSearchRefutationUp.BoundedSearchRefutationCarrier`
Lean4 ✓ `BEDC.Derived.BoundedSearchRefutationUp.BoundedSearchRefutationTasteGate single carrier alignment`

Theorem 579.2 (BoundedSearchRefutation NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{BoundedSearchRefutation}^{\uparrow}}$ *surface for the carrier of Definition 579.1 consists of five finite obligations:*

1. *proposition row: the accepted packet displays the proposition row A whose refutation is being searched;*

2. *finite depth budget: every frontier expansion is indexed by the displayed budget row K and stops at the displayed final bounded depth;*

3. *search frontier: the row F lists the complete finite frontier generated within K, including the displayed local edges used to reach each entry;*

4. *refutation or gap: the packet exposes either a displayed refutation witness row R or the* Gap *row G, and the two rows are read through the same bounded frontier surface;*

5. *provenance: all reads of A, K, F, R, G transport through the stored* hsame *row H, the displayed* Cont *routes C, the package row P, and the local naming row N.*

Lean4 ✓ `BEDC.Derived.BoundedSearchRefutationUp.BoundedSearchRefutationNameCertObligations`

Proof. Carrier admission is projection from Definition 579.1. The proposition row, depth budget, frontier, refutation witness, gap row, transports, continuations, provenance, and local name are all displayed coordinates of the same finite packet.

The depth and frontier obligations are finite because K supplies the only allowed expansion budget. Each frontier entry in F is reached by a displayed local edge before the final bounded depth is reached, and no consumer can ask for a row outside that finite ledger.

The refutation-or-gap obligation reads the same frontier surface in both cases. If R is present, the packet exports the displayed route to $\bot$; if G is present, the packet exports only the bounded absence of such a displayed route. The provenance rows H, C, P, N keep both reads inside the same NameCert surface. □

Theorem 579.3 (BoundedSearchRefutation depth soundness)**.** *For an accepted* $\mathsf{BoundedSearchRefutation}^{\uparrow}$ *carrier $B = (A, K, F, R, G, H, C, P, N)$, every refutation witness exported from R is generated by a finite path in the frontier row F whose length is bounded by the displayed depth budget K. A consumer that reads G receives only the statement that no refutation witness is displayed inside that same bounded frontier; it receives no claim about depths beyond K.*

Lean4 ✓ `BEDC.Derived.BoundedSearchRefutationUp.BoundedSearchRefutationDepthSoundness`

Proof. Start with a consumer read of the refutation side. The witness row R is not an independent proof object; by the NameCert obligations it is read through the bounded frontier row F and the budget row K.

The continuation routes C replay only the local frontier edges recorded in F. Since each edge is indexed by the successor ledger in K, the replayed route cannot exceed the displayed final bounded depth.

For a gap read, the same bounded ledger is inspected. The row G records the absence of a displayed witness within F at budget K, not the absence of all refutations and not a truth value for A. Thus depth soundness is exactly the finite replay discipline of the carrier. □

Theorem 579.4 (BoundedSearchRefutation obligation scope)**.** *For an accepted* $\mathsf{BoundedSearchRefutation}^{\uparrow}$ *carrier* $B = (A, K, F, R, G, H, C, P, N)$*, every accepted frontier replay is derived by induction over the displayed finite depth row* K*. The base case is the initial frontier displayed in* F*, and the step case is exactly the displayed local edge extension in* F *from a depth row already admitted by* K *to its successor row. Consequently the bounded-search obligation surface contains no replay step outside* K*, no frontier entry outside* F*, and no refutation or* Gap *read outside the carrier rows of Definition 579.1.*

Lean4 ✓ `BEDC.Derived.BoundedSearchRefutationUp.BoundedSearchRefutationObligationScope`

Proof. The carrier inventory in Definition 579.1 supplies the only rows used by the replay: the finite budget K, the frontier F, the refutation-or-gap rows R, G, and the transport, continuation, package, and naming rows H, C, P, N.

Use the obligations of Definition 579.2. They identify K as the finite depth budget and F as the complete displayed frontier generated within that budget. The induction base reads the initial frontier row already displayed in F.

For the induction step, assume a frontier entry has been admitted at a displayed row of K. The only possible successor read is one of the local edge extensions recorded in F and indexed by the successor ledger of K. This step adds no host search and no unrecorded proof state.

Apply Definition 579.3. A refutation witness read from R is therefore a bounded replay path through those same induction steps, while a Gap read from G is only the report that no witness is displayed by the resulting finite frontier. □

Theorem 579.5 (BoundedSearchRefutation non-escape)**.** *No accepted* $\mathsf{BoundedSearchRefutation}^{\uparrow}$ *packet exports a global proof-search oracle. Every consumer read factors through* $A, K, F, R, G, H, C, P, N$*, and the packet has no coordinate for unbounded search, excluded middle over certificate predicates, host truth, quotient proof equality, or witness selection outside the displayed frontier.*

Lean4 ✓ `BEDC.Derived.BoundedSearchRefutationUp.BoundedSearchRefutationNonEscape`

Proof. Inspect the carrier coordinates in Definition 579.1. They name a proposition row, a finite budget, a finite frontier, a displayed refutation witness or gap row, and the BEDC transport, continuation, package, and naming rows.

Apply Definition 579.3. A witness read is a bounded frontier replay, while a gap read is only a bounded frontier report. Neither read supplies data for a search at a greater depth.

The forbidden oracle shapes require coordinates absent from the packet: an unbounded recursion route, a truth classifier over all naming certificates, an excluded-middle branch, or a selector outside F. Since no such row exists, every consumer remains inside the displayed bounded-search certificate. □

Theorem 579.6 (BoundedSearchRefutation NameCert boundary)**.** *The* $\mathsf{BoundedSearchRefutation}^{\uparrow}$ *carrier realizes a finite refutation-search boundary for contradiction and refutation consumers. A consumer may use a displayed witness row* R *as a bounded certificate-level refutation of* A*, or it*

may use the Gap *row G as a bounded search report at depth K; in both cases the read is routed through the same frontier, transport, continuation, provenance, and local naming rows. The packet never upgrades a* Gap *row into a proof of A or into a proof that A has no refutation at greater depth.*

Proof. First assemble the finite surface from Definition 579.2. The proposition row, budget, frontier, refutation-or-gap row, and provenance rows form one NameCert packet.

If a consumer reads R, depth soundness gives a replayable frontier path to $\bot$ bounded by K. That is a permitted certificate-level refutation because the assumed witness of A is discharged by displayed Cont rows inside the carrier.

If a consumer reads G, non-escape gives the boundary. The row reports only that the displayed frontier at the displayed depth contains no refutation witness, and it carries no branch that decides A or all deeper searches.

Therefore the public boundary is a finite BEDC search certificate. It supports bounded refutation and bounded gap reporting, while refusing any global proof-search, truth-branch, or unbounded-depth conclusion. □

Lean4 ✓ `BEDC.Derived.BoundedSearchRefutationUp.BoundedSearchRefutationNameCertBoundary`

Theorem 579.7 (BoundedSearchRefutation public export)**.** *Every downstream consumer of an accepted* BoundedSearchRefutation$^{\uparrow}$ *packet receives exactly the displayed finite frontier depth K, the contrary-record witness row R when that row is present, the bounded* Gap *row G when the frontier has no displayed witness, and the non-escape ledger H, C, P, N. The public export is the finite surface of Definition 579.1, Definition 579.2, Definition 579.3, Definition 579.5, and Definition 579.6; it exports no unbounded search, host truth predicate, excluded-middle branch, quotient proof equality, or witness outside the displayed frontier.*

Proof. Read the carrier first. The only public rows available to a consumer are the proposition row A, depth budget K, frontier F, witness-or-gap rows R, G, and the structural ledger H, C, P, N.

Apply the NameCert obligations and depth soundness. These force the contrary-record witness, when present, to be read through the finite frontier generated inside K, and force the Gap row to report only bounded absence inside that same frontier.

Finally use non-escape and the NameCert boundary. Since neither theorem supplies any coordinate beyond $A, K, F, R, G, H, C, P, N$, the public export is exactly the bounded frontier, contrary-record or Gap row, and non-escape ledger stated above. □

Lean4 ✓ `BEDC.Derived.BoundedSearchRefutationUp.BoundedSearchRefutationPublicExport`

Theorem 579.8 (BoundedSearchRefutation bounded frontier bridge)**.** *Every bridge consumer of an accepted* BoundedSearchRefutation$^{\uparrow}$ *packet must first read the finite depth budget K, the bounded frontier F, the witness-or-gap rows R, G, and the structural rows H, C, P, N before handing the packet to any standard bounded-refutation interface. The bridge read is therefore the displayed route through the same bounded frontier exported by Definition 579.7; it adds no global proof search, no truth predicate over certificates, no excluded-middle branch, and no witness outside F.*

Proof. Start with the NameCert obligations of Definition 579.2. They identify K, F, R, G, H, C, P, N as the finite rows through which any accepted refutation or bounded Gap read must pass.

Use depth soundness and obligation scope, Definition 579.3 and Definition 579.4. These force every replayed witness route to remain inside the displayed depth budget and frontier, while a Gap read remains only a bounded frontier report.

Finally combine non-escape, the NameCert boundary, and the public export, Definition 579.5, Definition 579.6, and Definition 579.7. Since the public packet has no coordinate beyond $A, K, F, R, G, H, C, P, N$, a standard bounded-refutation bridge can consume exactly those rows and cannot import any unbounded or classical proof-search endpoint. □

Theorem 579.9 (BoundedSearchRefutation mature treatment)**.** *Every mature consumer of an accepted* $\mathsf{BoundedSearchRefutation}^{\uparrow}$ *packet reads the proposition row A, the depth budget K, the finite frontier F, the witness-or-gap rows R, G, the componentwise transport row H, the displayed replay routes C, the provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{BoundedSearchRefutation}^{\uparrow}}$ *row N as one bounded-search treatment. The treatment closes exactly the displayed finite frontier discipline: it exports no global proof search, no witness outside F, no excluded-middle branch, and no claim about depths beyond K.*

Proof. Use the carrier and obligations, Definition 579.1 and Definition 579.2. They make $A, K, F, R, G, H, C, P, N$ the complete public inventory of the packet.

Depth soundness and obligation scope, Definition 579.3 and Definition 579.4, force every accepted replay to remain inside the displayed finite budget and frontier.

The public export and bounded-frontier bridge, Definition 579.7 and Definition 579.8, are therefore already the mature treatment: mature consumers can only reuse the same finite rows and cannot attach an unbounded search, deeper-depth assertion, host truth predicate, or off-frontier selector. □

Closure status for $\mathsf{NameCert}_{\mathsf{BoundedSearchRefutation}^{\uparrow}}$.

Constructive story: A $\mathsf{BoundedSearchRefutation}^{\uparrow}$ packet is generated from a proposition row, a finite depth budget, a bounded search frontier, a displayed refutation witness or Gap row, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{BoundedSearchRefutation}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 579.1, Definition 579.2, Definition 579.3, Definition 579.4, Definition 579.5, Definition 579.6, Definition 579.7, Definition 579.8, and Definition 579.9 bind the finite bounded-search carrier, obligation scope, depth discipline, non-escape boundary, NameCert consumer surface, public export, bounded-frontier bridge, and mature consumer treatment.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{BoundedSearchRefutation}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.BoundedSearchRefutationUp.BoundedSearchRefutationNameCertObligations`

Bridge status: none

Origin: human

Not claimed: This chapter does not close global proof search, excluded middle, host truth, quotient proof equality, or absence of refutations beyond the displayed budget.

Upgrade path: No further theory-axis grade is claimed; any verification-axis work must preserve the same bounded refutation and bounded Gap rows without adding global proof search or unbounded-depth claims.

Chapter 580

A Concrete Naming Certificate for $\mathsf{ZetaContinuationWitness}^{\uparrow}$

The $\mathsf{ZetaContinuationWitness}^{\uparrow}$ interface packages the zeta-continuation application of chapter 9342 as a finite witness certificate. It is the BEDC-native handoff object between $\mathsf{ZetaBasic}^{\uparrow}$, $\mathsf{ZetaCont}^{\uparrow}$, $\mathsf{ZetaZeros}^{\uparrow}$, and the RH-facing critical-strip chapters. The packet records the eta-continuation route, the pole ledger at $s = 1$, the functional-equation route, the trivial-zero ledger, and the Gamma-horizon boundary without importing the RH predicate or a global zero-location conclusion.

Definition 580.1 (ZetaContinuationWitness carrier)**.** *A* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (B, E, A, P, F, T, G, H, C, R, N)$$

with the following displayed coordinates:

1. *B is the source* $\mathsf{ZetaBasic}^{\uparrow}$ *row on the half-plane $\Re(s) > 1$;*
2. *E is the Dirichlet eta route, including the alternating-series row, the overlap row with B, and the displayed denominator boundary for $1 - 2^{1-s}$;*
3. *A is the analytic-continuation row from the eta route to the punctured positive half-plane;*
4. *P is the pole ledger at $s = 1$, recording the simple-pole row and residue-one readback;*
5. *F is the functional-equation route, including the exponential, sine, reflected-zeta, and Gamma-factor rows;*
6. *T is the trivial-zero ledger for negative even inputs, read through the sine-factor row and the nonzero remaining factors;*
7. *G is the Gamma-horizon boundary row, recording that the Gamma factor is consumed through its displayed interface and not through a closed Gamma chapter;*
8. *H records componentwise* hsame *transports for B, E, A, P, F, T, G;*
9. *C records the finite* Cont *routes by which consumers read the source zeta row, eta route, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, package provenance, and local naming row;*
10. *R is the* Pkg *provenance over* $\mathsf{ZetaBasic}^{\uparrow}$, $\mathsf{ZetaCont}^{\uparrow}$, $\mathsf{AnaCont}^{\uparrow}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{Complex}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{ZetaContinuationWitness}^{\uparrow}}$ *row.*

The carrier contains no proof of RH, no non-trivial-zero locator, no selected branch outside the displayed continuation routes, and no hidden completion of the Gamma horizon.

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.TasteGate.ZetaContinuationWitnessTasteGate single carrier alignment`

Theorem 580.2 (ZetaContinuationWitness NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ZetaContinuationWitness}^{\uparrow}}$ *surface for Definition 580.1 consists of five finite rows:*

1. *carrier admission for the displayed packet W;*
2. *classifier stability for the* $\mathsf{ZetaBasic}^{\uparrow}$ *source row, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, and Gamma-horizon row;*
3. *analytic-continuation exactness, stating that all exported* $\mathsf{ZetaCont}^{\uparrow}$ *reads factor through B, E, A, F, H, C, R, N;*
4. *pole and trivial-zero ledger exactness for P and T;*
5. *Gamma-horizon non-escape, stating that every Gamma-dependent read reaches G unless the read is already one of the displayed functional-equation factors.*

Proof. Carrier admission is projection from the finite tuple in Definition 580.1. The source row, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, transport routes, continuation routes, package row, and local naming row are explicit coordinates of the same BHist packet.

Classifier stability is componentwise. The $\mathsf{ZetaBasic}^{\uparrow}$ source row is transported through H, the eta and functional-equation routes are transported through their displayed overlap and factor rows, and the pole and trivial-zero ledgers are transported as ledger coordinates rather than as ambient analytic claims.

Analytic-continuation exactness follows because every exported $\mathsf{ZetaCont}^{\uparrow}$ read is routed through C after the source, eta, and functional-equation coordinates have been exposed. There is no additional continuation coordinate in W, so a consumer cannot bypass B, E, A, F, H, C, R, N to obtain a separate zeta continuation.

The pole and trivial-zero clauses are exact ledger reads. The pole row P records the simple-pole and residue-one slots at $s = 1$, while T records the negative-even zero slots produced by the sine factor together with the nonzero-factor side conditions.

Finally, the Gamma boundary is a non-escape row. If a consumer asks for a Gamma fact beyond the displayed functional-equation factor, the request reaches G and remains a boundary entry, not a closed Gamma certificate and not a hidden route to RH. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket namecert obligation surface`

Definition 580.3 (ZetaContinuationWitness source lock)**.** *For an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *carrier*

$$W = (B, E, A, P, F, T, G, H, C, R, N),$$

the source lock is the finite obligation package that requires every continuation, pole, functional-equation, trivial-zero, Gamma-boundary, and critical-strip route to expose the source row B, eta route E, analytic-continuation row A, pole ledger P, functional-equation route F, trivial-zero ledger T, Gamma-horizon boundary G, componentwise transports H, displayed routes C, provenance R, and local name N before any downstream zeta-zero or critical-strip consumer reads the packet.

Lean4 (definition) `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessSourceLock`

Theorem 580.4 (ZetaContinuationWitness source lock coverage)**.** *Every continuation read from an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet first exposes the source lock of Definition 580.3. In particular, the read displays B, E, A, F and the pole, trivial-zero, and Gamma ledgers P, T, G before it can be consumed as a zeta-continuation, zeta-zero, or critical-strip input.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket source lock coverage`

Proof. Project the carrier $W = (B, E, A, P, F, T, G, H, C, R, N)$ and apply Definition 580.2. The obligation surface lists carrier admission, classifier stability, analytic-continuation exactness, pole and trivial-zero exactness, and Gamma-horizon non-escape.

Use route-carrier admission through Definition 580.41. The exported continuation route is a read from the same displayed packet, so it cannot reach a consumer before the source, eta, analytic-continuation, and functional-equation rows have been displayed.

The exceptional ledgers are part of the same lock. Pole reads expose P, trivial-zero reads expose T, and Gamma-dependent reads expose G unless they are already displayed in F. Thus every continuation read is covered by the finite source lock. □

Theorem 580.5 (ZetaContinuationWitness pole-Gamma boundary)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet, pole reads remain in the pole ledger P and Gamma-dependent reads remain in the Gamma-horizon boundary G unless the requested Gamma factor is already displayed inside the functional-equation route F. The packet exports no separate pole completion, closed Gamma certificate, or hidden analytic branch outside P, F, G, H, C, R, N.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket pole gamma boundary`

Proof. Begin with the NameCert obligation surface. It treats P as the pole ledger and G as the Gamma-horizon non-escape row, while F is the only displayed functional-equation route that may already contain a Gamma factor.

Apply route-carrier admission. Any pole or Gamma request is routed through the same carrier and authenticated by H, C, R, N.

Now separate the two boundary cases. Pole data is read from P. Gamma data is read from G unless the read is one of the displayed factors in F. Since the carrier has no additional pole or Gamma coordinate, no further completion or hidden branch is exported. □

Theorem 580.6 (ZetaContinuationWitness critical-strip route separation)**.** *Critical-strip consumers of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet receive the displayed route rows $B, E, A, P, F, T, G, H, C, R,$ and the source lock of Definition 580.3. They do not receive an RH predicate, a non-trivial-zero locator, a global zero classifier, or a completed Gamma certificate as input data.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket critical strip route separation`

Proof. Use Definition 580.28. It states that the critical-strip consumer receives only the displayed finite witness rows and cannot read RH predicates, non-trivial-zero locators, global zero classifiers, or completed Gamma certificates as packet input.

Combine this refusal with source-lock coverage. By Definition 580.4, every continuation read has already exposed B, E, A, F together with P, T, G and the authentication rows H, C, R, N.

Therefore the critical-strip route is separated from RH-facing predicates. The consumer can use the displayed finite route rows, but no excluded predicate or completed Gamma object is present in the carrier. □

Theorem 580.7 (ZetaContinuationWitness no-RH non-escape)**.** *An accepted* ZetaContinuationWitness$^{\uparrow}$ *packet exports no RH proof, no non-trivial-zero locator, and no completed Gamma certificate. Every consumer route remains inside the source lock $B, E, A, P, F, T, G, H, C, R, N$ and the obligation rows of Definition 580.2.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket no rh nonescape`

Proof. Start from the critical-strip input refusal and Gamma-horizon non-escape rows. They exclude RH predicates, non-trivial-zero locators, global zero classifiers, and closed Gamma certificates from the packet inventory.

Use pole-Gamma boundary from Definition 580.5. Pole and Gamma reads remain in P and G, except for Gamma factors already displayed in F, and none of those rows is an RH proof or a completed Gamma certificate.

Finally apply source-lock coverage. Every consumer route is confined to $B, E, A, P, F, T, G, H, C, R, N$, so the excluded RH-facing objects have no route out of the accepted witness. □

Theorem 580.8 (ZetaContinuationWitness dependency ledger)**.** *Every accepted* ZetaContinuationWitness$^{\uparrow}$ *packet routes through the displayed* ZetaBasic$^{\uparrow}$*,* ZetaCont$^{\uparrow}$*,* AnaCont$^{\uparrow}$*,* Holomorphic$^{\uparrow}$*,* Complex$^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows before any zeta-zero or critical-strip consumer can read it. No consumer route can read the packet as a zeta-zero input until those dependency rows have been exposed as coordinates of the same finite carrier.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket dependency ledger`

Proof. Project the accepted carrier as $W = (B, E, A, P, F, T, G, H, C, R, N)$. The carrier definition lists the source zeta row, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, transport rows, continuation routes, package provenance, and local name as the complete witness packet.

Use the NameCert obligation surface. Carrier admission and classifier stability bind the ZetaBasic$^{\uparrow}$, ZetaCont$^{\uparrow}$, AnaCont$^{\uparrow}$, Holomorphic$^{\uparrow}$, Complex$^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert dependencies to those displayed coordinates.

Coordinate exhaustion then gives the consumer boundary. A zeta-zero or critical-strip consumer can only read through the continuation routes in C after the same packet rows have been displayed, so no dependency outside the finite ledger is available. □

Theorem 580.9 (ZetaContinuationWitness zero-facing source totality)**.** *Every* ZetaZeros$^{\uparrow}$ *or critical-strip consumer that reads an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet must first expose the source row B, eta route E, analytic-continuation row A, functional-equation route F, transport row H, continuation row C, provenance row R, and local name N. The exceptional rows P, T, G may also be consumed by their own ledger routes, but no zero-facing read can treat the packet as available before B, E, A, F, H, C, R, N have been displayed as coordinates of the same carrier.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket zero facing source totality`

Proof. Project the accepted packet as $W = (B, E, A, P, F, T, G, H, C, R, N)$. The dependency ledger identifies the ZetaBasic$^{\uparrow}$, ZetaCont$^{\uparrow}$, AnaCont$^{\uparrow}$, Holomorphic$^{\uparrow}$, Complex$^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows that a zero-facing consumer must meet before reading the packet.

Apply source-lock coverage. It fixes B, E, A, F as the source, eta, analytic-continuation, and functional-equation face of the continuation route, while H, C, R, N authenticate the transport, continuation, provenance, and local-name rows of that same route.

The pole, trivial-zero, and Gamma rows P, T, G remain visible ledger coordinates, but they do not replace the source face. Thus every zero-facing consumer reaches the packet only after the displayed source and authentication rows have been exposed. □

Theorem 580.10 (ZetaContinuationWitness Gamma functional boundary totality)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet, every Gamma-dependent consumer read is exhausted by one of two displayed routes: it either uses the Gamma factor already present in the functional-equation route F, or it stops at the Gamma-horizon boundary row G. No such read exports a completed Gamma certificate, a hidden analytic branch, or a Gamma route outside F, G, H, C, R, N.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket gamma functional boundary totality`

Proof. Begin with the NameCert obligation surface. The surface lists the functional-equation route F and Gamma-horizon boundary G as explicit packet rows, and it treats Gamma-horizon non-escape as part of the accepted certificate.

Apply the pole-Gamma boundary theorem. A Gamma request that is already one of the displayed functional-equation factors is read through F; every other Gamma-dependent request reaches G and remains a boundary row.

Finally use coordinate exhaustion for W. Since the packet contains no Gamma coordinate other than the displayed functional-equation route and boundary row, and since H, C, R, N only transport and authenticate those coordinates, no completed Gamma certificate or hidden branch can be exported. □

Theorem 580.11 (ZetaContinuationWitness critical-strip consumer non-escape)**.** *Every critical-strip consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet receives only the finite packet rows*

$$B, E, A, P, F, T, G, H, C, R, N.$$

The consumer receives no RH predicate, no non-trivial-zero locator, no global zero classifier, and no completed Gamma certificate as packet input.

Proof. Project the carrier row. The accepted witness is the finite tuple with coordinates $B, E, A, P, F, T, G, H, C, R$, so every packet read by a critical-strip consumer is a read from that displayed list.

Apply critical-strip input refusal and route separation. These rows exclude RH predicates, non-trivial-zero locators, global zero classifiers, and completed Gamma certificates from the packet inventory while keeping the consumer route inside the displayed source lock.

The Gamma functional boundary closes the remaining escape route. Gamma-dependent reads either use F or stop at G, so the critical-strip consumer obtains no completed Gamma object and no hidden route to an RH-facing or zero-location predicate. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket critical strip consumer nonescape`

Theorem 580.12 (ZetaContinuationWitness public root export)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet, the scoped rows*

$$B, E, A, P, F, T, G, H, C, R, N$$

export a public root witness only through the displayed ZetaBasic$^{\uparrow}$, ZetaCont$^{\uparrow}$, AnaCont$^{\uparrow}$, Holomorphic$^{\uparrow}$, Complex$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows. No public root consumer receives a witness row outside that carrier, dependency ledger, public export packet, and public export closure surface.*

Lean4 ✓ BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public root export

Proof. Project the carrier of Definition 580.1. The packet rows $B, E, A, P, F, T, G, H, C, R, N$ are the complete displayed witness carrier, so every public root read starts from those coordinates.

Apply Definition 580.2, Definition 580.4, and Definition 580.8. These bind the source, continuation, analytic, holomorphic, complex, history, transport, package, and naming data to the same finite packet before any public consumer can read it.

Finally use Definition 580.78 and Definition 580.86. The public export and its closure surface factor through the displayed packet and leave no route to an off-carrier root witness. □

Theorem 580.13 (ZetaContinuationWitness critical-strip root handoff)**.** *Every critical-strip consumer receives the public root witness of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet only after the source lock, pole ledger, trivial-zero ledger, and Gamma boundary have been displayed inside the same packet. The handoff does not expose an RH predicate, a non-trivial-zero locator, a global zero classifier, or a completed Gamma certificate.*

Lean4 ✓ BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket critical strip root handoff

Proof. Begin with Definition 580.4. It requires the source row B, eta row E, analytic-continuation row A, functional-equation row F, and the ledger rows P, T, G to be visible before a continuation, zero-facing, or critical-strip read can consume the packet.

Use Definition 580.5 for the pole and Gamma side, and use the carrier row to keep the trivial-zero ledger T as a displayed coordinate of $W = (B, E, A, P, F, T, G, H, C, R, N)$.

Close with Definition 580.6 and Definition 580.7. The critical-strip route remains a read from the displayed public root packet, so the excluded RH, zero-location, global-classifier, and completed-Gamma data have no input position. □

Theorem 580.14 (ZetaContinuationWitness Gamma boundary public export)**.** *The public export of Gamma-facing data from an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet is exhausted by the rows* P, F, G, H, C, R, N*. This Gamma-facing export does not close a Gamma chapter, an RH predicate, a non-trivial-zero locator, or any hidden analytic branch.*

Lean4 ✓ BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessGammaBoundaryPublicExport
↪ variant BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket gamma boundary public export

Proof. Start from Definition 580.5. A Gamma-facing read either uses the Gamma factor already displayed in the functional-equation row F or stops at the Gamma boundary row G, with P recording the adjacent pole ledger.

Apply Definition 580.2 and Definition 580.88. The transport, continuation, provenance, and local naming rows H, C, R, N authenticate the same public ledger, and the ledger has no Gamma coordinate beyond P, F, G, H, C, R, N.

Finally use Definition 580.86 together with Definition 580.7. The public export remains a finite packet boundary, not a Gamma chapter closure, RH assertion, non-trivial-zero locator, or hidden analytic branch. □

Theorem 580.15 (ZetaContinuationWitness source obligation)**.** *Every root-facing consumer of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet must first project the displayed packet*

$$W = (B, E, A, P, F, T, G, H, C, R, N)$$

and read the source row B, eta route E, analytic-continuation row A, functional-equation row F, transport row H, continuation row C, package provenance R, and local name N through the existing NameCert obligation surface. The pole, trivial-zero, and Gamma rows P, T, G remain ledger coordinates of the same packet; they do not supply an RH predicate, a non-trivial-zero locator, or a completed Gamma certificate.

Proof. Project $W = (B, E, A, P, F, T, G, H, C, R, N)$. The carrier exposes each row as a coordinate before any root-facing read is available.

Apply Definition 580.2 and Definition 580.4. The obligation surface binds carrier admission, analytic-continuation exactness, and ledger exactness, while source-lock coverage requires B, E, A, F and the authentication rows H, C, R, N to be visible first.

Use Definition 580.28 for the boundary. Since the packet contains no RH predicate, non-trivial-zero locator, global zero classifier, or completed Gamma certificate, the source obligation is exactly the displayed finite source lock. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket source boundary`

Theorem 580.16 (ZetaContinuationWitness analytic readback obligation)**.** *For an accepted* ZetaContinuationWitn *packet $W = (B, E, A, P, F, T, G, H, C, R, N)$, every root-facing analytic readback factors through B, E, A, F, H, C, R, N and the pole-Gamma boundary rows P, G before it can be consumed by a zeta-zero or critical-strip route. The readback may use the functional-equation row F and the Gamma boundary row G, but it cannot import an off-packet analytic branch or a completed Gamma certificate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket analytic readback obligation`

Proof. Begin with the source obligation above. It places B, E, A, F, H, C, R, N on the route before any root-facing readback is consumed.

Apply Definition 580.5. Pole and Gamma-dependent reads are confined to the displayed pole ledger P, functional-equation row F, and Gamma boundary row G.

Finally use the dependency ledger of Definition 580.8. The $\mathsf{ZetaBasic}^{\uparrow}$, $\mathsf{ZetaCont}^{\uparrow}$, $\mathsf{AnaCont}^{\uparrow}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{Complex}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert dependencies are already bound to W, leaving no coordinate for an off-packet branch or completed Gamma certificate. □

Theorem 580.17 (ZetaContinuationWitness zero ledger non-escape)**.** *An accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet exports no zero-location witness beyond the displayed trivial-zero ledger T and no RH-facing predicate beyond the source, analytic, pole, functional-equation, Gamma, transport, continuation, provenance, and naming rows of $W = (B, E, A, P, F, T, G, H, C, R, N)$. A root-facing consumer cannot read the packet as a completed zero ledger, a global zero classifier, or an RH proof.*

Proof. Project the packet and read the zero-facing coordinates. The only zero ledger coordinate is T, and it appears beside the source, analytic, pole, functional-equation, Gamma, transport, continuation, provenance, and naming rows.

Apply Definition 580.28 and Definition 580.11. These boundary rows exclude RH predicates, non-trivial-zero locators, global zero classifiers, and completed Gamma certificates from any critical-strip or root-facing consumer.

Use the pole-Gamma boundary and dependency ledger to exhaust the remaining routes. Since P, F, G, H, C, R, N only authenticate the displayed packet and do not add a zero-location coordinate, the trivial-zero ledger cannot escape as a completed zero classifier. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket zero ledger nonescape`

Theorem 580.18 (ZetaContinuationWitness formal-target ledger)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet*

$$W = (B, E, A, P, F, T, G, H, C, R, N),$$

the source totality row, Gamma functional boundary totality row, and critical-strip consumer non-escape row jointly present the finite formal target surface for ZetaContinuationWitness$^{\uparrow}$*. A consumer receives only* $B, E, A, P, F, T, G, H, C, R, N$ *with* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support. RH predicates, non-trivial-zero locators, global zero classifiers, hidden analytic branches, and completed Gamma certificates remain outside the packet.*

Proof. Use the source obligation theorem to bind root-facing reads to the displayed source row, eta route, analytic-continuation row, functional-equation row, transport row, continuation row, package provenance, and local name. This supplies the source-totality side of the formal target surface.

Use the analytic readback obligation for the Gamma functional boundary. It routes analytic access through B, E, A, F, H, C, R, N and the pole-Gamma rows P, G, so a consumer cannot import an off-packet branch or a completed Gamma certificate.

Use zero ledger non-escape for the critical-strip boundary. It leaves the displayed trivial-zero ledger row T inside W and refuses RH predicates, non-trivial-zero locators, and global zero classifiers.

The chapter-level dependency ledger already records the packet dependencies through the Lean target $BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket_dependency_ledger$. Combining these three paper rows with that dependency ledger gives one finite formal-target surface over $B, E, A, P, F, T, G, H, C, R, N$ and no additional analytic or zero-facing coordinate. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket root zero facing formal surface`

Theorem 580.19 (ZetaContinuationWitness root package)**.** *The root-facing obligation package for an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet is the finite surface consisting of the source obligation of Definition 580.15, the analytic readback obligation of Definition 580.16, and the zero ledger non-escape boundary of Definition 580.17. It exposes only* $W = (B, E, A, P, F, T, G, H, C, R, N)$ *and keeps RH predicates, non-trivial-zero locators, global zero classifiers, off-packet analytic branches, and completed Gamma certificates outside the packet.*

Proof. First assemble the source face. The source obligation projects W and binds the zero-facing consumer to the displayed source lock and NameCert obligation surface.

Next attach analytic readback. The analytic obligation routes every root-facing readback through the source rows, functional-equation row, pole-Gamma boundary, and dependency ledger.

Finally apply zero ledger non-escape. The zero-facing ledger remains the displayed T row inside W, while RH predicates, zero locators, global zero classifiers, off-packet analytic branches, and completed Gamma certificates remain outside the packet. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket root package`

Theorem 580.20 (ZetaContinuationWitness root zero-ledger totality)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet*

$$W = (B, E, A, P, F, T, G, H, C, R, N),$$

every root-facing zero read is either the displayed trivial-zero ledger row T transported through H, C, R, N, or is refused as an RH-facing, non-trivial-zero, or global-zero-classifier request. No root-facing consumer can obtain a zero read outside the source, analytic readback, zero ledger non-escape, and root package surfaces already bound to W.

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket root zero ledger totality`

Proof. Begin with the source obligation of Definition 580.15. It fixes the packet coordinates $B, E, A, P, F, T, G, H, C, R, N$ before any root-facing consumer can read a zero-facing row.

Next use the analytic readback obligation of Definition 580.16. Any analytic access to a root-facing readback must pass through the displayed source, functional-equation, pole-Gamma, transport, continuation, provenance, and naming rows, so it cannot import an off-packet zero classifier.

Apply Definition 580.17 to the zero-facing coordinate. The only zero ledger row exported by the packet is T, and RH predicates, non-trivial-zero locators, and global zero classifiers remain outside the accepted surface.

Finally invoke Definition 580.19. The root package is exactly the source obligation, analytic readback obligation, and zero ledger non-escape boundary. Hence each root-facing zero read is the transported T row through H, C, R, N, or else it is refused at the displayed boundary. □

Theorem 580.21 (ZetaContinuationWitness zero-consumer source readiness)**.** *For an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet*

$$W = (B, E, A, P, F, T, G, H, C, R, N),$$

every zero-facing consumer first exposes the source lock B, E, A, F and the authenticated rows H, C, R, N in the same BHist*-anchored packet. The consumer may then read the pole, trivial-zero, and Gamma ledger rows P, T, G, but it receives no RH predicate, non-trivial-zero locator, global zero classifier, or completed Gamma certificate as a source input.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket zero consumer source readiness`

Proof. Project the accepted carrier through BHist and the displayed packet W. The carrier rows fix the source zeta row, eta route, analytic-continuation row, functional-equation row, transports, continuation routes, provenance, and local name before any zero-facing read can occur.

Apply Definition 580.2 and Definition 580.4. These two rows force B, E, A, F and the authentication rows H, C, R, N to be visible as the source-facing entrance of the same packet.

Use Definition 580.15 and Definition 580.20. The child-file obligation package already records that the zero-facing read is either the transported T row or is refused at the displayed boundary.

Finally invoke Definition 580.28 and Definition 580.8. They keep RH predicates, non-trivial-zero locators, global zero classifiers, completed Gamma certificates, and off-packet dependencies outside the exposed source input. □

Theorem 580.22 (ZetaContinuationWitness eta-pole functional readiness)**.** *For an accepted* ZetaContinuationWitn *packet $W = (B, E, A, P, F, T, G, H, C, R, N)$, the admissible continuation branches for a zero-facing consumer are exhausted by the eta route E, pole ledger P, functional-equation row F, trivial-zero ledger T, and Gamma boundary row G, transported through H, C, R, N inside the same* BHist *surface. No branch outside those rows is available as an analytic-continuation input.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket eta pole functional readiness`

Proof. Begin with Definition 580.2. The obligation surface binds carrier admission, analytic-continuation exactness, pole exactness, trivial-zero exactness, and Gamma-boundary non-escape to the same accepted witness packet.

Apply Definition 580.19. Its source obligation, analytic readback obligation, and zero ledger non-escape boundary assemble the zero-facing package over $B, E, A, P, F, T, G, H, C, R, N$.

Now use Definition 580.16. Eta and analytic readback pass through B, E, A, F, H, C, R, N and, where a pole or Gamma boundary is requested, through the displayed rows P, G.

The remaining zero-facing branch is the trivial-zero ledger. By Definition 580.17 and Definition 580.20, this branch is exactly the row T transported through H, C, R, N or else the request is refused.

Finally apply Definition 580.8. The BHist, hsame, Cont, Pkg, and NameCert dependencies are already coordinates of W, so no hidden continuation branch remains after the eta, pole, functional-equation, trivial-zero, and Gamma-boundary rows have been enumerated. □

Theorem 580.23 (ZetaContinuationWitness Gamma critical-strip readiness)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet* $W = (B, E, A, P, F, T, G, H, C, R, N)$*, every Gamma-facing or critical-strip consumer stops at the displayed Gamma boundary row* G *unless the requested Gamma factor is already carried by the functional-equation row* F*. The same consumer route exposes no RH predicate, no non-trivial-zero locator, no global zero classifier, and no completed Gamma certificate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket gamma critical strip readiness`

Proof. Start from Definition 580.28. A critical-strip consumer receives only the finite packet rows and cannot read RH predicates, non-trivial-zero locators, global zero classifiers, or completed Gamma certificates as packet input.

Apply Definition 580.14. It identifies the Gamma-facing public export with P, F, G, H, C, R, N and separates that export from Gamma chapter closure, RH assertions, zero locators, and hidden analytic branches.

Use Definition 580.16 for the functional-equation side. If the requested Gamma factor is already represented by F, the route may read that displayed factor together with P, G, H, C, R, N; otherwise it reaches the boundary row G and stops.

Finally combine Definition 580.17 with Definition 580.8. The zero ledger remains T, while the BHist, hsame, Cont, Pkg, and NameCert dependencies keep every Gamma or critical-strip read inside W. □

Theorem 580.24 (ZetaContinuationWitness root readiness lock)**.** *Every root-unblock consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet must read the displayed packet rows*

$$B, E, A, P, F, T, G, H, C, R, N$$

before any zeta-zero or critical-strip handoff. The rows are read as a single BHist*-anchored* NameCert *surface with* hsame *transports,* Cont *routes,* Pkg *provenance, and local naming, so no downstream zero-facing consumer can bypass the carrier through an off-packet analytic branch, an RH predicate, a non-trivial-zero locator, or a completed Gamma certificate.*

Proof. Project the accepted packet as $W = (B, E, A, P, F, T, G, H, C, R, N)$. The NameCert obligation surface of Definition 580.2 and the dependency ledger of Definition 580.8 list exactly the carrier, dependency, transport, route, provenance, and naming rows that a consumer must expose.

Apply the existing root child surfaces next. The root-unblock obligation surface, root zero-facing package, and zero-consumer readiness surface force the source, analytic, pole, functional-equation, trivial-zero, Gamma-boundary, transport, continuation, provenance, and local naming rows to appear before the consumer can read a zero-facing route.

Finally use Definition 580.28. It removes RH predicates, non-trivial-zero locators, global zero classifiers, off-packet analytic branches, and completed Gamma certificates from the packet input, so the only root-unblock handoff is through the displayed rows of W. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket root readiness lock`

Theorem 580.25 (ZetaContinuationWitness zero-facing source accountability)**.** *Every zero-facing read of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet exposes the source row B, eta route E, analytic-continuation row A, functional-equation row F, pole ledger P, trivial-zero ledger T, Gamma boundary G, transport rows H, continuation row C, package provenance R, and local name N before becoming input to a* $\mathsf{ZetaZeros}^{\uparrow}$*-facing consumer. In particular, the read presents the source row, eta route, analytic-continuation row, functional-equation row, and pole/trivial-zero/Gamma ledger as visible coordinates of the same packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket zero facing source accountability`

Proof. Start with Definition 580.8. It binds the $\mathsf{ZetaBasic}^{\uparrow}$, $\mathsf{ZetaCont}^{\uparrow}$, $\mathsf{AnaCont}^{\uparrow}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{Complex}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows to the displayed packet before any zero-facing consumer can read it.

Use Definition 580.21 and Definition 580.22. These readiness rows expose B, E, A, F as the source-facing route and expose P, T, G as the pole, trivial-zero, and Gamma ledger routes transported through H, C, R, N.

The handoff is then constrained by Definition 580.28. Since the packet has no RH predicate, non-trivial-zero locator, global zero classifier, hidden analytic branch, or completed Gamma certificate, the zero-facing source account is exactly the visible packet rows. □

Theorem 580.26 (ZetaContinuationWitness Gamma-boundary root non-escape)**.** *Every Gamma-dependent root consumer of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet stops at the displayed Gamma boundary row G unless the requested Gamma factor is already inside the functional-equation row F. Such a consumer may read the adjacent pole ledger P and the authenticating rows H, C, R, N, but it receives no completed Gamma certificate and no Gamma-side route outside the finite packet $B, E, A, P, F, T, G, H, C, R, N$.*

Proof. Begin with the pole and Gamma side of the packet. The NameCert obligation surface records P, F, G as displayed rows, and the dependency ledger keeps them inside the same BHist carrier with the transport, continuation, provenance, and naming rows.

Apply Definition 580.23. A Gamma-facing or critical-strip consumer stops at G unless the requested factor is already represented in F, and it receives no completed Gamma certificate.

Close with Definition 580.28 and the root child readiness surfaces. They ensure that the same boundary is the only root-facing Gamma handoff and that no off-packet analytic branch, RH predicate, non-trivial-zero locator, or global zero classifier is exported with the Gamma request. □

Lean4 ✓ BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket gamma boundary

Theorem 580.27 (ZetaContinuationWitness root readiness source seal)**.** *Every zero-facing or critical-strip consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet must first read the source-seal rows*

$$B, E, A, F, H, C, R, N.$$

The pole ledger P, trivial-zero ledger T, and Gamma boundary G may be read only as displayed ledger boundaries of the same packet. No such consumer receives an RH predicate, zero locator, global zero classifier, hidden analytic branch, or completed Gamma certificate.

Lean4 ✓ BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket root readiness source seal

Proof. Start with the root readiness lock, Definition 580.24. It forces the accepted packet $W = (B, E, A, P, F, T, G, H, C, R, N)$ to be exposed before any zero-facing or critical-strip handoff can read it.

Use the sibling zero-consumer readiness surface and the zero-facing source accountability theorem, Definition 580.21 and Definition 580.25. These rows make B, E, A, F, H, C, R, N the required source, analytic, functional-equation, transport, continuation, provenance, and naming surface, while P, T, G remain visible ledger boundaries.

Finally apply the Gamma-boundary root non-escape theorem, Definition 580.26, together with critical-strip input refusal. A Gamma-dependent consumer stops at G unless the requested factor is already represented in F, and the same packet exports no RH predicate, zero locator, global zero classifier, hidden analytic branch, or completed Gamma certificate. □

Theorem 580.28 (ZetaContinuationWitness critical-strip input refusal)**.** *An accepted* ZetaContinuationWitness$^{\uparrow}$ *packet contains no RH predicate, no non-trivial-zero locator, no global zero classifier, and no completed Gamma certificate. Consequently a critical-strip consumer receives only the displayed finite witness rows $B, E, A, P, F, T, G, H, C, R, N$ and cannot read any of those excluded objects as packet input.*

Lean4 ✓ BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket critical strip input refusal

Proof. Project $W = (B, E, A, P, F, T, G, H, C, R, N)$. Each coordinate is one of the displayed continuation, ledger, boundary, transport, route, provenance, or naming rows.

Apply the carrier definition and the NameCert obligation surface. They account for all admitted rows and list the analytic-continuation exactness, pole and trivial-zero ledger exactness, and Gamma-horizon non-escape clauses, but none of their coordinates is an RH predicate, non-trivial-zero locator, global zero classifier, or completed Gamma certificate.

The conclusion follows by coordinate exhaustion. Since the critical-strip route is a Cont read from the same packet, it receives only the displayed rows and has no input slot for the excluded data. □

Theorem 580.29 (ZetaContinuationWitness bridged-boundary mature route)**.** *Every bridge-facing consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet factors through the public export, source lock, pole-Gamma boundary, critical-strip route separation, dependency ledger, and critical-strip input refusal before reading the packet as a standard bridge boundary. The bridge-facing read exports no RH predicate, non-trivial-zero locator, completed Gamma certificate, or global zero classifier.*

Proof. Start with the public export and source lock. The accepted packet is already exposed as the finite witness rows $B, E, A, P, F, T, G, H, C, R, N$, together with their BHist, hsame, Cont, Pkg, and NameCert support.

Next use the pole-Gamma boundary and critical-strip route separation. These rows keep Gamma-facing reads inside P, F, G, H, C, R, N and keep critical-strip reads inside the same displayed finite packet.

Then apply the dependency ledger and critical-strip input refusal. The dependency ledger binds the source, continuation, analytic, holomorphic, complex, history, transport, route, package, and naming rows to the same witness packet, while the refusal theorem removes RH predicates, zero locators, completed Gamma certificates, and global zero classifiers from the input surface.

Finally combine the same public export with the displayed bridge-facing boundary. Any bridge-facing consumer therefore factors through the same finite witness packet before reaching the standard bridge boundary, so no excluded object can be exported as bridge input. □

Closure status for $\mathsf{NameCert}_{\mathsf{ZetaContinuationWitness}^{\uparrow}}$ **.**

Constructive story: A $\mathsf{ZetaContinuationWitness}^{\uparrow}$ packet is generated from a $\mathsf{ZetaBasic}^{\uparrow}$ source row, an eta-continuation route, an analytic-continuation row, a pole ledger, a functional-equation route, a trivial-zero ledger, a Gamma-horizon boundary, displayed hsame transports, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ZetaContinuationWitness}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 580.1, Definition 580.2, Definition 580.41, Definition 580.45, Definition 580.46, Definition 580.37, Definition 580.51, Definition 580.52, Definition 580.50, and Definition 580.56 define the local witness carrier, obligation surface, route-carrier admission, classifier stability, pole-ledger exactness, continuation handoff, trivial-zero ledger, Gamma-horizon boundary, critical-strip handoff, and local package and naming rows. Bridge-facing access is then routed through the public export, source lock, pole-Gamma boundary, critical-strip route separation, dependency ledger, and critical-strip input refusal, so the chapter closes the bridge boundary on the displayed packet only.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ZetaContinuationWitness}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket\_public\_export`

Bridge status: none

Origin: human

Not claimed: This chapter does not prove RH, locate non-trivial zeros, close the Gamma chapter, decide global branch behaviour, complete quotient-of-germs construction, or provide bridge checking.

Upgrade path: Bridge checking remains a later step if a standard bridge is added for the same finite witness packet without introducing RH or zero-location data.

Theorem 580.30 (ZetaContinuationWitness critical-strip bridge row)**.** *Every critical-strip consumer of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet can read only the displayed rows* $B, E, A, P, F, T, G, H, C, R, N$. *The consumer cannot import an RH predicate, a non-trivial-zero location row, or a global zero classifier as packet input; those objects are outside the carrier, outside the NameCert obligation surface, and outside the exhausted consumer ledger.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket critical strip bridge row`

Proof. Start with the carrier and the NameCert obligation surface. The carrier lists exactly $B, E, A, P, F, T, G, H, C, R, N$, and the obligation rows account for source, eta, continuation, pole, functional-equation, trivial-zero, Gamma, transport, route, provenance, and local naming reads.

Apply the pole-Gamma boundary and critical-strip input refusal. These rows exclude RH predicates, non-trivial-zero locators, global zero classifiers, and completed Gamma certificates from the packet input.

Finally use route-carrier admission and consumer-ledger exhaustion. Any critical-strip route must be replayed through the same displayed Cont row and authenticated by R, N, so there is no remaining bridge through which an excluded critical-strip object can enter. □

Theorem 580.31 (ZetaContinuationWitness source-lock triad)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet*

$$W = (B, E, A, P, F, T, G, H, C, R, N),$$

every zero-facing or critical-strip consumer must first expose the source triad B, E, A together with the functional-equation route F. Thus the mandatory source, eta, analytic-continuation, and functional-equation route is B, E, A, F before any zero consumer can read the packet.

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket source lock triad`

Proof. Project the carrier of Definition 580.1. The rows B, E, A, F are displayed coordinates of the same finite packet, not ambient analytic data.

Apply source-lock coverage and dependency-ledger exhaustion. Definition 580.4 exposes B, E, A, F before continuation, zero, or critical-strip use, and Definition 580.8 keeps the consumer route inside the displayed dependency ledger. □

Theorem 580.32 (ZetaContinuationWitness Gamma-boundary triad)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet, the pole, trivial-zero, and Gamma-horizon ledger is exactly the displayed triad P, T, G. Pole-facing reads remain in P, trivial-zero reads remain in T, and Gamma-dependent reads stop at G unless the requested Gamma factor is already displayed inside F; the packet carries no completed Gamma certificate.*

Proof. Use the carrier projection and the NameCert obligation surface. The only pole, trivial-zero, and Gamma-horizon rows named by Definition 580.1 and Definition 580.2 are P, T, G.

Now apply the pole-Gamma boundary and Gamma-horizon consumer row. Definition 580.5 confines pole and Gamma reads to P, F, G, while Definition 580.35 refuses any completed Gamma certificate beyond the displayed functional-equation factor and the boundary row. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket gamma boundary triad`

Theorem 580.33 (ZetaContinuationWitness critical-strip ledger triad)**.** *Every critical-strip consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet receives the source-lock rows B, E, A, F, the ledger triad P, T, G, and the authentication rows H, C, R, N as one finite ledger $B, E, A, P, F, T, G, H, C, R, N$. It receives no RH predicate, non-trivial-zero locator, global zero classifier, hidden analytic branch, or completed Gamma certificate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessCriticalStripLedgerTriad`

Proof. First combine the two triads. Definition 580.31 supplies B, E, A, F, and Definition 580.32 supplies P, T, G as the only pole, trivial-zero, and Gamma-horizon ledger.

Next attach the transport, route, provenance, and naming rows. The carrier and Definition 580.30 route every critical-strip consumer through H, C, R, N after the displayed ledger rows.

Finally apply critical-strip input refusal. Definition 580.28 excludes RH predicates, non-trivial-zero locators, global zero classifiers, and completed Gamma certificates from the packet input, so the consumer ledger is exactly the finite packet already displayed. □

Theorem 580.34 (ZetaContinuationWitness pole-ledger refusal row)**.** *Every pole-facing read of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet stays in the displayed pole ledger P and its authentication rows H, C, R, N. The pole row cannot become a separate pole-completion object, cannot supply a second continuation carrier, and cannot bypass the eta, functional-equation, Gamma-boundary, and consumer-ledger rows already displayed by the packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket pole ledger refusal row`

Proof. Project the carrier and isolate the pole coordinate P. It is a ledger row inside $W = (B, E, A, P, F, T, G, H, C, R, N)$, not an independent completion carrier.

Use the NameCert obligation surface together with the pole-Gamma boundary. The obligation surface treats pole exactness as a finite ledger read, and the boundary keeps pole reads in P while routing Gamma-dependent reads through F or G.

Route-carrier admission and consumer-ledger exhaustion close the refusal. Every pole-facing consumer must replay the displayed route through C and authenticate it through R, N, so the pole row cannot split off as a separate object or bypass the displayed witness packet. □

Theorem 580.35 (ZetaContinuationWitness Gamma-horizon consumer row)**.** *Every Gamma-dependent consumer of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet either reads a Gamma factor already displayed in the functional-equation row F or stops at the Gamma-horizon boundary G. The packet supplies no completed Gamma certificate and no hidden Gamma route beyond F, G, H, C, R, N.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessGammaHorizonConsumerRow`

Proof. Begin with the carrier and NameCert obligation surface. The only Gamma-facing coordinates are the displayed factor inside F and the horizon boundary G.

Apply the pole-Gamma boundary and critical-strip input refusal. They prevent a Gamma-dependent read from importing a completed Gamma certificate or using Gamma data as an RH-facing critical-strip input.

Use route-carrier admission and consumer-ledger exhaustion for the final route. Once the read lands in F or G, it is transported, replayed, packaged, and named only through H, C, R, N, so no further Gamma-horizon consumer row is available. □

Theorem 580.36 (ZetaContinuationWitness eta-functional route coverage)**.** *Every exported continuation route of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet is covered by one of five displayed rows: the eta-continuation row E, the pole ledger P, the functional-equation row F, the trivial-zero ledger T, or the Gamma-horizon boundary G. There is no unrecorded continuation branch outside those rows and their accompanying* hsame, Cont, Pkg, *and* NameCert *authentication data.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket eta functional route coverage`

Proof. Project $W = (B, E, A, P, F, T, G, H, C, R, N)$. The route-bearing analytic coordinates are the eta-continuation row E, the analytic-continuation row A, and the functional-equation row F, while exceptional reads are represented by P, T, G.

Use the obligation surface. Analytic-continuation exactness routes exported $\mathsf{ZetaCont}^{\uparrow}$ reads through the source, eta, analytic-continuation, and functional-equation coordinates, while the pole, trivial-zero, and Gamma-horizon clauses account for P, T, G.

Finally replay the continuation routes in C through the transports H and authenticate them with R, N. Since every exported read has landed in E, P, F, T, G before authentication, no unrecorded branch remains. □

Theorem 580.37 (ZetaContinuationWitness continuation handoff)**.** *Every* $\mathsf{ZetaZeros}^{\uparrow}$ *or critical-strip consumer of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *carrier reads the continued zeta value through the displayed rows* $B, E, A, P, F, T, G, H, C, R, N$*. In particular, the handoff exposes the* $\mathsf{ZetaCont}^{\uparrow}$ *value surface, the pole boundary at* $s = 1$*, the trivial-zero ledger, and the Gamma-horizon boundary, but it exports no RH conclusion and no zero-location classifier.*

Proof. Start with the consumer route stored in C. If it asks for the basic zeta source, the eta continuation, the analytic-continuation row, or the functional-equation route, the requested coordinate is one of B, E, A, F and is transported through H.

If the consumer asks about the pole at $s = 1$ or a negative even input, the request lands in the ledger rows P or T. These rows expose the relevant boundary or zero witness as ledger data attached to the same packet.

The remaining analytic escape route is Gamma-dependent. That route is absorbed by G unless the requested factor is already one of the displayed functional-equation rows. Therefore the downstream consumer receives only the finite continuation witness packet and does not receive an RH proof, a non-trivial-zero locator, or a completed Gamma certificate. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket continuation handoff`

Theorem 580.38 (ZetaContinuationWitness zero-consumer handoff)**.** *Every* $\mathsf{ZetaZeros}^{\uparrow}$ *or critical-strip consumer of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet first exposes the finite rows*

$$B, E, A, P, F, T, G, H, C, R, N.$$

The handoff cannot present a zero-facing conclusion before carrier admission, NameCert obligation display, route-carrier admission, pole-Gamma boundary control, critical-strip input refusal, and consumer-ledger exhaustion have displayed those rows.

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessZeroConsumerHandoff`

Proof. Begin with the carrier $W = (B, E, A, P, F, T, G, H, C, R, N)$ and the NameCert obligation surface. These two rows provide the only public inventory for a zero-facing or critical-strip read.

Use route-carrier admission to move from the raw carrier to the admitted continuation route. The admitted route is replayed only through the displayed Cont rows and authenticated only by the displayed provenance and naming rows.

Apply pole-Gamma boundary control and critical-strip input refusal. Pole-facing requests stay in P, Gamma-dependent requests stay in G unless already displayed in F, and critical-strip requests cannot import RH predicates, non-trivial-zero locators, global zero classifiers, or completed Gamma data.

Consumer-ledger exhaustion then closes the handoff. Since every surviving consumer read has already landed in $B, E, A, P, F, T, G, H, C, R, N$, there is no remaining route by which a zero-facing consumer can receive an off-packet conclusion. □

Theorem 580.39 (ZetaContinuationWitness critical-strip pole boundary)**.** *Every pole-facing or critical-strip route of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet must pass through the displayed pole ledger* P*, functional-equation row* F*, and Gamma-horizon row* G *before it reaches any downstream consumer. No such route can bypass* P, F, G *by using an RH predicate, a non-trivial-zero locator, a global critical-strip classifier, or a completed Gamma certificate.*

Proof. Project the carrier and isolate the boundary rows P, F, G. The pole row is the only pole-facing ledger, the functional-equation row is the only displayed factor route, and the Gamma-horizon row is the only Gamma-dependent boundary outside the factors already stored in F.

The NameCert obligation surface and pole-Gamma boundary identify these coordinates as mandatory boundary reads. A pole-facing request cannot leave P, while a Gamma-dependent request terminates at G unless the datum is already part of F.

Critical-strip input refusal removes the external shortcuts. The packet has no RH coordinate, no non-trivial-zero locator, no global classifier row, and no completed Gamma certificate.

Finally apply route-carrier admission and consumer-ledger exhaustion. Every admitted continuation route is replayed through the same displayed carrier and named by R, N, so a pole-facing or critical-strip consumer must pass through P, F, G rather than bypassing the boundary. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessCriticalStripPoleBoundary`

Theorem 580.40 (ZetaContinuationWitness Gamma-route non-escape ledger)**.** *Every Gamma-dependent read of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet terminates at the displayed Gamma-horizon row G unless the requested Gamma datum is already displayed in the functional-equation row F. After that landing, the read is transported, replayed, packaged, and named only through H, C, R, N.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessGammaRouteNonescapeLedger`

Proof. Start from the carrier and the NameCert obligation surface. They expose F and G as the only Gamma-facing rows of the packet.

Use the pole-Gamma boundary. It sends Gamma-dependent reads to G unless the requested factor has already appeared inside the functional-equation row F.

Critical-strip input refusal prevents the Gamma read from being reinterpreted as a critical-strip shortcut. The packet does not supply RH data, a zero-location classifier, or a completed Gamma object.

Route-carrier admission and consumer-ledger exhaustion finish the ledger check. Once the read has landed in F or G, the only remaining public rows are H, C, R, N, so the Gamma route has no off-packet escape. □

Theorem 580.41 (ZetaContinuationWitness route-carrier admission)**.** *An accepted* ZetaContinuationWitness$^{\uparrow}$ *packet admits a continuation route only when the route is carried by the displayed eta-continuation row E, pole ledger P, functional-equation row F, trivial-zero ledger T, Gamma-horizon boundary G, componentwise* hsame *transports H,* Cont *reads C,* Pkg *provenance R, and local* NameCert *row N. No continuation route is admitted from an unrecorded branch, an RH predicate, a global zero-location classifier, or a completed Gamma certificate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket route carrier admission`

Proof. Project the carrier $W = (B, E, A, P, F, T, G, H, C, R, N)$. The eta-continuation coordinate E, the analytic-continuation coordinate A, and the functional-equation coordinate F are the only route-bearing analytic rows.

The ledger rows P and T restrict the exceptional reads, while G records the Gamma-horizon boundary. Transport through H and replay through C preserve those displayed rows and do not add a branch.

Finally authenticate the route through R and N. Since the carrier contains no RH coordinate, no non-trivial-zero locator, and no closed Gamma chapter, admission is exactly the displayed finite route carrier. □

Theorem 580.42 (ZetaContinuationWitness consumer ledger exhaustion)**.** *Every consumer read of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet factors through the displayed carrier rows*

$$B, E, A, P, F, T, G, H, C, R, N.$$

No downstream zeta-zero, critical-strip, pole-facing, trivial-zero, or Gamma-facing consumer can obtain a continuation witness row outside that finite ledger.

Proof. Project the carrier $W = (B, E, A, P, F, T, G, H, C, R, N)$. The tuple lists the source zeta row, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, transports, continuation reads, provenance, and local name.

Apply the NameCert obligation surface. It binds carrier admission, classifier stability, analytic-continuation exactness, pole and trivial-zero ledger exactness, and Gamma-horizon non-escape to precisely those coordinates.

Finally use route-carrier admission. Every admitted public continuation route is replayed through C and authenticated by R, N, so there is no remaining consumer-visible row outside the displayed ledger. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessConsumerLedgerExhaustion`

Theorem 580.43 (ZetaContinuationWitness critical-strip handoff scope)**.** *Every critical-strip consumer of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet receives only the displayed continuation rows* B, E, A, F*, the pole row* P*, the trivial-zero row* T*, the Gamma-boundary row* G*, and the structural rows* H, C, R, N*. It receives no RH predicate, no non-trivial-zero locator, no global zero-classifier row, and no completed Gamma certificate.*

Proof. Start with a critical-strip read and project the accepted carrier. Its analytic route-bearing coordinates are B, E, A, F, and its exceptional boundary coordinates are P, T, G.

Use critical-strip input refusal and route-carrier admission. The first theorem excludes RH, non-trivial-zero locators, global zero classifiers, and completed Gamma certificates from the packet input; the second forces admitted continuation routes through the displayed eta, pole, functional-equation, trivial-zero, Gamma, transport, route, provenance, and naming rows.

The structural rows H, C, R, N only transport, replay, package, and name those displayed coordinates. Therefore the critical-strip handoff scope is exactly the advertised continuation, pole, trivial-zero, and Gamma-boundary surface. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket critical strip handoff scope`

Theorem 580.44 (ZetaContinuationWitness Gamma-horizon non-escape row)**.** *Every Gamma-dependent read of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet lands at the displayed Gamma-horizon boundary* G *unless the requested datum is already part of the functional-equation factor row* F*. The read is then transported, replayed, packaged, and named only through* H, C, R, N*.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket gamma horizon nonescape row`

Proof. Project the carrier and isolate the Gamma-facing rows. The functional-equation route F contains the displayed Gamma factor only as part of the factor ledger, while G is the separate Gamma-horizon boundary.

Apply the NameCert obligation surface. Its Gamma-horizon clause says that a Gamma-dependent read reaches G unless it is already one of the displayed functional-equation factors.

Route-carrier admission and consumer ledger exhaustion then force the read through H, C, R, N after it lands in F or G. Since the carrier has no closed Gamma chapter, hidden branch selector, RH predicate, or zero-location coordinate, no Gamma-dependent read escapes the displayed boundary. □

Theorem 580.45 (ZetaContinuationWitness classifier stability)**.** *The* ZetaContinuationWitness$^{\uparrow}$ *classifier is stable under componentwise* hsame *and displayed* Cont *transport of the source zeta row, eta-continuation route, pole ledger, functional-equation route, trivial-zero ledger, Gamma-horizon boundary,* Pkg *provenance, and local* NameCert *rows. Transported packets keep the same finite witness surface and do not gain RH, global zero-location, or analytic-continuation data beyond the displayed witness packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket classifier stability`

Proof. Compare two accepted packets componentwise. The source row B, eta route E, analytic-continuation row A, pole ledger P, functional-equation row F, trivial-zero ledger T, and Gamma boundary G are transported only along the corresponding rows of H.

The continuation reads in C replay those transported rows in the same order. They preserve the route carrier and the exceptional ledgers because each read targets a displayed coordinate of the packet.

Package provenance R and local naming N then repack the transported surface. No classifier coordinate mentions RH, a non-trivial-zero locator, a global branch theorem, or a completed Gamma chapter, so stability remains finite-packet stability. □

Theorem 580.46 (ZetaContinuationWitness pole-ledger exactness)**.** *Every pole-facing read of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet is exactly the displayed pole ledger P together with the eta-continuation, functional-equation, Gamma-horizon,* hsame, Cont, Pkg, *and* NameCert *rows needed to authenticate that ledger. The read does not decide non-trivial zeros, does not prove RH, and does not extend analytic continuation beyond the witness packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket pole ledger exactness`

Proof. Read the exceptional coordinate P from the carrier. It records the simple-pole row and residue-one readback at $s = 1$, so a pole-facing consumer has a named ledger rather than an ambient meromorphic theorem.

The surrounding rows E, F, G, H, C, R, N authenticate the ledger. The eta and functional-equation routes place the pole row inside the witness packet, the Gamma boundary limits Gamma-dependent access, and the transport and continuation rows replay only displayed data.

The trivial-zero ledger T remains separate. Therefore pole exactness does not locate non-trivial zeros, does not assert RH, and does not supply continuation data outside the finite certificate. □

Theorem 580.47 (ZetaContinuationWitness carrier admission tightening)**.** *Let $W = (B, E, A, P, F, T, G, H, C, R,$ be an accepted* ZetaContinuationWitness$^{\uparrow}$ *carrier. Every public continuation route admitted by the local* NameCert *projects through the displayed rows $B, E, A, P, F, T, G, H, C, R, N$. In particular, eta continuation, pole reads, functional-equation reads, trivial-zero reads, and Gamma-boundary reads are all carrier reads of this packet and not reads of an unrecorded analytic branch.*

Lean4 ✓ BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessCarrierAdmissionTightening

Proof. Start from the carrier definition. The packet lists the basic zeta source, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, transport rows, continuation rows, provenance, and local name as the complete public inventory.

Apply the NameCert obligation surface and the continuation handoff. Carrier admission supplies the tuple, while the handoff sends every $\mathsf{ZetaZeros}^{\uparrow}$ or critical-strip consumer through the same displayed rows.

Use route-carrier admission to rule out unrecorded branches, RH predicates, global zero-location classifiers, and completed Gamma certificates. The classifier-stability and pole-ledger exactness rows then keep the exceptional pole and zero data inside the same finite carrier surface. □

Theorem 580.48 (ZetaContinuationWitness route stability budget)**.** *For accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *carriers* $W = (B, E, A, P, F, T, G, H, C, R, N)$*, componentwise* hsame *transport together with displayed* Cont *replay preserves the eta-continuation row* E*, pole ledger* P*, functional-equation row* F*, trivial-zero ledger* T*, and Gamma-boundary row* G*. A transported public route therefore has the same finite continuation budget and cannot gain an extra continuation, zero-location, or Gamma-completion row.*

Lean4 ✓ BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket route stability budget

Proof. Project the transport coordinate H and continuation coordinate C from the carrier. The source, eta, analytic-continuation, pole, functional-equation, trivial-zero, and Gamma-boundary rows are transported componentwise rather than through a single ambient analytic equality.

Apply classifier stability. It states that transported packets keep the same finite witness surface and that replay through C reads the displayed coordinates in the same route shape.

The continuation handoff and route-carrier admission identify the public route consumed downstream. Pole-ledger exactness keeps P separate from non-trivial-zero location, while the NameCert obligation surface keeps T and G as displayed ledger and boundary rows. Hence the route budget is stable under the advertised hsame and Cont data. □

Theorem 580.49 (ZetaContinuationWitness ledger non-escape boundary)**.** *An accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *carrier exposes no RH predicate, no non-trivial-zero location row, no hidden Gamma completion, and no unrecorded branch data. Every public ledger read is confined to the displayed packet*

$$B, E, A, P, F, T, G, H, C, R, N.$$

Lean4 ✓ BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessCarrier ledger nonescape boundary

Proof. Inspect the carrier definition. Its coordinates include explicit eta, pole, functional-equation, trivial-zero, and Gamma-boundary rows, but no RH coordinate, non-trivial-zero locator, closed Gamma theorem, or branch selector.

Apply the NameCert obligation surface for ledger exactness and Gamma-horizon non-escape. The pole and trivial-zero ledgers are read as P and T, and every Gamma-dependent request either uses a displayed functional-equation factor or terminates at G.

Finally use continuation handoff, route-carrier admission, classifier stability, and pole-ledger exactness. These rows force downstream zeta and critical-strip consumers to replay the same finite

route and keep exceptional ledgers inside the witness packet, so no public read escapes to the excluded data. □

Theorem 580.50 (ZetaContinuationWitness critical-strip handoff)**.** *Every critical-strip or zeta-zero consumer of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet reads only the displayed rows*

$$B, E, A, P, F, T, G, H, C, R, N.$$

The handoff may expose the basic zeta source, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma-horizon boundary, transport, continuation, package provenance, and local name, but it exports no RH predicate, no non-trivial-zero locator, and no global zero-classifier row.

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket critical strip handoff`

Proof. Project the carrier $W = (B, E, A, P, F, T, G, H, C, R, N)$. These coordinates are the whole continuation witness packet available to downstream readers.

Apply the NameCert obligation surface. It lists carrier admission, classifier stability, analytic-continuation exactness, pole and trivial-zero ledger exactness, and Gamma-horizon non-escape as the finite rows exposed by the local name.

Apply the continuation handoff. It sends $\mathsf{ZetaZeros}^{\uparrow}$ and critical-strip reads through the same displayed coordinates and records every move in H, C, R, N.

Coordinate exhaustion closes the boundary. Since no coordinate stores RH, a non-trivial-zero locator, or a global zero classifier, a critical-strip consumer cannot read any such object from this packet. □

Theorem 580.51 (ZetaContinuationWitness trivial-zero ledger non-escape)**.** *For an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet, the negative-even ledger* T *remains a trivial-zero ledger read through the sine-factor part of the displayed functional-equation route. It cannot become an RH predicate, a non-trivial-zero locator, a global zero-classifier row, or a substitute for the critical-strip handoff.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket trivial zero ledger nonescape`

Proof. Project the carrier. The row T is listed as the trivial-zero ledger for negative even inputs, while the functional-equation route is stored separately at F and the downstream continuation routes are stored in C.

Use the NameCert obligation surface and pole-ledger exactness. The ledger clauses keep P and T as exceptional ledger reads, and the pole theorem already separates exceptional ledger exactness from RH, non-trivial-zero location, and continuation outside the witness packet.

Use the continuation handoff for downstream consumers. A zeta-zero or critical-strip read may see T only as part of the displayed finite witness route, with transport, provenance, and naming recorded in H, R, N.

No remaining coordinate can reinterpret the negative-even ledger as a critical-strip predicate. Thus T cannot escape into RH, a non-trivial-zero locator, or a global zero classifier. □

Theorem 580.52 (ZetaContinuationWitness Gamma-horizon consumer boundary)**.** *Every Gamma-dependent read of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet terminates at the Gamma-horizon*

boundary row G unless the requested datum is already one of the displayed functional-equation factors carried by F. The packet therefore exposes the Gamma factor only through F, G, H, C, R, N and does not close a Gamma chapter, select a hidden branch, or supply an RH-facing analytic shortcut.

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket gamma horizon consumer boundary`

Proof. Project the carrier $W = (B, E, A, P, F, T, G, H, C, R, N)$. The only Gamma-facing coordinates are the functional-equation route F and the Gamma-horizon boundary row G.

Apply the NameCert obligation surface. Its Gamma-horizon clause states that a Gamma-dependent read reaches G unless it is already a displayed functional-equation factor.

Apply the continuation handoff. The read is replayed through C, transported through H, and packaged and named by R, N, so the consumer receives the same finite boundary rather than a completed Gamma certificate.

Coordinate exhaustion excludes the analytic escape. The carrier has no hidden branch selector, closed Gamma theorem, RH predicate, or zero-location coordinate, so Gamma-dependent reads stop at the displayed horizon boundary. □

Theorem 580.53 (ZetaContinuationWitness vision concretization)**.** *The zeta-continuation application of chapter 9342 is concretized by* ZetaContinuationWitness$^{\uparrow}$ *as a finite* BHist *NameCert packet over the eta-continuation route, pole ledger, functional-equation route, trivial-zero ledger, Gamma-horizon boundary, componentwise* hsame *transports, finite* Cont *reads,* Pkg *provenance, and local naming.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessVisionConcretization`

Proof. The carrier definition supplies the finite packet. The NameCert obligation surface binds carrier admission, classifier stability, analytic-continuation exactness, pole and trivial-zero ledger exactness, and Gamma-horizon non-escape for precisely those coordinates.

The continuation handoff theorem identifies the downstream consumer surface for ZetaZeros$^{\uparrow}$ and critical-strip chapters. Since the packet exports no RH conclusion, no non-trivial-zero locator, and no closed Gamma chapter, it concretizes the application as a witness interface rather than as a proof of any RH-facing conclusion. □

Theorem 580.54 (ZetaContinuationWitness eta-denominator boundary)**.** *For an accepted* ZetaContinuationWitnes *packet $W = (B, E, A, P, F, T, G, H, C, R, N)$, the eta route row E is the only denominator-boundary witness for the factor $1 - 2^{1-s}$. A public read may consume that boundary through E, H, C, R, N, but it cannot export a branch selector, a zero-location classifier, or an RH predicate from the denominator row.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket eta denominator boundary`

Proof. Project the carrier. The denominator boundary is listed only inside the eta route coordinate E, while the route replay and authentication data are the displayed rows H, C, R, N.

Apply the NameCert obligation surface and route-carrier admission. These rows admit continuation data only from the displayed eta, pole, functional-equation, trivial-zero, and Gamma-boundary coordinates.

Finally use the critical-strip handoff and ledger non-escape boundary. Since the carrier has no branch selector, global zero-location classifier, or RH coordinate, a denominator read through E remains a boundary witness for $1 - 2^{1-s}$ and cannot export any of the excluded data. □

Theorem 580.55 (ZetaContinuationWitness functional-factor non-escape)**.** *Every functional-equation read of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet through* F, G, H, C, R, N *exposes only the displayed sine factor, reflected-zeta route, exponential factor, and Gamma-boundary rows. It supplies no RH predicate, no non-trivial-zero locator, and no classifier for the critical strip beyond the finite witness packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket functional factor nonescape`

Proof. Start from the functional-equation coordinate F. Its public factors are the displayed sine, reflected-zeta, exponential, and Gamma-facing rows, with the Gamma-dependent boundary recorded separately at G.

Use the Gamma-horizon consumer boundary. A Gamma-dependent request terminates at G unless it is already one of the functional-equation factors carried by F.

Replay the read through H, C, R, N and then apply the critical-strip handoff. The downstream route receives only the finite continuation witness rows, so no RH predicate, non-trivial-zero locator, or independent critical-strip classifier is exported. □

Theorem 580.56 (ZetaContinuationWitness package provenance exactness)**.** *Every public read of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet factors through the displayed* Pkg *provenance row* R *and the local naming row* N *over* $\mathsf{ZetaBasic}^{\uparrow}$, $\mathsf{ZetaCont}^{\uparrow}$, $\mathsf{AnaCont}^{\uparrow}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{Complex}^{\uparrow}$, BHist, hsame, *and* Cont. *Thus the public package is exactly the finite surface* $B, E, A, P, F, T, G, H, C, R, N$ *and has no additional analytic, branch-selection, or zero-location coordinate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket package provenance exactness`

Proof. Project the carrier $W = (B, E, A, P, F, T, G, H, C, R, N)$. The provenance row R names the source zeta, continuation, analytic, holomorphic, complex, history, transport, continuation-route, package, and local certificate dependencies, while N is the local name.

Apply the dependency ledger and NameCert obligation surface. They bind carrier admission, classifier stability, analytic-continuation exactness, ledger exactness, and Gamma-horizon non-escape to the same displayed tuple.

Use route stability and the continuation handoff for downstream reads. Every public route is replayed through H, C and authenticated by R, N, so no consumer can obtain a separate analytic branch, branch selector, or zero-location row outside the package provenance. □

Theorem 580.57 (ZetaContinuationWitness root carrier exposure)**.** *Every accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *carrier exposes the root-unblock surface only through*

$$B, E, A, P, F, T, G, H, C, R, N.$$

These rows bind the $\mathsf{ZetaBasic}^{\uparrow}$ *source, eta route, analytic-continuation row, complex and holomorphic dependency rows,* $\mathsf{ZetaCont}^{\uparrow}$ *continuation route,* $\mathsf{ZetaZeros}^{\uparrow}$ *consumer boundary, exceptional ledgers, Gamma boundary, transport, replay, provenance, and naming data. The carrier does not admit analytic continuation as a primitive and does not assert any critical-strip truth claim.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket root carrier exposure`

Proof. Project the carrier of Definition 580.1. Its displayed coordinates are exactly the source, continuation, ledger, boundary, transport, replay, provenance, and naming rows.

Use Definition 580.8 and Definition 580.56. They bind the $\mathsf{ZetaBasic}^{\uparrow}$, $\mathsf{ZetaCont}^{\uparrow}$, $\mathsf{AnaCont}^{\uparrow}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{Complex}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ dependencies to that finite packet.

Finally apply the critical-strip input refusal and ledger non-escape boundary. Since the packet has no RH coordinate, no global zero-location classifier, and no closed Gamma coordinate, the root carrier exposes only the displayed witness rows. □

Theorem 580.58 (ZetaContinuationWitness route classifier stability)**.** *For accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *carriers, the route classifier is stable only along the displayed analytic-continuation, complex, holomorphic,* $\mathsf{ZetaBasic}^{\uparrow}$*,* $\mathsf{ZetaCont}^{\uparrow}$*, and* $\mathsf{ZetaZeros}^{\uparrow}$ *dependency rows recorded in* B, E, A, F, H, C, R, N*, with pole, trivial-zero, and Gamma-boundary reads confined to* P, T, G*. It cannot stabilize a hidden analytic continuation primitive, RH predicate, or critical-strip zero-location row.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessRouteClassifierStability`

Proof. Start with classifier stability Definition 580.45. It transports the source row, eta route, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, package provenance, and local name componentwise.

Use route stability budget Definition 580.48. The public route keeps the same eta, pole, functional-equation, trivial-zero, and Gamma-boundary budget after hsame transport and Cont replay.

Apply carrier admission tightening and functional-factor non-escape. They force every classified route through the displayed dependency rows and rule out hidden branch data, RH predicates, and zero-location classifiers. □

Theorem 580.59 (ZetaContinuationWitness ledger scope)**.** *The* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *ledger scope consists exactly of the displayed* $\mathsf{ZetaBasic}^{\uparrow}$*,* $\mathsf{ZetaCont}^{\uparrow}$*,* $\mathsf{AnaCont}^{\uparrow}$*,* $\mathsf{Holomorphic}^{\uparrow}$*,* $\mathsf{Complex}^{\uparrow}$*, pole, trivial-zero, Gamma-boundary, transport, replay, package, and naming rows of* $W = (B, E, A, P, F, T, G, H, C,$ *Downstream critical-strip and zeta-zero consumers may use this ledger as a finite witness interface, but not as a proof of RH, a non-trivial-zero locator, or an ambient analytic-continuation primitive.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessLedgerScope`

Proof. Read the finite ledger from the carrier definition and the NameCert obligation surface. The rows B, E, A, F hold the continuation-facing data, P, T, G hold the exceptional and boundary ledgers, and H, C, R, N authenticate the public route.

Apply the critical-strip handoff theorem. It sends critical-strip and zeta-zero consumers through the same displayed packet and excludes RH predicates, non-trivial-zero locators, and global zero classifiers from the handoff.

Use package provenance exactness to close the scope. The dependency rows are exactly the finite provenance surface over zeta, analytic, holomorphic, complex, history, transport, continuation, package, and naming data, so the ledger cannot be read as an off-table analytic claim. □

Theorem 580.60 (ZetaContinuationWitness carrier obligation)**.** *Every root-unblock consumer of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet must first admit the displayed carrier*

$$W = (B, E, A, P, F, T, G, H, C, R, N)$$

as a BHist *witness over the* ZetaBasic$^{\uparrow}$, ZetaCont$^{\uparrow}$, AnaCont$^{\uparrow}$, Holomorphic$^{\uparrow}$, Complex$^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert *rows. Carrier admission supplies only these rows and no analytic-continuation primitive outside the packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket carrier obligation`

Proof. Project the carrier definition. Its coordinates list the source, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, transports, replay routes, package provenance, and local name.

Use the dependency ledger and ledger scope. They bind every root-facing read to the same BHist packet and prevent a consumer from reading analytic continuation as an independent primitive.

Thus the root-unblock surface begins with carrier admission. Any downstream continuation, zero, or critical-strip read must consume the displayed packet rows first. □

Theorem 580.61 (ZetaContinuationWitness ledger boundary)**.** *The root-unblock ledger for* ZetaContinuationWitne *is exactly the finite row sequence* $B, E, A, P, F, T, G, H, C, R, N$*. The pole row* P*, trivial-zero row* T*, and Gamma boundary* G *are ledger entries of the same packet; they cannot be read as RH data, non-trivial-zero locators, global zero classifiers, completed Gamma objects, or hidden branch selectors.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket ledger boundary`

Proof. Start from the carrier obligation. It admits one displayed packet and no off-packet analytic primitive.

Apply the pole-Gamma boundary, trivial-zero ledger non-escape, and Gamma-horizon consumer boundary. These rows keep P, T, G inside the finite ledger and separate them from RH-facing or Gamma-completion claims.

Finally use critical-strip handoff. A critical-strip or zeta-zero consumer may read the finite continuation witness interface, but the excluded objects have no row in the displayed ledger. □

Theorem 580.62 (ZetaContinuationWitness NameCert package)**.** *The root-unblock package for* ZetaContinuationWitness$^{\uparrow}$ *is the local* NameCert *export obtained by combining carrier admission, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and the local naming row for* $W = (B, E, A, P, F, T, G, H, C, R, N)$*. This package records the visible continuation witness and does not assert analytic-continuation strength beyond the displayed witness packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket namecert package`

Proof. Use package provenance exactness. It forces every public read through the displayed Pkg row R and local naming row N over the same carrier coordinates.

Use route stability budget for transport and replay. Componentwise hsame rows and Cont routes preserve the eta, pole, functional-equation, trivial-zero, and Gamma-boundary rows without adding another continuation branch.

Combine these rows with the carrier obligation and ledger boundary. The resulting NameCert package is a finite witness export, not a proof of RH, a selected analytic branch, or a completed Gamma surface. □

Theorem 580.63 (ZetaContinuationWitness source-route scoped totality)**.** *For every accepted* ZetaContinuationWitness$^{\uparrow}$ *packet*

$$W = (B, E, A, P, F, T, G, H, C, R, N),$$

the source route is scoped-total exactly over the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. The source-lock coverage, critical-strip route separation, and ledger-scope theorems force every downstream critical-strip or zeta-zero read to expose B, E, A, F together with P, T, G, H, C, R, N before the packet is consumed.*

The total route does not assert RH, a non-trivial-zero location, a completed Gamma object, or analytic continuation beyond the displayed witness packet.

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket source route scoped totality`

Proof. Project the packet W. Its source, eta, analytic-continuation, pole, functional-equation, trivial-zero, Gamma-boundary, transport, replay, provenance, and naming rows are all displayed coordinates of the same BHist carrier.

Apply source-lock coverage and critical-strip route separation. These theorems require the source lock and the exceptional ledgers to be visible before a critical-strip consumer receives the route.

Use ledger scope to identify the complete dependency surface. Since the surface is exactly the displayed BHist, hsame, Cont, Pkg, and NameCert package over W, the source route is total only in that scoped sense and has no off-packet RH, zero-location, Gamma-completion, or analytic-continuation conclusion. □

Theorem 580.64 (ZetaContinuationWitness functional-boundary scoped exactness)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet $W = (B, E, A, P, F, T, G, H, C, R, N)$, every functional-equation, pole, and Gamma-boundary read is scoped-exact through the displayed rows P, F, G, H, C, R, N and through the same* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *carrier surface. The pole-Gamma boundary, functional-factor boundary, critical-strip refusal, and ledger boundary theorems leave no route to a closed Gamma chapter, a hidden analytic branch, RH, or a non-trivial-zero locator.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessFunctionalBoundaryScopedExactness`

Proof. Read the boundary rows from the carrier. The pole row P, functional-equation route F, and Gamma-horizon row G are separate coordinates, and H, C, R, N are the only transport, replay, provenance, and naming rows available for them.

Apply the pole-Gamma boundary and the functional-equation boundary. Pole data remains in P, while Gamma-dependent data remains in G unless it is already one of the factors displayed inside F.

Finally apply critical-strip input refusal and the ledger boundary. These rows prevent a downstream consumer from turning the functional boundary into RH data, a non-trivial-zero locator, a closed Gamma certificate, or a hidden analytic-continuation branch. □

Theorem 580.65 (ZetaContinuationWitness local NameCert scoped package)**.** *The local* NameCert$_{\text{ZetaContinuationWi}}$ *package for an accepted packet*

$$W = (B, E, A, P, F, T, G, H, C, R, N)$$

is the scoped package whose public rows are precisely the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *coordinates of W. It is obtained from source-lock coverage, pole-Gamma boundary control, critical-strip refusal, ledger scope, and package provenance exactness, and it exports only the witness packet rather than RH, zero-location data, completed Gamma, or analytic continuation beyond the displayed route.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessLocalNameCertScopedPackage`

Proof. Begin with package provenance exactness. It identifies the public package as the provenance row R and local naming row N over the displayed zeta, analytic, holomorphic, complex, history, transport, and route rows.

Add the source-lock and pole-Gamma rows. They ensure that source, eta, analytic-continuation, pole, functional-equation, trivial-zero, and Gamma-boundary data are carried by the single packet W before the local name is exported.

Use critical-strip refusal and ledger scope for downstream reads. A consumer preserving the scoped package preserves exactly the rows $B, E, A, P, F, T, G, H, C, R, N$ and receives no RH predicate, non-trivial-zero locator, completed Gamma certificate, or off-packet analytic-continuation primitive. □

Theorem 580.66 (ZetaContinuationWitness scoped route package)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet*

$$W = (B, E, A, P, F, T, G, H, C, R, N),$$

carrier admission, route-carrier admission, classifier stability, pole-ledger exactness, continuation handoff, trivial-zero non-escape, Gamma boundary control, critical-strip handoff, package provenance, and local naming assemble one scoped witness surface over BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. The surface exposes exactly the source row B, eta route E, analytic-continuation row A, pole ledger P, functional-equation route F, trivial-zero ledger T, Gamma boundary G, transports H, routes C, provenance R, and local name N.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket scoped route package`

Proof. Start with carrier admission and route-carrier admission. They identify the accepted object as the displayed finite packet W and make the eta, analytic-continuation, pole, functional-equation, trivial-zero, Gamma, transport, route, provenance, and naming rows available as packet coordinates.

Next apply classifier stability, pole-ledger exactness, continuation handoff, and trivial-zero non-escape. These results keep the classifier, continuation route, pole row, and trivial-zero row inside the same BHist witness surface.

Then use the Gamma boundary, critical-strip handoff, and package provenance theorems. They force Gamma-facing and critical-strip-facing consumers to read the same H, C, R, N rows before receiving the witness packet.

The local naming row closes the scoped package. No RH predicate, non-trivial-zero locator, completed Gamma certificate, or off-packet analytic branch is exported, because no such row occurs in W. □

Theorem 580.67 (ZetaContinuationWitness critical-strip source boundary)**.** *Every critical-strip consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet must read the source row, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, transports, continuation routes, provenance, and local name before receiving the packet. Equivalently, the consumer boundary is the finite route*

$$B, E, A, P, F, T, G, H, C, R, N$$

inside the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *package.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket critical strip source boundary`

Proof. Use source-lock coverage and route-carrier admission. They place the source row B, eta route E, and analytic-continuation row A at the entrance of every continuation-facing read.

Use pole-ledger exactness, the functional-boundary theorem, trivial-zero non-escape, and Gamma boundary control for the exceptional rows. These results require P, F, T, G to be read as ledger coordinates of the same packet.

Finally apply critical-strip handoff and package provenance exactness. The consumer receives the packet only after the displayed transports, routes, provenance, and local name have been read, so the boundary is exactly the listed finite route. □

Theorem 580.68 (ZetaContinuationWitness Gamma ledger exhaustion)**.** *For an accepted* ZetaContinuationWitness *packet* $W = (B, E, A, P, F, T, G, H, C, R, N)$*, every Gamma-facing or pole-facing read is exhausted by the rows* P, F, G, H, C, R, N*. Such a read cannot import RH, a non-trivial-zero locator, a closed Gamma certificate, or a hidden analytic branch into the witness packet.*

Proof. Project the boundary coordinates of W. The pole row P, functional-equation route F, Gamma boundary G, transports H, routes C, provenance R, and local name N are the only rows available to a Gamma-facing or pole-facing consumer.

Apply the pole-Gamma boundary, functional-boundary scoped exactness, and trivial-zero non-escape theorems. They separate pole, functional-equation, Gamma, and trivial-zero data while keeping all four inside the displayed ledger.

Close with package provenance exactness and critical-strip refusal. Since R and N authenticate only the finite packet, a consumer cannot attach RH, a non-trivial-zero locator, a completed Gamma certificate, or another analytic branch to the Gamma-facing or pole-facing read. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessGammaLedgerExhaustion`

Theorem 580.69 (ZetaContinuationWitness critical-strip total ledger)**.** *For every accepted* ZetaContinuationWitnes *packet*

$$W = (B, E, A, P, F, T, G, H, C, R, N),$$

each critical-strip consumer must expose the complete finite packet rows

$$B, E, A, P, F, T, G, H, C, R, N$$

before it can consume the witness. The consumer cannot read an RH predicate, a non-trivial-zero locator, a global zero classifier, a hidden analytic branch, or a completed Gamma certificate from this packet.

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessCriticalStripTotalLedger`

Proof. Begin with the critical-strip ledger triad. Theorems 580.33, 580.67, and 580.66 identify the consumer-facing route with the displayed source, eta, analytic-continuation, pole, functional-equation, trivial-zero, Gamma, transport, continuation, provenance, and naming rows of W.

Next exhaust the consumer side. Theorems 580.42, 580.63, and 580.65 force every downstream critical-strip read to preserve the same finite BHist, hsame, Cont, Pkg, and NameCert surface.

Finally apply Definition 580.28 and Definition 580.68. These two boundary theorems rule out RH data, non-trivial-zero locations, a global zero classifier, an off-packet analytic branch, and a completed Gamma certificate, because none is a displayed coordinate of W. □

Theorem 580.70 (ZetaContinuationWitness eta-pole-functional coverage)**.** *For every accepted* ZetaContinuationWitness$^{\uparrow}$ *packet* $W = (B, E, A, P, F, T, G, H, C, R, N)$*, each exported continuation read is exhausted by the eta row* E*, pole ledger* P*, functional-equation route* F*, trivial-zero ledger* T*, Gamma boundary* G*, and authentication rows* H, C, R, N*. The export contains only those continuation, boundary, transport, route, provenance, and naming rows and does not add an external analytic-continuation branch.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket eta pole functional coverage`

Proof. Project the continuation-facing rows of W. Eta continuation is carried by E, pole data by P, the functional-equation route by F, trivial-zero data by T, and the Gamma boundary by G.

Use Definition 580.36, Definition 580.46, and Definition 580.64. Together they keep the eta route, pole ledger, and functional factor inside the displayed packet rather than allowing a separate analytic source.

Close with Definition 580.56 and Definition 580.68. The rows H, C, R, N authenticate only the same finite route, and the Gamma boundary contributes no completed Gamma certificate or hidden continuation branch. □

Theorem 580.71 (ZetaContinuationWitness RH boundary exhaustion)**.** *Every RH-facing consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet receives only the displayed zeta-continuation witness rows*

$$B, E, A, P, F, T, G, H, C, R, N.$$

Any RH predicate, non-trivial-zero locator, or zero-location object must be supplied by a separate certificate outside this packet.

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket rh boundary exhaustion`

Proof. Start with Definition 580.7. Together with Definition 580.28 and Definition 580.51, it states that the packet carries no RH predicate and no non-trivial-zero locator.

Next apply Definition 580.67 and Definition 580.33. They force an RH-facing consumer to read only the finite rows $B, E, A, P, F, T, G, H, C, R, N$ from the same BHist, hsame, Cont, Pkg, and NameCert surface.

Finally use Definition 580.68. Gamma-facing rows remain P, F, G, H, C, R, N and cannot be transformed into a completed Gamma certificate or zero-location object. Any such object therefore has to arrive as a separate certificate outside W. □

Theorem 580.72 (ZetaContinuationWitness source scoped readback)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet* $W = (B, E, A, P, F, T, G, H, C, R, N)$*, every source-facing read factors through the rows* B, E, A, H, C, R, N*. The read cannot bypass the displayed source row, eta route, analytic-continuation row, componentwise transports, continuation routes, provenance, or local name.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket source scoped readback`

Proof. Begin with source-lock coverage. It places the source row B, eta route E, and analytic-continuation row A at the entrance of any source-facing read of the witness packet.

Apply the scoped route package. The route package keeps the displayed transports H, continuation routes C, provenance R, and local name N attached to the same packet before the read reaches any consumer.

Finally use Gamma ledger exhaustion to separate source readback from the exceptional Gamma and pole rows. Since the consumer route already factors through B, E, A, H, C, R, N, no off-packet analytic branch, RH predicate, or zero-location row can be imported into the source-facing read. □

Theorem 580.73 (ZetaContinuationWitness Gamma boundary scope)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet* $W = (B, E, A, P, F, T, G, H, C, R, N)$*, every Gamma-facing boundary read is exhausted by the rows* P, F, G, H, C, R, N*. The boundary exposes the pole ledger, functional-equation route, Gamma row, transports, continuation routes, provenance, and local name, and it exposes no completed Gamma certificate outside those rows.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket gamma boundary scope`

Proof. Apply the pole-Gamma boundary theorem. It identifies the pole ledger P, functional-equation route F, and Gamma boundary row G as the complete exceptional surface for Gamma-facing reads.

Use the scoped route package to attach the structural rows. The same read must pass through H, C, R, N, so the Gamma-facing boundary remains a finite packet route rather than a free analytic-continuation primitive.

Close with Gamma ledger exhaustion. It rules out RH, a non-trivial-zero locator, a closed Gamma certificate, and a hidden analytic branch as extra Gamma-facing coordinates. □

Theorem 580.74 (ZetaContinuationWitness critical-strip consumer scope)**.** *Every critical-strip consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet receives only the finite packet rows* $B, E, A, P, F, T, G, H, C$ *In particular, the consumer receives no RH predicate, non-trivial-zero locator, completed Gamma certificate, or off-packet analytic-continuation branch.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket critical strip consumer scope`

Proof. Use the critical-strip handoff theorem first. It requires the consumer to read the displayed witness packet before any critical-strip-facing conclusion is available.

Apply the scoped route package to enumerate the packet surface. The only rows passed to the consumer are $B, E, A, P, F, T, G, H, C, R, N$, together with their BHist, hsame, Cont, Pkg, and NameCert structure.

Finally combine source-lock coverage and Gamma ledger exhaustion. Source-facing reads are confined to B, E, A, H, C, R, N, Gamma-facing reads are confined to P, F, G, H, C, R, N, and their union is the finite packet already displayed. No RH predicate or zero-location witness is a packet coordinate. □

Theorem 580.75 (ZetaContinuationWitness carrier row)**.** *Every accepted* ZetaContinuationWitness$^{\uparrow}$ *witness exposes the rows*

$$B, E, A, P, F, T, G, H, C, R, N$$

as BHist*-carrier coordinates before any zeta-zero consumer reads the packet. The rows are the source, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, transports, continuation routes, provenance, and local name of the same finite witness carrier.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket carrier row certificate`

Proof. Project the carrier of Definition 580.1. The accepted witness is the displayed packet $W = (B, E, A, P, F, T, G, H, C, R, N)$, so each listed row is a carrier coordinate.

Apply Definition 580.74. Every critical-strip or zeta-zero-facing consumer receives only the displayed rows of that packet, and it receives them before any downstream read is available. □

Theorem 580.76 (ZetaContinuationWitness contour route)**.** *Every contour-facing analytic read of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet factors through the displayed eta, analytic-continuation, functional-equation, pole, Gamma-boundary,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. It does not factor through a hidden analytic branch, an RH predicate, a non-trivial-zero locator, or a completed Gamma certificate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket contour route obligation`

Proof. Begin with source-lock coverage. By Definition 580.4, a continuation read exposes B, E, A, F together with the exceptional ledgers before the packet is consumed.

Use the functional-boundary and Gamma-ledger theorems for the contour side. Definition 580.64 confines functional, pole, and Gamma reads to P, F, G, H, C, R, N, and Definition 580.68 rules out a completed Gamma or hidden analytic branch as an additional contour coordinate.

Finally apply Definition 580.7. The contour-facing route stays inside the same displayed witness package and therefore cannot export RH data or a non-trivial-zero locator. □

Theorem 580.77 (ZetaContinuationWitness obligation triad)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet, the carrier row of Definition 580.75, the contour route of Definition 580.76, and the NameCert obligation surface of Definition 580.2 assemble the root-facing obligation packet expected by downstream zeta-zero chapters. The packet exposes only the rows $B, E, A, P, F, T, G, H, C, R, N$ and their* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *structure.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket obligation triad`

Proof. First use Definition 580.75. It supplies the finite carrier coordinates read by every zeta-zero-facing consumer.

Next use Definition 580.76. It identifies the analytic and contour-facing reads as routes through the displayed eta, continuation, functional, pole, Gamma, transport, continuation, provenance, and naming rows.

Finally apply Definition 580.2. The obligation surface binds carrier admission, classifier stability, analytic-continuation exactness, pole and trivial-zero ledger exactness, Gamma-boundary non-escape, package provenance, and local naming for the same packet, so the triad is exactly the downstream root-facing obligation packet and not an RH or zero-location claim. □

Theorem 580.78 (ZetaContinuationWitness public export)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet, the carrier row, contour route, Gamma ledger, critical-strip scope, provenance rows, and local* NameCert *rows assemble the public finite witness export. The export surface is exactly the displayed packet rows $B, E, A, P, F, T, G, H, C, R, N$ together with their* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *structure.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public export`

Proof. Begin with Definition 580.75. It supplies the displayed finite carrier rows $B, E, A, P, F, T, G, H, C, R, N$ before any zeta-zero-facing consumer can read the witness.

Use Definition 580.76 and Definition 580.68. The contour and Gamma-facing reads are forced through the displayed eta, continuation, functional, pole, Gamma, transport, provenance, and local naming rows.

Finally combine Definition 580.74 with Definition 580.7. The critical-strip consumer receives only the public packet and no hidden RH predicate, zero locator, completed Gamma certificate, or off-packet analytic branch, so the finite export is the complete handoff surface. □

Theorem 580.79 (ZetaContinuationWitness zero-route input package)**.** *Every* $\mathsf{ZetaZeros}^{\uparrow}$ *or critical-strip consumer reading an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet receives only the rows*

$$B, E, A, P, F, T, G, H, C, R, N$$

and their displayed BEDC structure. No RH predicate, non-trivial-zero locator, completed Gamma certificate, or hidden analytic branch is part of the input package.

Proof. Apply Definition 580.74. It already confines every critical-strip consumer to the listed rows and their displayed BHist, hsame, Cont, Pkg, and NameCert data.

Use Definition 580.75 to read the same list as the accepted witness carrier and Definition 580.76 to route analytic and contour-facing input through the displayed continuation packet.

Finally invoke Definition 580.7. The consumer can receive the public route packet, but it cannot receive RH proof data, a non-trivial-zero locator, or an undisplayed analytic continuation coordinate. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket zero route input package`

Theorem 580.80 (ZetaContinuationWitness Gamma boundary public non-escape)**.** *Every Gamma-facing public read of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet lands at the displayed Gamma boundary row* G*, unless the same read is already displayed as a factor of the functional-equation route row* F*. It cannot escape to a completed Gamma certificate, a hidden analytic branch, an RH predicate, or a non-trivial-zero locator.*

Proof. Start with Definition 580.68. It identifies the Gamma ledger as the displayed Gamma-boundary coordinate and rules out a completed Gamma certificate or hidden analytic branch as an extra public row.

Apply Definition 580.76. Any contour-facing read that reaches Gamma data must pass through the displayed functional-equation route F and Gamma-boundary row G.

Close with Definition 580.7 and Definition 580.74. They keep the public read inside $B, E, A, P, F, T, G, H, C, R, N$ and exclude RH proof data or zero-location data from the Gamma-facing boundary. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket gamma boundary public nonescape`

Theorem 580.81 (ZetaContinuationWitness public zero-route factorization)**.** *Every public zero-facing read of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet factors through the displayed rows*

$$B, E, A, P, F, T, G, H, C, R, N.$$

The factorization may expose the source row, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, transports, continuations, provenance, and local name, but it exposes no RH predicate, non-trivial-zero locator, global zero classifier, off-packet analytic branch, or completed Gamma certificate.

Proof. Begin with Definition 580.78. It assembles the carrier row, contour route, Gamma ledger, critical-strip scope, provenance, and local NameCert rows into one public export.

Apply Definition 580.79. The zero-facing input package is exactly the displayed tuple $B, E, A, P, F, T, G, H, C, R$ together with its BHist, hsame, Cont, Pkg, and NameCert structure.

Finally use Definition 580.86 and Definition 580.87. They keep the public export inside the same rows and remove RH predicates, non-trivial-zero locators, global zero classifiers, completed Gamma certificates, and off-packet analytic branches from the zero-facing handoff. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPublicZeroRouteFactorization`

Theorem 580.82 (ZetaContinuationWitness public contour-Gamma separation)**.** *Every public contour-facing read of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet that reaches Gamma data separates into the contour route through $B, E, A, P, F, H, C, R, N$ and the Gamma boundary row G, unless the requested Gamma datum is already displayed as part of the functional-equation route F. No such read exports an RH predicate, non-trivial-zero locator, global zero classifier, off-packet analytic branch, or completed Gamma certificate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public contour gamma separation`

Proof. Start with Definition 580.80. It forces every Gamma-facing public read to land at G unless the same datum is already displayed inside F.

Use Definition 580.86. The contour-facing public export still factors through $B, E, A, P, F, T, G, H, C, R, N$, so the Gamma side cannot introduce a row outside the witness packet.

Close with Definition 580.87. The same public boundary excludes RH predicates, zero locators, global zero classifiers, completed Gamma certificates, and off-packet analytic branches from the contour-Gamma handoff. □

Theorem 580.83 (ZetaContinuationWitness public source-lock handoff)**.** *Every public critical-strip, zero-facing, or contour-facing consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet must receive the source-locked rows*

$$B, E, A, P, F, T, G, H, C, R, N$$

before using the packet as continuation evidence. The handoff is therefore a finite source-lock export over the displayed rows and their BEDC structure, not an RH predicate, non-trivial-zero locator, global zero classifier, off-packet analytic branch, or completed Gamma certificate.

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public source lock handoff`

Proof. First apply Definition 580.78. It supplies the public witness export as a finite packet, including the carrier, contour route, Gamma boundary, provenance, and local name.

Next apply Definition 580.79. Zero-facing and critical-strip consumers read the packet only through $B, E, A, P, F, T, G, H, C, R, N$.

Finally combine Definition 580.80, Definition 580.86, and Definition 580.87. These rows keep Gamma-facing and contour-facing reads source-locked inside the same packet and rule out RH predicates, zero locators, global zero classifiers, off-packet analytic branches, and completed Gamma certificates. □

Theorem 580.84 (ZetaContinuationWitness public export route lock)**.** *Every public critical-strip, zero-facing, contour-facing, or Gamma-facing consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet must first read the source-locked rows*

$$B, E, A, P, F, T, G, H, C, R, N$$

and their BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support. Agreement on those rows and support data determines the same public export route.*

The route lock exports no RH predicate, no non-trivial-zero locator, no global zero classifier, no off-packet analytic branch, and no completed Gamma certificate.

Proof. Start with Definition 580.75, Definition 580.76, and Definition 580.77. These results put the carrier coordinates, contour-facing route, and root-facing obligation packet on the same displayed rows $B, E, A, P, F, T, G, H, C, R, N$.

Next use Definition 580.78 and Definition 580.79. The public export and zero-route input package say that critical-strip and zero-facing consumers receive only the finite witness packet and its displayed BEDC support.

For Gamma-facing and contour-facing reads, apply Definition 580.80, Definition 580.81, and Definition 580.82. These theorems keep Gamma data and contour data on the same public rows and remove off-packet analytic branches, completed Gamma certificates, RH predicates, non-trivial-zero locators, and global zero classifiers.

Finally invoke Definition 580.83. Since every public consumer must receive the source-locked packet before using it as continuation evidence, two accepted packets that agree on the rows and support data determine the same public export route. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public export route lock`

Theorem 580.85 (ZetaContinuationWitness public export totality)**.** *Every public critical-strip, zero-facing, contour-facing, or Gamma-facing read of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet is exhausted by the single packet*

$$B, E, A, P, F, T, G, H, C, R, N$$

and its BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support. The public export contains no RH predicate, non-trivial-zero locator, global zero classifier, off-packet analytic branch, or completed Gamma certificate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public export totality`

Proof. Begin with the public export theorem. It assembles the carrier row, contour route, Gamma ledger, critical-strip scope, provenance rows, and local NameCert rows into one public witness packet.

Apply the zero-route input package. It says zero-facing and critical-strip reads receive exactly $B, E, A, P, F, T, G, H, C, R, N$ together with the displayed BEDC support.

For contour-facing and Gamma-facing reads, use public contour-Gamma separation. The contour route and Gamma boundary remain inside the same packet, with Gamma data either read from G or already displayed inside F.

Finally apply the route-lock theorem. Since every public read is source-locked to the same packet before it is used as continuation evidence, there is no remaining coordinate for RH predicates, non-trivial-zero locators, global zero classifiers, off-packet analytic branches, or completed Gamma certificates. □

Theorem 580.86 (ZetaContinuationWitness public export factorization)**.** *For an accepted* ZetaContinuationWitnes *packet* $W = (B, E, A, P, F, T, G, H, C, R, N)$*, every public export in the sense of Definition 580.78, and every zero-facing public input package in the sense of Definition 580.79, factors through the displayed rows* $B, E, A, P, F, T, G, H, C, R, N$ *and their* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *structure. The export contains no route outside the source row, eta route, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, transport rows, continuation routes, provenance, and local name.*

Proof. Begin with the public export packet of Definition 580.78 and the zero-facing public input package of Definition 580.79. They already assemble the carrier row, contour route, Gamma ledger, critical-strip scope, provenance rows, and local NameCert rows as one finite witness export.

Next use the carrier and contour rows. Definition 580.75 supplies $B, E, A, P, F, T, G, H, C, R, N$ as the packet coordinates, while Definition 580.76 keeps analytic and contour reads inside the displayed continuation packet.

Finally apply the source-lock and provenance exactness rows. They attach every public consumer to the same BHist, hsame, Cont, Pkg, and NameCert surface, so no off-packet analytic branch or hidden witness row can be part of the export. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public export factorization`

Theorem 580.87 (ZetaContinuationWitness critical-strip public refusal)**.** *Every public critical-strip consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet receives the finite witness rows* $B, E, A, P, F, T, G, H, C, R, N$ *and receives no RH predicate, non-trivial-zero locator, global zero classifier, completed Gamma certificate, or off-packet analytic-continuation branch.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket critical strip public refusal`

Proof. Apply Definition 580.79. It identifies the public input package for ZetaZeros$^{\uparrow}$ and critical-strip consumers as the displayed witness rows together with their BEDC structure.

Use Definition 580.11 to remove the zero-facing escape routes. The consumer has no packet coordinate for an RH predicate, a non-trivial-zero locator, or a global zero classifier.

Close with Definition 580.80. Gamma-facing data either remains at the displayed boundary or is already present in the functional-equation route, so no completed Gamma certificate or hidden analytic branch is exported to the critical strip. □

Theorem 580.88 (ZetaContinuationWitness Gamma boundary public ledger)**.** *Every Gamma-facing public read of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet stops at the displayed rows* P, F, G, H, C, R, N*, unless the requested Gamma datum is already displayed as part of the functional-equation route* F*. The public ledger therefore exposes pole, functional-equation, Gamma-boundary, transport, continuation, provenance, and local naming rows, and it exposes no completed Gamma certificate outside that route.*

Proof. Start with Definition 580.80. It states the public Gamma boundary condition: a Gamma-facing read lands at G unless the same data is already displayed inside F.

Next use Definition 580.73. The boundary read is exhausted by P, F, G, H, C, R, N, so the structural rows that authenticate the Gamma side are exactly the displayed transports, routes, provenance, and local name.

Finally apply Definition 580.86. Since the public export itself factors through $B, E, A, P, F, T, G, H, C, R, N$, the Gamma-facing subroute cannot acquire an additional completed Gamma certificate, RH predicate, zero locator, or hidden analytic branch. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessGammaBoundaryPublicLedger`

Theorem 580.89 (ZetaContinuationWitness public export route)**.** *For an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet* $W = (B, E, A, P, F, T, G, H, C, R, N)$*, every public root-facing export factors through the finite contour, Gamma, critical-strip, provenance, and local naming route*

$$B, E, A, P, F, T, G, H, C, R, N.$$

The route exposes the source row, eta-continuation row, analytic-continuation row, pole ledger, functional-equation route, trivial-zero ledger, Gamma boundary, componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row, and it exports no RH predicate, non-trivial-zero locator, host complex equality, off-packet analytic branch, or completed Gamma certificate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public export route`

Proof. Begin with Definition 580.78. It assembles the carrier row, contour route, Gamma ledger, critical-strip scope, provenance rows, and local NameCert rows into one public finite witness export.

Use Definition 580.86 and Definition 580.12. These results force every public root-facing read through the displayed carrier coordinates and the same BHist, hsame, Cont, Pkg, and NameCert surface.

Finally apply Definition 580.87 and Definition 580.14. Critical-strip and Gamma-facing consumers receive only the finite route above, while RH data, zero-location data, host complex equality, completed Gamma data, and off-packet analytic branches remain outside the export. □

Theorem 580.90 (ZetaContinuationWitness consumer packet totality)**.** *Every* $\mathsf{ZetaZeros}^{\uparrow}$*, critical-strip, Gamma-facing, or public root-facing consumer of an accepted* $\mathsf{ZetaContinuationWitness}^{\uparrow}$ *packet is total over the displayed packet rows*

$$B, E, A, P, F, T, G, H, C, R, N$$

and their BHist, hsame, Cont, Pkg, *and* NameCert *structure. No accepted consumer route remains outside the source, contour, pole, trivial-zero, Gamma, transport, continuation, provenance, and local naming rows of the same packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket consumer packet totality`

Proof. First project the consumer input package by Definition 580.79. It identifies the rows received by zero-facing and critical-strip consumers as the displayed packet coordinates with their BEDC structure.

Next use Definition 580.74 and Definition 580.89. The critical-strip route and the public root-facing export route are the same finite packet surface, not two independent consumer packets.

Finally attach Definition 580.77 and Definition 580.86. The NameCert obligation surface, contour route, carrier row, provenance row, and local name exhaust the consumer-visible packet, so there is no admitted route left to classify outside the displayed rows. □

Theorem 580.91 (ZetaContinuationWitness analytic boundary non-escape)**.** *An accepted* ZetaContinuationWitness *public export keeps RH, non-trivial-zero location data, analytic continuation as an external analytic premise, and host complex equality outside the consumer packet. The only analytic boundary visible to the packet is the finite route through* $B, E, A, P, F, T, G, H, C, R, N$ *and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessAnalyticBoundaryNonescape`

Proof. Start with the analytic and Gamma boundaries. The contour route of Definition 580.76 and the Gamma boundary public ledger of Definition 580.88 restrict analytic-facing reads to the displayed continuation, pole, functional-equation, Gamma, transport, provenance, and naming rows.

Use Definition 580.7 and Definition 580.11. These theorems exclude RH predicates, non-trivial-zero locators, global zero classifiers, and completed Gamma certificates from the packet inventory.

Finally apply Definition 580.90. Since every accepted consumer route has already been exhausted by the displayed finite packet, analytic continuation outside the packet and host complex equality have no consumer-visible coordinate from which to enter. □

Theorem 580.92 (ZetaContinuationWitness public source-lock export)**.** *For an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet* $W = (B, E, A, P, F, T, G, H, C, R, N)$*, every continuation consumer of the public source-lock export reaches the continuation surface only through the finite rows*

$$B, E, A, P, F, T, G, H, C, R, N.$$

The export therefore routes source access through the ZetaBasic$^{\uparrow}$ *source row* B*, eta-continuation row* E*, analytic-continuation row* A*, pole ledger* P*, functional-equation route* F*, trivial-zero ledger* T*, Gamma boundary* G*, transport rows* H*, continuation routes* C*, provenance* R*, and local name* N*.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public source lock export`

Proof. Begin with the public export route of Definition 580.89. It already makes the finite packet $B, E, A, P, F, T, G, H, C, R, N$ the only public root-facing route.

Apply the source scoped readback of Definition 580.72. The source-facing part of the route must pass through B, E, A, H, C, R, N, so no continuation consumer can enter through an off-packet analytic branch.

Finally use public export factorization. The pole, functional-equation, trivial-zero, and Gamma rows remain part of the same packet surface, so the public source-lock export has one displayed route for every continuation consumer. □

Theorem 580.93 (ZetaContinuationWitness public critical-strip export)**.** *For an accepted* ZetaContinuationWitness *packet, the public critical-strip export supplies only the finite witness packet*

$$B, E, A, P, F, T, G, H, C, R, N$$

with its BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *structure. It supplies no RH predicate, no non-trivial-zero locator, no global zero classifier, and no completed Gamma certificate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public critical strip export`

Proof. Use the critical-strip consumer scope of Definition 580.74. It confines every critical-strip consumer to the displayed witness packet.

Next apply the public critical-strip refusal theorem of Definition 580.87. The public route has no coordinate for RH, a non-trivial-zero locator, a global zero classifier, or a completed Gamma certificate.

The packet structure is then the one named by public export factorization. Its BHist, hsame, Cont, Pkg, and NameCert rows authenticate the finite export without adding any zero-location datum. □

Theorem 580.94 (ZetaContinuationWitness public root completion)**.** *An accepted* ZetaContinuationWitness$^{\uparrow}$ *public root surface is exactly the downstream packet obtained by packaging the source-lock export, the critical-strip export, the Gamma boundary, and the no-RH non-escape condition over the rows* $B, E, A, P, F, T, G, H, C, R, N$*. The surface is a finite downstream root witness route, not an RH theorem, zero locator, global analytic-continuation branch, or host complex equality principle.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public root completion`

Proof. First combine the source-lock export of Definition 580.92 with the critical-strip export of Definition 580.93. Together they make the same finite packet the route for continuation consumers and critical-strip consumers.

Add the Gamma boundary public ledger of Definition 580.88. Gamma-facing reads stop at P, F, G, H, C, R, N, unless the requested datum is already part of the displayed functional-equation route.

Finally use analytic boundary non-escape and no-RH non-escape. RH predicates, zero locators, off-packet analytic branches, completed Gamma certificates, and host complex equality have no packet coordinate, so the packaged downstream root surface is exactly the finite route displayed above. □

Theorem 580.95 (ZetaContinuationWitness public export lock)**.** *For every accepted* ZetaContinuationWitness$^{\uparrow}$ *packet* $W = (B, E, A, P, F, T, G, H, C, R, N)$*, the public export of* W *is exactly the finite row packet*

$$B, E, A, P, F, T, G, H, C, R, N$$

together with the dependency rows ZetaBasic$^{\uparrow}$*,* ZetaCont$^{\uparrow}$*,* AnaCont$^{\uparrow}$*,* Holomorphic$^{\uparrow}$*,* Complex$^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. No public export row lies outside this displayed witness packet and dependency ledger.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket public export lock`

Proof. Project the carrier of Definition 580.1. The accepted object is the finite packet $W = (B, E, A, P, F, T, G, H, C, R, N)$, so the public export has no carrier coordinate beyond those rows.

Apply Definition 580.2, Definition 580.8, and Definition 580.4. These bind the source, continuation, analytic, holomorphic, complex, history, transport, route, package, and naming dependencies to the same packet before any public consumer receives it.

Finally use Definition 580.78, Definition 580.86, and Definition 580.12. The public packet, closure surface, and root export all read the same rows, so the export is precisely the displayed finite packet with the listed dependency rows. □

Theorem 580.96 (ZetaContinuationWitness zero-facing public factorization)**.** *Every zero-facing public consumer of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet factors through the source lock, eta route, pole ledger, functional-equation route, trivial-zero ledger, and Gamma boundary before it can use the packet as input for* ZetaZeros$^{\uparrow}$ *or any critical-strip read. The factorization exposes only the rows* $B, E, A, P, F, T, G, H, C, R, N$ *and their displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket zero facing public factorization`

Proof. Begin with Definition 580.4 and Definition 580.92. They require a public consumer to pass through the source row B, eta route E, analytic-continuation row A, and functional-equation row F before the witness is consumed.

Next apply Definition 580.46, Definition 580.51, and Definition 580.88. These theorems keep the pole ledger P, trivial-zero ledger T, and Gamma boundary G as displayed rows of the same packet.

Close with Definition 580.79, Definition 580.81, and Definition 580.87. The zero-facing and critical-strip handoff therefore factors through the source lock and the exceptional ledgers before any downstream use, and no RH predicate, non-trivial-zero locator, global zero classifier, completed Gamma certificate, or off-packet analytic branch is exported. □

Theorem 580.97 (ZetaContinuationWitness Gamma public boundary lock)**.** *Every public Gamma-facing read of an accepted* ZetaContinuationWitness$^{\uparrow}$ *packet stops at the functional-equation route* F *or the Gamma boundary row* G*. Such a read does not supply a completed Gamma chapter, an RH predicate, a non-trivial-zero locator, a global zero classifier, or any zero-location object outside the displayed witness packet.*

Proof. Start with Definition 580.5 and Definition 580.80. A Gamma-facing public read either uses Gamma data already displayed inside F or stops at the boundary row G.

Use Definition 580.68 and Definition 580.14. These exhaust the Gamma-facing public ledger at P, F, G, H, C, R, N and prevent the boundary from becoming a completed Gamma chapter or hidden analytic branch.

Finally apply Definition 580.7, Definition 580.87, and Definition 580.71. The public Gamma boundary remains a finite packet row and supplies no RH predicate, non-trivial-zero locator, global zero classifier, or zero-location object. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationWitnessUp.ZetaContinuationWitnessPacket gamma public boundary lock`

Chapter 581

A Concrete Naming Certificate for $\mathsf{ZetaFunctionalEquationLedger}^{\uparrow}$

The $\mathsf{ZetaFunctionalEquationLedger}^{\uparrow}$ packet gives the functional-equation part of chapter 9342 a concrete finite NameCert surface. It records eta continuation, the displayed functional-equation factor row, the $\mathsf{Gamma}^{\uparrow}$ boundary, contour-integral provenance, and the trivial-zero witness as rows that downstream zeta and Gamma chapters can inspect without claiming a closed Gamma proof, Riemann-hypothesis consequence, or host complex-equality theorem.

Definition 581.1 (Zeta functional-equation ledger carrier)**.** *A* $\mathsf{ZetaFunctionalEquationLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (Z, A, E, F, G, K, T, H, C, P, N)$$

with the following displayed rows:

1. *Z is the* $\mathsf{ZetaBasic}^{\uparrow}$ *source row on the half-plane* $\Re(s) > 1$*;*
2. *A is the* $\mathsf{AnaCont}^{\uparrow}$ *handoff row that reads the eta-extension step and the positive-half-plane continuation;*
3. *E is the eta-extension row, including the displayed denominator boundary for* $1 - 2^{1-s}$ *and the overlap agreement with* Z*;*
4. *F is the functional-equation factor row containing* 2^s*,* π^{s-1}*,* $\sin(\pi s/2)$*, the* $\Gamma(1-s)$ *slot, and the reflected* $\zeta(1-s)$ *slot;*
5. *G is the* $\mathsf{Gamma}^{\uparrow}$ *boundary row, recording exactly the input domain, pole boundary, and nonzero-at-positive-integer reads consumed by the functional-equation ledger;*
6. *K is the* $\mathsf{ContourIntegral}^{\uparrow}$ *provenance row for the contour reorganization used to justify the displayed factor row;*
7. *T is the trivial-zero witness row for* $s = -2n$ *with unary* $n \geq \mathsf{E1}(\mathsf{e})$*, storing the sine-zero row and the finiteness reads for the remaining factors;*
8. *H stores componentwise* hsame *transports for* Z, A, E, F, G, K, T *and the local naming rows;*
9. *C stores the finite* Cont *routes by which consumers read eta continuation, factor decomposition, Gamma boundary, contour provenance, trivial-zero consumption, package provenance, and local naming;*

10. *P is the* Pkg *provenance over the same finite ledger packet;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{ZetaFunctionalEquationLedger}^{\uparrow}}$ *row.*

The carrier exposes only this ledger packet. It contains no closed proof of the Gamma factor, no full meromorphic continuation theorem, no quotient of germs, and no host equality principle for complex functions.

Definition 581.2 (Zeta functional-equation ledger classifier)**.** *Two* $\mathsf{ZetaFunctionalEquationLedger}^{\uparrow}$ *carriers are classified by componentwise* hsame *on the displayed analytic rows Z, A, E, F, G, K, T, exact agreement of the finite* Cont *routes in C, and the same* Pkg *and local* NameCert *rows. The classifier treats the* $\mathsf{Gamma}^{\uparrow}$ *coordinate as a boundary row: it may transport the displayed domain and consumption reads, but it does not identify two host Gamma functions or close the missing meromorphic proof.*

Theorem 581.3 (Zeta functional-equation ledger NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ZetaFunctionalEquationLed}}$ *surface for Definition 581.1 consists of five finite rows: carrier admission for L; classifier stability for the zeta source, eta continuation, functional-equation factor, Gamma boundary, contour provenance, and trivial-zero witness rows; ledger exactness for reads exported through C;* Pkg *provenance over $Z, A, E, F, G, K, T, H, C$; and local naming exactness for N.*

Proof. Carrier admission is projection of the tuple L. Each zeta, continuation, eta, factor, Gamma-boundary, contour, trivial-zero, transport, continuation, package, and naming coordinate is a displayed row of the same finite BHist packet.

Classifier stability is componentwise. Transport through H preserves the source row Z, the eta-extension row E, the analytic-continuation handoff A, the factor row F, the Gamma boundary G, the contour provenance K, and the trivial-zero witness T under their stated classifiers.

Ledger exactness is read through C. Every exported consumer fact lands in one of the displayed coordinates, and any request for a closed Gamma theorem, a global meromorphic-continuation theorem, or host complex equality has no row in L.

The package and local naming rows repack the same finite coordinates. Thus the obligation surface is exactly the five rows stated in the theorem. □

Theorem 581.4 (Gamma boundary for the zeta functional-equation ledger)**.** *For an accepted* $\mathsf{ZetaFunctionalEquationLedger}^{\uparrow}$ *carrier $L = (Z, A, E, F, G, K, T, H, C, P, N)$, every exported use of $\Gamma(1-s)$ factors through the displayed* $\mathsf{Gamma}^{\uparrow}$ *boundary row G and the functional-equation factor row F. The ledger exports the domain and consumption reads needed by the factor row and the trivial-zero witness, but it does not export a closed Gamma construction or a host meromorphic equality proof.*

Proof. Begin with a consumer read of the Gamma slot in the functional-equation row. The route must pass through C, so it lands either in the factor row F or in the boundary row G.

If it lands in F, the read sees only the formal factor slot $\Gamma(1-s)$ as part of the displayed product. If it lands in G, the read sees the boundary information: the input-domain row, the pole-exclusion row, and the finite nonzero reads used at positive integers.

No other coordinate of L carries a Gamma construction. The classifier of Definition 581.2 therefore keeps Gamma use at the boundary level and prevents the ledger from exporting a closed Gamma proof. □

Theorem 581.5 (Trivial-zero seal for the zeta functional-equation ledger)**.** *For an accepted* ZetaFunctionalEquation *carrier, the trivial-zero witness row T consumes exactly the sine-zero coordinate at $s = -2n$ with*

unary $n \geq \mathsf{E1}(\mathsf{e})$, the finite Gamma-boundary reads from G, the reflected zeta read from Z through A and E, and the factor decomposition in F. It seals only the displayed negative even zero rows and does not assert any zero-location statement in the critical strip.

Proof. Read the witness row T. Its sine-zero coordinate is the constructive row for $\sin(\pi(-2n)/2) = 0$, and this coordinate is already part of the factor decomposition F.

The remaining factor reads are routed through the displayed ledger. Gamma finiteness and nonzero consumption pass through G, while the reflected zeta input is read through the zeta source and eta-continuation rows Z, A, E.

The row T has no coordinate for the critical strip and no classifier row for Riemann-hypothesis strength. Hence the seal closes only the displayed negative even zero witnesses consumed by this ledger. □

Closure status for $\mathsf{NameCert}_{\mathsf{ZetaFunctionalEquationLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{ZetaFunctionalEquationLedger}^{\uparrow}$ packet is generated from $\mathsf{ZetaBasic}^{\uparrow}$, $\mathsf{AnaCont}^{\uparrow}$, eta-extension, functional-equation factor, $\mathsf{Gamma}^{\uparrow}$ boundary, $\mathsf{ContourIntegral}^{\uparrow}$ provenance, trivial-zero witness, componentwise hsame transports, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ZetaFunctionalEquationLedger}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 581.1, Definition 581.2, Definition 581.3, Definition 581.4, and Definition 581.5 define the local ledger carrier, classifier, obligation rows, Gamma boundary, and trivial-zero seal.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ZetaFunctionalEquationLedger}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close a Gamma proof, RH, full meromorphic continuation, host complex equality, Quot, Classical choice, propext, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, classifier stability, Gamma-boundary exactness, trivial-zero consumption, package provenance, and local naming for the same finite ledger packet.

Chapter 582

A Concrete Naming Certificate for $\mathsf{InscribedRoute}^{\uparrow}$

The $\mathsf{InscribedRoute}^{\uparrow}$ surface isolates the reusable proof route carried by an inscription event. It names the finite path from a visible gap through a public statement, a displayed proof route, an accepted record row, and a downstream consumer, while leaving private discovery, host trust, and unrecorded choice outside the packet.

It consumes the inscription-event carrier of chapter 519 and the visible gap ledger of chapter 520. The source scope and visible gap rows come from those sibling certificates, while this chapter packages the route, acceptance row, downstream consumer row, and public GAP ledger as the reusable route certificate.

Definition 582.1 (InscribedRoute carrier)**.** *An* $\mathsf{InscribedRoute}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (S, G, M, R, A, U, L, P, N)$$

with the following displayed rows:

1. *S is the prior* BHist *source scope from which the route is read;*
2. *G is the visible gap row naming the local theorem, certificate, or consumer boundary that still requires a route;*
3. *M is the named statement row, fixing the public binders, hypotheses, and conclusion of the reusable route;*
4. *R is the proof-route row, recording the displayed constructor, projection, inversion, transitivity, symmetry, or transport steps that move from S and G to M;*
5. *A is the acceptance row, recording that the route is admitted as public record data;*
6. *U is the downstream consumer row naming the theorem site, citation, audit surface, or certificate boundary that may read the route;*
7. *L is the public* GAP *ledger row tying the visible gap, named statement, route, acceptance row, and consumer row to the same finite route packet;*
8. *P is the* Pkg *provenance over* BHist, hsame, Cont, *route-checking data,* GAP *ledger data, and local certificate dependencies;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{InscribedRoute}^{\uparrow}}$ *row.*

The classifier for accepted carriers compares only $S, G, M, R, A, U, L, P, N$ and their displayed hsame *and* Cont *transports. It has no coordinate for hidden psychology, host trust, or an unrecorded route selector.*

Lean4 ✓ `BEDC.Derived.InscribedRouteUp.InscribedRouteTasteGate single carrier alignment`

Theorem 582.2 (InscribedRoute NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{InscribedRoute}^{\uparrow}}$ *surface for the carrier of Definition 582.1 consists of five finite obligations:*

1. *carrier admission: every accepted route exposes exactly the packet $Q = (S, G, M, R, A, U, L, P, N)$;*
2. *route classifier stability: public comparison is restricted to the source scope, visible gap, named statement, proof route, acceptance row, downstream consumer, ledger, package provenance, local naming row, and displayed* hsame *and* Cont *routes;*
3. *proof-route determinacy: the route row R reaches M from S and G only through the displayed* Cont *path and the matching* hsame *rows;*
4. *acceptance-ledger exactness: the acceptance row A and* GAP *ledger row L record exactly the admitted route and the downstream consumer boundary that may cite it;*
5. *non-escape: the packet exports no hidden psychology, host trust predicate, or unrecorded choice of route.*

Lean4 ✓ `BEDC.Derived.InscribedRouteUp.InscribedRouteNameCertObligations`
↪ variant `BEDC.Derived.InscribedRouteUp.InscribedRouteCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 582.1. The source scope, visible gap, named statement, proof route, acceptance row, downstream consumer, ledger, package provenance, and local naming row are all displayed before the route can be consumed.

Classifier stability and proof-route determinacy are read from the displayed comparison surface. The classifier has access only to $S, G, M, R, A, U, L, P, N$, and the route from R to M is replayed through the recorded Cont path together with the matching hsame rows.

Acceptance-ledger exactness follows because A and L are coordinates of the same finite packet. The accepted route and the downstream consumer boundary are therefore ledgered in public data rather than inferred from a host-side process.

The non-escape clause is immediate from the carrier inventory. No row stores hidden psychology, host trust, or an unrecorded choice, so none of these can be exported by the local $\mathsf{NameCert}_{\mathsf{InscribedRoute}^{\uparrow}}$ surface. □

Theorem 582.3 (InscribedRoute carrier admission)**.** *Every accepted* $\mathsf{InscribedRoute}^{\uparrow}$ *carrier exposes exactly the rows*

$$S, G, M, R, A, U, L, P, N$$

before any route consumer can read it. No accepted carrier has an additional coordinate for hidden host trust, private route choice, or external proof memory.

Proof. Project the carrier of Definition 582.1. The tuple displayed there is exactly $Q = (S, G, M, R, A, U, L, P, N)$, so acceptance can expose only those nine rows.

The classifier sentence following the row inventory confirms that public comparison is restricted to the same rows and their displayed hsame and Cont transports. Since the carrier lists no further coordinate, hidden host trust, private route choice, and external proof memory cannot be admitted as carrier data. □

Theorem 582.4 (InscribedRoute continuation obligation)**.** *For every accepted* $\mathsf{InscribedRoute}^{\uparrow}$ *packet, the route row R reaches the named statement row M through the displayed* Cont *path and the matching* hsame *rows recorded in the same carrier. The continuation obligation does not use an unrecorded route selector or a host-side proof search.*

Proof. Use the proof-route determinacy clause of Definition 582.2. It states that R reaches M from S and G only through the displayed Cont path and matching hsame rows.

Carrier admission supplies the ambient packet $Q = (S, G, M, R, A, U, L, P, N)$. Because R, M, P, and the displayed transport data are all rows of the same packet, the continuation can be replayed by the recorded data before the downstream consumer U reads it. □

Theorem 582.5 (InscribedRoute NameCert ledger obligation)**.** *For every accepted* $\mathsf{InscribedRoute}^{\uparrow}$ *packet, the acceptance row A and the public* GAP *ledger row L bind the same downstream consumer row U. A consumer may cite the route only when acceptance, ledger entry, named statement, and route row are displayed in the same finite packet.*

Proof. Apply the acceptance-ledger exactness clause of Definition 582.2. It identifies A and L as coordinates of the same route packet and requires them to record the admitted route and downstream consumer boundary.

Now project the carrier. The rows M, R, A, U, L occur together in Q, so the named statement, route, acceptance row, consumer row, and public ledger row are not separate host facts. The downstream consumer can therefore cite the route only through the single displayed packet. □

Theorem 582.6 (InscribedRoute public export)**.** *For every accepted* $\mathsf{InscribedRoute}^{\uparrow}$ *packet, the public reusable route exported to a downstream consumer is exactly the displayed finite route*

$$S, G, M, R, A, U, L, P, N.$$

The export makes the source scope, visible gap, named statement, proof route, acceptance row, downstream consumer row, public ledger, provenance, and local NameCert *row visible together; it exports no hidden host trust predicate, private route selector, or external proof memory.*

Proof. Carrier admission in Definition 582.3 identifies the accepted packet with the displayed tuple $S, G, M, R, A, U, L, P, N$. Thus any public export begins with exactly those rows.

The NameCert obligations of Definition 582.2 bind the proof-route determinacy and acceptance-ledger exactness clauses to that same tuple. The continuation obligation of Definition 582.4 then replays R to M only through the displayed Cont path and matching hsame rows.

Finally Definition 582.5 ties the acceptance row A, downstream consumer row U, and public ledger row L together. Therefore the public consumer can cite the route precisely as the finite BEDC packet above, and no unrecorded host-side route data are exported. □

Theorem 582.7 (InscribedRoute standard bridge surface)**.** *The public reusable route of an accepted* $\mathsf{InscribedRoute}^{\uparrow}$ *packet can be read as a standard bridge surface in the sense of chapter 9204: the source scope row S names the BEDC carrier, the visible gap row G and named statement row M give the encode/decode surface, the proof route row R records the finite route, the acceptance row A and consumer row U give the public-object surface, the public ledger row L records the bridge-readable export, and the provenance and naming rows P, N keep the route local to the packet. This bridge is a paper-level witness only; it does not claim machine bridge checking.*

Proof. Start from the public export theorem of Definition 582.6. It identifies the displayed finite route $S, G, M, R, A, U, L, P, N$ as the export surface for downstream consumers.

Read the same route through the standard bridge protocol of chapter 9204. The source scope, visible gap, named statement, proof route, acceptance row, downstream consumer, and public ledger provide the encode/decode and theorem-preservation shape required for a paper bridge.

The bridge remains paper-level because the chapter does not add any host translation module or machine no-host-leak witness. It therefore presents the public route as a bridge surface while keeping the verification axis separate. □

Closure status for $\mathsf{NameCert}_{\mathsf{InscribedRoute}^{\uparrow}}$.

Constructive story: An $\mathsf{InscribedRoute}^{\uparrow}$ packet is generated from a prior source scope, visible gap row, named statement, proof route, acceptance row, downstream consumer, public GAP ledger, package provenance, and local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{InscribedRoute}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 582.1, Definition 582.2, Definition 582.3, Definition 582.4, Definition 582.5, Definition 582.6, and Definition 582.7 bind source-scope, visible-gap, route-witness, acceptance-ledger, downstream-consumer, public export, standard bridge surface, hsame/Cont transport, local NameCert scoping, and the public export surface for reusable inscribed routes.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{InscribedRoute}^{\uparrow}}, \mathsf{theoremChecked})$

Lean target: `BEDC.Derived.InscribedRouteUp.InscribedRouteNameCertObligations`

Bridge status: paperBridge

Not claimed: This chapter does not close machine bridge checking, complete inscription semantics, or hidden host route semantics.

Upgrade path: The paper bridge surface is mature; machine bridge checking remains a separate verification-axis obligation.

Chapter 583

A Concrete Naming Certificate for $\mathsf{ContourIntegralSocket}^{\uparrow}$

The $\mathsf{ContourIntegralSocket}^{\uparrow}$ interface turns the contour-integral operation surface of chapter 9340 into a finite BEDC operation socket. It names piecewise-linear contour rows, holomorphic input rows, Riemann-sum modulus rows, complex output rows, componentwise transport, continuation routes, package provenance, and a local naming ledger for consumers that need contour integration without a host complex-analysis oracle.

Definition 583.1 (Contour-integral socket carrier)**.** *A* $\mathsf{ContourIntegralSocket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (G, F, M, I, L, H, C, P, N)$$

with the following displayed rows:

1. *G is the* $\mathsf{PLContour}$ *row, including endpoints, segment list, concatenation boundary, reversal boundary, and reparameterization witness rows;*
2. *F is the* $\mathsf{Holomorphic}^{\uparrow}$ *input row on a displayed* $\mathsf{Complex}^{\uparrow}$ *neighbourhood of the contour image;*
3. *M is the Riemann-sum modulus row, carrying tagged-partition refinement data and the convergence modulus used to read the integral;*
4. *I is the* $\mathsf{Complex}^{\uparrow}$ *output row naming the contour-integral value;*
5. *L is the operation-law ledger for linearity, concatenation, reversal, reparameterization, Cauchy triangle, polygon subdivision, and Cauchy integral formula rows;*
6. *H stores componentwise* hsame *transports for G, F, M, I, L and for the local naming rows;*
7. *C stores the finite* Cont *routes by which analytic-continuation and Cauchy-operation consumers read the contour, input, modulus, output, operation ledger, package provenance, and local naming row;*
8. *P is the* Pkg *provenance over the same finite operation-socket packet;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ContourIntegralSocket}^{\uparrow}}$ *ledger.*

The carrier exposes only this finite socket. It contains no host contour-integral function, no quotient path space, no use of $\mathsf{Classical.choice}$*, and no undisplayed completeness principle.*

Lean4 ✓ `BEDC.Derived.ContourIntegralSocketUp.ContourIntegralSocketTasteGate single carrier alignment`

Theorem 583.2 (Contour-integral socket NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContourIntegralSocket}^{\uparrow}}$ *surface for Definition 583.1 consists of five finite rows: carrier admission for S; classifier stability for the* PLContour *row, the* $\mathsf{Holomorphic}^{\uparrow}$ *input row, the Riemann-sum modulus row, the* $\mathsf{Complex}^{\uparrow}$ *output row, and the operation ledger; operation-law ledger exactness for L;* Pkg *provenance over G, F, M, I, L, H, C; and local naming exactness for N.*

Lean4 ✓ `BEDC.Derived.ContourIntegralSocketUp.ContourIntegralSocketSemanticNameCert`

Proof. Carrier admission is projection of the tuple S. Each contour, input, modulus, output, ledger, transport, continuation, package, and local naming coordinate is a displayed row of one finite BHist packet.

Classifier stability is componentwise. Transport of G preserves the piecewise-linear contour data, transport of F preserves the holomorphic input row over the transported neighbourhood, transport of M preserves the Riemann-sum modulus, and transport of I preserves the complex output row.

The package and naming rows repack those same coordinates. Since the carrier definition lists no host contour-integral function, quotient path space, choice principle, or completeness oracle, the obligation surface is exactly the five displayed rows. □

Theorem 583.3 (Contour-integral socket transport)**.** *Let $S = (G, F, M, I, L, H, C, P, N)$ be an accepted* $\mathsf{ContourIntegralSocket}^{\uparrow}$ *carrier. Any componentwise* hsame *transport of the contour row, holomorphic input row, Riemann-sum modulus row, and complex output row preserves carrier admission, the finite* Cont *read routes, the operation-law ledger,* Pkg *provenance, and the local* NameCert *ledger.*

Lean4 ✓ `BEDC.Derived.ContourIntegralSocketUp.ContourIntegralSocketCarrier transport`
↪ variant `BEDC.Derived.ContourIntegralSocketUp.ContourIntegralSocketCarrier component transport closure`

Proof. Begin with the transport row H. It stores the componentwise hsame comparisons for the contour, holomorphic input, modulus, output, ledger, and local naming rows.

The continuation routes in C read only those transported coordinates. Therefore a consumer that follows a route before transport reaches the corresponding transported coordinate after transport.

The package and local naming rows are attached to the same finite packet. Repacking through H preserves admission, provenance, and the local certificate without exposing any host equality beyond the displayed hsame rows. □

Theorem 583.4 (Contour-integral socket ledger exactness)**.** *For an accepted* $\mathsf{ContourIntegralSocket}^{\uparrow}$ *carrier $S = (G, F, M, I, L, H, C, P, N)$, every exported contour-integral operation law factors through the ledger row L and one of the displayed rows G, F, M, I, H, C, P, N. The ledger entries are exactly the linearity, concatenation, reversal, reparameterization, Cauchy-triangle, polygon-subdivision, and Cauchy-integral-formula rows named by the contour-integral operation surface.*

Lean4 ✓ `BEDC.Derived.ContourIntegralSocketUp.ContourIntegralSocketCarrier ledger exactness`

Proof. Read an exported operation-law request through the finite routes in C. If the request asks for contour shape, holomorphic input data, modulus evidence, output value, transport, package, or local naming, the corresponding coordinate of S supplies it.

If the request asks for an operation law, the only classifier-visible destination is the ledger row L. Its entries are the displayed operation laws listed in the carrier definition.

Thus every exported law is accounted for by a row of the packet, and no additional analytic theorem, quotient-path equation, or host integral identity can enter the socket. □

Theorem 583.5 (Contour-integral socket non-escape)**.** *An accepted* ContourIntegralSocket$^{\uparrow}$ *carrier exports no host complex-analysis theorem, no quotient path equality, no* Classical.choice *witness, and no hidden completeness object. A consumer request outside the displayed contour, holomorphic input, modulus, output, operation-ledger, transport, continuation, package, and local naming rows is recorded as outside the socket boundary and is not returned as a contour-integral fact.*

Lean4 ✓ `BEDC.Derived.ContourIntegralSocketUp.ContourIntegralSocketNonescape`

Proof. Inspect the carrier coordinates. The packet contains the displayed rows $G, F, M, I, L, H, C, P, N$ and no further analytic carrier.

The continuation routes in C can only land in those rows. A request for a host complex-analysis theorem, quotient path equality, choice witness, or undisplayed completeness object has no coordinate to read.

The local naming ledger therefore records such a request as outside the operation socket. It does not manufacture a contour-integral fact or an additional Complex$^{\uparrow}$ output row. □

Theorem 583.6 (Contour-integral socket handoff)**.** *Every analytic-continuation or Cauchy-operation consumer of an accepted* ContourIntegralSocket$^{\uparrow}$ *carrier factors its read through the finite packet* $S = (G, F, M, I, L, H, C, P, N)$*. Analytic-continuation consumers receive the holomorphic input, contour-domain, transport, and output rows; Cauchy-operation consumers receive the Cauchy-triangle, polygon-subdivision, and Cauchy-integral-formula rows of* L *together with the same provenance and local naming rows.*

Lean4 ✓ `BEDC.Derived.ContourIntegralSocketUp.ContourIntegralSocketHandoff`

Proof. For an analytic-continuation consumer, follow the routes in C to the holomorphic input row F, the contour-domain information in G, the output row I, and the transports in H. These rows supply the finite handoff surface.

For a Cauchy-operation consumer, follow the routes in C to the operation ledger L. The Cauchy-triangle, polygon-subdivision, and Cauchy-integral-formula entries are ledger rows attached to the same contour and holomorphic input data.

Both consumers then read Pkg provenance and local naming through P and N. The handoff is therefore bounded by the displayed socket packet and does not expose any standalone host contour-integral operation. □

Theorem 583.7 (Contour-integral socket boundary route totality)**.** *Every accepted analytic-continuation, Cauchy-operation, or contour-law consumer route for* ContourIntegralSocket$^{\uparrow}$ *is exhausted by the displayed packet rows*

$$G, F, M, I, L, H, C, P, N.$$

Requests for data outside the contour row, holomorphic input row, Riemann-sum modulus row, complex output row, operation-law ledger, componentwise transport, finite route, package provenance, and local naming row are outside the socket boundary.

Proof. Start with the local obligations from Definition 583.2. They identify carrier admission, classifier stability, ledger exactness, provenance, and naming as finite rows of the same packet.

Apply ledger exactness. Any contour-law request must land in L or in one of the supporting rows G, F, M, I, H, C, P, N, so no separate analytic law row is available.

Use non-escape to handle requests outside the displayed boundary. A request for a host theorem, quotient path equality, choice witness, or hidden completeness object has no coordinate in S and is recorded as outside the socket.

Finally apply the handoff theorem. Analytic-continuation and Cauchy-operation consumers receive their data only by following the finite routes through C to G, F, M, I, L, H, P, N, which proves route totality for the socket boundary. □

Lean4 ✓ `BEDC.Derived.ContourIntegralSocketUp.ContourIntegralSocketBoundaryRouteTotality`

Closure status for $\mathsf{NameCert}_{\mathsf{ContourIntegralSocket}\uparrow}$.

Constructive story: A $\mathsf{ContourIntegralSocket}^{\uparrow}$ packet is generated from a PLContour row, a $\mathsf{Holomorphic}^{\uparrow}$ input row, a Riemann-sum modulus row, a $\mathsf{Complex}^{\uparrow}$ output row, operation-law ledger rows, componentwise hsame transports, finite Cont routes, Pkg provenance, and a local NameCert ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ContourIntegralSocket}\uparrow}, \mathsf{publicClosed})$

Scope closed: Definition 583.1, Definition 583.2, Definition 583.3, Definition 583.4, Definition 583.5, Definition 583.6, and Definition 583.7 define the finite operation socket, transport rows, operation-law ledger exactness, non-escape boundary, downstream handoff, and route-total boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ContourIntegralSocket}\uparrow}, \mathsf{auditClean})$

Lean target: `BEDC.Derived.ContourIntegralSocketUp.ContourIntegralSocketBoundaryRouteTotality`

Bridge status: none

Not claimed: This chapter does not close a host contour-integral function, quotient path spaces, global complex analysis, RH zero-location consequences, or bridge checking.

Upgrade path: Bridged closure requires a bridge theorem from the public socket package to the abstract contour-integral operation schema.

Chapter 584

A Concrete Naming Certificate for $\mathsf{ExternalityGate}^{\uparrow}$

The $\mathsf{ExternalityGate}^{\uparrow}$ interface is the concrete gate attached to the name-to-gate correspondence of Definition 9400.5. It turns a named externality into a finite NameCert packet: a socket-name row, a gate-question row, a classifier for visible use, a refusal ledger, an audit readback route, transport and continuation rows, package provenance, and a local naming certificate. The packet makes the gate question inspectable without turning the requested external supply into an internal BEDC object.

The packet consumes the apophatic-name row of chapter 543 and the socket-ledger row of chapter 536 before it exposes the gate question, visible-use classifier, refusal ledger, audit readback, transports, routes, provenance, and local NameCert row.

Definition 584.1 (ExternalityGate carrier)**.** *An* $\mathsf{ExternalityGate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (A, Q, U, R, D, H, C, P, N)$$

with the following visible coordinates:

1. *A is the apophatic-name row naming the externality;*
2. *Q is the gate-question row determined by that name;*
3. *U is the visible-use classifier row distinguishing cited socket use from hidden internalization;*
4. *R is the refusal ledger for requests that would make the externality available as an internal generator, theorem, axiom, quotient, or host datum;*
5. *D is the audit readback row exposing the name, gate question, visible-use classifier, and refusal outcome to downstream checks;*
6. *H records componentwise* hsame *transports for name, gate question, classifier, refusal, readback, provenance, and local certificate rows;*
7. *C records the* Cont *routes by which consumers read the gate question, classifier, refusal ledger, and audit readback;*
8. *P records* Pkg *provenance over* $\mathsf{ApophaticName}^{\uparrow}$*,* $\mathsf{ApophaticSocket}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ExternalityGate}^{\uparrow}}$ *row.*

The carrier contains no coordinate for the requested external supply itself.

Theorem 584.2 (ExternalityGate name-to-gate obligations)**.** *For every accepted* $\mathsf{ExternalityGate}^{\uparrow}$ *carrier*

$$E = (A, Q, U, R, D, H, C, P, N),$$

the apophatic-name row A determines the gate-question row Q as the public question by which hidden internalization is tested. The local $\mathsf{NameCert}_{\mathsf{ExternalityGate}^{\uparrow}}$ *surface consists of carrier admission, name readback, gate-question readback, visible-use classification, refusal-ledger exhaustion, audit readback, componentwise transport, continuation routing, package provenance, and the local naming row.*

Proof. Project the carrier. The tuple lists the name row A, gate-question row Q, visible-use classifier U, refusal ledger R, audit readback D, transport rows, continuation routes, provenance, and local certificate.

The name-to-gate obligation is the dependency from A to Q. A consumer that cites the externality must pass through the gate question before it can be classified as visible use by U or refused by R.

The remaining obligations are the ordinary NameCert routing obligations. The readback row D exposes exactly the name, question, classifier, and refusal outcome, while H, C, P, N preserve and name those rows without adding an internal supply coordinate. □

Theorem 584.3 (ExternalityGate non-internalization)**.** *Every accepted* $\mathsf{ExternalityGate}^{\uparrow}$ *packet keeps the externality named by A outside the generated substrate. A downstream consumer may cite A, ask the gate question Q, receive the visible-use classification U, read the refusal ledger R, and replay the audit readback D, but it cannot extract an internal generator, theorem, axiom, quotient representative, host datum, or unrecorded supply from the packet.*

Proof. Begin with the carrier inventory of Definition 584.1. The requested external supply is not a coordinate of E; only its name, gate question, classifier, refusal ledger, and audit readback are present.

Apply the name-to-gate obligations. Any consumer route must pass through Q, then through either the visible-use classifier U or the refusal ledger R.

The transport and continuation rows preserve the same finite surface. Since no route in C targets an internal supply coordinate, no downstream read can convert the named externality into generated substrate content. □

Theorem 584.4 (ExternalityGate NameCert surface)**.** *The public* $\mathsf{NameCert}_{\mathsf{ExternalityGate}^{\uparrow}}$ *surface is exhausted by the apophatic-name row A, gate-question row Q, visible-use classifier U, refusal ledger R, audit readback row D, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and local certificate row N. It has no second surface for anonymous external dependence, unmarked proof input, hidden setup fields, or host-side recognition content.*

Proof. Use the NameCert obligations of Definition 584.2. They list every row available to the local certificate.

The non-internalization theorem then removes any possible extra source for the named externality. What remains is exactly the finite public surface $A, Q, U, R, D, H, C, P, N$.

Thus any consumer that claims an externality gate must cite the displayed rows. A route through anonymous dependence or hidden host recognition has no row to project and is refused by the ledger. □

Theorem 584.5 (ExternalityGate audit readback)**.** *For an accepted* $\mathsf{ExternalityGate}^{\uparrow}$ *packet, the audit readback row D reports exactly four visible facts: the apophatic name A, the gate question Q, the visible-use classifier result U, and the refusal-ledger outcome R. The readback is stable under the displayed* hsame *and* Cont *routes and exposes no internal supply object beyond those four rows.*

Proof. Project the audit readback row D from the carrier. By definition, it is attached to A, Q, U, R and not to a hidden external supply coordinate.

Use the componentwise transport rows in H and replay routes in C. They move the name, gate question, classifier, refusal ledger, and readback together, so the audit report remains stable under displayed transport.

Finally apply the NameCert surface theorem. Since the certificate surface is exhausted by the listed rows, the audit readback cannot expose any additional internal object. □

Theorem 584.6 (ExternalityGate public consumer package)**.** *Every public consumer of an accepted* $\mathsf{ExternalityGate}^{\uparrow}$ *packet receives exactly the apophatic-name row A, gate-question row Q, visible-use classifier U, refusal ledger R, audit readback D, componentwise* hsame *transport, displayed* Cont *route,* Pkg *provenance, and local* NameCert *row N. The public package has no internal generator, theorem, axiom, quotient representative, host datum, hidden supply, anonymous dependence row, or unmarked proof input.*

Proof. Start from the NameCert surface theorem. It exhausts the accepted externality gate by the rows $A, Q, U, R, D, H, C, P, N$ and gives no second coordinate for anonymous dependence or host recognition content.

Use the audit readback theorem. The readback reports exactly the apophatic name, gate question, classifier result, and refusal outcome, and displayed transport keeps those rows attached to the same packet.

Finally apply non-internalization. Since the named externality is never converted into an internal generator or hidden supply object, the public consumer receives exactly the displayed package and no internal theorem, axiom, quotient representative, host datum, or extra supply. □

The Lean TasteGate boundary is `lean4/BEDC/Derived/ExternalityGateUp/TasteGate.lean`. It provides the chapter TasteGate instance for the displayed name, question, classifier, refusal, audit, transport, continuation, provenance, and naming carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{ExternalityGate}^{\uparrow}}$.

Constructive story: An $\mathsf{ExternalityGate}^{\uparrow}$ packet is generated from an apophatic-name row, a gate-question row, a visible-use classifier, a refusal ledger, an audit readback row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ExternalityGate}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 584.1, Definition 584.2, Definition 584.3, Definition 584.4, Definition 584.5, Definition 584.6, and

Lean4 ✓ `BEDC.Derived.ExternalityGateUp.taste gate`

bind the finite name-to-gate carrier, refusal ledger, audit readback, non-internalization surface, public consumer package, and checked TasteGate instance.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ExternalityGate}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ExternalityGateUp.ExternalityGateTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close the requested external supply, host recognition content, hidden setup fields, quotient representatives, bridge scope, or bridge checking.

Upgrade path: The theory axis is mature for the displayed externality-gate carrier, refusal ledger, audit readback, transport, continuation, provenance, public consumer package, and TasteGate rows; only formal bridge checking remains on the independent verification axis.

Chapter 585

A Concrete Naming Certificate for $\mathsf{FableBranchWitness}^{\uparrow}$

The $\mathsf{FableBranchWitness}^{\uparrow}$ interface turns the local selector-step surface of section 9399.4 into a finite naming certificate. It isolates a single realized branch from the accumulated selector ledger: a consumer sees the source Hist row, selected mark, result Hist row, empty-boundary step, local admissibility certificate, transport rows, read routes, provenance, and local naming row, but it receives no global chooser and no completed branch policy.

The enacted local branch row is supplied by chapter 685, while chapter 516 is the finite selector-ledger consumer of the same branch shape. The witness packet therefore sits between the one-step empty-boundary selector and the ledger surface that records the branch without turning it into a global policy.

Definition 585.1 (FableBranchWitness carrier)**.** *A* $\mathsf{FableBranchWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (h, m, r, E, A, H, C, P, N)$$

with the following visible rows:

1. *h is the source* Hist *row at which the local branch read is made;*
2. *m is the selected Mark exposed by the selector step;*
3. *r is the result* Hist *row produced by enacting m at h;*
4. *E is the* EmptyStep *and* Ext *row recording the empty-boundary extension from h through m to r;*
5. *A is the local admissibility certificate for the displayed branch predicate at (h, m, r);*
6. *H records componentwise* hsame *transport for the source, selected mark, result row, step row, admissibility row, continuation row, provenance row, and local naming row;*
7. *C records the finite* Cont *routes by which consumers read h, m, r, E, A, H, P, and N;*
8. *P records* Pkg *provenance over the Empty-fable selector-step surface,* Hist*, Mark,* Ext*,* hsame*,* Cont*, and* NameCert*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{FableBranchWitness}^{\uparrow}}$ *row.*

The carrier is finite and local. It contains no global selection function, no family of choices indexed by all branch predicates, no hidden mark selector, no infinite story ledger, and no truth oracle for admissibility.

Lean4 ✓ `BEDC.Derived.FableBranchWitnessUp.FableBranchWitnessTasteGate single carrier alignment`

Theorem 585.2 (FableBranchWitness NameCert obligations)**.** *For the carrier of Definition 585.1, the local* $\mathsf{NameCert}_{\mathsf{FableBranchWitness}^{\uparrow}}$ *surface consists of five finite obligations: carrier admission for* $W = (h, m, r, E, A, H, C, P, N)$*; mark exposure for the selected row* m*; step exactness for the* EmptyStep *and* Ext *row* E *from* h *to* r*; admissibility exactness for the local certificate* A*; and non-escape for hidden choosers, global branch policies, infinite ledgers, and truth oracles.*

Lean4 ✓ `BEDC.Derived.FableBranchWitnessUp.FableBranchWitnessNameCertObligations`

Proof. Carrier admission is projection of the displayed tuple. The source Hist, selected mark, result Hist, step row, admissibility row, transport row, continuation routes, package provenance, and local naming row are all visible coordinates of the same packet.

Mark exposure is the second coordinate m. Since the consumer reads m directly through one of the routes in C, the selected branch is not reconstructed by an outside selector.

Step exactness is supplied by E, which binds the source row h, the selected mark m, and the result row r as one empty-boundary extension. Admissibility exactness is supplied by A at the same triple.

The non-escape clause follows from the carrier inventory. There is no coordinate for a global choice function, a branch policy over all Hist rows, an infinite ledger, or a truth oracle, so no local naming projection can export one. □

Theorem 585.3 (FableBranchWitness selector exposure)**.** *Every accepted* $\mathsf{FableBranchWitness}^{\uparrow}$ *carrier exposes the realized selector mark as the displayed row* m *and routes every consumer read of the branch through the finite rows*

$$h, m, r, E, A, H, C, P, N.$$

Consequently a downstream Empty-fable consumer may inspect the local witnessed branch, but it may not infer a global chooser, a selected branch for an unrelated Hist row, or an accumulated selector ledger beyond this single witnessed step.

Lean4 ✓ `BEDC.Derived.FableBranchWitnessUp.FableBranchWitnessCarrier selector exposure`

Proof. Project the accepted carrier to the mark row m and the route row C. These two rows give the consumer a displayed selector and the finite routes by which that selector is read.

The rows E and A bind the selector to the same local branch: E records the empty-boundary extension from h through m to r, and A records admissibility for that displayed triple. The transport row H preserves those coordinates componentwise.

Finally apply the non-escape part of Definition 585.2. Since the packet has only the listed rows, it realizes local branch selection without exporting a global choice function or an accumulated ledger. □

Theorem 585.4 (FableBranchWitness local transport exactness)**.** *For every accepted* $\mathsf{FableBranchWitness}^{\uparrow}$ *carrier*

$$W = (h, m, r, E, A, H, C, P, N),$$

the componentwise hsame *row* H *transports exactly the displayed source row* h*, selected mark* m*, result row* r*, empty-boundary step row* E*, admissibility row* A*, continuation routes* C*, provenance row* P*, and local name* N*. This transport preserves the local selector surface exposed by Definition 585.3 and the TasteGate-aligned carrier row marked at Definition 585.1; it adds no global chooser, completed branch policy, hidden selector, infinite ledger, or truth oracle.*

Lean4 ✓ `BEDC.Derived.FableBranchWitnessUp.FableBranchWitnessCarrier local transport`

Proof. Start from the TasteGate-aligned carrier row of Definition 585.1. Its coordinates are exactly $h, m, r, E, A, H, C, P, N$, and the local NameCert obligations of Definition 585.2 require carrier admission, selected-mark exposure, empty-boundary step exactness, admissibility exactness, and non-escape for hidden choice principles.

Project the transport coordinate H. Componentwise hsame can only compare the displayed source, mark, result, step, admissibility, continuation, provenance, and local-name rows already present in the carrier.

Apply selector exposure from Definition 585.3. Since every consumer read of the branch routes through the same finite tuple, the transported packet remains the same local witnessed branch rather than a family of branches.

The carrier inventory contains no coordinate for a global chooser, completed branch policy, hidden selector, infinite ledger, or truth oracle. Transport exactness therefore preserves the local branch witness and exports none of those objects. □

Theorem 585.5 (FableBranchWitness empty-boundary selector dependency)**.** *Every accepted* FableBranchWitness$^{\uparrow}$ *packet reads*

$$h, m, r, E, A, H, C, P, N$$

as the same local branch shape supplied by chapter 685 and consumed by chapter 516. The source row, selected mark, result row, empty-boundary extension, admissibility witness, transport, continuation route, provenance, and local name remain a finite one-step selector surface, with no global chooser, completed branch policy, hidden selector, infinite ledger, or truth oracle.

Proof. Project the accepted carrier of Definition 585.1. Its visible rows are exactly the local branch tuple $h, m, r, E, A, H, C, P, N$.

Use Definition 585.3. The selected mark m and the route row C expose the same one-step branch to every consumer, while E binds h, m, r as the empty-boundary extension and A records local admissibility.

Compare this exposed tuple with chapter 685 and chapter 516. The former supplies the enacted local branch row, and the latter consumes the finite selector-ledger row. Since the witness carrier has no coordinate for a global chooser, completed branch policy, hidden selector, infinite ledger, or truth oracle, the dependency is exactly the displayed local branch shape. □

Lean4 ✓ `BEDC.Derived.FableBranchWitnessUp.FableBranchWitnessCarrier empty boundary selector dependency`

Theorem 585.6 (FableBranchWitness scoped dependency package)**.** *The* FableBranchWitness$^{\uparrow}$ *carrier, its local* NameCert *obligations, selector exposure, local transport row, and empty-boundary selector dependency scope the packet over*

$$\mathsf{EmptyBoundarySelector}^{\uparrow}, \mathsf{EmptyFableLedger}^{\uparrow}, \mathsf{BHist}, \mathit{Mark}, \mathsf{Ext}, \mathsf{hsame}, \mathsf{Cont}, \mathsf{Pkg}, \mathsf{NameCert}.$$

Within that scope every consumer read of the branch factors through the displayed source row, selected mark, result row, empty-boundary extension, admissibility row, componentwise transport, continuation routes, provenance, and local naming row. The scoped package exports no global chooser, completed branch policy, hidden selector, infinite ledger, or truth oracle.

Proof. Project the carrier of Definition 585.1. Its visible rows are exactly the local branch tuple $h, m, r, E, A, H, C, P, N$, so the carrier and local naming surface already live over BHist, *Mark*, Ext, hsame, Cont, Pkg, and NameCert.

Apply Definition 585.2, Definition 585.3, and Definition 585.4. These results expose the selected mark, bind the empty-boundary step and admissibility rows, and preserve the same displayed coordinates under local transport.

Finally use Definition 585.5. The row supplied by $\mathsf{EmptyBoundarySelector}^{\uparrow}$ and consumed by $\mathsf{EmptyFableLedger}^{\uparrow}$ is the same finite one-step selector surface, and the carrier inventory contains no coordinate from which a global chooser or truth oracle could be read. □

Lean4 ✓ `BEDC.Derived.FableBranchWitnessUp.FableBranchWitnessCarrier scoped dependency package`

Closure status for $\mathsf{NameCert}_{\mathsf{FableBranchWitness}^{\uparrow}}$.

Constructive story: A $\mathsf{FableBranchWitness}^{\uparrow}$ packet is generated from a source Hist row, selected mark, result Hist row, empty-boundary step and Ext row, local admissibility certificate, componentwise hsame transport, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FableBranchWitness}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 585.1, Definition 585.2, Definition 585.3, and Definition 585.4 bind the local witnessed branch carrier, selector exposure, step exactness, admissibility row, exact componentwise transport, continuation routes, provenance, and no-hidden-chooser boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FableBranchWitness}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not claim Lean verification, bridge checking, global choice, an accumulated selector ledger, branch determinacy for unrelated Hist rows, or a truth oracle for admissibility.

Upgrade path: Public export requires checked carrier admission, selector exposure, empty-boundary step exactness, admissibility exactness, transport stability, provenance, and local naming for the same finite branch-witness packet.

Chapter 586

A Concrete Naming Certificate for $\mathsf{ReflectionLimitBoundary}^{\uparrow}$

The $\mathsf{ReflectionLimitBoundary}^{\uparrow}$ interface packages the reflection-limit boundary of chapter 9461 as a finite naming certificate. It separates the rows that close the primitive ground loop from the rows that record structural meta-description, and it forces every truth-facing meta row to remain a boundary entry rather than an admitted ground-loop closure. The structural meta-description ledger is read against the self-compilation boundary of section 9235.3, while the ground-loop side stays inside the visible BMark, BHist, msame, hsame, Cont, Pkg, and NameCert rows.

The dependency row is horizontal across the concrete-instance lattice: the G row is read through chapter 674, the T row is read through chapter 472, and the local naming refusal is aligned with chapter 543. These siblings supply the closed ground-loop surface, the truth-total refusal boundary, and the apophatic naming discipline consumed by $\mathsf{ReflectionLimitBoundary}^{\uparrow}$.

Definition 586.1 (Reflection-limit boundary carrier)**.** *A* $\mathsf{ReflectionLimitBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (G, M, T, H, C, P, N)$$

with the following visible rows:

1. *G is the ground-loop ledger containing the raw* BMark *constructors, the primitive* msame *rows, and the closed constructor no-confusion boundary;*
2. *M is the structural meta-description ledger for coded inductive formation, dependent formation, recursor shape, and classifier closure rows over the internal* CIC^* *presentation;*
3. *T is the truth-boundary ledger recording every attempted truth-total, runtime-total, or validation-as-row query as an* GAP *boundary entry;*
4. *H stores displayed* hsame *transports for the ground, meta-description, and truth-boundary rows;*
5. *C stores the finite* Cont *routes by which consumers read the closed ground rows, the structural meta rows, and the boundary entries;*
6. *P is the* Pkg *provenance over* BMark, BHist, msame, hsame, Cont, Pkg, NameCert, *and* GAP *rows;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{ReflectionLimitBoundary}^{\uparrow}}$ *row.*

The carrier exports a closed ground-loop packet and an open meta-loop packet at once. It contains no BEDC truth predicate, no self-validating runtime, and no row that classifies all internal sentence codes by their truth value.

Theorem 586.2 (Reflection-limit NameCert obligations)**.** *For an accepted* $\mathsf{ReflectionLimitBoundary}^{\uparrow}$ *carrier* $L = (G, M, T, H, C, P, N)$*, the local* NameCert *surface consists of five finite obligations:*

1. *carrier admission for the displayed* BHist *packet of Definition 586.1;*
2. *ground-loop closure, requiring every exported primitive distinction read to factor through* G*;*
3. *meta-loop openness, requiring every structural self-description read to factor through* M *without becoming a truth predicate;*
4. *boundary exactness, requiring each truth-total, runtime-total, or validation-as-row query to be recorded in* T *as a* GAP *boundary entry;*
5. *package closure, requiring all transports, continuations, provenance, and naming rows to be exactly the displayed rows* H, C, P, N*.*

Thus a consumer may read the finite ground closure and the finite structural reflection surface, but it cannot export a closed meta-level truth row through the same packet.

Proof. Carrier admission is projection of the tuple in Definition 586.1. The ground ledger G, meta-description ledger M, truth-boundary ledger T, transport rows H, continuation rows C, package row P, and naming row N are the complete classifier-visible packet.

The ground-loop clause reads only G. The primitive constructors, primitive sameness rows, and constructor no-confusion boundary are finite rows of the packet, so closing the ground loop does not require a truth predicate or runtime validation row.

The meta-loop clause reads only M. The structural copy of formation and recursor behavior remains a description ledger over internal codes; it is not a classifier deciding the truth of every represented BEDC sentence.

For any truth-total, runtime-total, or validation-as-row query, the carrier exposes only T. That row records the query as a boundary entry, and H, C, P, N transport and name the same boundary entry without turning it into an admitted truth row. □

Theorem 586.3 (Reflection-limit meta-loop openness obligation)**.** *For an accepted* $\mathsf{ReflectionLimitBoundary}^{\uparrow}$ *carrier* $L = (G, M, T, H, C, P, N)$*, the row* M *remains a structural description ledger for coded formation, dependent formation, recursor shape, and classifier closure. It is never a truth-classification row and never decides represented BEDC sentence codes by truth value.*

Proof. Project M from Definition 586.1. Its declared role is structural meta-description over the internal CIC* presentation.

Apply the meta-loop openness clause of Definition 586.2. That clause permits consumers to read structural self-description through M while excluding the conversion of that row into a truth predicate. □

Theorem 586.4 (Reflection-limit boundary exactness obligation)**.** *For an accepted* $\mathsf{ReflectionLimitBoundary}^{\uparrow}$ *carrier* $L = (G, M, T, H, C, P, N)$*, every request for a truth-total row, runtime-total row, or validation-as-row judgment is recorded in* T *as a* GAP *boundary entry. No row of* G *or* M *discharges that request as a closed ground-loop or closed meta-loop fact.*

Proof. Read the truth-boundary coordinate T in the carrier. The carrier statement assigns exactly the truth-total, runtime-total, and validation-as-row requests to this boundary ledger.

Use the boundary exactness clause of Definition 586.2. It keeps those requests in T as GAP entries, while G remains a closed ground-loop ledger and M remains structural description only. □

Theorem 586.5 (Reflection-limit package closure obligation)**.** *For an accepted* $\mathsf{ReflectionLimitBoundary}^{\uparrow}$ *carrier* $L = (G, M, T, H, C, P, N)$*, the rows* H, C, P, N *only transport, route, package, and name the same finite packet. They add no truth predicate, no self-validating runtime row, and no validation row beyond the boundary entries already recorded in* T*.*

Proof. Project the structural rows H, C, P, N from the carrier. Their roles are componentwise transport, finite consumer routing, package provenance, and local naming.

Apply the package-closure clause of Definition 586.2. The clause identifies those rows with the displayed packet and gives them no extra target beyond G, M, T and the boundary entries already visible there. □

Theorem 586.6 (Reflection-limit truth-boundary non-escape)**.** *Let* $L = (G, M, T, H, C, P, N)$ *be an accepted* $\mathsf{ReflectionLimitBoundary}^{\uparrow}$ *carrier. Every consumer query asking for a truth-total row, a runtime-total row, or a validation-as-row judgment factors through the displayed boundary ledger* T*. No projection from* G, M, H, C, P, N *yields a BEDC truth predicate or a row classifying all represented BEDC sentence codes by truth value.*

Proof. Read the accepted carrier through Definition 586.1. The only coordinate whose declared role contains truth-facing, runtime-facing, or validation-facing queries is T; the carrier statement identifies those entries as GAP boundary rows.

The remaining coordinates have disjoint public roles. The G row contains primitive ground-loop data, M contains structural meta-description data, and H, C, P, N transport, route, package, and name already displayed rows. Projecting any of those coordinates therefore returns one of the listed finite rows, not a truth predicate over all represented BEDC sentence codes. □

Theorem 586.7 (Reflection-limit package-route closure)**.** *Let* $L = (G, M, T, H, C, P, N)$ *be an accepted* $\mathsf{ReflectionLimitBoundary}^{\uparrow}$ *carrier. Every accepted consumer route for* L *is exhausted by the displayed rows* G, M, T, H, C, P, N*: ground-loop reads pass through* G*, structural meta-description reads pass through* M*, boundary reads pass through* T*, and the rows* H, C, P, N *only transport, replay, package, and name those same rows.*

Proof. Apply the package-closure clause of Definition 586.2. It states that all transports, continuations, provenance, and naming rows are exactly the displayed rows H, C, P, N.

The carrier definition supplies the source rows G, M, T. Since the continuation row C has no consumer target outside the closed ground rows, structural meta rows, and boundary entries, every accepted route is a route to one of G, M, T followed by the displayed transport, package, provenance, and naming data. □

Theorem 586.8 (Reflection-limit TasteGate route alignment)**.** *The paper carrier* $L = (G, M, T, H, C, P, N)$ *is the single-carrier surface used by the checked Lean TasteGate theorem* BEDC.Derived.ReflectionLimitBoundaryU *Thus the ground row, structural meta row, truth-boundary row, transport row, continuation row, provenance row, and naming row are the rows compared by the gate, with no additional paper-side carrier.*

Proof. The Lean theorem is stated for the inductive carrier with seven visible coordinates: ground, meta row, truth boundary, transport, continuation, provenance, and name. These are the same seven coordinates displayed in Definition 586.1.

The paper route therefore reads the checked gate as an alignment statement for the displayed packet itself. The theorem adds no second carrier and no extra truth or runtime coordinate; it records that the gate compares exactly the carrier rows already used by the local NameCert obligations. □

Theorem 586.9 (Reflection-limit mature consumer separation)**.** *Let $L = (G, M, T, H, C, P, N)$ be an accepted* ReflectionLimitBoundary$^{\uparrow}$ *carrier. Every mature consumer of L separates the closed ground-loop row G, the structural meta-description row M, and the truth-boundary row T before reading the transport, replay, provenance, and local naming rows H, C, P, N. The consumer may route closed ground-loop data through G, structural descriptions through M, and boundary refusals through T, but it receives no BEDC truth predicate, self-validating runtime export, or validation-as-row classifier from the combined carrier.*

Proof. Start from the displayed carrier of Definition 586.1. Its coordinates assign disjoint public roles to G, M, and T: ground-loop closure, structural meta-description, and truth-boundary recording.

Apply Definition 586.6. Any truth-total, runtime-total, or validation-as-row request factors through T and cannot be projected from G, M, H, C, P, N.

Finally apply Definition 586.7. The rows H, C, P, N only transport, replay, package, and name the same separated packet, so a mature consumer can compose the three readings without acquiring a BEDC truth predicate or self-validating runtime export. □

Closure status for NameCert$_{\text{ReflectionLimitBoundary}^{\uparrow}}$.

Constructive story: A ReflectionLimitBoundary$^{\uparrow}$ packet is generated from a closed ground-loop ledger, a structural meta-description ledger, a truth-boundary ledger, displayed hsame transports, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ReflectionLimitBoundary}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 586.1, Definition 586.2, Definition 586.3, Definition 586.4, Definition 586.5, Definition 586.6, Definition 586.7, Definition 586.8, and
Lean4 ✓ `BEDC.Derived.ReflectionLimitBoundaryUp.taste gate`
bind the finite ground, structural meta-description, truth-boundary, transport, route, provenance, and naming rows.

Formal verification: FormalStatus(NameCert$_{\text{ReflectionLimitBoundary}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ReflectionLimitBoundaryUp.ReflectionLimitBoundaryTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a BEDC truth predicate, self-validating runtime, runtime-validation row, or bridge checking for ReflectionLimitBoundary$^{\uparrow}$.

Upgrade path: Mature closure requires downstream examples and completeness-style cross-chapter consumers for the boundary surface.

Chapter 587

A Concrete Naming Certificate for $\mathsf{ContourSumWindow}^{\uparrow}$

The $\mathsf{ContourSumWindow}^{\uparrow}$ interface gives the contour-integral operation a finite window packet that downstream analytic chapters can inspect without importing a host integration operator. It records one piecewise-linear contour row, one holomorphic input row, a finite subdivision and sample ledger, the resulting Riemann-sum value, the output complex-history row, transport and continuation rows, package provenance, and a local naming row.

The window packet is the finite Riemann-sum face of chapter 521. It consumes the holomorphic input surface before exposing the $\mathsf{Complex}^{\uparrow}$ output row, so the analytic dependency is the displayed contour-window route rather than an ambient contour-integral operator.

Definition 587.1 (ContourSumWindow carrier)**.** *A* $\mathsf{ContourSumWindow}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (\gamma, f, S, R, I, H, C, P, N)$$

with the following displayed rows:

1. γ *is the* PLContour *row naming the finite endpoint list and segment history used by the contour read;*
2. f *is the* $\mathsf{Holomorphic}^{\uparrow}$ *input row on the displayed neighbourhood of* γ*;*
3. S *is the finite subdivision and sample row, listing the segment subdivision, sample point, and local mesh witness for every segment;*
4. R *is the Riemann-sum ledger, recording the finite summands, the mesh comparison, and the value computed from* f *on the samples of* S*;*
5. I *is the output* $\mathsf{Complex}^{\uparrow}$ *history row classified as the window value associated to the displayed ledger* R*;*
6. H *is the componentwise* hsame *transport row for* γ*,* f*,* S*,* R*, and* I*;*
7. C *is the finite* Cont *route row carrying subdivision refinement, contour endpoint transport, holomorphic-input transport, and output readback;*
8. P *is the* Pkg *provenance over* PLContour*,* $\mathsf{Holomorphic}^{\uparrow}$*, finite subdivision rows, Riemann-sum rows,* $\mathsf{Complex}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* NameCert*;*
9. N *is the local* $\mathsf{NameCert}_{\mathsf{ContourSumWindow}^{\uparrow}}$ *row.*

Lean4 ✓ `BEDC.Derived.ContourSumWindowUp.ContourSumWindowCarrier semantic name certificate`

Theorem 587.2 (ContourSumWindow NameCert obligations)**.** *For every accepted* $\mathsf{ContourSumWindow}^{\uparrow}$ *carrier* $W = (\gamma, f, S, R, I, H, C, P, N)$*, the local* $\mathsf{NameCert}_{\mathsf{ContourSumWindow}^{\uparrow}}$ *surface consists exactly of finite carrier admission, subdivision ledger exactness, contour route stability, output readback through* I*, package provenance through* P*, and non-escape from host integration, open-cover compactness, selected limits, quotient values, or unlisted analytic function-space objects.*

Lean4 ✓ `BEDC.Derived.ContourSumWindowUp.ContourSumWindowCarrier namecert obligations`

Proof. Project the carrier of Definition 587.1. Carrier admission is the display of $\gamma, f, S, R, I, H, C, P, N$ as rows of one finite BHist packet, so no consumer can read a contour, integrand, subdivision, sum, or output row outside that list.

Read the subdivision and Riemann-sum coordinates next. The row S supplies the finite segment subdivision and sample data, while R supplies the summand ledger and mesh comparison attached to those samples. Exactness is therefore ledger exactness for the listed rows, not convergence in an ambient integration theory.

Finally apply the displayed transport and continuation rows. The hsame row transports the contour, input, ledger, and output componentwise, and the Cont row records only the finite routes named in the packet. Since no coordinate names host integration, compactness, selected limits, or quotient values, the local $\mathsf{NameCert}$ exports only the finite window surface. □

Theorem 587.3 (ContourSumWindow Cauchy boundary)**.** *Every Cauchy-facing read of an accepted* $\mathsf{ContourSumWindow}^{\uparrow}$ *carrier factors through the same* $\mathsf{PLContour}$ *row* γ*, the same* $\mathsf{Holomorphic}^{\uparrow}$ *row* f*, the displayed subdivision row* S*, the Riemann-sum ledger* R*, the* $\mathsf{Complex}^{\uparrow}$ *output row* I*, and the visible* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows. The boundary exports only finite contour-window data and does not assert a host Cauchy integral theorem, a host contour integral, open-cover compactness, selected limiting values, quotient complex histories, or an ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.ContourSumWindowUp.ContourSumWindowTasteGate single carrier alignment`

Proof. Start with the finite window packet. The only route from the contour and holomorphic input to an output row passes through the subdivision row S and the Riemann-sum ledger R before reaching the $\mathsf{Complex}^{\uparrow}$ row I.

The Cauchy-facing consumer can therefore inspect the displayed ledger and its transports, but it cannot replace the finite ledger by a host integral or by a selected limiting process. Those objects are not coordinates of the carrier.

The non-escape clauses of Definition 587.2 close the boundary. They keep Cauchy-style cancellation and boundary reads inside the displayed contour, subdivision, Riemann-sum, output, transport, continuation, package, and naming rows, with no open-cover compactness or quotient-value surface added. □

Theorem 587.4 (ContourSumWindow TasteGate provenance)**.** *The checked TasteGate single-carrier alignment displayed after Definition 587.3 is read only through the finite rows*

$$\gamma, f, S, R, I, H, C, P, N$$

of Definition 587.1. Consequently the taste evidence for $\mathsf{ContourSumWindow}^{\uparrow}$ *is tied to the same contour-window carrier governed by Definition 587.2 and Definition 587.3; it cannot be read as host contour integration, selected limits, quotient complex values, or a separate analytic operator.*

Lean4 ✓ `BEDC.Derived.ContourSumWindowUp.ContourSumWindowTasteGateProvenance`

Proof. Project the carrier definition. The tuple $\gamma, f, S, R, I, H, C, P, N$ is the only finite packet named by the chapter, so the TasteGate alignment has no independent coordinate outside that carrier.

Use the NameCert obligations theorem to bind each admissible read to carrier admission, subdivision ledger exactness, contour route stability, output readback, package provenance, and non-escape from host analytic objects. This makes the taste evidence a claim about the displayed finite window rather than about an ambient contour-integral operator.

Finally apply the Cauchy boundary theorem and the checked TasteGate marker immediately after it. The marker certifies single-carrier alignment at the same site where every Cauchy-facing read is forced through $\gamma, f, S, R, I, H, C, P, N$, so provenance remains attached to the finite contour-window rows. □

Theorem 587.5 (ContourSumWindow subdivision exactness)**.** *For every accepted* $\mathsf{ContourSumWindow}^{\uparrow}$ *carrier* $W = (\gamma, f, S, R, I, H, C, P, N)$*, each summand exposed by the window is read only through the displayed subdivision and sample row* S *together with the Riemann-sum ledger* R*. No summand may be supplied by a host contour integral, a selected limit, an unlisted mesh, or an ambient analytic function-space object.*

Lean4 ✓ `BEDC.Derived.ContourSumWindowUp.ContourSumWindowCarrier subdivision exactness`

Proof. Project the carrier of Definition 587.1. The row S names the finite segment subdivision, sample point, and mesh witness for every segment, while R records the finite summands and their mesh comparison.

Use Definition 587.2. Its subdivision ledger exactness clause makes S and R the only admissible readback for summand data, and its non-escape clause removes host integration, selected limits, quotient values, and unlisted analytic objects from the packet.

The Cauchy-facing boundary theorem Definition 587.3 preserves the same rows for every boundary read. Thus the subdivision and Riemann-sum ledger are the complete summand surface. □

Theorem 587.6 (ContourSumWindow refinement stability)**.** *Let* $W = (\gamma, f, S, R, I, H, C, P, N)$ *be an accepted* $\mathsf{ContourSumWindow}^{\uparrow}$ *carrier. Any subdivision refinement accepted by the window must replay through the displayed continuation row* C *after preserving* γ*,* f*,* S*,* R*, and* I *componentwise through* H*. The refinement route cannot introduce a host contour integral, a new holomorphic input, a quotient complex value, or a selected limiting process.*

Lean4 ✓ `BEDC.Derived.ContourSumWindowUp.ContourSumWindowCarrier refinement stability`

Proof. Read the transport coordinates in Definition 587.1. The row H transports the contour, input, subdivision, ledger, and output componentwise, and the row C records subdivision refinement as one of the finite continuation routes of the packet.

Apply Definition 587.2. Contour route stability and output readback require refinement to keep the same displayed rows before any consumer can inspect the refined window.

Finally use Definition 587.3. Since every Cauchy-facing read factors through $\gamma, f, S, R, I, H, C, P, N$, refinement has no coordinate for a host contour integral, a fresh analytic input, a quotient value, or a selected limit. □

Theorem 587.7 (ContourSumWindow residue boundary)**.** *Any residue-facing consumer of an accepted* ContourSumWindow$^{\uparrow}$ *carrier must first expose the* PLContour *row* γ*, the* Holomorphic$^{\uparrow}$ *row* f*, the subdivision and sample row* S*, the Riemann-sum ledger* R*, the* Complex$^{\uparrow}$ *output row* I*, and the structural rows* H, C, P, N *before reading a residue handoff. The boundary exports no host contour integral, no residue theorem, no quotient complex value, no selected limiting process, and no ambient analytic function-space object.*

Lean4 ✓ `BEDC.Derived.ContourSumWindowUp.ContourSumWindow residue boundary`

Proof. Project the carrier of Definition 587.1. The rows available to a residue-facing consumer are exactly $\gamma, f, S, R, I, H, C, P, N$, with I read only after the finite Riemann-sum ledger R has been displayed.

Apply subdivision exactness, Definition 587.5. It forces each summand to be read from the subdivision and sample row S together with the ledger R, so a residue handoff cannot replace the window by an unlisted contour-integral value.

Apply refinement stability, Definition 587.6, and then the Cauchy boundary theorem Definition 587.3. The same contour, holomorphic input, subdivision, ledger, output, transport, replay, provenance, and naming rows remain visible at the boundary, while host contour integrals, residue theorems, quotient values, selected limits, and ambient analytic function spaces remain outside the packet. □

Theorem 587.8 (ContourSumWindow output seal nonescape)**.** *For every accepted* ContourSumWindow$^{\uparrow}$ *carrier* $W = (\gamma, f, S, R, I, H, C, P, N)$*, the* Complex$^{\uparrow}$ *output row* I *is sealed only after the* PLContour *row* γ*, the* Holomorphic$^{\uparrow}$ *row* f*, the subdivision row* S*, and the Riemann-sum ledger* R *have been displayed. The sealed output exports no quotient complex value, no selected limiting value, and no host contour integral.*

Lean4 ✓ `BEDC.Derived.ContourSumWindowUp.ContourSumWindowCarrier output seal nonescape`

Proof. Project the carrier rows. The output row I is classified as the window value associated to the displayed ledger R, and R itself is computed from the samples listed in S against the contour and input rows γ and f.

Use Definition 587.2 to read output readback through I and package provenance through P. These clauses make the output seal depend on the visible contour, holomorphic-input, subdivision, and Riemann-sum rows.

The boundary theorem Definition 587.3 keeps the same seal for Cauchy-facing consumers. It therefore exports only the finite contour-window output row and refuses quotient complex values, selected limits, and host contour integration. □

Theorem 587.9 (ContourSumWindow public finite-window certificate)**.** *The public* ContourSumWindow$^{\uparrow}$ *certificate is exactly the finite route through the* PLContour *row, holomorphic input row, subdivision row, Riemann-sum ledger,* Complex$^{\uparrow}$ *output seal, componentwise transport, continuation replay, package provenance, and local NameCert. Any consumer of the certificate must read*

$$\gamma, f, S, R, I, H, C, P, N$$

as the same finite packet before it can inspect the window output.

Proof. Start with the NameCert obligations of Definition 587.2. They identify the public surface with carrier admission, subdivision ledger exactness, contour route stability, output readback, package provenance, and non-escape from host analytic objects.

Use subdivision exactness and refinement stability next. Theorems Definition 587.5 and Definition 587.6 keep every summand and every refinement replay attached to $\gamma, f, S, R, I, H, C, P, N$.

Finally apply the residue boundary and output-seal nonescape theorems, Definition 587.7 and Definition 587.8. They force any residue-facing or output-facing read to pass through the same finite rows and therefore repack the displayed window as the public certificate. □

Lean4 ✓ `BEDC.Derived.ContourSumWindowUp.ContourSumWindowPublicFiniteWindowCertificate`

Theorem 587.10 (ContourSumWindow obligation closure package)**.** *The carrier, NameCert obligations, subdivision exactness, refinement stability, residue boundary, output-seal nonescape, and public finite-window certificate assemble the full obligation surface for* ContourSumWindow$^{\uparrow}$ *over the finite* PLContour *row,* Holomorphic$^{\uparrow}$ *input, subdivision row, Riemann-sum ledger,* Complex$^{\uparrow}$ *seal,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert*. The package closes exactly the displayed finite contour-window obligations and does not claim a host contour integral, Cauchy's theorem, a residue theorem, selected limits, quotient complex values, open-cover compactness, or an ambient analytic function-space object.*

Proof. Begin with the carrier of Definition 587.1 and the NameCert obligations theorem Definition 587.2. They identify $\gamma, f, S, R, I, H, C, P, N$ as the finite packet and bind admissible reads to carrier admission, subdivision ledger exactness, contour route stability, output readback, package provenance, and non-escape from host analytic objects.

Apply subdivision exactness and refinement stability next. Theorems Definition 587.5 and Definition 587.6 keep each summand and each refinement replay attached to the displayed PLContour row, Holomorphic$^{\uparrow}$ input, subdivision row, Riemann-sum ledger, Complex$^{\uparrow}$ output seal, hsame transport, and Cont route.

Finally combine the residue boundary, output-seal nonescape, and public finite-window certificate, namely Definition 587.7, Definition 587.8, and Definition 587.9. These results repack the same rows as the chapter's public obligation surface while leaving host contour integration, Cauchy's theorem, residue theorems, selected limits, quotient complex values, compactness, and ambient function spaces outside the packet. □

Lean4 ✓ `BEDC.Derived.ContourSumWindowUp.ContourSumWindowObligationClosurePackage`

Closure status for NameCert$_{\text{ContourSumWindow}^{\uparrow}}$**.**

Constructive story: A ContourSumWindow$^{\uparrow}$ packet is generated from a displayed PLContour row, a Holomorphic$^{\uparrow}$ input row, finite subdivision and sample rows, a Riemann-sum ledger, a Complex$^{\uparrow}$ output row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ContourSumWindow}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 587.1, Definition 587.2, Definition 587.5, Definition 587.6, Definition 587.7, Definition 587.8, Definition 587.9, and Definition 587.10 bind the carrier, NameCert obligations, subdivision exactness, refinement stability, residue boundary, output-seal nonescape, public finite-window certificate, and obligation-closure package as the scoped finite contour-window surface.

Formal verification: FormalStatus(NameCert$_{\text{ContourSumWindow}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close host contour integration, Cauchy's integral theorem, open-cover compactness, selected limits, quotient complex values, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, subdivision ledger exactness, contour route stability, Cauchy boundary, and non-escape for the same finite packet.

Chapter 588

A Concrete Naming Certificate for $\mathsf{ZetaContinuationApplication}^{\uparrow}$

The $\mathsf{ZetaContinuationApplication}^{\uparrow}$ packet records the application-level certificate that turns the zeta continuation surface into a finite NameCert object. It reads the eta continuation row, the functional-equation continuation row, pole and zero ledgers, Gamma horizon rows, application routes, transport rows, package provenance, and a local naming row. The packet is an application certificate only: it does not assert RH, complete the constructive $\mathsf{Gamma}^{\uparrow}$ chapter, classify nontrivial zeros, or export a continuation branch outside the displayed routes.

The carrier consumes the $\mathsf{Gamma}^{\uparrow}$ horizon row from chapter 75, the analytic-operation routing surface from chapter 577, and the $\mathsf{ZetaBasic}^{\uparrow}$ source row from chapter 71. These sibling rows are classifier inputs for the finite packet: G bounds Gamma reads, A routes analytic continuation through the operation surface, and E records the eta handoff from the basic zeta source without turning that source row into a global continuation theorem.

Definition 588.1 (ZetaContinuationApplication carrier)**.** *A* $\mathsf{ZetaContinuationApplication}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (E, F, P, T, G, A, H, C, Q, N)$$

with the following displayed rows:

1. *E is the eta-continuation row, recording the η handoff from the* $\mathsf{ZetaBasic}^{\uparrow}$ *source and the denominator boundary $1 - 2^{1-s}$;*
2. *F is the functional-equation continuation row, recording the reflected input $1 - s$, the factors 2^s, π^{s-1}, $\sin(\pi s/2)$, and their displayed product route;*
3. *P is the pole ledger row at $s = 1$, recording the simple-pole boundary and residue* $\mathsf{E1(e)}$ *without exporting a regular zeta value there;*
4. *T is the zero ledger row, recording the trivial-zero inputs witnessed by the sine factor and the absence of any nontrivial-zero-location conclusion;*
5. *G is the* $\mathsf{Gamma}^{\uparrow}$ *horizon row, recording the domain boundary for $\Gamma(1 - s)$, its pole exclusions, and the fact that the full constructive Gamma carrier is not supplied here;*
6. *A is the application-certificate row, reading E, F, P, T, G as the finite application of analytic continuation to the zeta source;*
7. *H stores componentwise* hsame *transports for E, F, P, T, G, A and for the local naming row;*

8. *C stores the finite* Cont *routes by which consumers read eta continuation, functional-equation continuation, pole and zero ledgers, Gamma horizon rows, application provenance, and local naming;*
9. *Q is the* Pkg *provenance row over the same application packet;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{ZetaContinuationApplication}^{\uparrow}}$ *row.*

The carrier exposes exactly this finite application packet. It has no coordinate for a value at the pole, no complete $\mathsf{Gamma}^{\uparrow}$ *construction, no branch selector outside the displayed eta and functional-equation routes, and no RH-facing nontrivial-zero classifier.*

Lean4 (definition) `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationUp`

Theorem 588.2 (ZetaContinuationApplication NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ZetaContinuationApplication}^{\uparrow}}$ *surface for Definition 588.1 consists of carrier admission for Z, componentwise classifier stability for E, F, P, T, G, A, ledger exactness for pole and zero rows, Gamma-horizon boundary exactness,* Cont *replay through C,* Pkg *provenance through Q, and local naming exactness for N.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier namecert obligations`

Proof. Carrier admission is projection from the tuple Z. Each continuation, ledger, horizon, application, transport, replay, package, and naming coordinate is displayed as a row of the same finite BHist packet.

Classifier stability is componentwise. The transports in H preserve the eta-continuation row, the functional-equation row, the pole row, the zero ledger, the Gamma horizon row, and the application-certificate row without adding a new analytic object.

The replay and provenance rows then repack the same data. The routes in C expose only the displayed application coordinates, Q records their package provenance, and N names the local certificate surface. □

Theorem 588.3 (ZetaContinuationApplication carrier admission)**.** *For the displayed carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$ of Definition 588.1, the admissible* $\mathsf{ZetaContinuationApplication}^{\uparrow}$ *packet is exactly the finite application certificate whose source locks are the* $\mathsf{Gamma}^{\uparrow}$ *horizon row of chapter 75, the analytic-operation routing surface of chapter 577, and the* $\mathsf{ZetaBasic}^{\uparrow}$ *eta source of chapter 71. The checked TasteGate alignment recorded at this site fixes those rows as the single carrier surface consumed by the chapter.*

Proof. Project the tuple Z. Its displayed coordinates are precisely the eta row E, functional-equation row F, pole row P, zero row T, Gamma horizon row G, application row A, transport row H, replay row C, provenance row Q, and local naming row N.

The sibling source locks identify where those coordinates may be read. The Gamma-facing data enters only through G, the analytic-operation data enters only through A, and the zeta source data enters only through E.

The TasteGate marker attached to the carrier definition records that these rows share one carrier alignment. Hence carrier admission is the displayed finite packet rather than an undisplayed analytic object. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrierAdmission`

Theorem 588.4 (ZetaContinuationApplication componentwise stability)**.** *For an accepted carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$, every* hsame *or* Cont *replay that preserves the checked TasteGate alignment preserves the components E, F, P, T, G, A separately. In particular, the* $\mathsf{Gamma}^{\uparrow}$*, analytic-operation, and* $\mathsf{ZetaBasic}^{\uparrow}$ *sibling locks may be transported only through their own displayed rows and may not be exchanged for a different continuation source.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier componentwise stability`

Proof. Read the transport coordinate H componentwise. It stores preservation data for the eta, functional-equation, pole, zero, Gamma-horizon, application, and naming rows without adding a mixed row between them.

Replay through C keeps the same separation. Eta-side requests return to E, functional-equation requests return to F, ledger requests return to P or T, Gamma-facing requests return to G, and application requests return to A.

Since the TasteGate marker fixes the single-carrier alignment, these componentwise routes cannot swap the sibling locks. The accepted packet remains stable row by row. □

Theorem 588.5 (ZetaContinuationApplication ledger exactness)**.** *For an accepted carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$, the pole ledger P, zero ledger T, Gamma horizon row G, application provenance Q, and local name N are exact ledgers for the displayed application certificate. They record only the pole boundary, trivial-zero surface, Gamma horizon boundary, analytic-operation application route, package provenance, and local naming already present in Z, and they export no pole value, completed* $\mathsf{Gamma}^{\uparrow}$ *construction, nontrivial-zero classifier, or continuation branch outside the finite replay routes in C.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier ledger exactness`

Proof. Inspect the ledger coordinates. The pole boundary is stored in P, the zero surface is stored in T, the Gamma boundary is stored in G, and provenance and naming are stored in Q and N.

Apply the carrier admission and componentwise stability rows. Each ledger read is routed back through the same coordinate of Z and through the same sibling source lock named in the chapter introduction.

The carrier has no coordinate for the positive objects excluded in the statement. Therefore exactness is ledger exactness for the displayed packet, not a hidden continuation theorem. □

Theorem 588.6 (Eta factorization route)**.** *For an accepted* $\mathsf{ZetaContinuationApplication}^{\uparrow}$ *carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$, every eta-side continuation read factors through E, the application row A, the transport row H, and one of the finite replay routes in C. Such a read may use the displayed denominator boundary and overlap agreement with* $\mathsf{ZetaBasic}^{\uparrow}$*, but it cannot export a value at $s = 1$ or a continuation branch outside the eta route.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier eta factorization`

Proof. Read an eta-side request through the finite routes stored in C. If the request is inside the eta continuation surface, the route lands in E and then in the application row A.

Transport through H preserves the same eta row and denominator boundary. The pole request is not part of E as a regular value; it is routed to the pole ledger P.

Thus the eta factorization is a finite application route. The certificate exports the eta handoff and overlap evidence, while pole and outside-route requests remain ledger reads. □

Theorem 588.7 (Gamma horizon boundary)**.** *For an accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier, every functional-equation read that touches the factor* $\Gamma(1-s)$ *must pass through the Gamma horizon row* G*. Inputs where the Gamma factor is outside the displayed horizon are recorded in* G *as boundary data and are not exported as values of the continued zeta function.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier gamma horizon boundary`

Proof. Begin with a functional-equation read. The factorization row F records the reflected input and the elementary factors, while the Gamma factor is named only by the horizon row G.

If the input is inside the displayed Gamma horizon, the read may continue through F, G, A, H, C. If the input is at a Gamma boundary, the route terminates in the ledger part of G.

The application row A therefore never converts the Gamma horizon into a completed Gamma$^{\uparrow}$ construction. It records exactly the boundary needed by the zeta continuation application. □

Theorem 588.8 (Gamma eta handoff source lock)**.** *For an accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, every eta-factorization read that uses a Gamma-facing horizon fact consumes the* Gamma$^{\uparrow}$ *row through chapter 75. The read must pass through* E*,* G*,* A*, the componentwise* hsame *transport row* H*, and a finite route in* C*; it cannot replace the Gamma horizon row by an undisplayed Gamma construction.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier gamma eta handoff`

Proof. Start with the carrier definition. The eta side is stored in E, while the only Gamma-facing coordinate is the horizon row G.

Use Definition 588.6 to route the eta read through E, A, H, C. If the route also needs a Gamma-facing horizon fact, Definition 588.7 forces that fact to pass through G.

The sibling Gamma$^{\uparrow}$ chapter supplies the source row named by G, and the local packet only records that consumption. Since no coordinate of Z stores a completed Gamma construction, the handoff remains a finite source lock. □

Theorem 588.9 (Analytic operation boundary)**.** *For an accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, every application-level continuation read factors through the analytic-operation surface of chapter 577. The row* A *records the application of that operation to the eta, functional-equation, pole, zero, and Gamma-horizon rows; it does not create a second continuation operation outside* E, F, P, T, G, H, C*.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier analytic operation boundary`

Proof. Read an application-level continuation request through C. By the carrier definition, the only row that names application of continuation data is A, and its inputs are the displayed rows E, F, P, T, G.

The analytic-operation sibling supplies the operation boundary consumed by A. Componentwise transport through H preserves the inputs as inputs to that operation surface rather than as independent analytic continuations.

Apply Definition 588.23 to the outside cases. A request for an undisplayed branch or another operation row has no carrier coordinate, so the application route remains locked to the finite analytic-operation boundary. □

Theorem 588.10 (ZetaBasic source lock)**.** *For an accepted* $\mathsf{ZetaContinuationApplication}^{\uparrow}$ *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, the* $\mathsf{ZetaBasic}^{\uparrow}$ *row consumed from chapter 71 is only the finite source lock for the eta handoff. It licenses the displayed source row and its* hsame *transport into* E*, but it does not by itself license analytic continuation, pole removal, Gamma-factor transport, or any branch outside the routes displayed in* C*.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier zeta basic source lock`

Proof. Project the source dependency from the carrier. The source row enters through E, where the eta handoff and denominator boundary are stored.

Use Definition 588.6 to read the source through E, A, H, C. The transport row H preserves the source handoff componentwise, and the replay row C exposes only the finite eta route.

The remaining analytic content is held in F, P, T, G, A, not in the $\mathsf{ZetaBasic}^{\uparrow}$ source row. By Definition 588.23, pole removal, Gamma transport, and outside-branch requests therefore remain outside the source lock unless the corresponding displayed row supplies them. □

Theorem 588.11 (ZetaContinuationApplication route totality)**.** *For an accepted* $\mathsf{ZetaContinuationApplication}^{\uparrow}$ *packet, every eta, functional-equation, Gamma-horizon, pole-ledger, zero-ledger, or application read factors through the displayed rows*

$$E, F, P, T, G, A, H, C, Q, N.$$

The row E *carries eta input,* F *carries the functional-equation route,* P *and* T *carry the pole and trivial-zero ledgers,* G *carries the Gamma horizon,* A *carries the application route,* H *carries componentwise transport,* C *carries finite replay,* Q *carries package provenance, and* N *carries the local* NameCert *row.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier route totality`

Proof. Project the carrier of Definition 588.1. It lists exactly the rows $E, F, P, T, G, A, H, C, Q, N$, so every application read starts from the finite NameCert packet rather than from an ambient analytic-continuation object.

Use the componentwise and ledger rows next. Theorem 588.4 keeps eta, functional-equation, pole, zero, Gamma, and application rows separate under H and C, while Definition 588.5 routes pole, zero, Gamma, provenance, and naming reads through their displayed ledgers.

Finally attach the sibling source locks. The Gamma eta handoff, analytic-operation boundary, and ZetaBasic source lock force source-facing reads through G, A, and E respectively. Hence every listed read factors through the ten-row carrier surface. □

Theorem 588.12 (ZetaContinuationApplication boundary exhaustion)**.** *An accepted* $\mathsf{ZetaContinuationApplication}^{\uparrow}$ *packet exports no pole value, completed* $\mathsf{Gamma}^{\uparrow}$ *construction, nontrivial-zero classifier, RH statement, or off-route continuation branch. All boundary requests are exhausted by the pole ledger* P*, trivial-zero ledger* T*, Gamma horizon* G*, application row* A*, transport* H*, replay* C*, provenance* Q*, and local certificate* N *of the displayed packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier boundary exhaustion`

Proof. Start from route totality. Every boundary-facing request must already be a read of $E, F, P, T, G, A, H, C, Q,$

The ledger exactness theorem then handles the exceptional analytic surfaces. Pole requests terminate at P, trivial-zero requests at T, and Gamma-horizon requests at G; none of these rows contains a regular pole value, completed Gamma construction, or nontrivial-zero classifier.

It remains to rule out route escape. The analytic-operation boundary and ZetaBasic source lock keep A and E from becoming a second continuation theorem, and the carrier definition has no coordinate for RH or an off-route branch. Therefore the displayed boundary rows exhaust the public application packet. □

Theorem 588.13 (ZetaContinuationApplication root boundary triad)**.** *For every accepted* ZetaContinuationApplica *carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$, the root source locks are the Gamma horizon row G, the analytic-operation routing row A, and the* ZetaBasic$^{\uparrow}$ *source row E. Every root read of $E, F, P, T, G, A, H, C, Q, N$ must expose that triad before the application row is consumed, and the support rows H, C, Q, N may only transport, replay, package, and name the same displayed triad.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root boundary triad`

Proof. Start with carrier admission and route totality. The accepted packet is the finite carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$, and every eta, functional-equation, pole, zero, Gamma, or application read factors through those rows.

Now attach the three source locks. The Gamma horizon boundary and Gamma eta handoff place Gamma-facing reads in G, the analytic-operation boundary places application routing in A, and the ZetaBasic source lock places eta-source reads in E.

Finally use ledger exactness and boundary exhaustion. The rows P, T remain pole and trivial-zero ledgers, while H, C, Q, N only preserve the displayed packet. Thus the root source locks are exactly the triad G, A, E inside the carrier. □

Theorem 588.14 (ZetaContinuationApplication root source readiness)**.** *Any eta, Gamma, or analytic-operation consumer of an accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier must expose its source lock before using the application row. Eta consumers expose E, Gamma consumers expose G, and analytic-operation consumers expose A; only after that exposure may the consumer read F, P, T, H, C, Q, N as the displayed application support surface.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root source readiness`

Proof. Read the source route from Definition 588.13. The triad G, A, E is the complete root source-lock surface for the accepted packet.

Handle the three consumer classes separately. An eta consumer reaches the packet through the ZetaBasic source lock at E, a Gamma consumer reaches it through the Gamma horizon and eta handoff at G, and an analytic-operation consumer reaches it through the operation boundary at A.

The support rows then become available only as support. Route totality and ledger exactness allow F, P, T, H, C, Q, N to be read after the source lock is displayed, and boundary exhaustion prevents those support rows from supplying a hidden source. □

Theorem 588.15 (ZetaContinuationApplication root source-lock exhaustion)**.** *Every root read of an accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier must expose exactly the source-lock triad E, G, A before it reads the support rows F, P, T, H, C, Q, N. Eta reads expose E, Gamma reads expose G, and analytic-operation reads expose A; no support row can stand in for this triad.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationRootSourceLockExhaustion`

Proof. Start with root source readiness. It requires source exposure before any eta, Gamma, or analytic-operation consumer may use the application support surface.

Use the root boundary triad. The only root source locks inside the carrier are E, G, A, with E supplied by the ZetaBasic source lock, G supplied by the Gamma horizon and eta handoff, and A supplied by the analytic-operation boundary.

Finally attach route totality and ledger exactness. They allow F, P, T, H, C, Q, N only as support rows after the triad is displayed, while boundary exhaustion prevents any support row from becoming a hidden source. □

Theorem 588.16 (ZetaContinuationApplication application row totality)**.** *For an accepted* ZetaContinuationApplic *carrier, the row A is the only analytic-operation consumer row. It cannot be replaced by a branch selector, off-route continuation branch, or hidden analytic-operation coordinate while preserving the same root source-lock surface.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationApplicationRowTotality`

Proof. Begin with the analytic-operation boundary. It places analytic-operation routing in the displayed row A and excludes off-route continuation branches from the carrier.

Now use root source readiness together with root source-lock exhaustion. Any analytic-operation consumer must expose A as its source lock before reading the support rows, so a branch selector cannot occupy the analytic-operation role without adding a new coordinate.

Route totality and boundary exhaustion close the argument. Every accepted route is already on $E, F, P, T, G, A, H, C, Q, N$, and no hidden branch selector or second analytic-operation row is present in that inventory. □

Theorem 588.17 (ZetaContinuationApplication boundary ledger non-escape)**.** *The rows P, T, G, Q, N exhaust all root requests for pole, trivial-zero, Gamma-horizon, provenance, and local-name data in an accepted* ZetaContinuationApplication$^{\uparrow}$ *packet. A root consumer cannot refine the same carrier by adding a regular pole value, nontrivial-zero classifier, completed Gamma construction, detached provenance row, or second local naming row.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier boundary ledger nonescape`

Proof. Start from ledger exactness. Pole requests terminate at P, trivial-zero requests terminate at T, and the Gamma-horizon boundary is read at G.

Next use route totality. Provenance and local naming requests are displayed as Q and N inside the same carrier, with transport and replay handled by H and C rather than by additional ledger rows.

Finally apply boundary exhaustion. It excludes pole values, nontrivial-zero classifiers, completed Gamma data, off-route branches, and additional boundary ledgers, so P, T, G, Q, N are the complete root ledger boundary. □

Theorem 588.18 (ZetaContinuationApplication root non-escape)**.** *Every root-facing consumer of an accepted* ZetaContinuationApplication$^{\uparrow}$ *packet factors through the displayed rows*

$$E, F, P, T, G, A, H, C, Q, N.$$

The root boundary excludes RH, a completed Gamma$^{\uparrow}$ *construction, a pole value, a nontrivial-zero classifier, and any off-route continuation branch.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root nonescape`

Proof. Begin with root source readiness. Eta, Gamma, and analytic-operation consumers must first expose E, G, A respectively before they may use the application support rows.

Apply route totality and ledger exactness. They place all pole, trivial-zero, Gamma, application, transport, replay, provenance, and naming reads on P, T, G, A, H, C, Q, N inside the same finite carrier.

Finally invoke analytic-operation boundary, Gamma horizon boundary, ZetaBasic source locking, and boundary exhaustion. These results exclude RH, completed Gamma data, pole values, nontrivial-zero classification, and off-route continuation branches because none has a coordinate in Z. □

Theorem 588.19 (ZetaContinuationApplication carrier source obligation)**.** *Every accepted* ZetaContinuationApplic *carrier presents* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows before any root source read of* Gamma$^{\uparrow}$*,* AnalyticContinuationOperation$^{\uparrow}$*, or* ZetaBasic$^{\uparrow}$ *is available. The* Gamma$^{\uparrow}$ *row G, analytic-operation row A, and* ZetaBasic$^{\uparrow}$ *row E are displayed source rows of the packet, not analytic primitives imported outside the carrier.*

Proof. Project the accepted carrier and the root source-readiness theorem. The carrier supplies $E, F, P, T, G, A, H, C, Q, N$, while readiness requires E, G, A to be exposed before any consumer reaches the support rows.

The support rows then determine the source shape. The transport row H, replay row C, package row Q, and local naming row N keep the read inside BHist, hsame, Cont, Pkg, and NameCert data.

Thus Gamma$^{\uparrow}$, AnalyticContinuationOperation$^{\uparrow}$, and ZetaBasic$^{\uparrow}$ appear only as displayed source rows of the same packet. They are not primitives from which the carrier is reconstructed. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier carrier source obligation`

Theorem 588.20 (ZetaContinuationApplication classifier stability obligation)**.** *For any two accepted* ZetaContinuationApplication$^{\uparrow}$ *carriers whose* BHist *rows are related componentwise by* hsame *and replayed by the same* Cont *routes, classifier stability preserves the displayed* Gamma$^{\uparrow}$*,* AnalyticContinuationOpera *and* ZetaBasic$^{\uparrow}$ *source rows together with* Pkg *provenance and local* NameCert *data. The comparison classifies packet rows only; it does not classify analytic primitives outside the displayed carrier.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationClassifierStabilityObliga`

Proof. Start from componentwise stability and root source-lock exhaustion. They compare accepted packets row by row and require the source-lock triad E, G, A to remain visible before support rows are read.

Transport the comparison through the structural rows. The hsame row moves the displayed BHist coordinates, the Cont row replays the same route, and the Pkg and NameCert rows preserve provenance and local naming.

Consequently the classifier comparison preserves the $\mathsf{Gamma}^{\uparrow}$, $\mathsf{AnalyticContinuationOperation}^{\uparrow}$, and $\mathsf{ZetaBasic}^{\uparrow}$ source rows as source rows of the packet. No external analytic object is introduced by the classifier. □

Theorem 588.21 (ZetaContinuationApplication ledger route obligation)**.** *Every root ledger route of an accepted* $\mathsf{ZetaContinuationApplication}^{\uparrow}$ *packet reads* $\mathsf{Gamma}^{\uparrow}$, $\mathsf{AnalyticContinuationOperation}^{\uparrow}$, *and* $\mathsf{ZetaBasic}^{\uparrow}$ *only through the displayed* BHist *carrier, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *row. The route may expose pole, trivial-zero, Gamma-horizon, provenance, and local-name ledgers, but it cannot export RH, a completed* $\mathsf{Gamma}^{\uparrow}$ *construction, an analytic-operation primitive, or a* $\mathsf{ZetaBasic}^{\uparrow}$ *source outside the packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier ledger route obligation`

Proof. Begin with boundary ledger non-escape. It exhausts pole, trivial-zero, Gamma-horizon, provenance, and local-name requests at P, T, G, Q, N inside the accepted packet.

Next use root non-escape and carrier source obligation. These rows force all root-facing reads through $E, F, P, T, G, A, H, C, Q, N$ and keep E, G, A as displayed $\mathsf{ZetaBasic}^{\uparrow}$, $\mathsf{Gamma}^{\uparrow}$, and $\mathsf{AnalyticContinuationOperation}^{\uparrow}$ source rows.

Finally apply the structural support rows. The route is carried by BHist, hsame, Cont, Pkg, and NameCert data, so a request for RH, completed Gamma data, or an external analytic primitive has no ledger coordinate to read. □

Theorem 588.22 (ZetaContinuationApplication public export)**.** *The public application packet consumed by* $\mathsf{Gamma}^{\uparrow}$, $\mathsf{AnalyticContinuationOperation}^{\uparrow}$, *and* $\mathsf{ZetaBasic}^{\uparrow}$ *is exactly the finite NameCert surface*

$$E, F, P, T, G, A, H, C, Q, N.$$

Downstream consumers may read the packet only through the displayed carrier admission, componentwise stability, ledger exactness, Gamma eta handoff, analytic-operation boundary, and ZetaBasic source lock; no additional analytic, RH-facing, or completed-Gamma row is exported.

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationPublicExport`

Proof. First combine carrier admission with route totality. The accepted packet is the ten-row carrier of Definition 588.1, and every public route factors through those rows.

Next identify the three sibling-facing entry points. The Gamma eta handoff supplies G, the analytic-operation boundary supplies A, and the ZetaBasic source lock supplies E; the remaining rows F, P, T, H, C, Q, N stay inside the same finite application packet.

Finally apply boundary exhaustion. Since pole values, completed Gamma data, nontrivial-zero classifiers, RH statements, and off-route branches have no exported coordinate, the public packet consumed by the sibling chapters is exactly the displayed NameCert surface. □

Theorem 588.23 (Application certificate non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{ZetaContinuationApplication}^{\uparrow}$ *packet factors through the displayed rows* $E, F, P, T, G, A, H, C, Q, N$. *Requests for a pole value, a Gamma value beyond the horizon row, an undisplayed continuation*

branch, or a nontrivial-zero-location claim have no carrier coordinate and are recorded only as ledger or horizon boundary reads.

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier non escape`

Proof. Let a downstream consumer route be given. By the carrier definition, the route can inspect only the eta row, functional-equation row, pole row, zero ledger, Gamma horizon, application row, transport row, continuation routes, package row, and local naming row.

Pole requests land in P, Gamma-boundary requests land in G, and trivial-zero requests land in T. An undisplayed branch or a nontrivial-zero-location claim is absent from the carrier inventory.

Consequently every exported application fact is a read of the finite packet. The missing objects remain outside the certificate surface rather than becoming hidden application outputs. □

Theorem 588.24 (ZetaContinuationApplication primitive scope package)**.** *Every accepted* ZetaContinuationApplic *packet reads the* $\mathsf{Gamma}^{\uparrow}$*, analytic-operation, and* $\mathsf{ZetaBasic}^{\uparrow}$ *sibling rows only through the displayed carrier*

$$Z = (E, F, P, T, G, A, H, C, Q, N)$$

and through the BEDC primitives BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. In particular, the packet exposes the Gamma horizon by G, the analytic-operation route by A, the zeta source by E, componentwise transport by H, replay by C, package provenance by Q, and local naming by N, without importing analytic continuation as an external theorem.*

Proof. Start with the carrier admission of Definition 588.3. It fixes the visible packet as the finite BHist carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$ and identifies the Gamma, analytic-operation, and zeta-source rows as sibling inputs to that carrier.

Use componentwise stability from Definition 588.4. The hsame row H preserves E, F, P, T, G, A separately, so no sibling row can be exchanged for a different continuation source during transport.

Now apply the source-lock theorems. The Gamma eta handoff of Definition 588.8 routes Gamma-facing reads through G; the analytic-operation boundary of Definition 588.9 routes operation reads through A; and the ZetaBasic source lock of Definition 588.10 routes zeta-source reads through E.

Finally use non-escape from Definition 588.23. Since every downstream consumer factors through $E, F, P, T, G, A, H, C, Q, N$, the only remaining public structure is Cont replay through C, Pkg provenance through Q, and the local NameCert row N over the same BHist packet. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier primitive scope package`

Theorem 588.25 (ZetaContinuationApplication visible-boundary lock)**.** *Every accepted* ZetaContinuationApplicati *application read preserving the sibling locks keeps Gamma horizon reads in G, analytic-operation reads in A, ZetaBasic eta-source reads in E, and boundary exclusions in P, T, G, N. Such a read cannot merge those rows into a completed Gamma construction, an off-route continuation branch, a pole value, an RH statement, or a nontrivial-zero classifier.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier visible boundary lock`

Proof. Start with componentwise stability. Theorem 588.4 preserves $E, F, P, T, G, A, H, C, Q, N$ row by row, so a preserving read cannot exchange the Gamma, analytic-operation, eta-source, pole, trivial-zero, or naming rows.

Next apply the source locks. The Gamma eta handoff routes Gamma-facing reads through G, the analytic-operation boundary routes operation reads through A, and the ZetaBasic source lock routes eta-source reads through E.

Now attach route totality. Every accepted application route stays on the displayed packet and reads sibling data through the primitive scope package rather than through a second analytic continuation object.

Finally use boundary exhaustion. The pole, trivial-zero, Gamma horizon, and local naming boundaries remain in P, T, G, N, and the chapter exports no coordinate for completed Gamma data, an off-route continuation branch, a pole value, an RH statement, or a nontrivial-zero classifier. □

Theorem 588.26 (ZetaContinuationApplication root NameCert obligation surface)**.** *For an accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, the root NameCert obligation surface is the local package consisting of carrier admission, componentwise stability, ledger exactness, Gamma horizon boundary, eta factorization, analytic-operation routing, ZetaBasic source locking, primitive scope, and non-escape for the same displayed rows. Every root obligation is therefore a row obligation over* $E, F, P, T, G, A, H, C, Q, N$ *and the primitives* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root namecert obligation surface`

Proof. Start from the carrier and NameCert rows in Definition 588.1 and Definition 588.2. These identify the local packet and list the rows whose admission, stability, replay, provenance, and naming must be checked.

Next attach the carrier admission, componentwise stability, and ledger exactness theorems. They keep the accepted packet on the displayed rows and make the pole, zero, Gamma horizon, application, provenance, and naming ledgers exact for that packet.

Finally use the eta factorization, Gamma horizon, analytic-operation boundary, ZetaBasic source lock, primitive scope package, and non-escape theorems. Together they give the root obligation surface as a finite NameCert package rather than an off-table continuation theorem. □

Theorem 588.27 (ZetaContinuationApplication source route exactness)**.** *For an accepted* ZetaContinuationApplica *carrier, every read of the* Gamma$^{\uparrow}$ *horizon, analytic-operation surface, or* ZetaBasic$^{\uparrow}$ *source row factors through the displayed source routes* G*,* A*, and* E *respectively, then through componentwise transport* H*, finite replay* C*, provenance* Q*, and local naming* N*. No source read may replace these routes by a completed Gamma object, a second analytic operation, or an independent zeta continuation branch.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier source route exactness`

Proof. Read the three source locks separately. The Gamma eta handoff theorem routes Gamma-facing requests through G, the analytic-operation boundary routes operation-facing requests through A, and the ZetaBasic source lock routes zeta-source requests through E.

Componentwise stability then prevents exchange among those rows. Transport through H preserves the source identities separately, while replay through C returns each request to the corresponding displayed route.

The primitive scope package repacks the same source routes with BHist, hsame, Cont, Pkg, and NameCert. The non-escape theorem excludes completed Gamma data, a second analytic operation, and an undisplayed continuation branch, so the displayed source routes are exact. □

Theorem 588.28 (ZetaContinuationApplication ledger non-escape)**.** *Every ledger-facing consumer of an accepted* ZetaContinuationApplication$^{\uparrow}$ *packet factors through the pole ledger P, trivial-zero ledger T, Gamma horizon ledger G, application provenance Q, and local name N inside $Z = (E, F, P, T, G, A, H, C, Q, N)$. The ledger surface rules out RH, nontrivial-zero classification, completed Gamma construction, and undisplayed continuation branches.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier ledger nonescape`

Proof. Begin with ledger exactness. The pole boundary is recorded in P, the trivial-zero surface in T, the Gamma horizon in G, and the package and naming records in Q and N.

Use carrier admission and componentwise stability to keep these ledgers attached to the accepted packet. A ledger read transported by H and replayed by C returns to the same coordinate of Z.

Finally apply the primitive scope package and non-escape theorem. Since the carrier has no coordinate for RH, nontrivial-zero classification, completed Gamma construction, or an undisplayed continuation branch, no ledger-facing consumer can export one. □

Theorem 588.29 (ZetaContinuationApplication public export surface)**.** *For an accepted* ZetaContinuationApplicati *carrier, the public export surface is exactly the finite packet*

$$Z = (E, F, P, T, G, A, H, C, Q, N).$$

The row E exports the ZetaBasic$^{\uparrow}$ *eta handoff, F exports the functional-equation route, P exports the pole ledger, T exports the trivial-zero ledger, G exports the* Gamma$^{\uparrow}$ *horizon row, A exports the analytic-operation application row, H exports componentwise* hsame *transport, C exports finite* Cont *replay, Q exports* Pkg *provenance, and N exports the local* NameCert$_{\text{ZetaContinuationApplication}^{\uparrow}}$ *row. No public export coordinate lies outside those ten displayed rows.*

Proof. Project the accepted carrier through Definition 588.1. Its complete row inventory is the displayed tuple $E, F, P, T, G, A, H, C, Q, N$.

The source-lock theorems identify the public meaning of the rows. The ZetaBasic$^{\uparrow}$ source is read through E, the Gamma horizon through G, and the analytic-operation boundary through A; transport, replay, provenance, and local naming are read through H, C, Q, N.

Use Definition 588.23 for exclusion. Since every downstream read factors through the displayed inventory, no hidden continuation branch, pole value, completed Gamma construction, or nontrivial-zero classifier becomes part of the export surface. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier public export surface`

Theorem 588.30 (ZetaContinuationApplication bridge consumer boundary)**.** *Every bridge-facing or application-facing consumer of an accepted* ZetaContinuationApplication$^{\uparrow}$ *packet factors through the* Gamma$^{\uparrow}$ *row G, the analytic-operation row A, the* ZetaBasic$^{\uparrow}$ *eta row E, componentwise transport H, replay C, provenance Q, and the local name N. The remaining public rows F, P, T may be inspected only as the displayed functional-equation, pole-ledger, and trivial-zero-ledger coordinates of the same packet.*

Proof. Begin with a bridge-facing consumer route. By Definition 588.24, sibling data enters the packet only through the primitive rows of Z and the BEDC rows BHist, hsame, Cont, Pkg, and NameCert.

The consumer must therefore read the sibling boundaries through their named coordinates. Gamma-facing requests pass through G, analytic-operation requests through A, and zeta-source eta requests through E.

The route then remains public only by using H for componentwise transport, C for replay, Q for package provenance, and N for the local certificate name. The rows F, P, T are available as internal displayed coordinates of the same route, not as independent bridge endpoints. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier bridge consumer boundary`

Theorem 588.31 (ZetaContinuationApplication public non-escape package)**.** *The public* ZetaContinuationApplicat *package is the conjunction of the non-escape theorem, the primitive scope package, and the sibling source locks for* Gamma$^{\uparrow}$*, analytic continuation, and* ZetaBasic$^{\uparrow}$*. Consequently every public consumer is confined to $E, F, P, T, G, A, H, C, Q, N$ and the package excludes RH, nontrivial-zero classification, a completed* Gamma$^{\uparrow}$ *construction, and undisplayed continuation branches.*

Proof. First combine Definition 588.29 with Definition 588.24. The public surface is the same finite carrier that the primitive scope theorem reads through BHist, hsame, Cont, Pkg, and NameCert.

Next attach the sibling source-lock theorems. The Gamma eta handoff, analytic-operation boundary, and ZetaBasic source lock keep the three external sources behind G, A, E respectively, while H, C, Q, N supply transport, replay, provenance, and naming.

Finally use Definition 588.23. The excluded objects have no displayed coordinate in the carrier, so the public package cannot export them through a bridge or application consumer. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier public nonescape package`

Theorem 588.32 (ZetaContinuationApplication root source lock)**.** *For an accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$, every root-level read of the* Gamma$^{\uparrow}$ *horizon, the analytic-operation application surface, or the* ZetaBasic$^{\uparrow}$ *eta source must pass through the displayed rows G, A, E and then through the transport, replay, provenance, and naming rows H, C, Q, N. The root packet has no source coordinate outside G, A, E, H, C, Q, N.*

Proof. Begin with the carrier definition and the NameCert obligation surface. The tuple $Z = (E, F, P, T, G, A, H, C, Q, N)$ displays the Gamma horizon row G, analytic-operation row A, eta source row E, transport row H, replay row C, provenance row Q, and local name N as named coordinates of one finite packet.

Apply the source-lock theorems. The Gamma eta handoff forces Gamma-facing reads through G, the analytic-operation boundary forces operation-facing reads through A, and the ZetaBasic source lock forces eta-source reads through E.

Finally use componentwise stability, primitive scope, and the public non-escape package. Transport and replay preserve the three source rows separately through H and C, while Q and N record only the package provenance and local name of the same carrier. Therefore every root source read is locked to G, A, E, H, C, Q, N. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root source lock`

Theorem 588.33 (ZetaContinuationApplication root ledger boundary)**.** *For an accepted* ZetaContinuationApplicat *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, the root ledgers for the pole boundary, trivial-zero surface, Gamma horizon, application provenance, and local naming are exhausted by* P, T, G, Q, N*. They export no pole value, completed* $\mathsf{Gamma}^{\uparrow}$ *construction, nontrivial-zero classifier, RH statement, or ledger row outside the displayed packet.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root ledger boundary`

Proof. Start with ledger exactness. The pole ledger is P, the trivial-zero ledger is T, the Gamma horizon ledger is G, and the provenance and local naming ledgers are Q and N.

Use carrier admission and componentwise stability to keep these rows attached to the same accepted packet. A root ledger read transported by H and replayed by C returns to the corresponding coordinate of Z rather than to an external analytic object.

Now attach boundary exhaustion and the public non-escape package. The carrier has no coordinate for a regular pole value, completed Gamma construction, nontrivial-zero classifier, RH statement, or additional ledger surface, so the root ledger boundary is exactly P, T, G, Q, N. □

Theorem 588.34 (ZetaContinuationApplication root replay non-escape)**.** *For an accepted* ZetaContinuationApplica *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, every root consumer replay after the displayed carrier rows factors through* H, C, Q, N*. Such replay may inspect the source rows* E, G, A *and the public coordinates* F, P, T *only through the same finite package, and it exports no RH statement, completed* $\mathsf{Gamma}^{\uparrow}$ *construction, pole value, nontrivial-zero classifier, or off-route continuation branch.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root replay nonescape`

Proof. Begin with route totality and the public export surface. They identify the complete replay-readable inventory as the displayed carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$.

Next apply the primitive scope package and bridge consumer boundary. A root consumer can move across the packet only by using componentwise hsame transport in H, finite Cont replay in C, package provenance in Q, and the local $\mathsf{NameCert}$ row N.

It remains to exclude replay escape. The public non-escape package combines the sibling source locks with boundary exhaustion, so RH, completed Gamma data, pole values, nontrivial-zero classifiers, and off-route branches have no carrier coordinate. Every root consumer replay therefore factors through H, C, Q, N over the displayed finite packet. □

Theorem 588.35 (ZetaContinuationApplication functional-row totality)**.** *For an accepted* ZetaContinuationApplica *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, every functional-equation read of the application surface remains on the displayed rows*

$$F, G, A, H, C, Q, N.$$

It may use the Gamma horizon row, analytic-operation row, componentwise transport, replay route, provenance, and local naming only as they occur in Z*; it exports no completed* $\mathsf{Gamma}^{\uparrow}$ *construction, pole value, RH statement, nontrivial-zero classifier, or off-packet continuation branch.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier functional row totality`

Proof. Begin with the local carrier and componentwise stability theorems. They project the rows F, G, A, H, C, Q, N from the accepted carrier and keep them attached under the displayed hsame transports and Cont replay.

Use ledger exactness and the Gamma horizon boundary next. The functional row F may read the Gamma horizon only through G, and the cited boundary prevents that read from becoming completed Gamma data or a pole-value computation.

Finally apply the analytic-operation boundary, ZetaBasic source lock, public non-escape package, and root replay non-escape. These results exhaust the application source route through G, A, E, H, C, Q, N and leave no coordinate for RH, nontrivial-zero classification, or an off-packet branch. □

Theorem 588.36 (ZetaContinuationApplication pole-zero ledger separation)**.** *For an accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, the pole ledger* P *and the trivial-zero ledger* T *remain separate public ledgers. They can be transported and replayed only through* H, C, Q, N*, and they cannot export RH, nontrivial-zero classification, regular pole values, completed Gamma data, or a ledger row outside* P, T*.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier pole zero ledger separation`

Proof. First read the exact ledger rows. The carrier admission and ledger exactness theorems identify P as the pole ledger and T as the trivial-zero ledger, with no shared coordinate that could merge the two public records.

Next use componentwise stability and root ledger boundary. Transport through H and replay through C return to the displayed P, T, Q, N rows, so a pole read cannot become a trivial-zero classifier and a trivial-zero read cannot become a pole-value computation.

The public non-escape package and root replay non-escape then remove the off-table conclusions. Since RH, nontrivial-zero classification, completed Gamma data, regular pole values, and extra ledgers have no carrier coordinate, neither P nor T can export them. □

Theorem 588.37 (ZetaContinuationApplication source-triad exhaustion)**.** *For an accepted* ZetaContinuationApplic *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, the Gamma, analytic-operation, and ZetaBasic source triad is exhausted by the rows* G, A, E *before any replay through* H, C, Q, N*. Every downstream functional-equation, pole-ledger, trivial-zero-ledger, or root consumer therefore reads the source triad through*

$$G, A, E, H, C, Q, N$$

and not through completed Gamma data, an ambient meromorphic continuation, RH, or an unrecorded zero classifier.

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier source triad exhaustion`

Proof. Start from the source locks. The Gamma eta handoff source lock, analytic operation boundary, and ZetaBasic source lock identify the only source rows available to the application packet as G, A, E.

Attach route totality and boundary exhaustion. They place each source read before the replay rows H, C, Q, N, so downstream consumers receive the triad through the same finite carrier rather than through a host analytic object.

Finally use the public non-escape package together with root replay non-escape. The exhausted triad has no coordinate for completed Gamma data, ambient meromorphic continuation, RH, or unrecorded zero classification, and every consumer route remains on G, A, E, H, C, Q, N. □

Theorem 588.38 (ZetaContinuationApplication row-inventory coverage)**.** *For every accepted* ZetaContinuationApp *carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$, every public read is covered by the eta source row E, the Gamma source row G, the analytic-operation source row A, the functional row F, the pole and trivial-zero ledger rows P, T, and the support rows H, C, Q, N. No additional analytic coordinate, RH-facing coordinate, ambient continuation branch, or zero-classifier row is part of the public inventory.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier row inventory coverage`

Proof. Begin with the carrier definition and the NameCert obligations. The carrier is the displayed ten-row packet $Z = (E, F, P, T, G, A, H, C, Q, N)$, and the obligation surface assigns those rows to eta source, functional equation, pole ledger, trivial-zero ledger, Gamma source, analytic-operation source, componentwise transport, replay, provenance, and local naming.

Apply root source lock, root ledger boundary, and root replay non-escape. These results exhaust source reads through E, G, A, ledger reads through P, T, and root consumer replay through H, C, Q, N, while keeping F as the displayed functional row of the same packet.

The inventory is therefore exactly the displayed carrier inventory. Any analytic branch, RH-facing conclusion, or zero-classifier output outside those rows lacks a coordinate in Z and cannot be a public read of the accepted carrier. □

Theorem 588.39 (ZetaContinuationApplication source-lock triad separation)**.** *For every accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$, the Gamma, analytic-operation, and ZetaBasic source reads remain separated through the rows G, A, E under* hsame *transport and* Cont *replay. No one source lock can substitute for another, and no replay route can identify the Gamma row, analytic-operation row, and eta source row as a single source coordinate.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier source lock triad visible separation`

Proof. Use the root source lock to locate the three source reads. Gamma-facing reads enter through G, analytic-operation reads through A, and ZetaBasic eta reads through E.

Now apply the NameCert obligations and componentwise stability. The transport row H carries hsame information componentwise, while the replay row C records Cont replay for the displayed packet rather than replacing one source row by another.

Finally combine source-triad exhaustion with root replay non-escape. Downstream routes may replay the triad only over G, A, E, H, C, Q, N, so substituting a single source lock for the other two would require an undisplayed coordinate. The accepted packet has no such coordinate. □

Theorem 588.40 (ZetaContinuationApplication root-obligation readiness)**.** *For every accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier $Z = (E, F, P, T, G, A, H, C, Q, N)$, row-inventory coverage, source-lock triad separation, root ledger boundary, and root replay non-escape form the root-obligation packet available to downstream zeta and RH boundary chapters. The packet certifies only the displayed finite carrier interface and does not assert RH, nontrivial-zero classification, a completed* Gamma$^{\uparrow}$ *construction, or bridge verification.*

Proof. First collect the local inventory. Row-inventory coverage supplies the complete public read table $E, F, P, T, G, A, H, C, Q, N$, and the NameCert obligations attach those reads to the accepted carrier.

Next attach the separated source route and ledger boundary. Source-lock triad separation keeps G, A, E distinct under hsame and Cont, while root ledger boundary keeps pole, trivial-zero, Gamma, provenance, and naming ledgers on P, T, G, Q, N.

Finally apply root replay non-escape. Any downstream zeta or RH boundary consumer receives only the displayed root packet through H, C, Q, N, so the packet is ready as a boundary obligation without exporting RH, zero classification, completed Gamma data, or bridge verification. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root obligation readiness`

Theorem 588.41 (ZetaContinuationApplication root functional-row readiness)**.** *For every accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, the functional-equation continuation row* F *is root-ready for downstream zeta and RH boundary consumers exactly as a finite* BHist *row transported by the displayed* hsame *data and replayed through* Cont*,* Pkg*, and* NameCert*. The row is read together with the eta source row* E*, the separated Gamma and analytic-operation rows* G, A*, the pole and trivial-zero ledgers* P, T*, and the replay support* H, C, Q, N*; it does not assert RH, classify nontrivial zeros, construct a completed* Gamma$^{\uparrow}$ *object, or verify a bridge.*

Proof. Start with row-inventory coverage. It places F inside the same accepted carrier as $E, P, T, G, A, H, C, Q, N$, so a downstream consumer cannot read a functional-equation continuation row apart from the displayed packet.

Use source-lock triad separation and the root ledger boundary. The source rows G, A, E remain separated under hsame and Cont, while P, T carry only the pole and trivial-zero ledgers needed by the root interface.

Finally apply root replay non-escape and root-obligation readiness. The functional row is available as a finite replay row of Z, but the carrier has no coordinate for RH, nontrivial-zero classification, completed Gamma data, or bridge verification. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root functional row readiness`

Theorem 588.42 (ZetaContinuationApplication root Gamma handoff readiness)**.** *For every accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, the Gamma handoff available to root consumers is the separated source row* G *together with its finite replay through* H, C, Q, N *and its boundary interaction with* F, P, T, A, E*. The handoff is a* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *route of the displayed packet; it is not a completed* Gamma$^{\uparrow}$ *construction, an RH assertion, a nontrivial-zero classifier, or a checked bridge.*

Proof. Use the Gamma eta handoff and source-lock triad separation. The Gamma source row is G, and the eta and analytic-operation rows remain E and A rather than substitutes for G.

Apply the root ledger boundary. The pole and trivial-zero rows P, T record the ledger side of the handoff, while F records the functional row adjacent to the Gamma source route.

Root replay non-escape then keeps the handoff on $G, F, P, T, A, E, H, C, Q, N$. Since no completed Gamma coordinate, RH coordinate, zero-classifier row, or bridge verification row is present, none can be exported by the handoff. □

Lean4 ✓ BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root gamma handoff readiness

Theorem 588.43 (ZetaContinuationApplication root public-export readiness)**.** *For every accepted* ZetaContinuationApplication$^{\uparrow}$ *carrier* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, the public export available to downstream zeta and RH boundary chapters is exactly the root packet formed by row-inventory coverage, source-lock triad separation, root ledger boundary, root replay non-escape, root functional-row readiness, and root Gamma handoff readiness. The export is anchored in the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows and refuses RH, nontrivial-zero classification, completed Gamma construction, and bridge verification.*

Lean4 ✓ BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root public export readiness

Proof. First collect the finite rows. Row-inventory coverage gives $E, F, P, T, G, A, H, C, Q, N$, while source-lock triad separation keeps the three source rows G, A, E distinct under transport and replay.

Next attach the two root handoffs. Functional-row readiness exposes F as the functional-equation continuation row of the same packet, and Gamma handoff readiness exposes G only through its finite replay and ledger boundary.

Finally use root ledger boundary, root replay non-escape, and root-obligation readiness. The public export is therefore the displayed root packet, with no coordinate for RH, nontrivial-zero classification, completed Gamma construction, or bridge verification. □

Theorem 588.44 (ZetaContinuationApplication open-phase root readiness)**.** *Any open-phase consumer of an accepted* ZetaContinuationApplication$^{\uparrow}$ *application packet must expose the eta source lock* E*, Gamma horizon row* G*, analytic-operation row* A*, pole and trivial-zero ledgers* P, T*, componentwise transport* H*, replay row* C*, provenance row* Q*, and local name row* N *before it can read continuation application output. The readable output is therefore a finite* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *route of the displayed packet.*

The readiness row asserts no RH conclusion, no analytic continuation beyond the displayed routes, no completed Gamma construction, and no standard bridge.

Lean4 ✓ BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier open phase root readiness

Proof. First use source route exactness. The application output can be reached only through the displayed source route, so the eta source lock, Gamma horizon row, and analytic-operation row must appear as the visible E, G, A portion of the carrier.

Next apply source-triad exhaustion. It prevents an open-phase consumer from collapsing E, G, A into an undisplayed source coordinate and keeps the pole and trivial-zero ledgers P, T attached to the same packet.

Finally invoke root-obligation readiness together with root public-export readiness. These rows add H, C, Q, N as the componentwise transport, replay, provenance, and local name surface needed by downstream root consumers. Since the same readiness package refuses RH, nontrivial-zero classification, completed Gamma data, and bridge verification, the open-phase root read is exactly the displayed finite obligation row. □

Theorem 588.45 (ZetaContinuationApplication root consumer exactness)**.** *Every root consumer of an accepted* ZetaContinuationApplication$^{\uparrow}$ *packet* $Z = (E, F, P, T, G, A, H, C, Q, N)$ *reads exactly the displayed rows* $E, F, P, T, G, A, H, C, Q, N$ *through the Gamma horizon lock, analytic-operation*

lock, and ZetaBasic$^{\uparrow}$ *source lock. The consumer receives no RH statement, nontrivial-zero classifier, completed* Gamma$^{\uparrow}$ *construction, or bridge verification.*

Proof. Use open-phase root readiness to place the consumer on the displayed carrier rows. Then apply root public-export readiness and source-lock triad separation: G remains the Gamma-facing row, A remains the analytic-operation row, and E remains the ZetaBasic$^{\uparrow}$ source row.

Finally use root replay non-escape. Since the packet has no coordinate for RH, nontrivial-zero classification, completed Gamma data, or bridge verification, the root consumer surface is exactly the ten-row packet. □

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root consumer exactness`

Theorem 588.46 (ZetaContinuationApplication root pole-zero consumer readiness)**.** *Every pole- or zero-facing root consumer of an accepted* ZetaContinuationApplication$^{\uparrow}$ *packet* $Z = (E, F, P, T, G, A, H, C, Q, N)$ *reads the pole ledger* P *and trivial-zero ledger* T *only inside the same carrier route that exposes* E, F, G, A, H, C, Q, N*. The read may use the displayed Gamma, analytic-operation, and* ZetaBasic$^{\uparrow}$ *sibling locks, but it exports no pole value, RH conclusion, nontrivial-zero classification, completed* Gamma$^{\uparrow}$ *object, or bridge verification.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root pole zero consumer readiness`

Proof. Start with root ledger boundary and pole-zero ledger separation. They identify P, T as ledger rows of the same accepted packet rather than as external analytic conclusions.

Next attach root consumer exactness. The sibling locks keep Gamma reads in G, analytic-operation reads in A, and zeta source reads in E, so the ledger consumer cannot leave $E, F, P, T, G, A, H, C, Q, N$. □

Theorem 588.47 (ZetaContinuationApplication root Gamma operation handoff)**.** *For every accepted* ZetaContinuationApplication$^{\uparrow}$ *packet* $Z = (E, F, P, T, G, A, H, C, Q, N)$*, the root handoff between the Gamma horizon row and the analytic-operation row is the displayed pair* G, A *transported through* H, C, Q, N *and read against the eta source row* E*, functional row* F*, and ledgers* P, T*. This handoff remains a finite NameCert route and does not complete* Gamma$^{\uparrow}$*, assert RH, classify nontrivial zeros, or verify a bridge.*

Lean4 ✓ `BEDC.Derived.ZetaContinuationApplicationUp.ZetaContinuationApplicationCarrier root gamma operation handoff`

Proof. Apply root Gamma handoff readiness and root functional-row readiness. They expose G and F as finite rows adjacent to the application row A.

Then use root consumer exactness and root pole-zero consumer readiness. These keep the handoff inside $E, F, P, T, G, A, H, C, Q, N$ and leave RH, nontrivial-zero classification, completed Gamma data, and bridge verification outside the packet. □

Closure status for NameCert$_{\text{ZetaContinuationApplication}^{\uparrow}}$**.**

Constructive story: A ZetaContinuationApplication$^{\uparrow}$ packet is generated from eta continuation, functional-equation continuation, pole and zero ledgers, Gamma horizon rows, application routes, componentwise hsame transports, Cont replay, Pkg provenance, and a local NameCert row.

Formal verification: FormalStatus(NameCert$_{\text{ZetaContinuationApplication}\uparrow}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close RH, nontrivial-zero classification, full constructive Gamma$^{\uparrow}$ construction, global meromorphic uniqueness, Lean verification, or bridge checking.

Upgrade path: Paper-side closure is complete for the displayed public application packet; formal verification and bridge checking remain separate verification-axis work.

Chapter 589

A Concrete Naming Certificate for $\mathsf{CauchyNet}^{\uparrow}$

The $\mathsf{CauchyNet}^{\uparrow}$ surface records directed convergence data as finite observation packets. Kelley-style Cauchy nets and uniform-space convergence provide the mathematical precedent, but the BEDC packet below is not a quotient net, a selected limit, or an ambient completeness theorem. It is a finite BHist boundary that exposes the directed windows actually inspected by downstream $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers.

The directed-window packet is a downstream consumer of chapter 126, chapter 301, chapter 291, and chapter 38: those sibling chapters supply the schedule, regular rational readback, dyadic tolerance ledger, and real-name handoff rows used in the carrier below.

Definition 589.1 (CauchyNet carrier)**.** *A* $\mathsf{CauchyNet}^{\uparrow}$ *carrier is a finite directed-window* BHist *packet*

$$K = (D, S, R, W, T, L, H, C, P, N)$$

over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *with the following displayed rows:*

1. *D is the finite directed index-window ledger, naming the inspected vertices and the common upper-window witnesses used by the packet;*
2. *S is the* $\mathsf{StreamName}^{\uparrow}$ *schedule that turns each requested directed window into displayed observation names;*
3. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *row read from the scheduled rational observations on those windows;*
4. *W is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation row for the dyadic tolerances and rational comparisons used inside the finite windows;*
5. *T is the eventual common-window classifier row, asserting that each displayed tolerance request is witnessed by one finite directed window in D;*
6. *L is the* $\mathsf{Real}^{\uparrow}$ *handoff row through which downstream real consumers read the regular rational data;*
7. *H stores componentwise* hsame *transports for D, S, R, W, T, L and the local naming rows;*
8. *C stores the finite* Cont *routes that expose directed windows, observations, common-window witnesses, classifier reads, and real handoffs;*

9. *P is the* Pkg *provenance over the listed BEDC dependencies;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyNet}^\uparrow}$ *row.*

The carrier exports only this finite directed-window packet. It contains no quotient of nets, no selected limit point, no ambient uniform-space completeness theorem, and no choice operator selecting cofinal windows.

Lean4 ✓ `BEDC.Derived.CauchyNetUp.CauchyNetCarrier transport semanticNameCert`
Lean4 ✓ `BEDC.Derived.CauchyNetUp.CauchyNetCarrier commonWindow semanticNameCert`

Theorem 589.2 (CauchyNet NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{CauchyNet}^\uparrow}$ *surface for Definition 589.1 consists of five finite obligations:*

1. *carrier admission for the displayed directed-window packet K;*

2. *eventual common-window classification through T, stating that each exposed tolerance request is routed to a common upper window recorded in D;*

3. *directed-window transport along H and C, preserving the scheduled* $\mathsf{StreamName}^\uparrow$ *observations,* $\mathsf{DyadicRatCore}^\uparrow$ *comparisons, and* $\mathsf{RegSeqRat}^\uparrow$ *handoff rows;*

4. *ledger non-escape, stating that a consumer read without a displayed common-window witness is recorded as outside the packet rather than exported as convergence data;*

5. $\mathsf{Real}^\uparrow$ *handoff through L, so real-facing consumers see only the regular rational data certified by the same finite directed-window rows.*

Lean4 ✓ `BEDC.Derived.CauchyNetUp.CauchyNetNameCert obligation surface`
↪variant `BEDC.Derived.CauchyNetUp.CauchyNetCarrier namecert obligation surface`

Proof. Carrier admission is projection from the finite tuple in Definition 589.1. The directed index-window ledger, stream schedule, dyadic observations, regular rational handoff, classifier row, real handoff, transports, routes, package provenance, and local naming row are all visible coordinates of one BHist packet.

The eventual common-window classifier reads T only after the finite directed ledger D has supplied a displayed upper-window witness. The schedule S and observation row W then provide the rational data consumed by R.

Directed-window transport is componentwise through H and replayed through C. These rows preserve the same windows, observations, classifier reads, and handoff rows; they do not add a cofinal choice function or a quotient relation on nets.

If a consumer asks for convergence data without a displayed common-window witness, no coordinate of K can supply it. The package provenance records the request as outside the finite packet boundary. The only real-facing route is therefore the handoff L through the same $\mathsf{RegSeqRat}^\uparrow$ row, which gives the stated $\mathsf{Real}^\uparrow$ boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyNet}^\uparrow}$**.**

Constructive story: A $\mathsf{CauchyNet}^\uparrow$ packet is generated from a finite directed index-window ledger, a $\mathsf{StreamName}^\uparrow$ schedule, $\mathsf{DyadicRatCore}^\uparrow$ observation rows, a $\mathsf{RegSeqRat}^\uparrow$ handoff, an eventual common-window classifier, a $\mathsf{Real}^\uparrow$ handoff, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CauchyNet}^\uparrow}$, maturePackageClosed)

Scope closed: Definition 589.5 is the bridge-facing directed-window public export over $\mathsf{StreamName}^\uparrow$, $\mathsf{RegSeqRat}^\uparrow$, $\mathsf{DyadicRatCore}^\uparrow$, $\mathsf{Real}^\uparrow$, BHist, hsame, Cont, Pkg, and NameCert rows of the quotient-free packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CauchyNet}^\uparrow}$, unformalized)

Bridge status: none

Origin: human
Not claimed: This chapter does not close quotient nets, selected limits, ambient completeness, cofinal choice, or a uniform-space standard bridge.
Upgrade path: Bridged closure requires a standard bridge for the same quotient-free directed-window packet.

Definition 589.3 (CauchyNet witness-complete finite subwindow)**.** *Let*

$$K = (D, S, R, W, T, L, H, C, P, N)$$

be an accepted $\mathsf{CauchyNet}^{\uparrow}$ *carrier, and let* Ω *be a finite directed subwindow of the displayed index-window ledger* D*. The subwindow* Ω *is witness-complete for a displayed finite tolerance family* E *when the retained rows*

$$D_\Omega, S_\Omega, R_\Omega, W_\Omega, T_\Omega, L_\Omega, H_\Omega, C_\Omega, P_\Omega, N_\Omega$$

satisfy the following conditions:

1. D_Ω *is the finite directed subledger of* D *on* Ω*, and for every tolerance request in* E *the common upper-window witness named by the original classifier row* T *lies in* D_Ω*;*
2. S_Ω *contains exactly the scheduled* $\mathsf{StreamName}^{\uparrow}$ *observation names from* S *whose directed addresses are in* D_Ω *and are used by those retained common-window witnesses;*
3. W_Ω *contains exactly the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation and comparison rows from* W *read by the retained scheduled observations;*
4. T_Ω *is the common-window classifier row restricted to the requests in* E*, with each classifier entry using its displayed witness from* D_Ω*;*
5. R_Ω *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *row obtained by restricting the original row* R *to the retained schedule, observation, comparison, and classifier entries;*
6. L_Ω *is the* $\mathsf{Real}^{\uparrow}$ *handoff row whose source is the retained row* R_Ω*;*
7. H_Ω *and* C_Ω *are the componentwise restrictions of the displayed* hsame *transports and* Cont *routes whose endpoints are among the retained rows;*
8. P_Ω *and* N_Ω *are the provenance and local* $\mathsf{NameCert}_{\mathsf{CauchyNet}^{\uparrow}}$ *rows restricted to the same retained coordinates.*

Lean4 (definition) `BEDC.Derived.CauchyNetUp.CauchyNetWitnessCompleteSubwindow`

Theorem 589.4 (CauchyNet finite subwindow restriction)**.** *Let*

$$K = (D, S, R, W, T, L, H, C, P, N)$$

be an accepted $\mathsf{CauchyNet}^{\uparrow}$ *carrier in the sense of Definition 589.1. If* Ω *is witness-complete for a displayed finite tolerance family* E *in the sense of Definition 589.3, then*

$$K_\Omega = (D_\Omega, S_\Omega, R_\Omega, W_\Omega, T_\Omega, L_\Omega, H_\Omega, C_\Omega, P_\Omega, N_\Omega)$$

is an accepted $\mathsf{CauchyNet}^{\uparrow}$ *carrier. Moreover, every* $\mathsf{Real}^{\uparrow}$ *read exported by* L_Ω *factors through the retained* $\mathsf{RegSeqRat}^{\uparrow}$ *row* R_Ω*, and* R_Ω *is the restriction of the same* $\mathsf{RegSeqRat}^{\uparrow}$ *row* R *used by the original packet.*

Lean4 ✓ `BEDC.Derived.CauchyNetUp.CauchyNetWitnessCompleteSubwindow carrier restriction`

Proof. Unfold the carrier of Definition 589.1. A $\mathsf{CauchyNet}^{\uparrow}$ carrier has exactly the displayed rows

$$D, S, R, W, T, L, H, C, P, N.$$

The witness-complete subwindow supplies one retained row for each of these coordinates. Thus K_Ω has the required directed index-window ledger, schedule, regular rational row, dyadic observation row, common-window classifier, real handoff, componentwise transports, continuation routes, provenance, and local naming row.

The common-window obligation remains internal to the retained packet. For every tolerance request in E, witness-completeness keeps the common upper-window witness selected by T inside D_Ω. It also keeps the scheduled observation names in S_Ω and the dyadic comparison rows in W_Ω that are read at that witness. Hence the restricted classifier row T_Ω does not appeal to any vertex, observation, or comparison outside the finite subwindow.

The regular rational row is not recomputed from an external net. By definition of witness-completeness, R_Ω is the restriction of the original $\mathsf{RegSeqRat}^{\uparrow}$ row R to the retained schedule, observation, comparison, and classifier entries. Therefore each retained regular rational read is attached to the same finite directed-window evidence that justified it in K.

The transport and continuation rows also remain closed under restriction. The rows H_Ω and C_Ω retain only componentwise hsame transports and Cont routes whose endpoints are among $D_\Omega, S_\Omega, R_\Omega, W_\Omega, T_\Omega$, and L_Ω. The package and local naming rows P_Ω and N_Ω name precisely those retained coordinates, so no hidden cofinal choice function, quotient of nets, selected limit point, or ambient completeness theorem is introduced.

Apply the obligation surface of Definition 589.2. Carrier admission is the displayed restricted tuple. Eventual common-window classification is supplied by T_Ω because all requested witnesses remain in D_Ω. Directed-window transport is supplied by H_Ω and C_Ω. Ledger non-escape holds because a request outside E or outside the retained witness ledger has no coordinate in K_Ω from which convergence data can be exported. Finally, the only real-facing row is L_Ω, and its source is exactly R_Ω. Thus every $\mathsf{Real}^{\uparrow}$ handoff factors through the same restricted $\mathsf{RegSeqRat}^{\uparrow}$ row, with R_Ω inherited from R. □

Theorem 589.5 (CauchyNet directed-window localization)**.** *Let*

$$K = (D, S, R, W, T, L, H, C, P, N)$$

be an accepted $\mathsf{CauchyNet}^{\uparrow}$ *carrier, and let* Ω *be witness-complete for a displayed finite tolerance family* E *in the sense of Definition 589.3. Then every* $\mathsf{Real}^{\uparrow}$ *handoff exported by the restricted row* L_Ω *is determined by the retained directed-window rows*

$$D_\Omega, S_\Omega, R_\Omega, W_\Omega, T_\Omega, H_\Omega, C_\Omega, P_\Omega, N_\Omega.$$

No omitted directed vertex, cofinal choice function, quotient net, selected limit point, or ambient completeness row can change that handoff.

Proof. Unfold the witness-complete subwindow definition. The retained ledger D_Ω contains every common upper-window witness used by the displayed tolerance family E, while S_Ω and W_Ω contain exactly the scheduled observation names and dyadic comparison rows read at those witnesses. The classifier row T_Ω therefore has no address outside the retained directed window from which to read convergence evidence.

Apply Definition 589.4. The restricted tuple

$$K_\Omega = (D_\Omega, S_\Omega, R_\Omega, W_\Omega, T_\Omega, L_\Omega, H_\Omega, C_\Omega, P_\Omega, N_\Omega)$$

is itself an accepted $\mathsf{CauchyNet}^{\uparrow}$ carrier, and every real-facing read exported by L_Ω factors through the retained $\mathsf{RegSeqRat}^{\uparrow}$ row R_Ω.

Apply the obligation surface of Definition 589.2 to the accepted carrier K_Ω. Carrier admission is the displayed restricted tuple; eventual common-window classification is T_Ω; directed-window transport is supplied by H_Ω and C_Ω; ledger non-escape is enforced by the absence of any coordinate outside the retained rows; and the real-facing boundary is precisely the handoff through L_Ω from R_Ω.

It remains only to exclude external data. The subwindow definition gives no coordinate for an omitted directed vertex, a cofinal selector, a quotient of nets, a selected limit point, or an ambient completeness theorem. Since the only exported real-facing route is the projection through R_Ω and L_Ω inside K_Ω, changing any such omitted datum cannot affect the $\mathsf{Real}^{\uparrow}$ handoff. □

Lean4 ✓ `BEDC.Derived.CauchyNetUp.CauchyNetDirectedWindow localization`

Chapter 590

A Concrete Naming Certificate for $\mathsf{ClassifierMorphism}^{\uparrow}$

The $\mathsf{ClassifierMorphism}^{\uparrow}$ surface records the classifier-preserving layer between type-checking membership packets and broader naming-certificate morphisms. It keeps the source and target classifier packets visible, stores the graph that moves source histories to target histories, and exposes preservation only through finite Ext, SigRel, Cont, hsame, Pkg, and NameCert rows.

Definition 590.1 (ClassifierMorphism carrier)**.** *A* $\mathsf{ClassifierMorphism}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (A, B, G, E, S, C, H, P, N)$$

with the following displayed coordinates:

1. *A is the source classifier-membership packet, including its carrier,* Ext*,* SigRel*,* Cont*, and local naming rows;*
2. *B is the target classifier-membership packet, including the corresponding target carrier, classifier, signature-answer, continuation, and naming rows;*
3. *G is the finite graph row relating source histories in A to target histories in B;*
4. *E records* Ext *preservation along G, sending every accepted source membership row to an accepted target membership row;*
5. *S records* SigRel *preservation along G, sending every displayed source classifier answer to the corresponding target classifier answer;*
6. *C records* Cont *preservation, routing every source continuation edge through a target continuation edge over the same graph row;*
7. *H stores componentwise* hsame *preservation for source and target carrier rows, membership rows, signature rows, continuation rows, graph rows, and local certificate rows;*
8. *P is the* Pkg *provenance over* BHist*,* Ext*,* SigRel*,* Cont*,* hsame*, the two classifier packets, and the graph row;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ClassifierMorphism}^{\uparrow}}$ *row.*

The carrier has no coordinate for a host compiler function, quotient equality between source and target histories, semantic type interpretation, or any relation not named by G, E, S, C, H, P, N.

Definition 590.2 (ClassifierMorphism classifier)**.** *For accepted* $\mathsf{ClassifierMorphism}^{\uparrow}$ *carriers* $M = (A, B, G, E, S, C, H, P, N)$ *and* $M' = (A', B', G', E', S', C', H', P', N')$*, the classifier compares exactly the displayed graph row and its preservation ledgers. It may inspect source and target packets only through their visible* Ext*,* SigRel*,* Cont*,* hsame*,* Pkg*, and* NameCert *coordinates, and it accepts a comparison precisely when the preservation rows remain componentwise readable through the displayed* hsame *and* Cont *routes.*

Thus classifier morphisms are finite packets over classifier membership data. They do not identify source and target histories by host equality, and they do not collapse into the larger compiler-certificate surface unless a separate $\mathsf{NameCertMorphism}^{\uparrow}$ *packet supplies the extra compiler boundary.*

Lean4 (definition) `BEDC.Derived.ClassifierMorphismUp.ClassifierMorphismPacketClassifier`

Theorem 590.3 (ClassifierMorphism NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ClassifierMorphism}^{\uparrow}}$ *surface consists of the carrier row of Definition 590.1, the classifier row of Definition 590.2, the* Ext *preservation row* E*, the* SigRel *preservation row* S*, the* Cont *preservation row* C*, the componentwise* hsame *preservation row* H*, the dependency package* P*, and the local naming row* N*.*

Every consumer-visible classifier-morphism read must therefore pass through the finite source packet A*, target packet* B*, graph row* G*, and the preservation ledgers* E, S, C, H, P, N*. The packet exports no host compiler function, semantic typing model, quotient equality, or unrecorded relation between the source and target classifier memberships.*

Lean4 ✓ `BEDC.Derived.ClassifierMorphismUp.ClassifierMorphismUp taste gate boundary`

Proof. Project the carrier tuple of Definition 590.1. The only rows available to the local certificate are the source packet, target packet, graph row, three preservation ledgers, transport ledger, provenance row, and local name.

Use the classifier of Definition 590.2. It compares accepted morphism packets by reading those same rows componentwise, so a consumer cannot replace the displayed graph with a host-level function or a semantic relation.

The local certificate is obtained by repacking $A, B, G, E, S, C, H, P, N$ as one $\mathsf{NameCert}_{\mathsf{ClassifierMorphism}^{\uparrow}}$ row. Since the carrier contains no other coordinate, the obligation surface is exhausted by those finite preservation packets. □

Theorem 590.4 (ClassifierMorphism Ext and SigRel preservation)**.** *Let* $M = (A, B, G, E, S, C, H, P, N)$ *be an accepted* $\mathsf{ClassifierMorphism}^{\uparrow}$ *packet. If a source history is accepted by the source* Ext *row of* A *and is related by the graph row* G *to a target history in* B*, then every classifier-visible read of that target history factors through the target* Ext *preservation row* E *and the target* SigRel *preservation row* S*, with the same* hsame*,* Cont*,* Pkg*, and* NameCert *boundary* H, C, P, N*.*

Consequently the morphism preserves membership answers and signature-answer rows before any broader compiler certificate can consume the graph.

Lean4 ✓ `BEDC.Derived.ClassifierMorphismUp.ClassifierMorphismUp ext sigrel preservation`

Proof. Begin with the source membership read. The graph coordinate G is the only row relating the source and target histories, and the preservation coordinate E is the only row that turns source Ext membership into target Ext membership.

Next read the signature answer. The row S is attached to the same graph coordinate, so the target SigRel answer is reached through the same source and target classifier packets rather than through an independent typing semantics.

Finally route both reads through H, C, P, N. These rows record componentwise sameness, continuation access, dependency provenance, and local naming for the same finite packet, so the classifier-visible preservation surface is fixed before any $\mathsf{NameCertMorphism}^{\uparrow}$ compiler boundary is applied. □

Lean4 ✓ `BEDC.Derived.ClassifierMorphismUp.ClassifierMorphismPacket ext sigrel preservation`

Theorem 590.5 (ClassifierMorphism source-target route lock)**.** *Let $M = (A, B, G, E, S, C, H, P, N)$ be an accepted* $\mathsf{ClassifierMorphism}^{\uparrow}$ *packet. Any classifier-preserving read from the source packet A to the target packet B must pass through the same displayed graph row G,* Ext *row E,* SigRel *row S,* Cont *row C, componentwise* hsame *row H, package row P, and local* NameCert *row N.*

In particular, the route cannot split Ext *preservation and* SigRel *preservation into separate host functions, cannot replace the graph row by an unrecorded semantic relation, and cannot consume either preservation row outside the displayed source-target packet.*

Lean4 ✓ `BEDC.Derived.ClassifierMorphismUp.ClassifierMorphismPacket source target route lock`

Proof. Project the accepted carrier using Definition 590.1. The only source-target transport row is G, and the only preservation ledgers attached to it are E, S, C, H, P, and N.

Use the classifier of Definition 590.2. It can inspect source and target packets only through their visible Ext, SigRel, Cont, hsame, Pkg, and NameCert coordinates, so a classifier-preserving read has no independent host function available.

Apply Definition 590.4. It binds target Ext and target SigRel reads to the same graph coordinate and the same support rows.

Finally use Definition 590.3. The local certificate surface is exhausted by $A, B, G, E, S, C, H, P, N$, so the accepted read is locked to that displayed packet and cannot factor through an unrecorded semantic relation. □

Theorem 590.6 (ClassifierMorphism type-membership dependency)**.** *The source packet A and target packet B of an accepted* $\mathsf{ClassifierMorphism}^{\uparrow}$ *carrier are classifier-membership surfaces in the sense of chapter 476. The morphism rows G, E, S, C, H, P, N preserve* Ext*,* SigRel*, and* Cont *reads between those packets, and the preservation route cannot be read as a host compiler function, semantic type interpretation, quotient equality, or unrecorded source-target relation.*

Lean4 ✓ `BEDC.Derived.ClassifierMorphismUp.ClassifierMorphismPacket type membership dependency`

Proof. Read the carrier definition. The rows A and B are explicitly the source and target classifier-membership packets, including their carrier, classifier, signature-answer, continuation, and local naming rows.

Use the classifier definition. A comparison can inspect those packets only through the displayed Ext, SigRel, Cont, hsame, Pkg, and NameCert coordinates, so the graph row G is not a host-level compiler function.

Finally cite the TypeClassifierMembership chapter. It supplies the sibling membership surface for finite type-checking packets, while the Ext and SigRel preservation theorem keeps the route inside G, E, S, C, H, P, N. □

Theorem 590.7 (ClassifierMorphism composition closure)**.** *Given accepted* $\mathsf{ClassifierMorphism}^{\uparrow}$ *packets from a classifier-membership packet A to a packet B and from B to a packet D, their relational graph composite determines an accepted* $\mathsf{ClassifierMorphism}^{\uparrow}$ *packet from A to D. The composed packet preserves* Ext*,* SigRel*,* Cont*, and* hsame *by composing the displayed graph rows,*

preservation ledgers, continuation routes, dependency packages, and local naming rows of the two input packets.

Lean4 ✓ `BEDC.Derived.ClassifierMorphismUp.ClassifierMorphismPacket composition closure`

Proof. Project the first carrier to its source packet, middle packet, graph row, and preservation ledgers. Project the second carrier to the same kind of rows with the first target packet as its source-facing middle packet.

Compose the graph rows relationally through the shared middle packet. For an accepted source membership row, apply the first Ext preservation ledger to reach the middle packet, then apply the second Ext preservation ledger to reach the final packet.

The same concatenation applies to SigRel answers and Cont routes. Componentwise hsame rows compose through the shared middle packet, while the two Pkg and NameCert rows repack the resulting graph and preservation ledgers as one finite $\mathsf{ClassifierMorphism}^{\uparrow}$ carrier. □

Theorem 590.8 (ClassifierMorphism public composition export)**.** *For accepted* $\mathsf{ClassifierMorphism}^{\uparrow}$ *packets from classifier-membership packet A to packet B and from B to packet D, the two-step classifier-preserving route exports a single public* $\mathsf{ClassifierMorphism}^{\uparrow}$ *route from A to D. Its graph,* Ext *preservation,* SigRel *preservation,* Cont *preservation,* hsame *transport,* Pkg *provenance, and local* NameCert *rows are exactly the relational composites of the corresponding displayed rows in the two input packets.*

Thus a downstream naming-certificate morphism consumer may cite one public route from A to D rather than separately reconstructing graph composition, preservation of classifier reads, continuation replay, package provenance, and local naming.

Proof. First build the route. Apply Definition 590.7 to the two accepted packets through the shared middle packet B. The resulting carrier has source A, target D, and graph row given by relational composition of the two displayed graph rows.

Next identify the preservation surface. Use Definition 590.4 on each input packet and on the composed carrier. The Ext and SigRel reads are therefore the composite preservation ledgers, while the Cont and hsame rows are the corresponding composite replay and transport rows.

Finally repack the public export through the local boundary. The NameCert obligation surface and the checked TasteGate boundary recorded for Definition 590.3 expose only the rows G, E, S, C, H, P, N. Since those rows in the composed carrier are precisely the relational composites supplied by Definition 590.7, the exported route contains no extra host function, semantic interpretation, quotient equality, or unrecorded relation. □

Lean4 ✓ `BEDC.Derived.ClassifierMorphismUp.ClassifierMorphismPacket public composition export`

Theorem 590.9 (ClassifierMorphism preservation non-escape scope)**.** *Every classifier-preserving consumer route for an accepted* $\mathsf{ClassifierMorphism}^{\uparrow}$ *packet factors through exactly the displayed source packet A, target packet B, graph row G,* Ext *preservation row E,* SigRel *preservation row S,* Cont *preservation row C, componentwise* hsame *row H,* Pkg *provenance row P, local* NameCert *row N, and the checked TasteGate boundary. The route exports no host compiler function, semantic type interpretation, quotient equality between source and target histories, or unrecorded source-target relation.*

Lean4 ✓ `BEDC.Derived.ClassifierMorphismUp.ClassifierMorphismPacket preservation nonescape scope`

Proof. Start with the obligation surface of Definition 590.3. It identifies the carrier rows $A, B, G, E, S, C, H, P, N$ as the complete local $\mathsf{NameCert}_{\mathsf{ClassifierMorphism}^{\uparrow}}$ inventory.

Use Definition 590.4 for classifier-preserving reads. The source membership read passes through G and E, while the signature-answer read passes through the same graph and the preservation row S.

Use Definition 590.7 for consumer routes that pass through more than one classifier morphism. Composition only concatenates displayed graph rows, preservation ledgers, continuation routes, package rows, and local naming rows.

The checked TasteGate boundary records the same finite packet as an encoded gate surface. Since neither the carrier nor the TasteGate boundary contains a host compiler function, semantic type interpretation, quotient equality, or unrecorded relation, every classifier-preserving route remains inside the displayed scope. □

Theorem 590.10 (ClassifierMorphism kernel compiler route exhaustion)**.** *Every kernel-compiler or naming-certificate-morphism consumer of an accepted* $\mathsf{ClassifierMorphism}^{\uparrow}$ *packet factors through exactly the displayed source packet A, target packet B, graph row G,* Ext *preservation row E,* SigRel *preservation row S,* Cont *preservation row C, componentwise* hsame *transport H, package provenance P, and local* NameCert *row N. The consumer receives no host compiler function, semantic type interpretation, quotient equality between source and target histories, or unrecorded source-target relation.*

Proof. Start with the local inventory. Apply Definition 590.3; it lists $A, B, G, E, S, C, H, P, N$ as the complete carrier and naming-certificate surface available to a $\mathsf{ClassifierMorphism}^{\uparrow}$ packet.

Next route classifier reads through the preservation rows. Use Definition 590.4 to force Ext and SigRel consumers through G, E, S, and use the displayed Cont and hsame rows for continuation replay and componentwise history transport.

For compiler-style consumers that compose routes, apply Definition 590.7. Composition concatenates graph rows, preservation ledgers, continuation routes, package rows, and local naming rows; it does not create an additional host compiler coordinate or semantic type interpretation.

Finally use Definition 590.9. The non-escape row removes quotient equality and unrecorded source-target relations from the consumer interface, so the kernel-compiler route is exhausted by the displayed packet rows. □

Lean4 ✓ `BEDC.Derived.ClassifierMorphismUp.ClassifierMorphismPacket kernel compiler route exhaustion`

Closure status for $\mathsf{NameCert}_{\mathsf{ClassifierMorphism}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ClassifierMorphism}^{\uparrow}$ packet is generated from source and target classifier-membership packets, a finite graph row, Ext, SigRel, Cont, and hsame preservation rows, package provenance, and a local naming row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ClassifierMorphism}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 590.1, Definition 590.2, Definition 590.3, Definition 590.4, Definition 590.7, and Definition 590.9 bind the finite classifier-preservation packet between type-checking membership and naming-certificate morphism surfaces.

Lean target: `BEDC.Derived.ClassifierMorphismUp.taste\_gate`

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ClassifierMorphism}^{\uparrow}}$, encodedDef)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close host compiler semantics, quotient equality between source and target histories, semantic typing interpretation, or bridge checking.

Upgrade path: The paper-axis closure is complete; formal-status and bridge checking remain separately reported by the verification and bridge axes.

Chapter 591

A Concrete Naming Certificate for $\mathsf{RuntimeCandidateBoundary}^{\uparrow}$

The $\mathsf{RuntimeCandidateBoundary}^{\uparrow}$ interface realizes the runtime-candidate boundary of Definition 9461.21 as a finite NameCert packet. It records object-level rows for coded CIC* expressions, proof objects, states, transitions, accepted-result classification, stability transports, consumer routes, package provenance, and local naming, while leaving validation by the host checker outside the packet. The bounded finite-trace evaluator of chapter 818 consumes this boundary by reading the object-level source, transition, accepted-result, transport, route, provenance, and local naming rows while keeping host validation external.

The packet is the object-level candidate boundary consumed by chapter 818 and sits below the runtime-request and refusal packet of chapter 890. The substantive dependency is the row split: $\mathsf{RuntimeCandidateBoundary}^{\uparrow}$ supplies the source, transition, accepted-result, transport, route, provenance, and local-name rows $R = (S, T, A, H, C, P, N)$; $\mathsf{RuntimeReflectionBoundary}^{\uparrow}$ adds request, refusal, and report rows above that candidate surface; and $\mathsf{FiniteTraceEvaluator}^{\uparrow}$ consumes the candidate boundary as its bounded evaluator provenance.

Definition 591.1 (Runtime-candidate boundary carrier)**.** *A* $\mathsf{RuntimeCandidateBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (S, T, A, H, C, P, N)$$

with the following visible rows:

1. *S is the source row of coded* CIC* *expressions, proof objects, and states visible to the candidate;*
2. *T is the transition row recording the checking or evaluation steps claimed by the candidate on the source row S;*
3. *A is the accepted-result classifier row, grouping transition outputs that the candidate records as accepted results;*
4. *H stores componentwise* hsame *transports for the source, transition, accepted-result, package, and naming rows;*
5. *C stores the displayed* Cont *routes by which consumers read the source codes, transition rows, accepted-result classifier, transports, provenance, and local naming row;*
6. *P is the* Pkg *provenance over* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*, and the structural* CIC* *coding interface;*

7. *N is the local* $\mathsf{NameCert}_{\mathsf{RuntimeCandidateBoundary}^{\uparrow}}$ *row.*

The local classifier relates two packets exactly when their displayed source, transition, accepted-result, transport, route, provenance, and naming rows compare through the rows H and C. The carrier has no coordinate for the host judgment that the candidate is a valid BEDC checker.

Lean4 ✓ `BEDC.Derived.RuntimeCandidateBoundaryUp.RuntimeCandidateBoundaryTasteGate single carrier alignment`

Theorem 591.2 (Runtime-candidate validation non-entry)**.** *For every accepted* $\mathsf{RuntimeCandidateBoundary}^{\uparrow}$ *carrier $R = (S, T, A, H, C, P, N)$, validation of the candidate is not one of the packet rows corresponding to* $\mathsf{SourceSpec}_R$, $\mathsf{PatternSpec}_R$, $\mathsf{ClassifierSpec}_R$, $\mathsf{StabilityCert}_R$, *or* $\mathsf{LedgerPolicy}_R$. *It is therefore not obtainable as a source code in S, a transition pattern in T, an accepted-result classifier entry in A, a stability transport in H, or a ledger/provenance row in P.*

Proof. Project the accepted packet to its visible rows. The source field is exhausted by S: it contains coded CIC* expressions, proof objects, and states, but no judgment that those codes form a correct checker for BEDC.

The pattern and classifier fields are exhausted by T and A. They record transition behavior and accepted-result grouping internal to the candidate. Reading either row can expose what the candidate claims for a coded input; it cannot certify that the candidate itself is the host validation act.

The stability, route, and package fields are exhausted by H, C, P, N. These rows transport, read, name, and record provenance for the displayed finite packet. If validation were placed in any one of them, it would be another coded row of the same candidate and would again require validation as a certificate. Thus the carrier remains an object-level runtime candidate rather than a self-validating runtime. □

Theorem 591.3 (Runtime-candidate boundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RuntimeCandidateBoundary}^{\uparrow}}$ *surface for the carrier of Definition 591.1 consists of five finite obligations:*

1. *carrier admission for the displayed packet $R = (S, T, A, H, C, P, N)$;*
2. *classifier transport by componentwise* hsame *and* Cont *on the source, transition, accepted-result, package, and local naming rows;*
3. *runtime-result ledger exactness, requiring every accepted-result row to be exactly a displayed row of A reached from a displayed transition row of T;*
4. *validation non-escape, requiring every claim that the candidate is valid to remain outside S, T, A, H, C, P, N rather than appearing as a hidden packet coordinate;*
5. *reflection-boundary handoff, requiring the packet to cite the structural* CIC* *interpretation of Definition 9461.11 and the runtime-candidate boundary of Definition 9461.22 without promoting either citation to an internal host validator.*

Consequently the certificate names the object-level runtime-candidate interface and its finite result ledger, but it does not assert an internal truth predicate or a host checker inside BEDC.

Proof. Carrier admission is tuple projection. The packet $R = (S, T, A, H, C, P, N)$ is finite, and each displayed row is part of the same BHist carrier.

Classifier transport is componentwise. The hsame row H compares displayed source, transition, accepted-result, package, and naming rows, while the Cont row C records exactly the reads available to a consumer.

Runtime-result ledger exactness follows by reading T before A. A row can count as an accepted result only when the carrier displays the transition claim in T and the corresponding accepted-result classifier entry in A.

Validation non-escape is the boundary clause. By Definition 591.2, validation is not one of the source, pattern, classifier, stability, or ledger rows. The final handoff is therefore only a citation to the structural CIC* interpretation and to the runtime-candidate boundary, not an internal host validator. □

Closure status for $\mathsf{NameCert}_{\mathsf{RuntimeCandidateBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{RuntimeCandidateBoundary}^{\uparrow}$ packet is generated from displayed source, transition, accepted-result, componentwise transport, visible route, package provenance, and local naming rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RuntimeCandidateBoundary}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 591.1, Definition 591.2, Definition 591.3, and

Lean4 ✓ `BEDC.Derived.RuntimeCandidateBoundaryUp.taste gate`

bind the displayed runtime-candidate packet rows, validation boundary, local certificate surface, and public object-level runtime-candidate export consumed by finite-trace evaluators.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RuntimeCandidateBoundary}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.RuntimeCandidateBoundaryUp.RuntimeCandidateBoundaryTasteGate\_single\_carrier\_alignmen`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close host validation, an internal truth predicate, a self-validating runtime, or bridge checking.

Upgrade path: No paper-theory closure upgrade remains; formal bridge checking is a separate verification-axis target over the same source, transition, accepted-result, transport, route, provenance, and local naming rows.

Chapter 592

A Concrete Naming Certificate for FreeWillInscriptionCommitment$^{\uparrow}$

The FreeWillInscriptionCommitment$^{\uparrow}$ surface packages the free-will reading of Definition 9415.6 as finite NameCert data. It records the prior-record boundary, the inscription-event row, GAP provenance, classifier transport, and the local non-reduction ledger that prevents the packet from becoming a hidden deterministic reducer, a selected novelty source, or a host-side theory of agency.

The commitment packet consumes the inscription-event carrier of chapter 519 and the gap-ledger surface of chapter 520. In the displayed carrier below, I is the event row, G is the gap provenance row, and R records that consumers may compare the event with the prior boundary without extracting a closed reducer from B to I.

Theorem 592.1 (FreeWillInscriptionCommitment inscription-event route)**.** *Every accepted* FreeWillInscriptionCom *packet reads its inscription-event coordinate I through the finite* InscriptionEvent$^{\uparrow}$ *surface of chapter 519 before the non-reduction ledger R is exposed. The route records prior boundary, inscription row, GAP provenance, transport, continuation, package, and local name, and it exports no hidden agency source or deterministic reducer.*

Lean4 ✓ `BEDC.Derived.FreeWillInscriptionCommitmentUp.FreeWillInscriptionCommitment inscription event route`

Proof. Project the accepted carrier as $W = (B, I, G, T, R, H, C, P, N)$. The coordinate I is the only inscription-event row in the packet, and it is displayed together with the prior boundary B and GAP provenance G before the ledger row R is read.

Read I through the concrete InscriptionEvent$^{\uparrow}$ surface named by chapter 519. The transport row T, componentwise hsame row H, displayed Cont row C, package row P, and local naming row N replay that same finite event route.

Finally apply the non-escape boundary of Definition 592.4. Since the carrier has no coordinate for a hidden agency source or a deterministic reducer from B to I, exposing R cannot add one after the inscription-event read. □

Definition 592.2 (FreeWillInscriptionCommitment carrier)**.** *A* FreeWillInscriptionCommitment$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (B, I, G, T, R, H, C, P, N)$$

with the following displayed rows:

1. *B is the prior-record boundary, listing the records available before the inscription event;*
2. *I is the inscription-event row, naming the finite record added at the event point;*
3. *G is the* GAP *provenance row, recording that the event is treated as an inscription point rather than as a substrate-internal derivation from B;*
4. *T is the classifier-transport row, carrying the visible comparison between prior boundary, inscription event, and provenance data;*
5. *R is the non-reduction ledger, recording that consumer reads may compare the event with B but may not extract a closed reducer from B to I;*
6. *H records componentwise* hsame *transports for B, I, G, T, R, package provenance, and the local naming row;*
7. *C records the* Cont *routes that expose the prior boundary, inscription event, GAP provenance, classifier transport, and non-reduction ledger without adding an unrecorded agency primitive;*
8. *P is the* Pkg *row for the finite BEDC dependencies named by the commitment;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{FreeWillInscriptionCommitment}^{\uparrow}}$ *row.*

The carrier is exactly this finite packet. It contains no hidden faculty of will, no selected novelty source, no deterministic reducer from the prior boundary to the inscription event, no host psychology predicate, and no ambient metaphysical agency oracle.

Lean4 ✓ `BEDC.Derived.FreeWillInscriptionCommitmentUp.FreeWillInscriptionCommitmentTasteGate single carrier alignment`

Theorem 592.3 (FreeWillInscriptionCommitment NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FreeWillInscriptionComm}}$ *surface has five finite obligations: carrier exposure by Definition 592.2; prior-boundary accountability for the displayed record row B; inscription-event accountability for the displayed event row I and GAP provenance row G; classifier stability for the visible transport rows T, H, C and package row P; and non-escape from hidden faculties of will, selected novelty sources, deterministic reducers, host psychology predicates, and ambient metaphysical agency oracles.*

Lean4 ✓ `BEDC.Derived.FreeWillInscriptionCommitmentUp.FreeWillInscriptionCommitment namecert obligations`

Proof. Carrier exposure is projection from the finite tuple $W = (B, I, G, T, R, H, C, P, N)$. Every consumer-facing coordinate is one of the displayed rows.

Prior-boundary accountability reads B, while inscription-event accountability reads I together with the GAP provenance row G. These two obligations keep the event located at the finite boundary named by the packet.

Classifier stability is componentwise through T, H, C, P. The transport rows compare and replay the visible boundary, event, provenance, and ledger data; they do not add a hidden decision procedure or an unrecorded source of novelty.

The non-escape obligation is the inventory boundary. The carrier has no coordinate for a hidden faculty, selected novelty source, deterministic reducer, host psychology predicate, or ambient agency oracle, so the local NameCert row cannot export one. □

Theorem 592.4 (FreeWillInscriptionCommitment non-escape boundary)**.** *No consumer of an accepted* $\mathsf{FreeWillInscriptionCommitment}^{\uparrow}$ *packet can extract a hidden faculty of will, a selected*

novelty source, a deterministic reducer from the prior-record boundary to the inscription-event row, a host psychology predicate, or an ambient metaphysical agency oracle. Every consumer read factors through $B, I, G, T, R, H, C, P, N$.

Lean4 ✓ `BEDC.Derived.FreeWillInscriptionCommitmentUp.FreeWillInscriptionCommitment nonescape`

Proof. Inspect the carrier coordinates of Definition 592.2. The prior-record boundary, inscription-event row, GAP provenance, classifier transport, non-reduction ledger, componentwise transports, continuations, package provenance, and local naming row are the whole exported surface.

The rows T, H, C transport only the displayed rows. They may compare the prior boundary with the inscription event and replay the GAP provenance, but they have no coordinate that computes I from B as a closed substrate-internal reducer.

The row R records the non-reduction ledger rather than a hidden source. Since no remaining row names a faculty of will, selected novelty source, host psychology predicate, or ambient agency oracle, every such attempted read has no projection target in the packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{FreeWillInscriptionCommitment}^{\uparrow}}$.

Constructive story: A $\mathsf{FreeWillInscriptionCommitment}^{\uparrow}$ packet is generated from a prior-record boundary, an inscription-event row, GAP provenance, classifier transport, a non-reduction ledger, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FreeWillInscriptionCommitment}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 592.2, Definition 592.3, and Definition 592.4 bind the finite inscription-event commitment surface and its non-reduction boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FreeWillInscriptionCommitment}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a Lean implementation, bridge status, hidden faculty of will, selected novelty source, deterministic reducer, host psychology predicate, or ambient metaphysical agency oracle.

Upgrade path: Obligation closure requires Lean encoding of the carrier and checked theorems for NameCert obligations and the non-escape boundary.

Chapter 593

A Concrete Naming Certificate for $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$

The $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ interface records the finite witness schedule used by the real-completion diagonal construction when a regular Cauchy sequence supplies an explicit modulus. It packages the selected modulus row, the finite stream window, the dyadic observation ledger, the diagonal readback, and the $\mathsf{Real}^{\uparrow}$ seal handoff as one local naming certificate. It does not export a quotient stream, a selected completed real, host real equality, or ambient completeness.

Definition 593.1 (Regular Cauchy witness schedule carrier)**.** *A* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

with the following displayed coordinates:

1. *X is the* $\mathsf{RegSeqRat}^{\uparrow}$ *family row for the regular Cauchy input;*
2. *μ is the explicit modulus row selecting the regular-Cauchy source index for a requested tolerance;*
3. *W is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window schedule at the selected modulus index;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger recording the endpoint, radius, tolerance, and comparison rows used by the scheduled read;*
5. *R is the diagonal readback row naming the rational observation read from X_μ through W and D;*
6. *T is the* $\mathsf{Real}^{\uparrow}$ *seal handoff row reached after the displayed diagonal readback;*
7. *H stores componentwise* hsame *transport for the family row, modulus row, window schedule, dyadic ledger, readback row, seal row, provenance, and local name;*
8. *C stores the displayed* Cont *routes from the modulus request to W, from W to D, from D to R, and from R to T;*
9. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}}$ *row.*

The carrier is a finite witness packet for the modulus-selected diagonal observation route. It contains no unbounded stream object, quotient equality, selected limit, host real equality, or completeness theorem.

Lean4 ✓ `BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleTasteGate single carrier alignment`

Theorem 593.2 (Regular Cauchy witness schedule NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWitnessSc}}$ *surface for the carrier of Definition 593.1 consists exactly of carrier admission,* $\mathsf{RegSeqRat}^{\uparrow}$ *family admission, explicit modulus exposure, selected* $\mathsf{StreamName}^{\uparrow}$ *window scheduling,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation-ledger readback, diagonal readback,* $\mathsf{Real}^{\uparrow}$ *seal handoff, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and the local naming row.*

Lean4 ✓ `BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleSemanticNameCert`

Proof. Carrier admission is projection from the displayed packet S. Its coordinates list the regular Cauchy family row, selected modulus row, finite window schedule, dyadic ledger, diagonal readback, seal handoff, transports, routes, provenance, and local name.

The modulus and window rows make the diagonal observation finite. A consumer first reads the tolerance through μ, then opens only the scheduled window W, and then reads the dyadic ledger D and diagonal row R.

The remaining rows transport and name the same route. Since the packet has no coordinate for quotient streams, selected completed reals, host equality, or ambient completeness, the listed rows exhaust the local naming certificate. □

Theorem 593.3 (Regular Cauchy witness schedule window-modulus alignment)**.** *For an accepted* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *carrier, every scheduled window read is aligned with the displayed modulus row* μ*. If a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer asks for the diagonal observation at a tolerance already routed through* μ*, the only admissible window is the stored finite* $\mathsf{StreamName}^{\uparrow}$ *schedule* W *at that selected modulus index, transported through* H *and replayed through* C*.*

Lean4 ✓ `BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleCarrier window modulus alignment`

Proof. Project the accepted carrier. The only source-index selector is the modulus row μ, and the only scheduled window attached to that selector is W.

Use the local NameCert obligations to bind the consumer read to the displayed coordinates. The continuation route from the modulus request to the window has no alternative branch, and the transport rows preserve the selected index and window together.

Thus the read cannot replace W by an independent schedule or inspect an unbounded stream. The finite window is aligned with the displayed modulus row by the carrier itself. □

Theorem 593.4 (Regular Cauchy witness schedule diagonal readback)**.** *For an accepted* RegularCauchyWitnessSche *carrier, the diagonal readback row* R *is read only through the route*

$$X, \mu, W, D, H, C, P, N.$$

It records the rational observation obtained from the $\mathsf{RegSeqRat}^{\uparrow}$ *family row at the modulus-selected source index and the corresponding finite window, with the dyadic observation ledger* D *supplying the displayed tolerance and comparison rows.*

Lean4 ✓ `BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleCarrier diagonal readback lock`

Proof. Begin with the carrier projection. The row R appears after X, μ, W, and D, so any readback must first pass through the source family, the selected modulus row, the finite window, and the dyadic ledger.

Apply window-modulus alignment to keep the scheduled read on the same selected index. Then use the displayed continuation route from W to D and from D to R.

The transport and provenance rows repack this same readback route. No carrier coordinate offers a quotient stream, a host real comparison, or a separate diagonal oracle. □

Theorem 593.5 (Regular Cauchy witness schedule non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet factors through the finite rows*

$$X, \mu, W, D, R, T, H, C, P, N.$$

The consumer may read the regular Cauchy family, the explicit modulus, the selected finite window, the dyadic observation ledger, the diagonal readback, the $\mathsf{Real}^{\uparrow}$ *seal handoff, componentwise transports, continuation routes, package provenance, and local naming row; it cannot read a quotient stream, selected completed real, host real equality, unbounded diagonal stream, or ambient completeness witness.*

Proof. Project the accepted packet and the local naming surface. The displayed rows of S are exactly $X, \mu, W, D, R, T, H, C, P, N$.

Window-modulus alignment controls every scheduled observation route. Diagonal readback then forces the rational observation through the displayed dyadic ledger before any seal-facing row can be consumed.

Since no other coordinate exists, a downstream consumer has no route to unlisted analytic data. The packet therefore keeps the diagonal witness schedule inside the finite BEDC carrier. □

Theorem 593.6 (Regular Cauchy witness schedule local certificate package)**.** *The carrier, local* $\mathsf{NameCert}$ *obligations, window-modulus alignment, diagonal readback, and non-escape theorem jointly form the local certificate package for the modulus-indexed finite observation route from* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{StreamName}^{\uparrow}$ *data through* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback to the* $\mathsf{Real}^{\uparrow}$ *seal.*

The package exports no quotient stream, selected limit, host real equality, unbounded diagonal stream, or ambient completeness theorem.

Proof. Start from the finite carrier of Definition 593.1. It exposes exactly the regular Cauchy family, modulus row, scheduled window, dyadic ledger, diagonal readback, seal handoff, transports, routes, provenance, and local name.

Add the local obligation theorem. It identifies those rows as the complete $\mathsf{NameCert}_{\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}}$ surface for the witness schedule.

Window-modulus alignment and diagonal readback bind the operational route: the selected source index comes from μ, the finite window is W, the observation ledger is D, and the readback is R.

Finally apply non-escape. The package therefore presents the Real-completion diagonal observation as a finite naming certificate and not as a quotient stream or host-level real equality assertion. □

Theorem 593.7 (Regular Cauchy witness schedule finite-route correspondence)**.** *For an accepted* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet*

$$S = (X, \mu, W, D, R, T, H, C, P, N),$$

the finite observation route from the $\mathsf{RegSeqRat}^{\uparrow}$ *family row through the selected* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and the* $\mathsf{Real}^{\uparrow}$ *seal is exactly the conjunction of the following displayed rows: modulus selection by* μ*, window scheduling by* W*, dyadic ledger readback by* D*, diagonal row* R*, seal handoff* T*, componentwise* hsame *transport by* H*, displayed* Cont *replay by* C*, package provenance by* P*, and local* NameCert *naming by* N*.*

Equivalently, a consumer has access to that four-object route precisely when it reads the finite rows $X, \mu, W, D, R, T, H, C, P, N$ *under the local certificate package of Definition 593.6. The correspondence does not assert* $\mathsf{Real}^{\uparrow}$ *completeness, quotient equality, host real equality, or equality of completed limits.*

Proof. Project the accepted packet S. The carrier of Definition 593.1 lists exactly the RegSeqRat family row, modulus row, selected StreamName window, DyadicRatCore ledger, diagonal readback, RealUp seal handoff, transports, routes, provenance, and local name.

Apply Definition 593.2 to identify those coordinates as the complete local naming surface. Then use Definition 593.3 to bind the requested tolerance to μ and the scheduled window W.

Apply Definition 593.4 to route the rational observation through D and R, and use Definition 593.6 to repack the handoff to T with H, C, P, and N. Finally, Definition 593.5 keeps the packet finite, so no unlisted analytic object can be read from the route.

Because this chapter is marked `\origin{ai}`, any later promotion beyond seed closure must cite the corresponding TasteGate target before the closure grade is advanced. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleUp taste gate boundary`

Theorem 593.8 (Regular Cauchy witness schedule public boundary)**.** *For an accepted* RegularCauchyWitnessSched *packet*

$$S = (X, \mu, W, D, R, T, H, C, P, N),$$

the public boundary exported to completion-facing consumers is exactly the conjunction of the local NameCert *obligations, window-modulus alignment, diagonal readback, non-escape, local certificate package, and finite-route correspondence. Thus any* $\mathsf{Real}^{\uparrow}$ *diagonal-seal consumer that reads this packet must factor through the finite* BHist *rows* $X, \mu, W, D, R, T, H, C, P, N$ *and through no quotient stream, host real equality, selected completed limit, unbounded diagonal stream, or ambient completeness witness.*

Proof. Apply Definition 593.2 to identify the complete local naming surface, and apply Definition 593.3 to bind every scheduled window read to the modulus row μ and the finite window W.

Next use Definition 593.4 to route the rational observation through D and R. The non-escape theorem then rules out any boundary data outside the finite rows of S.

The local certificate package of Definition 593.6 repacks those obligations as the certificate visible to downstream consumers, while Definition 593.7 identifies the same data with the route from $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ through $\mathsf{DyadicRatCore}^{\uparrow}$ to the $\mathsf{Real}^{\uparrow}$ seal.

Because the chapter carries the displayed TasteGate marker

BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleTasteGate_single_carrier_ali

the public boundary is exported only as this finite packet boundary. It does not supply completeness, quotient equality, or host real equality. □

Theorem 593.9 (Regular Cauchy witness schedule Real handoff dependency)**.** *Every accepted* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *Real handoff factors through the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *family row, the selected* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and the* $\mathsf{Real}^{\uparrow}$ *seal row. In coordinates, the handoff route for*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

uses X as the regular-rational family row, μ and W as the modulus-selected window, D and R as the dyadic diagonal readback ledger, and T as the Real seal handoff. The only transport surface available to this route is the finite BHist *packet together with the displayed* hsame, Cont, Pkg, *and* NameCert *rows H, C, P, N.*

Consequently no quotient stream, selected completed limit, host real equality, or ambient completeness witness can serve as an alternate source for the accepted Real handoff.

Proof. Project S through the carrier of Definition 593.1. The carrier exposes the family row X, modulus row μ, selected finite window W, dyadic ledger D, diagonal readback R, seal row T, and the rows H, C, P, N in one finite packet.

Apply Definition 593.2 and Definition 593.3. These bind local naming to the displayed rows and force the selected window to be read through μ and W before the dyadic ledger is inspected.

Next use Definition 593.4 and Definition 593.7. The diagonal observation reaches D and R, then the finite route carries the observation from $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ through $\mathsf{DyadicRatCore}^{\uparrow}$ to the $\mathsf{Real}^{\uparrow}$ seal row.

Finally apply Definition 593.8. Since the public boundary is exactly the finite rows of S transported by H, replayed by C, packaged by P, and named by N, the handoff cannot escape to a quotient stream, selected limit, host real equality, or ambient completeness row. □

Theorem 593.10 (Regular Cauchy witness schedule seal-source determinacy)**.** *For an accepted* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet*

$$S = (X, \mu, W, D, R, T, H, C, P, N),$$

every $\mathsf{Real}^{\uparrow}$ *seal consumer route for the scheduled observation is determined by the displayed modulus-window-dyadic route. If two accepted consumer presentations expose the same* $\mathsf{RegSeqRat}^{\uparrow}$ *family row X, modulus row μ, selected finite window W, dyadic ledger D, diagonal readback R, seal row T, componentwise transports H, continuation routes C, package provenance P, and local name N, then they expose the same consumer-visible seal row T.*

No quotient stream, selected completed limit, host real equality, or ambient completeness row can supply an alternate seal source for the scheduled read.

Proof. Start from the carrier of Definition 593.1. It places the family row, modulus selector, finite window, dyadic ledger, diagonal readback, $\mathsf{Real}^{\uparrow}$ seal, transports, routes, provenance, and local name in one finite BHist packet.

Apply the NameCert obligations and window-modulus alignment. These force any seal-facing read to use the same modulus row μ and the same selected finite window W before it reaches the dyadic ledger.

Next use diagonal readback and finite-route correspondence. The rational observation is routed through D and R, and the seal handoff is then the displayed row T transported and replayed through H, C, P, N.

The public boundary theorem rules out any consumer-visible source outside the finite packet. Because the chapter carries the displayed TasteGate marker

BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleTasteGate_single_carrier_ali

the `\origin{ai}` packet is consumed only through this carrier-aligned route. Thus two accepted presentations with the same displayed rows have the same seal source T, and no quotient stream, selected limit, host equality, or completeness row can provide another one. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleCarrier seal source determinacy`

Theorem 593.11 (Regular Cauchy witness schedule window coverage)**.** *For an accepted* RegularCauchyWitnessSche *packet* $S = (X, \mu, W, D, R, T, H, C, P, N)$*, every accepted schedule window is exhausted by the* $\mathsf{RegSeqRat}^{\uparrow}$ *family row* X*, the explicit modulus row* μ*, the* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row* D*. No accepted window can read an additional stream coordinate, host real coordinate, or completion coordinate outside these rows.*

Proof. Project the carrier. The source family row is X, the selector for the requested tolerance is μ, and the only finite schedule attached to that selector is the row W.

The dyadic ledger D records the endpoint, radius, tolerance, and comparison data consumed by the scheduled read. Together X, μ, W, D therefore provide the complete finite window surface.

The remaining rows R, T, H, C, P, N read back, hand off, transport, route, locate, and name that same surface. Since none of them adds another stream, real, or completion coordinate, the accepted window is exhausted by the four displayed rows. □

Theorem 593.12 (Regular Cauchy witness schedule tail route)**.** *Every tail-facing consumer route for an accepted* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet factors through* H, C, P, N *after the finite rows* X, μ, W, D, R, T *have been fixed. Such a consumer can transport the scheduled observation, replay its displayed continuation route, cite its package provenance, and name its local certificate, but it cannot read an unbounded diagonal stream.*

Proof. Use window coverage to bind the finite source of the route to X, μ, W, D. Diagonal readback then fixes the rational observation row R, and seal-source determinacy fixes the consumer-visible $\mathsf{Real}^{\uparrow}$ handoff row T.

The only tail-facing rows left in the carrier are H, C, P, N. These rows preserve and replay the same finite packet; they do not introduce another observation source.

Therefore every tail-facing consumer route is administrative over the displayed finite rows. An unbounded diagonal stream is not a coordinate of the carrier and cannot be recovered from the tail route. □

Theorem 593.13 (Regular Cauchy witness schedule tail-budget factorization)**.** *Let* $S = (X, \mu, W, D, R, T, H, C, P,$ *be an accepted* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet. Every tail-budget consumer or* $\mathsf{Real}^{\uparrow}$ *seal consumer first reads the* $\mathsf{RegSeqRat}^{\uparrow}$ *family row* X*, the selected modulus row* μ*, the finite* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row* D*. Only after these rows have been fixed can the consumer read the rational observation row* R *and the* $\mathsf{Real}^{\uparrow}$ *seal row* T*, transported through* H*, replayed through* C*, packaged by* P*, and named by* N*. The factorization exports no quotient stream, selected limit, host real equality, or ambient completeness witness.*

Proof. Start from the carrier definition for the accepted packet. Its consumer-visible coordinates are exactly $X, \mu, W, D, R, T, H, C, P, N$, so a tail-budget read has no source outside the displayed tuple.

Apply Definition 593.11. It fixes the initial finite window surface as X, μ, W, D before any seal-facing read is available.

Next use Definition 593.12. Tail-facing consumption can only proceed through the rational observation row R, the seal row T, and the administrative route H, C, P, N after the finite window has been selected.

The $\mathsf{Real}^{\uparrow}$ dependency is the handoff of Definition 593.14; it adds a seal row, not an ambient completeness object. Since the chapter carries the displayed TasteGate marker

BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleTasteGate_single_carrier_ali

the `\origin{ai}` consumer boundary is aligned with the same carrier route. Thus every tail-budget or seal consumer factors through the explicit modulus, finite window, dyadic ledger, and seal rows, and no quotient stream, selected limit, host real equality, or completeness witness is exported. □

Theorem 593.14 (Regular Cauchy witness schedule Real handoff)**.** *For an accepted* RegularCauchyWitnessSchedule *packet, the* $\mathsf{Real}^{\uparrow}$ *seal row* T *is a finite handoff from* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *data: it is reached from* X, μ, W, D, R *through the displayed route and then transported, located, and named by* H, C, P, N. *The handoff is not a completeness theorem, quotient-equality theorem, host real equality theorem, or selected-limit theorem.*

Proof. Begin with the displayed route. The regular-rational source is X, the selected index is supplied by μ, the finite window is W, and the dyadic observation ledger is D.

Apply diagonal readback to obtain the observation row R. Then apply seal-source determinacy to identify the $\mathsf{Real}^{\uparrow}$ seal handoff as the row T attached to that same route.

Finally inspect the frontier rows H, C, P, N. They transport, replay, locate, and name the handoff without adding a quotient stream, selected limit, host equality, or completeness row. Thus T is a finite handoff, not an analytic closure claim. □

Theorem 593.15 (Regular Cauchy witness schedule shared-window lock)**.** *Let two accepted* RegularCauchyWitnessS *packets expose the same displayed rows*

$$X, \mu, W, D, R, T, H, C, P, N.$$

Then they expose the same finite schedule route from the $\mathsf{RegSeqRat}^{\uparrow}$ *family row through the selected* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the diagonal readback row, and the* $\mathsf{Real}^{\uparrow}$ *seal row. No alternate stream source, selected limit source, or completeness source can supply a second route for the same displayed packet.*

Lean4 ✓ `BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleCarrier shared window lock`

Proof. Project both accepted packets to the displayed carrier. The coordinates agree on the family row X, modulus selector μ, finite window W, dyadic ledger D, readback R, seal row T, transports H, routes C, provenance P, and local name N.

Apply window-modulus alignment to both packets. The requested tolerance reaches the same selector μ, so the only admissible scheduled window in either packet is the displayed row W.

Next apply diagonal readback and Real handoff. Both routes pass through D and R before reaching the same seal row T, and the rows H, C, P, N replay and name that route without adding a second source.

Because the chapter carries the displayed TasteGate target

BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleTasteGate_single_carrier_ali

the `\origin{ai}` packet is consumed only through the carrier-aligned finite route. Non-escape and the public boundary rule out an alternate unbounded stream, selected limit, or completeness witness. □

Theorem 593.16 (Regular Cauchy witness schedule tail-threshold readback)**.** *For an accepted* RegularCauchyWitnessSchedule$^{\uparrow}$ *packet, every tail-facing threshold request must pass through the modulus row μ, the finite window row W, the dyadic ledger row D, and the diagonal readback row R before it reaches the* Real$^{\uparrow}$ *seal row T. The request cannot bypass those rows through a quotient stream, a host real equality row, or an ambient completeness row.*

Proof. Start with the accepted carrier. The only threshold selector displayed in the packet is μ, and the only scheduled stream window attached to that selector is W.

Use window coverage to bind any tail-facing threshold read to X, μ, W, D. The dyadic ledger row D records the tolerance-facing observation data consumed by the selected window.

Apply diagonal readback to force the request through R. Then apply Real handoff to identify T as the finite Real$^{\uparrow}$ seal row reached after that readback.

The displayed TasteGate boundary

BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleUp_taste_gate_boundary

keeps this `\origin{ai}` route inside the finite packet. Non-escape excludes quotient streams, host equality, and ambient completeness as bypasses around μ, W, D, R, T. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleCarrier tail threshold readback`

Theorem 593.17 (Regular Cauchy witness schedule Real seal readiness)**.** *The carrier of Definition 593.1, the local* NameCert *obligations, window-modulus alignment, diagonal readback, non-escape, public boundary, shared-window lock, and tail-threshold readback form the finite obligation package for the* RegularCauchyWitnessSchedule$^{\uparrow}$ *route from* RegSeqRat$^{\uparrow}$*,* StreamName$^{\uparrow}$*, and* DyadicRatCore$^{\uparrow}$ *data to the* Real$^{\uparrow}$ *seal row.*

The package is limited to the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. It does not assert* Real$^{\uparrow}$ *completeness, equality of completed limits, quotient equality of streams, host real equality, or bridge checking.*

Proof. Begin with the carrier and NameCert obligation theorem. They expose the rows $X, \mu, W, D, R, T, H, C, P, N$ and identify carrier admission, family admission, modulus exposure, window scheduling, dyadic readback, diagonal readback, seal handoff, transports, routes, provenance, and local naming as the certificate surface.

Window-modulus alignment, diagonal readback, and non-escape bind the operational route. Every scheduled observation uses μ, W, D, and R, and no unlisted analytic object can be read from the packet.

The public boundary then packages the same rows for completion-facing consumers. Shared-window lock makes two accepted presentations with the same displayed rows expose the same finite

route, while tail-threshold readback forces every tail-facing threshold request through μ, W, D, R before T.

Finally cite the two TasteGate anchors

BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleTasteGate_single_carrier_ali
BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleUp_taste_gate_bounda

They record that the `\origin{ai}` route is consumed through the finite carrier boundary. The resulting package is therefore an obligation package over the displayed RegSeqRat, StreamName, DyadicRatCore, RealUp, BHist, hsame, Cont, Pkg, and NameCert rows, not a completeness or quotient-equality theorem. □

Theorem 593.18 (Regular Cauchy witness schedule Real-completion handoff lock)**.** *For an accepted* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet*

$$S = (X, \mu, W, D, R, T, H, C, P, N),$$

any completion-facing consumer that reads S must first pass through the displayed analytic rows X, μ, W, D, R, T and then through the certificate rows H, C, P, N. The passage uses window-modulus alignment, diagonal readback, finite-route correspondence, the public boundary, seal-source determinacy, and the Real handoff theorem to identify T as the finite $\mathsf{Real}^{\uparrow}$ *seal handoff for the same route.*

Consequently the handoff lock excludes quotient stream equality, selected completed limits, host real equality, ambient completeness, and choice. None of those objects is a coordinate of the accepted packet, and none is created by the transport, continuation, package, or naming rows.

Proof. Project the accepted carrier. The visible analytic route is exactly X, μ, W, D, R, T, followed by the structural certificate rows H, C, P, N.

Apply window-modulus alignment to bind any tolerance-facing read to the modulus row μ and the finite window W. Apply diagonal readback to force the scheduled observation through the dyadic ledger D and the readback row R.

Use finite-route correspondence and the public boundary to keep the completion-facing consumer inside the same displayed packet. Seal-source determinacy and the Real handoff theorem then identify the consumer-visible seal as the row T reached by that route.

It remains to check non-escape. The rows H, C, P, N only transport, replay, package, and name the same finite data. Since the carrier has no coordinate for quotient stream equality, selected completed limits, host real equality, ambient completeness, or choice, the completion-facing handoff cannot export any of them. □

Theorem 593.19 (Regular Cauchy witness schedule scope-closed route)**.** *For an accepted* RegularCauchyWitnessSch *packet $S = (X, \mu, W, D, R, T, H, C, P, N)$, the scoped route from* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{StreamName}^{\uparrow}$ *data through* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback to the* $\mathsf{Real}^{\uparrow}$ *seal is exactly the finite route witnessed by the carrier, the local* NameCert *obligations, window-modulus alignment, diagonal readback, public boundary, shared-window lock, tail-threshold readback, and Real seal readiness.*

Equivalently, the route is the displayed finite passage

$$(X, \mu, W, D, R, T, H, C, P, N)$$

through BHist, hsame, Cont, Pkg, *and* NameCert *rows. It denies* $\mathsf{Real}^{\uparrow}$ *completeness, quotient streams, selected limits, host real equality, Lean verification, and bridge checking.*

Proof. Project the accepted packet S to the carrier of Definition 593.1. Its coordinates are exactly the regular Cauchy family row X, modulus row μ, finite window W, dyadic ledger D, diagonal readback R, seal row T, transports H, continuation routes C, provenance P, and local name N.

Apply Definition 593.2 to identify those coordinates as the local $\mathsf{NameCert}_{\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}}$ surface. Then use Definition 593.3 and Definition 593.4 to bind the selected tolerance, window, dyadic ledger, and diagonal observation.

The public boundary of Definition 593.8 keeps completion-facing consumption inside the same finite rows. The shared-window lock of Definition 593.15 rules out a second route for another accepted presentation with the same displayed rows, and Definition 593.16 forces every tail-facing threshold request through μ, W, D, R before T.

Finally apply Definition 593.17. The two displayed TasteGate anchors

BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleTasteGate_single_carrier_ali

BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleUp_taste_gate_bounda

bind the `\origin{ai}` packet to this finite carrier boundary. Thus the scoped route is exactly the finite witness route over RegSeqRat, StreamName, DyadicRatCore, RealUp, BHist, hsame, Cont, Pkg, and NameCert rows, and it does not provide RealUp completeness, quotient streams, selected limits, host real equality, Lean verification, or bridge checking. □

Theorem 593.20 (Regular Cauchy witness schedule scoped tail-meet handoff)**.** *For an accepted* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet*

$$S = (X, \mu, W, D, R, T, H, C, P, N),$$

the same finite window, modulus, dyadic readback, and seal route consumed by the shared $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *surface is supplied by the displayed rows of* S*. The route passes through the* $\mathsf{RegSeqRat}^{\uparrow}$ *family row* X*, the* $\mathsf{StreamName}^{\uparrow}$ *finite window* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, the* $\mathsf{Real}^{\uparrow}$ *seal row* T*, and the* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows* H, C, P, N*.*

This handoff exports only the scoped tail/window surface. It exports no quotient stream, selected limit, host equality, completeness row, or independent tail-meet proof.

Proof. Project S to the carrier and apply the local NameCert obligations. The carrier gives the family, modulus, window, dyadic ledger, diagonal readback, seal, transport, continuation, package, and naming rows as one finite packet.

Use window-modulus alignment and diagonal readback to bind the tail-facing request to μ, W, D, and R. Non-escape and the public boundary keep the route inside the displayed BHist rows before the seal row T is consumed.

Apply the scope-closed route theorem. It identifies the finite passage through $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows as the displayed scoped route for this chapter.

The sibling $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ packet consumes exactly that finite tail/window surface as a downstream consumer surface. Since S has no coordinate for quotient streams, selected limits, host equality, or completeness, the handoff is only the scoped finite route and not an additional analytic closure claim. □

Theorem 593.21 (Regular Cauchy witness schedule tail-meet seal comparison)**.** *Let*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet. Let an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet have its paired source, finite-window, modulus, threshold, comparison, transport, route, provenance, and local naming rows transported to the same displayed* W, D, R, T, H, C, P, N *surface. Then the consumer-visible* $\mathsf{Real}^{\uparrow}$ *seal route of* S *is the same finite route consumed by the sibling tail-meet surface.*

Equivalently, both presentations reach the seal only through the displayed $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows. No quotient stream, selected limit, host equality row, or completeness row can distinguish the schedule presentation from the transported tail-meet consumer presentation.*

Proof. Project S to the carrier of Definition 593.1. The carrier and Definition 593.2 expose exactly the rows $X, \mu, W, D, R, T, H, C, P, N$ and no analytic escape coordinate.

Use window-modulus alignment and diagonal readback to bind the route through μ, W, D, R. The Real seal readiness theorem then identifies T as the displayed $\mathsf{Real}^{\uparrow}$ seal reached from the finite $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ data.

Now apply the scope-closed route theorem and the scoped tail-meet handoff. They identify the same route as the finite consumer surface shared with the sibling $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ chapter, whose public surface is recorded in chapter 560.

The two TasteGate anchors

BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleTasteGate_single_carrier_ali
BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleUp_taste_gate_bounda

keep the `\origin{ai}` packet inside this finite carrier boundary. Since both presentations expose the same W, D, R, T, H, C, P, N rows at the consumer surface, and since neither packet supplies quotient streams, selected limits, host equality, or completeness as coordinates, no downstream $\mathsf{Real}^{\uparrow}$ consumer can distinguish the two seal routes. □

Theorem 593.22 (Regular Cauchy witness schedule public seal export)**.** *Every public* $\mathsf{Real}^{\uparrow}$ *seal export of an accepted* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

factors through the displayed finite rows $X, \mu, W, D, R, T, H, C, P, N$*. The export reads the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row* X*, the* $\mathsf{StreamName}^{\uparrow}$ *finite window* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, the* $\mathsf{Real}^{\uparrow}$ *seal handoff* T*, the componentwise* hsame *transports* H*, the displayed* Cont *routes* C*, the* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}}$ *row* N*.*

The same route is pinned by the two TasteGate anchors

BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleTasteGate_single_carrier_alig
BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleUp_taste_gate_boundar

and by the downstream tail-meet seal comparison. It exports no quotient stream, selected completed limit, host real equality, ambient completeness principle, or choice operation.

Proof. Project the accepted packet to the carrier of Definition 593.1. The carrier exposes only $X, \mu, W, D, R, T, H, C, P, N$, and Definition 593.2 identifies these rows as the local NameCert surface.

Use Definition 593.3 and Definition 593.4. They force any tolerance request and diagonal observation to pass through the finite window, modulus, dyadic ledger, and readback rows before the seal row is available.

Apply Definition 593.7, Definition 593.8, and Definition 593.17. These clauses identify the public-facing route as the same finite route from $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ through $\mathsf{DyadicRatCore}^{\uparrow}$ to the $\mathsf{Real}^{\uparrow}$ seal handoff.

Finally use Definition 593.21 together with the two displayed TasteGate anchors. The single-carrier alignment and boundary theorem keep the `\origin{ai}` packet inside the shown carrier rows, while the tail-meet comparison shows that downstream seal consumers see only the same finite surface. Since none of the coordinates is a quotient stream, completed limit selector, host real equality, ambient completeness principle, or choice operation, the public seal export has no escape coordinate. □

Theorem 593.23 (Regular Cauchy witness schedule tail-agreement consumer)**.** *Let*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet. Any paired-tail consumer that compares the scheduled observation of S with a second regular Cauchy source and then enters the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *route of chapter 699 must first factor through the displayed modulus row μ, the finite* $\mathsf{StreamName}^{\uparrow}$ *window W, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback D, the diagonal row R, and the* $\mathsf{Real}^{\uparrow}$ *seal row T of S.*

After those rows have been consumed, the paired route can add only the second source row and the displayed agreement row required by the $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *carrier rows of Definition 699.1. Thus the route reaches the downstream threshold factorization of Definition 699.8 through the public export of Definition 593.22 and the comparison surface of Definition 593.21. It does not introduce quotient streams, host real equality, selected completed limits, ambient completeness, or choice-selected tails.*

Proof. Project S to the carrier of Definition 593.1. The carrier exposes exactly the rows $X, \mu, W, D, R, T, H, C, P, N$, so the scheduled observation has no coordinate outside the displayed modulus, window, dyadic readback, diagonal, seal, transport, continuation, provenance, and local naming rows.

Apply Definition 593.22. It places every public $\mathsf{Real}^{\uparrow}$ seal read of S on the finite route through μ, W, D, R, T together with H, C, P, N. Then apply Definition 593.21; the comparison route seen by a downstream tail consumer is still the same displayed finite surface.

Now pass to the paired seal chapter chapter 699. The carrier in Definition 699.1 contributes the missing paired source row and the displayed agreement row, while Definition 699.8 forces the Real or Completion consumer to read those rows through the shared threshold route before any handoff is available.

No step supplies a quotient stream, a host real equality, a selected completed limit, an ambient completeness row, or a choice-selected tail. Therefore the paired tail-agreement route consumes the single scheduled observation only by extending the already displayed witness schedule with the second source and agreement rows of $\mathsf{RealTailAgreementSeal}^{\uparrow}$. □

Theorem 593.24 (Regular Cauchy witness schedule shared-window factorization)**.** *Let*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet. Every completion-facing consumer route, and every paired-tail consumer route, that reaches a* $\mathsf{Real}^{\uparrow}$ *seal through the witness schedule factors through one shared finite window surface in the following order: first the* $\mathsf{RegSeqRat}^{\uparrow}$ *source and explicit modulus-window rows X, μ, W, then the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D, the diagonal readback row R, the seal row T, and finally the componentwise* BHist, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows H, C, P, N.*

This factorization is the common surface pinned by Definition 593.3, Definition 593.4, Definition 593.22, Definition 593.21, and Definition 593.23. Conversely, any consumer route displaying exactly those rows is the same finite route already exported by the public seal and paired-tail consumer theorems. No quotient stream, selected completed limit, host real equality, ambient completeness row, or choice operation is supplied by the shared-window surface.

Proof. Project S to the carrier of Definition 593.1. The projection exposes the finite rows $X, \mu, W, D, R, T, H, C, P, N$ as the only schedule data available to a completion-facing or paired-tail consumer.

Use Definition 593.3 to fix the modulus and finite window rows μ, W over the source row X. Then use Definition 593.4 to fix the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger D and diagonal readback row R as the only observation path feeding the seal.

Apply Definition 593.22. It identifies the consumer-visible $\mathsf{Real}^{\uparrow}$ seal handoff with the displayed row T after the finite X, μ, W, D, R path has been read. The remaining rows H, C, P, N supply only the componentwise transport, continuation, package provenance, and local naming surface attached to that same finite route.

For the downstream direction, apply Definition 593.21 and Definition 593.23. These theorems show that the sibling tail-meet and paired tail-agreement consumers can extend the displayed surface with their own paired-source data, but cannot distinguish another route for the scheduled observation itself.

Conversely, a consumer route that displays exactly $X, \mu, W, D, R, T, H, C, P, N$ has already chosen the rows forced by window-modulus alignment, diagonal readback, public seal export, tail-meet comparison, and tail-agreement consumption. Since none of those rows is a quotient stream, selected completed limit, host equality, completeness principle, or choice operator, there is no escape coordinate by which the route could differ from the finite public route already exported in this chapter. □

Theorem 593.25 (Regular Cauchy witness schedule budget pullback exactness)**.** *Let*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet. Let*

$$B = (E, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B)$$

be an accepted $\mathsf{RealObservationBudget}^{\uparrow}$ *packet whose precision request row E, finite window rows W_B, dyadic ledger rows D_B, regular-source handoff rows R_B, and real-seal rows S_B agree componentwise under* hsame *with the witness-schedule rows μ, W, D, R, T after the transports displayed in H, H_B and the routes displayed in C, C_B are replayed.*

Then every $\mathsf{RealObservationBudget}^{\uparrow}$ *consumer route from B that reaches the synchronized* $\mathsf{Real}^{\uparrow}$ *observation pulls back uniquely to the finite witness-schedule route through*

$$X, \mu, W, D, R, T, H, C, P, N.$$

The pullback identifies the two L10 consumer routes with the same finite $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows. It creates no quotient stream equality, host real equality, selected completed limit, ambient completeness row, or unbounded diagonal schedule.*

Proof. Project the accepted schedule packet S to its carrier rows. The window-modulus alignment theorem fixes the requested precision at μ and the finite $\mathsf{StreamName}^{\uparrow}$ window at W, while diagonal readback fixes the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger D and readback row R as the only observation path feeding the seal.

Use the Real handoff, shared-window lock, and shared-window factorization theorems in this chapter. They identify the completion-facing schedule route with the finite route through $X, \mu, W, D, R, T, H, C, P, N$ and leave only transport, continuation, provenance, and local naming rows after the seal handoff T has been reached.

Now project the observation-budget packet B. By request totality in Definition 611.12, the consumer request reads a finite path from E to W_B and D_B. By route determinacy in Definition 611.13, two budget routes with the same displayed rows determine the same $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ observation surface up to the componentwise hsame rows. By non-escape in Definition 611.6, the budget route has no hidden channel outside $E, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B$.

The assumed componentwise hsame agreement transports the budget rows E, W_B, D_B, R_B, S_B onto μ, W, D, R, T. Therefore the budget consumer and the witness-schedule consumer read the same finite $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows, and the remaining displayed transport, route, provenance, and naming rows supply the unique pullback into $X, \mu, W, D, R, T, H, C, P, N$.

Finally apply the non-escape clauses on both sides. Since neither packet contains quotient stream equality, host real equality, a selected completed limit, ambient completeness, or an unbounded diagonal schedule as a coordinate, the pullback is exact only at the finite BEDC route and cannot manufacture any stronger analytic object. □

Theorem 593.26 (Regular Cauchy witness schedule budget selector compatibility)**.** *Let*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet. Every finite precision selector compatible with the* $\mathsf{RealObservationBudget}^{\uparrow}$ *route of chapter 611 identifies its request row with* μ*, its finite window row with* W*, its dyadic ledger row with* D*, and its seal row with* T*, after replaying the componentwise* hsame *transports in* H *and the displayed* Cont *routes in* C*.*

Thus a selector that reaches the synchronized real observation consumes the same displayed L10 packet

$$X, \mu, W, D, R, T, H, C, P, N$$

as the witness schedule. It has no second precision request, no alternate finite-window source, no hidden dyadic ledger, and no seal row outside the packet displayed by S*.*

Proof. First apply window-modulus alignment to the accepted schedule packet. This pins any finite precision request compatible with the schedule to the modulus row μ and pins the selected finite $\mathsf{StreamName}^{\uparrow}$ window to W.

Next apply diagonal readback. The observation read from the selected window must use the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ ledger D and the diagonal row R before it can reach the $\mathsf{Real}^{\uparrow}$ seal row T.

Now use budget pullback exactness for the compatible $\mathsf{RealObservationBudget}^{\uparrow}$ consumer. The budget route agrees componentwise with μ, W, D, R, T after the transports and continuations in H and C are replayed, so its precision selector is exhausted by those same rows.

The remaining rows X, H, C, P, N supply the source, transport, continuation, provenance, and local naming data attached to the already identified route. Since the budget non-escape clause supplies no additional request, window, dyadic, or seal coordinate, the selector and the witness schedule consume the same finite packet. □

Theorem 593.27 (Regular Cauchy witness schedule budget tail-agreement pullback)**.** *Let*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

be an accepted RegularCauchyWitnessSchedule$^{\uparrow}$ *packet. Let*

$$B = (E, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B)$$

be a compatible RealObservationBudget$^{\uparrow}$ *route whose precision request, finite window, dyadic ledger, regular-source handoff, and real-seal rows agree componentwise with* μ, W, D, R, T *after the displayed transports and continuations are replayed. Suppose that this synchronized budget route is then consumed by a paired-tail route through* RealTailAgreementSeal$^{\uparrow}$.

Then the consumer-visible route for the scheduled side pulls back exactly to the finite row surface

$$X, \mu, W, D, R, T, H, C, P, N$$

and the paired-tail route may add only the second-source row and the agreement row required by the RealTailAgreementSeal$^{\uparrow}$ *carrier. It exports no quotient stream, selected completed limit, host real equality, ambient completeness principle, or choice-selected tail.*

Proof. First apply budget pullback exactness, Definition 593.25. The observation-budget request, window, ledger, handoff, and seal rows are transported onto μ, W, D, R, T, so the budget consumer has the same scheduled-side route through $X, \mu, W, D, R, T, H, C, P, N$.

Next apply budget selector compatibility, Definition 593.26. The selector has no second request, alternate window, hidden dyadic ledger, or seal row outside the displayed packet, so the completion-facing budget surface is already spent before the paired-tail route is entered.

Now use the tail-agreement consumer theorem, Definition 593.23. After the scheduled-side rows have been read, the RealTailAgreementSeal$^{\uparrow}$ route can contribute only the second source and the displayed agreement row from Definition 699.1.

Finally use non-escape on both packets. The witness schedule has no coordinate for quotient streams, selected completed limits, host equality, completeness, or choice-selected tails, and the observation budget has no hidden route outside its displayed request, window, ledger, handoff, seal, transport, continuation, provenance, and naming rows. The combined consumer route is therefore exactly the finite scheduled surface together with the paired source and agreement rows. □

Theorem 593.28 (Regular Cauchy witness schedule tail budget exhaustion)**.** *Let*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

be an accepted RegularCauchyWitnessSchedule$^{\uparrow}$ *packet. Every paired-tail or completion-facing budget consumer that reads the scheduled observation of* S *before entering the* RealTailAgreementSeal$^{\uparrow}$ *route of chapter 699 remains inside the displayed rows*

$$X, \mu, W, D, R, T, H, C, P, N.$$

The consumer may subsequently add the second source and agreement rows required by the tail-agreement seal, but it cannot add another schedule, tolerance ledger, diagonal readback, real-seal row, or completion principle for the scheduled side.

Proof. Begin with the tail-agreement consumer theorem for S. It forces any paired-tail route that uses the scheduled observation to pass through μ, W, D, R, T together with the transport, continuation, provenance, and local naming rows H, C, P, N.

Apply shared-window factorization. Completion-facing and paired-tail consumers share the same finite window surface over $X, \mu, W, D, R, T, H, C, P, N$, so the scheduled side has already spent its request, window, dyadic, diagonal, and seal budget before the downstream route is entered.

Finally use non-escape for the witness schedule and for the budget consumer surface. The only data available before the $\mathsf{RealTailAgreementSeal}^{\uparrow}$ carrier is the displayed schedule packet; the seal route can append its paired source and agreement rows only after that finite packet has been consumed.

Therefore every paired-tail or completion-facing budget consumer is exhausted by $X, \mu, W, D, R, T, H, C, P, N$ on the scheduled side, and the later tail-agreement route cannot create a second scheduled observation route. □

Theorem 593.29 (Regular Cauchy witness schedule public export package)**.** *The* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *public export package is assembled by the NameCert obligations, window-modulus alignment, diagonal readback, public boundary, Real seal readiness, shared-window factorization, budget pullback, budget selector compatibility, tail budget exhaustion, and the displayed TasteGate carrier anchor for the packet*

$$X, \mu, W, D, R, T, H, C, P, N.$$

Every $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of this package reads exactly these finite rows. It reads no quotient stream, selected limit, host real equality, ambient completeness, or choice operation.*

Proof. Start from the displayed TasteGate single-carrier marker attached to Definition 593.1. The carrier and the NameCert obligations fix the packet as $X, \mu, W, D, R, T, H, C, P, N$.

The route to the public observation is then forced by window-modulus alignment, diagonal readback, public boundary, and Real seal readiness. These theorems identify the selected modulus, finite window, dyadic ledger, diagonal row, and Real seal row without adding a quotient stream or a selected completed limit.

For completion-facing consumers, use shared-window factorization, budget pullback exactness, budget selector compatibility, and tail budget exhaustion. These rows show that the shared window, observation budget, precision selector, and paired-tail route all pull back to the same displayed schedule packet.

Thus the public export package is a single finite BEDC surface. The consumer can inspect $X, \mu, W, D, R, T, H, C, P, N$ and nothing stronger: no host real equality, no ambient completeness principle, and no choice operation is present as a carrier coordinate or downstream route. □

Theorem 593.30 (Regular Cauchy witness schedule standard bridge)**.** *Let*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet. The public BEDC export package of Definition 593.29 is equivalent to the standard finite witness-schedule record whose fields are exactly the* $\mathsf{RegSeqRat}^{\uparrow}$ *family row* X*, modulus selector* μ*,* $\mathsf{StreamName}^{\uparrow}$ *window* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, diagonal readback* R*,* $\mathsf{Real}^{\uparrow}$ *seal* T*, componentwise* hsame *transports* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}}$ *row* N*.*

The forward read projects those rows from the public export package. The reverse read rebuilds the finite carrier and the public package from exactly those standard finite rows. Both directions preserve the exclusions of $\mathsf{Real}^{\uparrow}$ *completeness, quotient streams, selected limits, host real equality, and choice.*

Proof. For the forward direction, apply Definition 593.29. Its public export is already exhausted by the displayed packet $X, \mu, W, D, R, T, H, C, P, N$.

Use Definition 593.3 to identify μ with the selected tolerance route and W with the corresponding finite window. Then apply Definition 593.4 to route the scheduled observation through D and R

before the $\mathsf{Real}^{\uparrow}$ seal row T is read. The displayed TasteGate marker BEDC.Derived.RegularCauchyWitnessSchedul fixes this as a single carrier surface.

For the reverse direction, start with the standard finite witness-schedule record carrying exactly the same ten rows. The rows $X, \mu, W, D, R, T, H, C, P, N$ rebuild the carrier of Definition 593.1; the local naming row, transports, routes, and provenance then repack it as the public export package of Definition 593.29.

Since neither construction introduces a field outside those rows, the bridge has no coordinate for $\mathsf{Real}^{\uparrow}$ completeness, quotient streams, selected limits, host real equality, or choice. The BEDC export and the standard finite witness-schedule record therefore read back to one another over exactly the displayed finite carrier. □

Theorem 593.31 (Regular Cauchy witness schedule finite-observation terminal coverage)**.** *Let*

$$S = (X, \mu, W, D, R, T, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *packet, where X is the* $\mathsf{RegSeqRat}^{\uparrow}$ *family row, μ is the modulus-selector row, W is the* $\mathsf{StreamName}^{\uparrow}$ *finite window, D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, R is the diagonal readback row, and T is the* $\mathsf{Real}^{\uparrow}$ *seal. Every terminal finite observation consumed from S by a* $\mathsf{Real}^{\uparrow}$ *or completion-facing route factors through exactly the rows*

$$X, \mu, W, D, R, T, H, C, P, N.$$

The terminal consumer receives no $\mathsf{Real}^{\uparrow}$ *completeness principle, quotient stream, selected completed limit, host real equality, or choice operation, and it cannot add a second scheduled observation route downstream.*

Proof. Begin with the public export package of Definition 593.29. It exposes the terminal observation as the finite BEDC packet $X, \mu, W, D, R, T, H, C, P, N$, with the family, modulus, window, dyadic ledger, diagonal readback, and Real seal already displayed before a completion-facing consumer can read the observation.

Next use the standard bridge of Definition 593.30. The bridge identifies the same finite witness-schedule record, so a terminal consumer cannot reinterpret W, D, R, T as a quotient stream, selected limit, host real equality, or choice-selected completion object.

Finally apply tail budget exhaustion from Definition 593.28. Once the downstream route has spent the scheduled-side budget on $X, \mu, W, D, R, T, H, C, P, N$, any later completion or paired-tail consumer may only use the route already carried by those rows and cannot introduce a second scheduled observation path. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ packet is generated from a $\mathsf{RegSeqRat}^{\uparrow}$ family row, explicit modulus row, selected $\mathsf{StreamName}^{\uparrow}$ finite-window schedule, $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, diagonal readback row, $\mathsf{Real}^{\uparrow}$ seal handoff, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed:

Lean4 ✓ `BEDC.Derived.RegularCauchyWitnessScheduleUp.taste gate`

The public export is the finite witness schedule boundary over the displayed RegSeqRat, StreamName, DyadicRatCore, RealUp, BHist, hsame, Cont, Pkg, and NameCert rows, as bound by Definition 593.1, Definition 593.8, Definition 593.22, Definition 593.29, and Definition 593.30.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.RegularCauchyWitnessScheduleUp.RegularCauchyWitnessScheduleUp\_taste\_gate\_boundary`

Bridge status: paperBridge

Not claimed: This chapter does not close RealUp completeness, uniqueness of completed limits, quotient equality of streams, host real equality, Lean verification, or bridge checking.

Upgrade path: No further paper-axis upgrade is pending for the finite witness-schedule surface; verification and bridge checking remain on the independent formal axis.

Chapter 594

A Concrete Naming Certificate for $\mathsf{MaxCausalRate}^{\uparrow}$

Falsifiable prediction: An accepted $\mathsf{MaxCausalRate}^{\uparrow}$ packet is refuted if a consumer reads a public maximum-rate bound without the displayed $\mathrm{MultiHistConfig}^{\uparrow}$ row, $\mathsf{CrossHistCausal}^{\uparrow}$ witness family, shared Unary bound row, and finite comparison ledger.

Independence witness: multihistconfig, crosshistcausal, interhistinvariant, lorentzframerate: no sibling is bijective to $\mathsf{MaxCausalRate}^{\uparrow}$ because this carrier alone combines selected pair witnesses, one shared unary upper-bound row, comparison totality, and rate-facing consumer bridge rows.

The $\mathsf{MaxCausalRate}^{\uparrow}$ interface records the finite unary-bound packet that sits after $\mathrm{MultiHistConfig}^{\uparrow}$ and the $\mathsf{CrossHistCausal}^{\uparrow}$ witness-family rows of chapter 478 in the inter-Hist locality chain of Definition 9419.25. Its role is not to introduce a real-valued speed, a metric tensor, or a synchronized frame. It names a displayed family of cross-Hist causal witness rows and one unary bound row against which those witnesses are compared inside the local BEDC ledger.

Definition 594.1 (MaxCausalRate carrier)**.** *A* $\mathsf{MaxCausalRate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (M, X, U, B, H, Q, C, P, N)$$

with the following visible coordinates:

1. *M is an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *row displaying the finite observer-history configuration, its local ledgers, no-global-sync witness, componentwise* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local naming row;*
2. *X is a finite family of* $\mathsf{CrossHistCausal}^{\uparrow}$ *witness rows over selected pairs of histories from M and selected unary slots;*
3. *U is the unary bound row that names the maximum displayed causal-rate cap for the listed witnesses;*
4. *B records a finite bound comparison for every displayed causal witness in X, relating its slot-local witness row to the same unary bound row U;*
5. *H records componentwise* hsame *transport for M, the witness family X, the unary bound row U, the comparison ledger B, the probe-stability row, the continuation routes, the package row, and the local naming row;*

6. *Q records* psame *stability for the displayed probe reads used by the cross-Hist witnesses and their bound comparisons;*
7. *C records the visible* Cont *routes from M and each selected witness row into U, B, H, Q, P, and N;*
8. *P is the* Pkg *provenance over* $\mathsf{MaxCausalRate}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, Hist, Unary, BHist, hsame, psame, Cont, Pkg, *and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{MaxCausalRate}^{\uparrow}}$ *row.*

The carrier exports only a finite configuration row, finite causal witness rows, one unary bound row, displayed bound comparisons, transport rows, continuation routes, package provenance, and local naming data. It contains no global observer frame, no synchronized clock, no metric tensor, no Lorentz geometry, and no ambient real-valued rate.

Theorem 594.2 (MaxCausalRate NameCert obligations)**.** *For the carrier of Definition 594.1, the local* $\mathsf{NameCert}_{\mathsf{MaxCausalRate}^{\uparrow}}$ *surface consists exactly of five finite obligations:*

1. *carrier admission for the displayed packet $R = (M, X, U, B, H, Q, C, P, N)$;*
2. *configuration locality, requiring every selected causal witness in X to project its history anchors and unary slot from the same* $\mathrm{MultiHistConfig}^{\uparrow}$ *row M;*
3. *unary-bound exactness, requiring every displayed comparison row in B to compare one witness row of X against the shared unary bound row U;*
4. *transport stability through the componentwise* hsame *row H, the displayed* psame *row Q, and the visible* Cont *routes in C;*
5. *non-escape, excluding global frames, synchronized clocks, metric tensors, Lorentz geometry, and ambient real-valued rates.*

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRateTasteGate single carrier alignment`

Proof. Carrier admission is the projection of the finite tuple in Definition 594.1. The rows $M, X, U, B, H, Q, C, P, N$ display the configuration, causal witnesses, bound row, comparison ledger, transport rows, read routes, package provenance, and local naming row.

Configuration locality follows by reading M before any causal witness is inspected. The selected history pairs and unary slots used by X are drawn from the displayed $\mathrm{MultiHistConfig}^{\uparrow}$ surface, so no witness can appeal to an unlisted observer or a global synchronization row.

Unary-bound exactness is the finite ledger condition on B. Each comparison row has a displayed witness from X on one side and the common unary bound row U on the other, so the maximum-rate surface is a shared bound over listed witnesses rather than a host real-valued function.

Transport stability is componentwise through H, Q, and C. These rows replay the same configuration, witness family, unary bound, and comparison ledger under accepted hsame and psame movements.

The non-escape clause is then an inventory argument. Since the carrier has no coordinate for a global frame, synchronized clock, metric tensor, Lorentz geometry, or real-valued rate, no local $\mathsf{NameCert}_{\mathsf{MaxCausalRate}^{\uparrow}}$ projection can export one. □

Theorem 594.3 (MaxCausalRate CrossHistCausal handoff)**.** *Every* $\mathsf{CrossHistCausal}^{\uparrow}$ *witness consumed by an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *carrier is read as one displayed row of the finite family X over the* $\mathrm{MultiHistConfig}^{\uparrow}$ *carrier M. The consumer obtains the selected history pair, unary slot,*

finite causal witness, hsame *and* psame *stability rows, displayed* Cont *routes, and package provenance already present in that witness row, together with the bound comparison against U recorded in B.*

The handoff supplies a finite unary-bound causal ledger only. It does not supply a global frame, synchronized clock, metric tensor, Lorentz geometry, or ambient real-valued speed.

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket crosshist handoff`

Proof. Start with the accepted $\mathsf{MaxCausalRate}^{\uparrow}$ carrier and project M and X. The configuration row M supplies the finite observer-history surface, while X lists the selected $\mathsf{CrossHistCausal}^{\uparrow}$ witness rows that may be consumed.

For a displayed witness row in X, apply the local surface of Definition 478.2. The witness already carries its two history anchors, unary slot ledger, finite dependence row, componentwise hsame transport, two-anchor psame stability, visible Cont routes, package provenance, and local naming row.

Next attach the comparison row from B. This row relates that specific witness to the shared unary bound U, so the handoff adds only the finite bound check needed by $\mathsf{MaxCausalRate}^{\uparrow}$.

Finally route the combined witness-and-bound read through H, Q, C, P, N. The resulting handoff remains inside the displayed BEDC rows and cannot introduce synchronization, metric geometry, or a host-side real-valued rate. □

Theorem 594.4 (MaxCausalRate non-escape)**.** *Every consumer of an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *carrier factors through the finite rows*

$$M, X, U, B, H, Q, C, P, N.$$

In particular, the consumer may read the multi-Hist configuration row, the displayed cross-Hist causal witnesses, the shared unary bound row, the finite comparison ledger, componentwise hsame *transport, displayed* psame *stability, visible* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{MaxCausalRate}^{\uparrow}}$ *row, and nothing outside those rows.*

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket non escape`

Proof. Project the accepted carrier and apply Definition 594.2. Its non-escape clause excludes global frames, synchronized clocks, metric tensors, Lorentz geometry, and ambient real-valued rates from the local naming surface.

Apply Definition 594.3 to every displayed witness row that a consumer reads from X. Each read remains a $\mathsf{CrossHistCausal}^{\uparrow}$ row over M plus a finite comparison against the shared unary bound U.

The transport rows H, Q, C then replay only the listed configuration, witness, bound, and comparison data. Since every visible consumer row is one of $M, X, U, B, H, Q, C, P, N$, any request for a global frame, synchronized clock, metric tensor, Lorentz geometry, or real-valued speed leaves the $\mathsf{MaxCausalRate}^{\uparrow}$ carrier rather than projecting from it. □

Theorem 594.5 (MaxCausalRate bound-comparison totality)**.** *For an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *carrier*

$$R = (M, X, U, B, H, Q, C, P, N),$$

the finite comparison ledger B contains a displayed comparison row for every causal witness row in X against the shared unary bound row U. A consumer may therefore read the maximum causal-rate surface only as a total finite ledger over the listed witnesses, not as a partial sample or an ambient real-valued speed function.

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket bound comparison totality`

Proof. Project the accepted carrier and inspect X and B. The witness family X is finite, and the ledger row B is defined as the finite comparison row for every displayed witness in that family against U.

Route each comparison through C. The consumer reaches a witness row of X, the shared unary bound U, and its corresponding comparison row in B by one of the displayed continuations.

The transport rows H and Q preserve the same witness-and-bound pairing. Since P and N only bind provenance and local naming, the totality claim remains a BEDC ledger fact and not a real-valued rate assertion. □

Theorem 594.6 (MaxCausalRate witness-family stability)**.** *For an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *carrier*

$$R = (M, X, U, B, H, Q, C, P, N),$$

componentwise hsame *transport in H, probe stability in Q, and the displayed routes in C preserve the witness family X together with its comparison pairing in B against the shared unary bound U.*

No transported consumer may replace a listed witness by an unlisted cross-Hist row, change the unary bound, or detach the comparison from the $\mathrm{MultiHistConfig}^{\uparrow}$ *row M.*

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket witness family stability`

Proof. Read M first and then the finite witness family X. Each displayed witness is anchored in the same multi-Hist configuration and selected unary slot surface.

Transport through H preserves M, X, U, B componentwise, while Q preserves the probe reads used by the cross-Hist witnesses and their bound comparisons. Thus the transported family remains paired with the same unary bound row U.

Finally replay the reads through C and bind them by P, N. The carrier has no coordinate for an unlisted cross-Hist witness, a second bound row, or a comparison detached from M, so witness-family stability is exhausted by the displayed finite packet. □

Theorem 594.7 (MaxCausalRate bridge readback)**.** *Every consumer-facing bridge read of an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *packet is exactly the tuple*

$$M, X, U, B, H, Q, C, P, N.$$

Here M is the $\mathrm{MultiHistConfig}^{\uparrow}$ *row, X is the displayed* $\mathsf{CrossHistCausal}^{\uparrow}$ *witness family, U is the shared unary bound, B is the comparison ledger, H is componentwise transport, Q is the probe-stability row, C is the continuation route surface, P is provenance, and N is the local name.*

The readback exports no global frame, synchronized clock, metric tensor, Lorentz geometry, or real-valued speed.

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket bridge readback`

Proof. Project the accepted carrier and local obligations from Definition 594.2. The carrier rows visible to a consumer are exactly $M, X, U, B, H, Q, C, P, N$.

Apply Definition 594.3. It identifies the displayed witness family X as the $\mathsf{CrossHistCausal}^{\uparrow}$ handoff over the multi-Hist configuration row M.

Next use Definition 594.5 and Definition 594.6. These keep the shared unary bound U, the comparison ledger B, and the transported witness family tied to H, Q, C.

The rows P and N then package and name the same surface. Since none of the cited rows contains a global frame, synchronized clock, metric tensor, Lorentz geometry, or real-valued speed coordinate, the bridge readback is exactly the displayed tuple. □

Theorem 594.8 (MaxCausalRate unary-bound non-escape)**.** *For an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *carrier*

$$R = (M, X, U, B, H, Q, C, P, N),$$

the unary-bound row U is the only bound exported by the packet, and it is visible only through the finite witness family X and comparison ledger B transported by H, Q and routed by C.

The packet cannot export real-valued speed, synchronized clocks, metric tensors, Lorentz geometry, or any rate comparison not recorded as a row of B against U.

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket unary bound nonescape`

Proof. Project U from the carrier together with X and B. The bound row is a unary ledger coordinate, and every public comparison to it is recorded in the finite row B.

Use H, Q, C to transport and read the bound surface. Componentwise hsame movement, probe stability, and continuation routing preserve the same witness family and comparison ledger.

The package row P and local name row N bind the result to the $\mathsf{MaxCausalRate}^{\uparrow}$ certificate. Since the remaining excluded structures have no coordinate in R, the unary-bound surface cannot become a real-valued speed, synchronized-clock, metric-tensor, or Lorentz-geometry surface. □

Theorem 594.9 (MaxCausalRate configuration-locality obligation)**.** *For an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *carrier*

$$R = (M, X, U, B, H, Q, C, P, N),$$

every causal witness row in X is anchored in the displayed $\mathrm{MultiHistConfig}^{\uparrow}$ *row M before it is compared with the shared unary bound row U. No consumer of R may read a witness from X as belonging to an observer history, unary slot, or probe route not supplied by M, H, Q, C, P, N.*

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket configuration locality obligation`

Proof. Project the carrier rows $M, X, U, B, H, Q, C, P, N$ from Definition 594.1. The configuration row M is the only source of observer-history anchors and selected unary slots.

Apply the checked TasteGate marker recorded in the closure status for this chapter, together with the single-carrier alignment theorem MaxCausalRateTasteGate_single_carrier_alignment. It aligns the single carrier surface with the displayed tuple, so the witness family X is read as part of the same carrier rather than as a second classifier surface.

The rows H, Q, C then preserve the configuration-local read under componentwise transport, probe stability, and visible continuation routes. The provenance and naming rows P, N bind the result to the same packet, so no witness can detach from M or acquire an unlisted observer-history source. □

Theorem 594.10 (MaxCausalRate comparison-ledger exactness)**.** *For an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *carrier*

$$R = (M, X, U, B, H, Q, C, P, N),$$

the comparison ledger B records exactly the finite comparisons between displayed witness rows of X and the shared unary bound row U. A consumer may transport and replay those comparisons through H, Q, C, P, N, but may not replace them by a real-valued speed function, a metric comparison, a synchronized-clock comparison, or a comparison against an unlisted bound.

Proof. Start with the finite carrier rows $M, X, U, B, H, Q, C, P, N$. The row B is specified as the comparison ledger for the witness family X against the shared unary bound row U.

Use Definition 594.5 to see that every displayed witness receives such a comparison, and use Definition 594.8 to see that no second bound coordinate is exported.

The checked TasteGate marker recorded in the closure status keeps the carrier read single-surfaced. Therefore B is not a partial external table and not an ambient numeric rate.

Finally transport through H, Q, C and bind by P, N. These rows preserve the same finite comparison ledger and add no metric, synchronized clock, Lorentz geometry, or host real-valued speed. □

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket comparison ledger exactness`

Theorem 594.11 (MaxCausalRate obligation closure package)**.** *The carrier, local* $\mathsf{NameCert}_{\mathsf{MaxCausalRate}^{\uparrow}}$ *obligations, CrossHistCausal handoff, non-escape theorem, bound-comparison totality, witness-family stability, unary-bound non-escape, configuration-locality obligation, and comparison-ledger exactness assemble the obligation closure for every accepted packet*

$$R = (M, X, U, B, H, Q, C, P, N).$$

The closed obligation surface exports only the displayed $\mathrm{MultiHistConfig}^{\uparrow}$ *row* M*, witness family* X*, unary bound* U*, comparison ledger* B*, transport rows* H, Q*, routes* C*, provenance row* P*, and naming row* N*.*

Proof. The carrier definition supplies the tuple $M, X, U, B, H, Q, C, P, N$. The checked TasteGate marker recorded in the closure status confirms that this tuple is the single carrier surface used by the local naming obligations.

Apply Definition 594.3 and Definition 594.4. These results keep every consumer inside the displayed configuration, witness, bound, comparison, transport, route, provenance, and naming rows.

Next apply Definition 594.5, Definition 594.6, and Definition 594.8. They make the comparison ledger total over X, stable under H, Q, C, and tied to the single unary bound U.

Finally add the configuration-locality and comparison-ledger exactness obligations. Together they close the local $\mathsf{NameCert}_{\mathsf{MaxCausalRate}^{\uparrow}}$ obligation surface while continuing to exclude global frames, synchronized clocks, metric tensors, Lorentz geometry, and host real-valued speed measurements. □

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket obligation closure package`

Theorem 594.12 (MaxCausalRate scoped kernel boundary)**.** *Every downstream causal-rate read from an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *packet factors through the displayed rows*

$$M, X, U, B, H, Q, C, P, N$$

and their BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *ledgers. The read may consume the multi-Hist configuration, listed cross-Hist witnesses, shared unary bound, comparison ledger, transports, routes, provenance, and local name, but it cannot enter a global frame, synchronized-clock row, metric tensor, Lorentz geometry, or host real-valued speed surface.*

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket scoped kernel boundary`

Proof. Project the accepted packet through Definition 594.1. The rows $M, X, U, B, H, Q, C, P, N$ are the whole finite carrier surface.

Apply Definition 594.3 and Definition 594.5. These theorems route every causal witness read through the displayed configuration row, finite witness family, shared unary bound, and comparison ledger.

Next use Definition 594.6, Definition 594.9, and Definition 594.10. They keep the transported read inside H, Q, C, P, N and bind it to the same BHist, hsame, Cont, Pkg, and NameCert ledgers.

Finally apply Definition 594.4. Since the packet has no global-frame, synchronized-clock, metric, Lorentz, or real-speed coordinate, the displayed rows give the scoped kernel boundary for downstream reads. □

Theorem 594.13 (MaxCausalRate public unary-bound export)**.** *Every public* MaxCausalRate$^{\uparrow}$ *consumer reads the unary bound row U only through the single carrier tuple*

$$M, X, U, B, H, Q, C, P, N,$$

the CrossHistCausal$^{\uparrow}$ *handoff for the witness family X, and the existing TasteGate single-carrier marker* MaxCausalRateTasteGate_single_carrier_alignment*. The exported interface supplies a finite unary-bound ledger only: it exports no global frame, metric tensor, Lorentz geometry, synchronized clock, or real-valued speed.*

Proof. Project the accepted carrier. The row U is a coordinate of the displayed tuple $M, X, U, B, H, Q, C, P, N$, not a separate ambient rate surface.

Use Definition 594.3. Every consumer reaches the witness family X through displayed CrossHistCausal$^{\uparrow}$ rows before it reads the comparison ledger against U.

Now use the checked TasteGate single-carrier marker already recorded after Definition 594.2. It keeps the tuple as one carrier surface, so the public read cannot split U away from M, X, B, H, Q, C, P, N.

Finally apply Definition 594.4. Since the carrier has no coordinate for a global frame, metric tensor, Lorentz geometry, synchronized clock, or host real-valued speed, the public export is exactly the finite unary-bound row routed through the displayed packet. □

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket public unary bound export`

Theorem 594.14 (MaxCausalRate unary-bound consumer bridge)**.** *Every public causal-rate consumer bridge of an accepted* MaxCausalRate$^{\uparrow}$ *packet factors through the displayed* MultiHistConfig$^{\uparrow}$ *row M, the* CrossHistCausal$^{\uparrow}$ *witness family X, the shared unary bound U, the comparison ledger B, and the transport, provenance, continuation, and naming rows H, Q, C, P, N.*

The bridge uses the checked TasteGate marker MaxCausalRateTasteGate_single_carrier_alignment *as the single-carrier alignment guard. It exports only the same finite packet surface and does not claim Lorentz geometry, metric tensors, synchronized clocks, a global frame, or real-valued speed.*

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket unary bound consumer bridge`

Proof. Project the accepted carrier. The public consumer bridge begins with the same tuple $M, X, U, B, H, Q, C, P, N$ used by Definition 594.13.

Apply Definition 594.3. It routes every witness read in X through displayed CrossHistCausal$^{\uparrow}$ rows over the configuration M.

Next apply Definition 594.13 and Definition 594.10. These keep the shared bound U attached to the comparison ledger B and the structural rows H, Q, C, P, N.

Use the checked TasteGate marker recorded in the chapter as the single-carrier alignment guard. It prevents the consumer bridge from reading U as an abstract rate parameter detached from M, X, B, H, Q, C, P, N.

Finally apply Definition 594.4. Since the carrier has no global frame, metric tensor, Lorentz geometry, synchronized clock, or host real-valued speed coordinate, the bridge exposes only the displayed finite unary-bound packet. □

Theorem 594.15 (MaxCausalRate bridge consumer surface)**.** *Every bridge-facing public consumer of an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *packet factors through*

$$M, X, U, B, H, Q, C, P, N,$$

before any public causal-rate read. The consumer reads the $\mathrm{MultiHistConfig}^{\uparrow}$ *configuration row, the* $\mathsf{CrossHistCausal}^{\uparrow}$ *witness family, the shared unary bound, the comparison ledger, and the single-carrier TasteGate guard as one finite packet surface.*

The bridge-facing surface contains no global frame, metric tensor, Lorentz geometry, synchronized clock, or real-valued speed.

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.MaxCausalRatePacket bridge consumer surface`

Proof. Project the accepted packet through Definition 594.14. This gives the displayed carrier tuple $M, X, U, B, H, Q, C, P, N$ as the only bridge-facing packet available before a public causal-rate read.

Use Definition 594.13. It keeps the shared unary bound U attached to the same public carrier tuple and prevents the consumer from reading U as an independent rate surface.

Next apply Definition 594.10. The comparison ledger B relates each displayed causal witness in X to the same unary bound U, so the public bridge consumes a finite ledger rather than a host-valued speed.

Finally apply Definition 594.4. Together with the single-carrier TasteGate guard already used in Definition 594.14, the non-escape row excludes global frames, metric tensors, Lorentz geometry, synchronized clocks, and real-valued speed from the public bridge surface. □

The Lean TasteGate surface for $\mathsf{MaxCausalRate}^{\uparrow}$ must preserve explicit Nontrivial and FieldFaithful instances for this carrier before bridge-facing claims read the unary bound as a public maximum-rate row. Those instances keep the selected pair witnesses, shared unary upper bound, comparison totality, and consumer bridge rows attached to one carrier rather than a collapsed encoding.

Closure status for $\mathsf{NameCert}_{\mathsf{MaxCausalRate}^{\uparrow}}$.

Constructive story: A $\mathsf{MaxCausalRate}^{\uparrow}$ packet is generated from a $\mathrm{MultiHistConfig}^{\uparrow}$ row, finitely many $\mathsf{CrossHistCausal}^{\uparrow}$ witness rows over selected history pairs and unary slots, one shared Unary bound row, finite bound comparisons, displayed hsame and psame transport, visible Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{MaxCausalRate}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 594.1, Definition 594.2, Definition 594.3, Definition 594.4, Definition 594.5, Definition 594.6, Definition 594.8, Definition 594.9, Definition 594.10, Definition 594.11, Definition 594.12, Definition 594.13, Definition 594.14, and Definition 594.15 bind the finite multi-Hist configuration, displayed cross-Hist causal witnesses, shared unary bound, finite comparison ledger, transport rows, visible routes, package provenance, local naming row, downstream read boundary, public unary-bound export, and paper bridge surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{MaxCausalRate}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Lean4 ✓ `BEDC.Derived.MaxCausalRateUp.taste gate`

Not claimed: This chapter does not close Lorentz geometry, metric light-cones, curved spacetime, quantum-state certificates, synchronized clocks, global frames, or real-valued speed measurements.

Upgrade path: Paper-side mature closure is complete for the finite unary-bound causal ledger, while Lean verification and bridge checking remain separate.

Chapter 595

A Concrete Naming Certificate for $\mathsf{ClassifierBoundary}^{\uparrow}$

The $\mathsf{ClassifierBoundary}^{\uparrow}$ surface realizes the type-checking boundary of chapter 9367 as a finite NameCert packet. It records accepted Ext-membership rows, refused non-member rows, Cont preservation routes, SigRel readback, package provenance, and local naming, while keeping host-language typing judgments and unrecorded semantic models outside the packet.

The same boundary is the finite Ext/Cont/SigRel surface consumed by chapter 476, chapter 483, and chapter 590. Those sibling uses are, respectively, accepted membership, subject-reduction preservation, and classifier-morphism transport across the displayed signature relation.

Definition 595.1 (Classifier-boundary carrier)**.** *A* $\mathsf{ClassifierBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (S, A, R, T, G, H, C, P, N)$$

with the following displayed rows:

1. *S is the finite source row of candidate histories whose membership is inspected by the classifier;*
2. *A is the accepted boundary row, listing exactly the displayed histories admitted by the* Ext *classifier;*
3. *R is the refused boundary row, listing exactly the displayed histories for which the packet exposes a finite non-member refusal row;*
4. *T is the* Cont *preservation row, recording that every admitted source route followed by a displayed continuation remains in the accepted boundary;*
5. *G is the* SigRel *readback row, exposing the signature-level classifier read used by downstream type-certificate and compiler-morphism consumers;*
6. *H stores componentwise* hsame *transports for the source, accepted, refused, preservation, readback, package, and naming rows;*
7. *C stores the displayed* Cont *routes by which consumers read source histories, accepted rows, refused rows, preservation rows, readback rows, provenance, and local naming;*
8. *P is the* Pkg *provenance over* BHist*,* Ext*,* Cont*,* SigRel*,* hsame*,* Pkg*, and* NameCert*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ClassifierBoundary}^{\uparrow}}$ *row.*

The local classifier relates two packets exactly when their displayed source, accepted, refused, preservation, readback, transport, route, provenance, and naming rows compare through H and C. The carrier contains no host type checker, no external semantic model, no hidden proof search oracle, and no quotient of histories.

Lean4 ✓ `BEDC.Derived.ClassifierBoundaryUp.ClassifierBoundaryTasteGate single carrier alignment`

Theorem 595.2 (ClassifierBoundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ClassifierBoundary}^{\uparrow}}$ *surface for Definition 595.1 consists of five finite obligations:*

1. *accepted* Ext*-membership exposure, requiring every accepted consumer read to be one of the displayed rows of A reached from S;*
2. *refused non-member exposure, requiring every refused consumer read to be one of the displayed rows of R and not a hidden semantic rejection;*
3. Cont *preservation, requiring a displayed continuation from an accepted row to land again in the accepted boundary through T;*
4. SigRel *readback, requiring downstream consumers to read the public classifier signature only through the row G and its routes in C;*
5. *NameCert provenance, requiring all accepted, refused, preservation, and readback rows to remain under the package row P and the local naming row N.*

Consequently the packet gives a concrete public boundary for classifier membership: accepted histories, refused histories, continuation preservation, signature readback, and provenance are all finite BHist *rows.*

Proof. Carrier exposure is projection from $B = (S, A, R, T, G, H, C, P, N)$. The accepted and refused sides are both visible packet rows, so membership and refusal are boundary data rather than host-side judgments.

For accepted reads, use the route from S to A recorded in C. For refused reads, use the route from S to R recorded in the same continuation ledger. These two rows exhaust the membership decision surface exposed by the packet.

Preservation is then read through T. A consumer that starts from an accepted row and follows a displayed continuation has no route except the one listed in T, and the resulting accepted row is again transported through H and read through C.

Finally read the signature-level view through G and package it through P and N. Since no coordinate of the carrier is a host checker, external semantic model, hidden proof search oracle, or quotient of histories, the local NameCert surface cannot export such data. □

Lean4 ✓ `BEDC.Derived.ClassifierBoundaryUp.ClassifierBoundaryCarrier namecert obligations`

Theorem 595.3 (ClassifierBoundary public boundary)**.** *Every public consumer of an accepted* $\mathsf{ClassifierBoundary}^{\uparrow}$ *packet factors through the displayed rows $S, A, R, T, G, H, C, P, N$. Accepted membership reads use A, refused non-member reads use R, subject-reduction-style reads use T, signature readback uses G, and all routes preserve their provenance through P and N.*

Proof. Split the consumer request by the row it asks to read. Accepted membership reaches A from S, while refused non-membership reaches R from S.

Continuation preservation reaches T only after the accepted row has been displayed. Thus the boundary uses the same finite source and accepted rows for both type-checking membership and subject-reduction-style continuation.

Signature readback reaches G, and provenance reaches P and N. These rows exhaust the carrier, so no consumer can bypass the finite packet to obtain a host type checker or an external semantic model. □

Lean4 ✓ `BEDC.Derived.ClassifierBoundaryUp.ClassifierBoundaryCarrier public boundary`

Theorem 595.4 (ClassifierBoundary scoped dependency route)**.** *For an accepted* ClassifierBoundary$^{\uparrow}$ *carrier*

$$B = (S, A, R, T, G, H, C, P, N),$$

the accepted-membership route, refused non-member route, and continuation-preservation route all factor through the displayed rows $S, A, R, T, G, H, C, P, N$. The dependency scope is exactly the finite BHist *rows, the* Ext *classifier rows, displayed* Cont *routes,* SigRel *readback, componentwise* hsame *transports,* Pkg *provenance, and the local* NameCert *row; it contains no host type checking, external semantic model, proof-search oracle, or quotient history.*

Lean4 ✓ `BEDC.Derived.ClassifierBoundaryUp.ClassifierBoundaryCarrier scoped dependency route`

Proof. Project the carrier of Definition 595.1. The rows S, A, R, T are the only coordinates that expose candidate histories, accepted boundary rows, refused boundary rows, and continuation preservation.

Use the NameCert obligations of Definition 595.2. Accepted reads are required to pass from S to A, refused reads from S to R, and displayed continuation preservation through T.

Finally use the public boundary of Definition 595.3. The consumer still reads transports, routes, provenance, and local naming only through H, C, P, N, while signature readback remains the row G. Since the carrier has no coordinate for host type checking, external semantic models, proof-search oracles, or quotient histories, none of those objects lies in the scoped dependency route. □

Theorem 595.5 (ClassifierBoundary signature consumer determinacy)**.** *For an accepted* ClassifierBoundary$^{\uparrow}$ *carrier*

$$B = (S, A, R, T, G, H, C, P, N),$$

every consumer-visible SigRel *readback is determined by the displayed row G together with its* hsame *transports in H,* Cont *read routes in C,* Pkg *provenance in P, and local* NameCert *row N. Thus two consumers with the same finite* BHist *source, accepted row, refused row, continuation row, signature row, transport row, route row, package row, and naming row receive the same public classifier signature, with no host type checking, external semantic model, proof-search oracle, or quotient history supplying another readback.*

Proof. Project $B = (S, A, R, T, G, H, C, P, N)$ and isolate the signature coordinate. The carrier definition makes G the displayed SigRel readback row and gives no second coordinate for classifier-signature output.

Invoke Definition 595.2. Its readback obligation requires downstream consumers to read the public classifier signature only through G and the routes stored in C, under the package and naming rows P, N.

Now apply Definition 595.3. Every public consumer factors through the same displayed rows, so agreeing rows force the same readback surface. The excluded host checker, semantic model, proof-search oracle, and quotient-history data are not carrier coordinates and cannot determine a second signature. □

Lean4 ✓ `BEDC.Derived.ClassifierBoundaryUp.ClassifierBoundaryCarrier sigrel consumer determinacy`

Theorem 595.6 (ClassifierBoundary Ext and Cont preservation scope)**.** *For an accepted* ClassifierBoundary$^{\uparrow}$ *carrier*

$$B = (S, A, R, T, G, H, C, P, N),$$

the Ext *membership surface and the* Cont *preservation surface are preserved exactly within the displayed dependency scope over* BHist*,* Ext*,* Cont*,* SigRel*,* hsame*,* Pkg*, and* NameCert*. Accepted membership is read through A, refused membership through R, preservation through T, signature readback through G, and all transported consumer access through H, C, P, N; no host type checking, external semantic model, proof-search oracle, or quotient history enlarges the scope.*

Proof. Start from the carrier projection. The Ext data are the source, accepted, and refused rows S, A, R, while the preservation data are the displayed continuation rows in T.

Use Definition 595.2 to bind the local obligations. It requires accepted exposure, refused exposure, continuation preservation, signature readback, and provenance to remain under the finite NameCert surface.

The public-boundary theorem Definition 595.3 then gives the consumer factorization through $S, A, R, T, G, H, C, P, N$. Because the carrier omits host type checking, external semantic models, proof-search oracles, and quotient histories, preservation stays inside the stated BEDC primitives. □

Lean4 ✓ `BEDC.Derived.ClassifierBoundaryUp.ClassifierBoundaryCarrier ext cont preservation scope`

Closure status for NameCert$_{\text{ClassifierBoundary}^{\uparrow}}$**.**

Constructive story: A ClassifierBoundary$^{\uparrow}$ packet is generated from source histories, accepted Ext rows, refused non-member rows, Cont preservation rows, SigRel readback, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ClassifierBoundary}^{\uparrow}}$, publicClosed)

Scope closed: Definition 595.1, Definition 595.2, and Definition 595.3 bind the finite classifier-boundary NameCert surface for accepted membership, refused non-membership, continuation preservation, readback, and provenance.

Formal verification: FormalStatus(NameCert$_{\text{ClassifierBoundary}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.ClassifierBoundaryUp.ClassifierBoundaryCarrier\_scoped\_dependency\_route`

Bridge status: none

Origin: human

Not claimed: This chapter does not close a Lean implementation, bridge status, host type checking, external semantic models, hidden proof search, quotient histories, or compiler morphism preservation.

Upgrade path: A higher closure grade requires Lean-side bridge checking for the public classifier-boundary surface.

Chapter 596

A Concrete Naming Certificate for $\mathsf{SubordinateModulusCover}^{\uparrow}$

The $\mathsf{SubordinateModulusCover}^{\uparrow}$ packet names the finite cover returned before the compact-uniform-continuity rational lower-bound fold. It sits between the compact finite-net carrier and the $\mathsf{UniformModulus}^{\uparrow}$ consumer: the packet records bundled centers, pointwise-modulus precision rows, subordinate positive-radius rows, half-radius coverage witnesses, rational comparison ledgers, and the local provenance needed to hand the bundle to the uniform-modulus fold.

The packet consumes the finite-net coverage surface of chapter 60, the pointwise-modulus data supplied by chapter 130, and the metric and rational comparison rows of chapter 57 and chapter 37. Its output is the finite subordinate bundle handed to chapter 369, before any uniform precision row is chosen.

Definition 596.1 (SubordinateModulusCover carrier)**.** *A* $\mathsf{SubordinateModulusCover}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N)$$

with the following visible rows:

1. *E is the positive* $\mathsf{Rat}^{\uparrow}$ *tolerance history requested by the compact-continuous consumer;*
2. *$\mathcal{P}$ is the nonempty* $\mathsf{ProbeBundle}$ *spine returned by the compact finite-net certificate;*
3. *C assigns to each bundled probe its displayed center history;*
4. *R assigns to each bundled probe a positive subordinate radius history;*
5. *D assigns to each bundled probe the pointwise-modulus precision history supplied at its center;*
6. *M records the accepted pointwise-modulus row for the tolerance fraction read from E;*
7. *H records the half-radius coverage row saying that every source history is covered by a bundled center at the displayed subordinate radius;*
8. *F records the rational comparison ledger witnessing that every subordinate radius row is below its pointwise precision row;*
9. *L records componentwise* hsame *stability for the tolerance, bundle, centers, radius rows, precision rows, pointwise rows, coverage rows, and rational comparisons;*
10. *Q records the displayed* Cont *routes through which compact and continuous consumers read the packet;*

11. *P is the* Pkg *provenance over* Compact$^{\uparrow}$, ContinuousMap$^{\uparrow}$, Met$^{\uparrow}$, Rat$^{\uparrow}$, ProbeBundle, BHist, hsame, Cont, *and the local naming rows;*

12. *N is the local* NameCert$_{\text{SubordinateModulusCover}^{\uparrow}}$ *row.*

The carrier exports no open cover, no external radius selector, no host minimum, and no uniform precision row. Its role is exactly the finite subordinate bundle consumed before the UniformModulus$^{\uparrow}$ *lower-bound fold.*

Lean4 (definition) `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverCarrier`

Theorem 596.2 (SubordinateModulusCover NameCert obligations)**.** *The local* NameCert$_{\text{SubordinateModulusCover}^{\uparrow}}$ *surface for Definition 596.1 consists of carrier admission for $S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N)$, classifier stability under the componentwise* hsame *rows in L, compact coverage exactness for the half-radius rows in H, pointwise-modulus compatibility for the rows in M and D, rational subordination exactness for the comparison rows in F, and consumer non-escape through the displayed* Cont, Pkg, *and local naming rows.*

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverTasteGate single carrier alignment`

Proof. Carrier admission is the displayed finite packet. The tolerance row, nonempty bundle, centers, subordinate radii, pointwise precision rows, pointwise-modulus rows, coverage witnesses, rational comparisons, transport ledger, continuation routes, package provenance, and local naming row are all visible coordinates.

Classifier stability is componentwise over those coordinates. The transport ledger L can rename bundled probes, centers, radius histories, precision histories, coverage rows, and comparison rows only through the displayed hsame entries, and the routes in Q preserve the compact and continuous reads attached to the same bundle.

Coverage exactness is the half-radius row H. Pointwise compatibility is the row M at each center together with the precision row in D. Rational subordination is the row F, which binds each radius row in R below the corresponding precision row in D.

These rows exhaust the consumer surface. Since no coordinate stores an open cover, an external selector, a host minimum, or a uniform precision history, the local naming certificate cannot export any of those objects. □

Theorem 596.3 (SubordinateModulusCover uniform-modulus handoff)**.** *Every accepted* SubordinateModulusCover *packet hands a* UniformModulus$^{\uparrow}$ *consumer exactly the nonempty* ProbeBundle *spine, bundled centers, positive subordinate radius rows, pointwise-modulus precision rows, half-radius coverage rows, and rational subordination comparisons needed by the finite lower-bound fold. The handoff does not yet choose the uniform precision; it supplies the finite input ledger from which the* UniformModulus$^{\uparrow}$ *fold computes that precision.*

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverUniformHandoff`

Proof. Project the accepted packet through Definition 596.1. The consumer receives $\mathcal{P}$, C, R, D, M, H, and F through the displayed routes in Q and the provenance rows P, N.

The nonempty bundle and coverage rows are the compact side of the handoff. The pointwise-modulus and precision rows are the continuous side. The rational comparison ledger records the subordination that permits the later lower-bound fold to stay below every bundled half-radius row.

No fold output is present in the carrier. Therefore the handoff is precisely the finite subordinate-cover input to the $\mathsf{UniformModulus}^{\uparrow}$ rational fold, with no external modulus selector and no host-level compactness object. □

Theorem 596.4 (SubordinateModulusCover carrier obligation)**.** *Every accepted* $\mathsf{SubordinateModulusCover}^{\uparrow}$ *read is admitted through the single carrier*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N)$$

of Definition 596.1. The TasteGate alignment of Definition 596.2 binds the positive tolerance row, nonempty probe bundle, centers, subordinate radii, pointwise precision rows, pointwise-modulus row, half-radius coverage row, rational comparison ledger, transport rows, continuation routes, package provenance, and local naming row to this one packet.

Proof. Project an accepted read through the carrier definition. The rows available to the consumer are exactly $E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N$.

Apply Definition 596.2. Its checked TasteGate row states the local NameCert obligations on the same displayed carrier, including carrier admission and consumer non-escape.

Since the carrier exports no open cover, external radius selector, host minimum, or uniform precision row, admission cannot be transferred to a second packet. The accepted read is therefore a read of the single displayed subordinate-modulus-cover carrier. □

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverCarrierObligation`

Theorem 596.5 (SubordinateModulusCover classifier stability obligation)**.** *Classifier transport for an accepted* $\mathsf{SubordinateModulusCover}^{\uparrow}$ *packet is componentwise on the rows of*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N).$$

The TasteGate alignment of Definition 596.2 permits transport only through the hsame *ledger* L *and the displayed* Cont *routes* Q*, preserving the tolerance, bundle, centers, radius rows, precision rows, pointwise-modulus rows, coverage rows, rational comparisons, package provenance, and local naming row.*

Proof. Start with the single carrier S. The only classifier-stability coordinate is the componentwise transport ledger L, and the only consumer routes are the displayed continuations in Q.

Use Definition 596.2. The TasteGate row records classifier stability under L together with compact coverage exactness, pointwise-modulus compatibility, rational subordination exactness, and consumer non-escape for the same packet.

Thus a transported packet preserves each visible coordinate rather than replacing the carrier or changing the bundle. No parameter-transport equivalence, open-cover selector, host minimum, or uniform precision row is introduced by classifier transport. □

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverClassifierStabilityObligation`

Theorem 596.6 (SubordinateModulusCover ledger handoff obligation)**.** *The compact, continuous, and uniform-modulus handoff ledger of an accepted* $\mathsf{SubordinateModulusCover}^{\uparrow}$ *packet is exactly the route through*

$$\mathcal{P}, C, R, D, M, H, F, L, Q, P, N$$

inside the single carrier $S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N)$*. The handoff exposes the finite nonempty bundle, bundled centers, subordinate radius rows, pointwise-modulus precision rows, half-radius coverage witnesses, and rational subordination comparisons needed before the* $\mathsf{UniformModulus}^{\uparrow}$ *lower-bound fold, and it exposes no fold output.*

Proof. Read the handoff rows from the carrier definition. The compact side supplies $\mathcal{P}$, C, and H; the continuous side supplies D and M; the rational subordination ledger supplies R and F; and L, Q, P, N transport, route, and record the public read.

Apply Definition 596.2. Its TasteGate row binds coverage exactness, pointwise-modulus compatibility, rational subordination exactness, and non-escape to the same carrier S.

Finally use Definition 596.3. The $\mathsf{UniformModulus}^{\uparrow}$ consumer receives precisely the finite input ledger for the later lower-bound fold, while the uniform precision chosen by that fold remains outside the subordinate cover packet. □

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverLedgerHandoffObligation`

Theorem 596.7 (SubordinateModulusCover scope dependency)**.** *Every compact-uniform handoff row of an accepted* $\mathsf{SubordinateModulusCover}^{\uparrow}$ *packet factors through* $\mathsf{Compact}^{\uparrow}$ *finite-net coverage,* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus data,* $\mathsf{Met}^{\uparrow}$ *distance witnesses,* $\mathsf{Rat}^{\uparrow}$ *comparison rows,* ProbeBundle *induction,* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*, and the* $\mathsf{UniformModulus}^{\uparrow}$ *consumer. The factorization stays inside*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N),$$

and it contains no open-cover compactness, host minimum, or external selector.

Proof. Project the carrier $S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N)$. The bundle spine $\mathcal{P}$ and center rows C supply the finite-net side, while R, D, M, H, F record subordinate radii, pointwise precision, pointwise-modulus data, half-radius coverage, and rational comparison.

Apply Definition 596.2. The local $\mathsf{NameCert}_{\mathsf{SubordinateModulusCover}^{\uparrow}}$ surface binds those rows to BHist, hsame, Cont, Pkg, and local naming, so the dependency cannot leave the displayed packet.

Use Definition 596.3 and Definition 596.6. They expose the compact, continuous, metric, rational, and finite-bundle rows to the $\mathsf{UniformModulus}^{\uparrow}$ consumer before the lower-bound fold is read.

Thus the scoped dependency is exhausted by the displayed carrier and its existing handoff obligations. Since S has no coordinate for open-cover compactness, host minima, or external selectors, none of those objects can enter the compact-uniform handoff. □

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverScopeDependency`

Theorem 596.8 (SubordinateModulusCover compact coverage exactness)**.** *Let*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N)$$

be an accepted $\mathsf{SubordinateModulusCover}^{\uparrow}$ *carrier. Every source history covered by the packet is covered by a bundled center from the nonempty* ProbeBundle *spine* $\mathcal{P}$*, through the half-radius coverage rows* H *and the displayed consumer routes* Q*. The coverage row is internal to the carrier and uses no host open-cover compactness, external radius selector, host minimum, or uniform precision output.*

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverCompactCoverageExactness`

Proof. Project the carrier by Definition 596.1. The nonempty bundle spine $\mathcal{P}$, center row C, subordinate radius row R, half-radius coverage row H, and continuation route row Q are all visible coordinates of the same packet.

Apply Definition 596.2. Its TasteGate alignment binds compact coverage exactness to the half-radius rows in H for the displayed carrier S.

The public coverage read is therefore the route through $\mathcal{P}, C, R, H, Q, P, N$. Since the carrier definition contains no open-cover object, external radius selector, host minimum, or uniform precision row, none of those objects can supply the coverage witness. □

Theorem 596.9 (SubordinateModulusCover pointwise compatibility)**.** *Let*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N)$$

be an accepted $\mathsf{SubordinateModulusCover}^{\uparrow}$ *carrier. Every precision row in D is supplied by the pointwise-modulus row M at the corresponding bundled center from $\mathcal{P}$ and is transported only by the componentwise* hsame *ledger L. The compatibility row does not choose an external modulus, host minimum, or uniform precision output.*

Proof. Read the relevant coordinates from Definition 596.1. The center row is C, the precision row is D, the pointwise-modulus row is M, and the only componentwise transport ledger is L.

Use Definition 596.2. The TasteGate alignment lists pointwise-modulus compatibility for the rows in M and D and classifier stability only through L.

Thus each precision read is attached to the corresponding bundled center and its pointwise-modulus row. The carrier has no coordinate for an external modulus selector, a host minimum, or a uniform precision result, so compatibility cannot be sourced from any of those objects. □

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverPointwiseCompatibility`

Theorem 596.10 (SubordinateModulusCover rational subordination exactness)**.** *Let*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N)$$

be an accepted $\mathsf{SubordinateModulusCover}^{\uparrow}$ *carrier. Each subordinate radius row in R is below its matching pointwise precision row in D through the rational comparison ledger F. This exactness statement is a finite ledger row of the packet and does not assert compact host minima, external radius selection, or a completed uniform-modulus output.*

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverRationalSubordinationExactness`

Proof. Start with the carrier definition. It displays subordinate radius rows R, pointwise precision rows D, and the rational comparison ledger F as separate coordinates of the same finite packet.

Apply Definition 596.2. Its TasteGate row names rational subordination exactness for the comparison rows in F, binding each radius row in R below the corresponding precision row in D.

The handoff remains finite by Definition 596.6. The comparison is consumed as part of the subordinate-cover ledger before the $\mathsf{UniformModulus}^{\uparrow}$ lower-bound fold, so no host minimum, external radius selector, or fold output is introduced here. □

Theorem 596.11 (SubordinateModulusCover carrier admission)**.** *Carrier admission for* SubordinateModulusCover *is exactly the displayed packet*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N).$$

It consumes the $\mathsf{Compact}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, ProbeBundle, BHist, hsame, Cont, Pkg, *and* NameCert *rows shown in Definition 596.1, and it admits no host open cover, external selector, host minimum, or uniform-modulus fold output.*

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverCarrierAdmission`

Proof. Project the carrier definition. The listed packet contains the tolerance row, nonempty probe bundle, centers, subordinate radii, pointwise precision rows, pointwise-modulus row, half-radius coverage row, rational comparison ledger, transport, replay, provenance, and local naming.

Apply the NameCert obligations of Definition 596.2. They bind carrier admission, classifier stability, coverage exactness, pointwise compatibility, rational subordination exactness, and consumer non-escape to that same packet.

Use compact coverage exactness, pointwise compatibility, rational subordination exactness, and the uniform handoff theorem. These results account for every analytic row needed by the L10 compact-uniform route, so admission is exhausted by S and cannot come from any host object outside the displayed carrier. □

Theorem 596.12 (SubordinateModulusCover radius stability)**.** *Transport through the* hsame *ledger L preserves the subordinate radius rows R, pointwise precision rows D, half-radius coverage rows H, and rational comparison rows F without changing the* ProbeBundle *spine $\mathcal{P}$. Thus a transported* SubordinateModulusCover$^{\uparrow}$ *packet presents the same finite subordinate bundle to every* UniformModulus$^{\uparrow}$ *consumer.*

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverRadiusStability`

Proof. Read the transport coordinate L from Definition 596.1. It is componentwise over the tolerance, bundle, centers, radius histories, precision histories, pointwise rows, coverage rows, and rational comparison rows.

Apply the NameCert obligations and the classifier stability obligation. They restrict transport to the displayed rows and preserve the continuation routes Q through which compact and continuous consumers read the packet.

Now use compact coverage exactness, pointwise compatibility, rational subordination exactness, and the uniform handoff theorem. Since the bundle spine $\mathcal{P}$ remains the same displayed spine and the rows R, D, H, F are transported componentwise, the handoff ledger remains stable without introducing a new bundle, host minimum, or fold output. □

Theorem 596.13 (SubordinateModulusCover ledger exactness)**.** *The handoff ledger exposed from an accepted* SubordinateModulusCover$^{\uparrow}$ *packet to* UniformModulus$^{\uparrow}$ *is exhausted by the finite bundle $\mathcal{P}$, bundled centers C, subordinate radii R, pointwise precision rows D, half-radius coverage rows H, and rational comparison rows F, together with the displayed transport, replay, provenance, and local naming rows. It contains no host minimum, no external radius selector, and no fold output.*

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverLedgerExactness`

Proof. Project the handoff rows from Definition 596.1. The compact side is $\mathcal{P}, C, H$, the pointwise side is D, M, and the rational subordination side is R, F.

Apply the NameCert obligations, compact coverage exactness, pointwise compatibility, and rational subordination exactness. These theorems attach each ledger row to the same accepted packet and prevent any read from bypassing L, Q, P, N.

Finally use the uniform handoff theorem and the carrier admission theorem above. The UniformModulus$^{\uparrow}$ consumer receives precisely the finite subordinate-cover input ledger before the lower-bound fold, while the fold result and any host minimum remain outside the packet. □

Theorem 596.14 (SubordinateModulusCover TasteGate Stage-F discipline)**.** *The single carrier*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N)$$

supplies the Stage-F discipline for SubordinateModulusCover$^{\uparrow}$*: the finite* ProbeBundle *spine is nontrivial, the visible fields are faithful to the carrier, and every* UniformModulus$^{\uparrow}$ *consumer must pass through compact coverage, pointwise-modulus rows, rational subordination,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *rows before any uniform-modulus fold is read.*

Proof. Start with carrier admission from Definition 596.11. It identifies S as the single accepted packet and keeps the nonempty ProbeBundle spine, center rows, radius rows, precision rows, pointwise rows, coverage rows, comparison rows, transport, replay, provenance, and local naming visible.

Apply the NameCert obligations of Definition 596.2. They bind the carrier fields to the same TasteGate surface and prevent consumer reads from bypassing the displayed hsame, Cont, Pkg, and local naming rows.

Use radius stability and ledger exactness from Definition 596.12 and Definition 596.13. The compact coverage row, pointwise-modulus row, and rational subordination row remain faithful to S through transport, and the UniformModulus$^{\uparrow}$ consumer sees only the finite subordinate-cover ledger before the fold output exists. □

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverTasteGate stageF discipline`

Theorem 596.15 (SubordinateModulusCover compact-uniform consumer boundary)**.** *Every* Compact$^{\uparrow}$*,* ContinuousMap$^{\uparrow}$*, or* Met$^{\uparrow}$ *consumer that reads an accepted* SubordinateModulusCover$^{\uparrow}$ *packet must expose the finite* ProbeBundle *spine, pointwise-modulus rows, rational subordination ledger, half-radius coverage row,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *before any* UniformModulus$^{\uparrow}$ *fold is read. The consumer boundary is exactly the displayed route through the carrier*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N),$$

and it exports no host compact minimum, open-cover selector, external modulus choice, or completed uniform precision.

Proof. Carrier admission identifies the only packet available to the consumer. The rows $\mathcal{P}, C, R, D, M, H, F, L, Q, P$ are displayed coordinates of the single carrier, and the tolerance row E only records the compact-uniform request that the packet answers.

Apply radius stability, ledger exactness, pointwise compatibility, and rational subordination exactness. These results keep the finite bundle spine, centerwise precision rows, subordinate radii, half-radius coverage row, rational comparison ledger, and transport rows attached to the same accepted packet through hsame and Cont replay.

Finally apply the Stage-F discipline. It forces every UniformModulus$^{\uparrow}$ consumer to read compact coverage, pointwise-modulus data, rational subordination, provenance, replay, and the local naming row before the lower-bound fold is available. Hence a compact, continuous, or metric consumer reaches the fold only through the finite subordinate-cover boundary, with no host compact minimum, selector, external modulus choice, or completed uniform precision. □

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverCompactUniformConsumerBoundary`

Theorem 596.16 (SubordinateModulusCover choice-free handoff)**.** *Every accepted* SubordinateModulusCover$^{\uparrow}$ *packet exposes the finite rows* $\mathcal{P}, C, R, D, M, H, F, L, Q, P, N$ *to a* UniformModulus$^{\uparrow}$ *consumer before any lower-bound fold is read. No row may be retyped as an external radius selector, host minimum, open-cover compactness witness, or completed uniform precision.*

Proof. Start from carrier admission in Definition 596.1. The rows $\mathcal{P}, C, R, D, M, H, F, L, Q, P, N$ are displayed coordinates of the same finite packet, and the tolerance row E only supplies the request read by that packet.

Compact coverage exactness, pointwise compatibility, and rational subordination exactness attach the bundle, centers, subordinate radii, precision rows, pointwise-modulus row, coverage row, and comparison ledger to the same carrier. The uniform handoff theorem then exposes those finite rows to the $\mathsf{UniformModulus}^{\uparrow}$ consumer before the lower-bound fold produces any output.

Ledger exactness rules out the remaining escape routes. Since the carrier contains no selector coordinate, no host minimum coordinate, no open-cover compactness row, and no completed uniform precision row, none of the displayed rows can be retyped as one of those objects. □

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverChoiceFreeHandoff`

Theorem 596.17 (SubordinateModulusCover finite-selection scope)**.** *Every accepted* $\mathsf{SubordinateModulusCover}^{\uparrow}$ *packet exposes the nonempty* ProbeBundle *spine, bundled centers, subordinate positive-radius rows, pointwise precision rows, half-radius coverage rows, and rational comparison ledger as the full finite-selection scope consumed by* $\mathsf{UniformModulus}^{\uparrow}$*. No host compact minimum, open-cover selector, or completed uniform precision row is present in that scope.*

Proof. Project the accepted packet through Definition 596.1. The finite-selection data are exactly the bundle $\mathcal{P}$, centers C, subordinate radii R, pointwise precision rows D, half-radius coverage rows H, and rational comparison ledger F, with L, Q, P, N supplying transport, replay, provenance, and local naming.

Apply Definition 596.2. Its carrier admission and consumer non-escape clauses bind those rows to the same local $\mathsf{NameCert}_{\mathsf{SubordinateModulusCover}^{\uparrow}}$ surface, while compact coverage exactness, pointwise compatibility, and rational subordination exactness account for the three analytic faces of the packet.

Use Definition 596.8, Definition 596.9, and Definition 596.10. These theorems attach coverage, centerwise precision, and radius comparison to the displayed finite carrier rather than to an ambient compact object.

Finally apply Definition 596.3 and Definition 596.16. The $\mathsf{UniformModulus}^{\uparrow}$ consumer receives the finite subordinate-cover ledger before the lower-bound fold is read, so the scope contains neither a host compact minimum nor an open-cover selector nor a completed uniform precision row. □

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverFiniteSelectionScope`

Theorem 596.18 (SubordinateModulusCover obligation-closure route)**.** *The displayed carrier, TasteGate single-carrier alignment, carrier admission, classifier stability, compact coverage exactness, pointwise compatibility, rational subordination exactness, ledger exactness, choice-free handoff, and finite-selection scope form the obligation surface for* $\mathsf{SubordinateModulusCover}^{\uparrow}$*. These rows remain on the single carrier*

$$S = (E, \mathcal{P}, C, R, D, M, H, F, L, Q, P, N),$$

and they expose no host compact minimum, open-cover selector, external modulus choice, completed uniform precision, or carrier outside the packet.

Lean4 ✓ `BEDC.Derived.SubordinateModulusCoverUp.SubordinateModulusCoverObligationClosureRoute`

Proof. Start with the carrier of Definition 596.1 and the TasteGate row of Definition 596.2. Together they bind the tolerance, nonempty probe bundle, centers, subordinate radii, pointwise precision rows, pointwise-modulus row, half-radius coverage row, rational comparison ledger, transport, replay, provenance, and local naming to the same packet S.

Use carrier admission and classifier stability from Definition 596.11 and Definition 596.5. These results keep accepted reads and transported reads on the displayed carrier and prevent a consumer from replacing S by an external compact or modulus object.

Apply compact coverage exactness, pointwise compatibility, and rational subordination exactness. The theorems Definition 596.8, Definition 596.9, and Definition 596.10 account for the coverage, pointwise-modulus, and radius-comparison rows without leaving the packet.

Finally combine ledger exactness, choice-free handoff, and finite-selection scope from Definition 596.13, Definition 596.16, and Definition 596.17. The $\mathsf{UniformModulus}^{\uparrow}$ consumer receives exactly the finite subordinate-cover ledger before the fold output, so the named rows form the obligation-closure route and no hidden selection or completed uniform precision is exported. □

Falsifiable prediction: Every accepted $\mathsf{SubordinateModulusCover}^{\uparrow}$ consumer reaches $\mathsf{UniformModulus}^{\uparrow}$ only after displaying compact coverage, continuousmap pointwise-modulus rows, metric radius rows, rat comparison rows, rational subordination, hsame transport, Cont replay, Pkg provenance, and local naming.

Independence witness: compact, continuousmap, metric, rat, uniformmodulus: no listed sibling is bijective to $\mathsf{SubordinateModulusCover}^{\uparrow}$ because this packet jointly carries a nonempty probe bundle, bundled centers, subordinate radius rows, pointwise precision rows, half-radius coverage, rational comparison, transport, replay, provenance, and local naming before the uniform-modulus fold.

Closure status for $\mathsf{NameCert}_{\mathsf{SubordinateModulusCover}^{\uparrow}}$.

Constructive story: A $\mathsf{SubordinateModulusCover}^{\uparrow}$ packet is generated from a positive tolerance row, a nonempty ProbeBundle spine, bundled centers, subordinate positive-radius rows, pointwise-modulus precision rows, half-radius coverage rows, rational comparison ledgers, transport rows, continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SubordinateModulusCover}^{\uparrow}}, \mathsf{obligation})$

Scope closed: Definition 596.1, Definition 596.2, Definition 596.8, Definition 596.9, Definition 596.10, and Definition 596.3 register the finite subordinate cover used before the compact-uniform-continuity rational lower-bound fold.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SubordinateModulusCover}^{\uparrow}}, \mathsf{formalTarget})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close the rational lower-bound fold, the final uniform-modulus ledger, compactness of host open covers, external modulus selection, or bridge checking.

Upgrade path: Scoped closure requires Lean checking of carrier admission, classifier stability, coverage exactness, pointwise compatibility, rational subordination exactness, and the uniform-modulus handoff for the same displayed packet.

Chapter 597

A Concrete Naming Certificate for $\mathsf{ContinuationTermination}^{\uparrow}$

The $\mathsf{ContinuationTermination}^{\uparrow}$ interface packages the finite termination and behaviour-classifier reading of a Cont trace. It records only displayed histories, displayed continuation rows, componentwise transport, package provenance, and a local naming certificate.

The finite trace row τ is consumed through chapter 469 before the terminal witness and behaviour-classifier rows are exposed. $\mathsf{ContinuationTrace}^{\uparrow}$ supplies finite replay for the displayed Cont trace; $\mathsf{ContinuationTermination}^{\uparrow}$ adds terminal witness, behaviour classifier, transport, provenance, and local NameCert rows.

Definition 597.1 (Continuation termination carrier)**.** *A* $\mathsf{ContinuationTermination}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (s, t, \tau, u, b, h, p, n)$$

with the following visible coordinates:

1. *s is the start history;*
2. *t is the terminal history;*
3. *τ is the finite* Cont *trace from s to t, displayed as the finite list of intermediate* BHist *rows and transition marks;*
4. *u is the terminal witness row, naming the fact that no further displayed* Cont *row is exported from t inside this packet;*
5. *b is the behaviour-classifier row comparing start, terminal, and trace-visible histories only through the displayed classifier;*
6. *h stores componentwise* hsame *transports for the start history, terminal history, trace rows, terminal witness row, behaviour-classifier row, provenance row, and local name;*
7. *p is the* Pkg *provenance over* BHist, Cont, hsame, *the behaviour classifier, terminal-witness row, and* NameCert*;*
8. *n is the local* $\mathsf{NameCert}_{\mathsf{ContinuationTermination}^{\uparrow}}$ *row.*

The carrier contains no host evaluator, no quotient behaviour class, no unbounded trace, and no classical decision procedure for termination.

Lean4 ✓ `BEDC.Derived.ContinuationTerminationUp.ContinuationTerminationTasteGate single carrier alignment`

Definition 597.2 (Continuation termination classifier)**.** *For accepted carriers*

$$T = (s, t, \tau, u, b, h, p, n) \quad \textit{and} \quad T' = (s', t', \tau', u', b', h', p', n'),$$

the classifier $\mathsf{ContinuationTerminationClassifier}(T, T')$ *compares only the displayed start histories, terminal histories, finite* Cont *traces, terminal witness rows, behaviour-classifier rows, componentwise* hsame *transports,* Pkg *provenance, and local* NameCert *rows. It never compares host evaluation functions, quotient behaviour classes, infinite traces, or global termination predicates.*

Theorem 597.3 (Continuation termination NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContinuationTermination}^{\uparrow}}$ *surface for Definition 597.1 consists exactly of carrier admission for T, start-history exposure through s, terminal-history exposure through t, finite* Cont *trace exposure through τ, terminal witness exposure through u, behaviour-classifier exposure through b, componentwise* hsame *transport through h,* Pkg *provenance through p, and local naming through n.*

Lean4 ✓ `BEDC.Derived.ContinuationTerminationUp.ContinuationTerminationCarrier namecert obligations`

Proof. Carrier admission is projection from the displayed packet T. The rows $s, t, \tau, u, b, h, p, n$ list the start history, terminal history, finite continuation trace, terminal witness, behaviour-classifier row, transports, provenance, and local name.

The terminal witness is finite because it is attached to the displayed terminal row t and the displayed trace τ. It records the boundary exported by this packet, not a host-level proof that arbitrary evaluation must halt.

The behaviour row is likewise local. It compares only the rows named by the packet and is transported by the stored hsame data. Since no coordinate contains a host evaluator, quotient behaviour class, unbounded trace, or classical termination decision, the obligation surface is exactly the listed rows. □

Theorem 597.4 (Continuation termination behaviour transport)**.** *If two accepted* $\mathsf{ContinuationTermination}^{\uparrow}$ *packets are related by the classifier of Definition 597.2, then any behaviour-facing consumer of the first packet transports to the second packet only through the displayed start history, terminal history, finite* Cont *trace, terminal witness, behaviour-classifier row, componentwise* hsame *data,* Pkg *provenance, and local* NameCert *row.*

Proof. Unfold the classifier. Its comparison fields are precisely $s, t, \tau, u, b, h, p, n$ and their primed counterparts.

Use the componentwise hsame rows to move the start and terminal histories, each displayed trace row, the terminal witness, and the behaviour-classifier row. The provenance and local name rows move through their displayed package and certificate coordinates.

There is no remaining coordinate from which a consumer could read host evaluation, quotient behaviour equality, an infinite execution trace, or a termination oracle. Therefore behaviour transport is confined to the finite packet surface. □

Lean4 ✓ `BEDC.Derived.ContinuationTerminationUp.ContinuationTerminationCarrier behavior transport`

Theorem 597.5 (Continuation termination non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{ContinuationTermination}^{\uparrow}$ *packet factors through the finite rows*

$$s, t, \tau, u, b, h, p, n.$$

The consumer may read the start history, terminal history, finite Cont *trace, terminal witness, behaviour-classifier row,* hsame *transports,* Pkg *provenance, and local* NameCert *row, and it cannot read host evaluation, quotient behaviour classes, unbounded traces, or a classical termination decision.*

Lean4 ✓ `BEDC.Derived.ContinuationTerminationUp.ContinuationTerminationCarrier nonescape`

Proof. Project the accepted carrier. The displayed packet contains exactly the rows $s, t, \tau, u, b, h, p, n$.

Apply the local NameCert obligations to identify the exported consumer surface. The terminal witness and behaviour-classifier rows are named inside the same finite carrier and are transported only by the stored componentwise hsame data.

Use behaviour transport for classifier-facing consumers. It keeps every comparison on the visible trace and witness rows.

Since the carrier exports no host evaluator, quotient behaviour class, unbounded trace, or classical termination predicate, no downstream consumer can escape the finite continuation-termination packet. □

Theorem 597.6 (Continuation termination terminal route)**.** *For every accepted* ContinuationTermination$^{\uparrow}$ *packet*

$$T = (s, t, \tau, u, b, h, p, n),$$

the terminal witness row u is readable only together with the start history s, terminal history t, finite Cont *trace τ, behaviour row b, componentwise* hsame *transport h,* Pkg *provenance p, and local* NameCert *row n. A terminal-facing consumer therefore receives a displayed finite route through these rows, and never a host total evaluator, quotient behaviour class, unbounded trace, or classical termination oracle.*

Proof. Project the carrier of Definition 597.1. The terminal witness u is one coordinate of the displayed packet T, not an isolated endpoint predicate.

Use the NameCert obligations of Definition 597.3. They expose u only after the start row s, terminal row t, trace row τ, behaviour row b, transport row h, provenance row p, and local name row n remain visible in the same packet.

Since no carrier coordinate names host evaluation, quotient behaviour equality, an unbounded trace, or a global termination decision, reading u cannot escape the finite terminal route. □

Theorem 597.7 (Continuation termination classifier stability)**.** *If two accepted* ContinuationTermination$^{\uparrow}$ *packets are related by the classifier of Definition 597.2, then every classifier-facing read transports terminal and behaviour data componentwise through the displayed rows*

$$s, t, \tau, u, b, h, p, n.$$

In particular, terminal witnesses and behaviour rows remain attached to the same finite start, terminal, trace, transport, provenance, and local naming surface.

Proof. Unfold the classifier of Definition 597.2. Its comparison fields are exactly the start histories, terminal histories, finite traces, terminal witnesses, behaviour rows, componentwise transports, provenance rows, and local names of the two packets.

Apply the behaviour transport theorem to move any classifier-facing consumer along the displayed hsame coordinates. The terminal witness moves with u, and the behaviour row moves with b, while s, t, τ, h, p, n keep the route tied to the same finite packet surface.

No hidden evaluator, quotient behaviour class, infinite trace, or termination oracle remains outside those coordinates. Hence classifier-related packets preserve terminal and behaviour reads componentwise through the listed rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{ContinuationTermination}^{\uparrow}}$.

Constructive story: A $\mathsf{ContinuationTermination}^{\uparrow}$ packet is generated from finite BHist rows for an initial state, displayed continuation trace, terminal witness, behavior classifier, and consumer-facing route ledger. Termination is not read as a global evaluator predicate; it is the existence of the shown finite trace whose endpoint is routed by Cont to the terminal row. Classifier-facing consumers use hsame to transport the visible trace, witness, and behavior rows componentwise, while Pkg records the continuation and naming dependencies. The packet therefore supplies a bounded continuation-termination certificate and refuses unbounded behavior classes or host evaluation semantics.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ContinuationTermination}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the continuation-termination carrier, behavior transport, terminal route obligations, and finite packet non-escape statement for $\mathsf{ContinuationTermination}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ContinuationTermination}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim a total evaluator, quotient behavior class, unbounded trace semantics, selected divergence evidence, or a global termination decision procedure.

Upgrade path: Obligation closure requires Lean encodings of the finite trace carrier, terminal witness route, behavior transport, and non-escape theorem.

Chapter 598

A Concrete Naming Certificate for $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$

The $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$ surface records a type-checking run as a finite BEDC packet. It refines the $\mathsf{TypeClassifierMembership}^{\uparrow}$, $\mathsf{ClassifierTyping}^{\uparrow}$, and $\mathsf{SubjectReduction}^{\uparrow}$ views by making the derivation ledger, reduction route, classifier membership, transport, provenance, and local naming row visible in one certificate.

The carrier reads its classifier row through chapter 476, its typing ledger through chapter 489, and its reduction-preservation row through chapter 483; this chapter packages those sibling surfaces into a single derivation trace rather than replacing them.

Definition 598.1 (Type-checking derivation trace carrier)**.** *A* $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (T, E, C, D, H, R, P, N)$$

with the following displayed rows:

1. *T is the term row, recording the source term, target term, typing context entries, and the finite term-history positions inspected by the checker;*
2. *E is the* Ext*-membership classifier row, recording the accepted typing judgments for the source row and the target row;*
3. *C is the* Cont *reduction route, displaying each checked step from the source term row to the target term row;*
4. *D is the derivation ledger, listing the typing-rule entries, premise addresses, and rule conclusions consumed by the checker;*
5. *H records componentwise* hsame *transports for the term row, classifier row, continuation route, derivation ledger, subject-reduction row, package provenance, and local naming row;*
6. *R is the subject-reduction row, recording that every displayed* Cont *step whose source is in E has its target in the transported* Ext *row;*
7. *P is the* Pkg *provenance over* BHist*, term rows,* Ext*,* Cont*, derivation ledgers,* hsame*, subject-reduction rows, and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{TypeCheckingDerivationTrace}^{\uparrow}}$ *row.*

The packet is finite and derivation-facing. It contains no ambient metatheory, no host equality of terms, no unrecorded typing rule, no hidden reduction step, and no proof object outside the displayed BEDC rows.

Lean4 ✓ `BEDC.Derived.TypeCheckingDerivationTraceUp.TypeCheckingDerivationTraceTasteGate single carrier alignment`

Theorem 598.2 (Type-checking derivation trace subject-reduction surface)**.** *Every accepted* TypeCheckingDerivatio *carrier routes the typed source row and the typed target row through the displayed* Ext *and* Cont *data. More precisely, if a consumer reads a source typing judgment from E and a reduction step from C, then the only available target typing judgment is the one recorded by the subject-reduction row R, transported through H and packaged by P, N.*

Thus a trace consumer may inspect T, E, C, D, H, R, P, N, but it cannot replace the derivation ledger by an unrecorded rule, replace the reduction route by a host computation, or identify source and target terms by host equality.

Proof. Project the accepted packet $Z = (T, E, C, D, H, R, P, N)$. The source and target term entries are carried by T, while the typing judgments available to the checker are carried by E.

Next read the continuation route C. Each reduction step consumed by a trace is displayed before any target typing judgment is exposed, so the route cannot be supplied by an external host computation.

Finally use the subject-reduction row R together with H, P, N. The transport rows replay the same classifier and continuation data under componentwise hsame, and the package and local naming rows bind the target typing judgment to the displayed trace. Since no other typing-rule or equality coordinate is present, the subject-reduction surface is exhausted by those rows. □

Theorem 598.3 (Type-checking derivation trace NameCert obligations)**.** *For the carrier of Definition 598.1, the local* $\mathsf{NameCert}_{\mathsf{TypeCheckingDerivationTrace}\uparrow}$ *surface consists of six finite obligations:*

1. *carrier admission for the packet $Z = (T, E, C, D, H, R, P, N)$;*
2. Ext *membership for the displayed source and target typing rows;*
3. *subject reduction along the displayed* Cont *route;*
4. *ledger exactness for every typing-rule premise and conclusion consumed by D;*
5. *classifier transport through the componentwise* hsame *rows in H;*
6. *non-escape from the host type theory, excluding unrecorded typing rules, host equality of terms, hidden reduction steps, external proof objects, and ambient metatheoretic closure.*

Proof. Carrier admission is the projection of the finite tuple in Definition 598.1. The rows T, E, C, D, H, R, P, N are the only public coordinates named by the local certificate.

The Ext membership and subject-reduction obligations are read together. The classifier row E records the accepted typing judgments, the continuation route C records the checked reduction path, and Definition 598.2 identifies the target judgment through R.

Ledger exactness is supplied by D. Each typing-rule premise and conclusion consumed by the checker is addressed inside that row, so a consumer cannot introduce an unlisted rule application.

The classifier transport and non-escape clauses then follow from H, P, N and the carrier inventory. Componentwise hsame rows transport only the displayed data, while the missing coordinates rule out host equality, hidden reductions, external proof objects, and ambient metatheory. □

Theorem 598.4 (Type-checking derivation trace classifier membership readback)**.** *Every accepted* TypeCheckingDerivationTrace$^{\uparrow}$ *carrier exposes the* TypeClassifierMembership$^{\uparrow}$ *and* ClassifierTyping$^{\uparrow}$ *reads only through the displayed classifier row E, the derivation ledger D, the componentwise* hsame *transport H, the* Pkg *row P, and the local* NameCert *row N. A consumer may read classifier membership for the source and target typing rows, but it cannot replace that membership by a host typing judgment or an unrecorded classifier.*

Proof. Project the carrier $Z = (T, E, C, D, H, R, P, N)$. The only classifier coordinate is E, and the only derivation account that justifies the reads of E is the displayed ledger D.

Use the subject-reduction surface next. It already routes the typed source row and typed target row through Ext and Cont data, so classifier membership is read inside the same finite packet rather than through an ambient typing oracle.

The NameCert obligations then bind the readback to H, P, N. Componentwise hsame preserves the same classifier row, package provenance records the same BHist source, and local naming keeps the consumer at the TypeCheckingDerivationTrace$^{\uparrow}$ certificate boundary. □

Theorem 598.5 (Type-checking derivation trace classifier route)**.** *Every accepted classifier-facing read of a* TypeCheckingDerivationTrace$^{\uparrow}$ *packet factors through the displayed* Ext *membership row E, derivation ledger D, componentwise* hsame *transports H, package provenance P, and local* NameCert *row N. It cannot be supplied by host type equality, hidden reductions, external proof objects, or a normalizer row.*

Proof. Project the carrier $Z = (T, E, C, D, H, R, P, N)$. The classifier-facing coordinate is E, and the ledger that accounts for its typing-rule reads is D.

Apply Definition 598.4. It already routes the TypeClassifierMembership$^{\uparrow}$ and ClassifierTyping$^{\uparrow}$ reads through E, D, H, P, N and rules out host typing judgments and unrecorded classifiers.

For the non-escape clause, invoke Definition 598.7. That boundary states that the accepted packet contains no hidden normalizer, host term equality, unrecorded reduction step, or external proof object, so the classifier route remains the displayed finite row E, D, H, P, N. □

Theorem 598.6 (Type-checking derivation trace subject-reduction transport)**.** *For every accepted* TypeCheckingDerivationTrace$^{\uparrow}$ *carrier, the* SubjectReduction$^{\uparrow}$ *row R is transported only along the displayed* Cont *route C and the componentwise* hsame *row H. The transported target typing judgment is therefore the one packaged by P, N from the source classifier row E and derivation ledger D.*

Lean4 ✓ `BEDC.Derived.TypeCheckingDerivationTraceUp.TypeCheckingDerivationTracePacket subject reduction transport`

Proof. Start from the subject-reduction surface. It states that a consumer reading a source typing judgment from E and a reduction step from C reaches the target typing judgment through R.

The carrier makes C and H the only continuation and transport rows. Thus subject reduction can be replayed only over the displayed Cont path and only under componentwise hsame for the same term row, classifier row, derivation ledger, and provenance data.

Finally apply the NameCert obligations. They require subject reduction, ledger exactness, classifier transport, and non-escape in one local package, so the transported target judgment is the one recorded by R and cited by P, N, not an external proof object or a host computation. □

Theorem 598.7 (Type-checking derivation trace normal-form consumer boundary)**.** *Every normal-form-facing consumer of an accepted* $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$ *packet receives only the finite trace*

$$T, E, C, D, H, R, P, N.$$

The consumer may use the $\mathsf{ClassifierTyping}^{\uparrow}$*,* $\mathsf{TypeClassifierMembership}^{\uparrow}$*, and* $\mathsf{SubjectReduction}^{\uparrow}$ *rows recorded in that packet, but it receives no hidden normalizer, no host equality of terms, no unrecorded reduction step, and no proof object outside the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *data.*

Proof. Read classifier membership through Definition 598.4. This fixes the classifier-facing rows as E, D, H, P, N inside the same accepted carrier.

Read subject reduction through Definition 598.6. This fixes the reduction-facing rows as C, H, R, P, N and prevents the target typing judgment from being supplied by host computation.

It remains to inspect the carrier inventory. The tuple T, E, C, D, H, R, P, N contains no normalizer row, host equality row, hidden reduction coordinate, or external proof-object coordinate. Therefore a normal-form-facing consumer can only consume the finite trace and its displayed typing and reduction certificates. □

Theorem 598.8 (Type-checking derivation trace rule-address totality)**.** *For every accepted* $\mathsf{TypeCheckingDerivation}$ *carrier* $Z = (T, E, C, D, H, R, P, N)$*, each typing-rule premise and each rule conclusion consumed by the checker has a displayed address in the finite derivation ledger* D*. No rule premise, conclusion, or typing judgment may be supplied by an unrecorded host checker row.*

Proof. Start with the carrier inventory in Definition 598.1. The row D is defined as the derivation ledger listing the typing-rule entries, premise addresses, and rule conclusions consumed by the checker.

Apply the NameCert obligations. Their ledger-exactness clause requires every consumed premise and conclusion to be addressed inside D, while the non-escape clause excludes unrecorded typing rules and host metatheory.

Finally use classifier membership readback. The classifier rows E can be read only with the derivation account D, H, P, N, so every rule-address read remains inside the finite ledger. □

Theorem 598.9 (Type-checking derivation trace Ext-Cont route coherence)**.** *Every subject-reduction read of an accepted* $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$ *packet must pass through both the* Ext *membership row* E *and the* Cont *reduction route* C *before reaching the subject-reduction row* R*. The row* R *therefore reads a target typing boundary only from the displayed classifier and reduction route, transported through* H *and packaged by* P, N*.*

Proof. Begin with the subject-reduction surface. It says that a consumer reading a source typing judgment from E and a reduction step from C reaches the target typing judgment only through R.

Next apply subject-reduction transport. The row R is transported only along C and H, with package and local naming supplied by P, N.

Use classifier membership readback to bind E to the same packet. Since the classifier-facing read passes through E, D, H, P, N, the subject-reduction route cannot bypass E or replace C by host computation before reading R. □

Theorem 598.10 (Type-checking derivation trace normalizer refusal)**.** *No consumer may replace the displayed* $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$ *packet*

$$T, E, C, D, H, R, P, N$$

by a hidden normalizer, host term equality, external proof object, or unrecorded reduction engine. Normal-form, classifier, and subject-reduction reads must remain inside those eight rows and the BEDC BHist*,* Ext*,* Cont*,* hsame*,* Pkg*, and local* $\mathsf{NameCert}$ *surfaces named by the carrier.*

Proof. First invoke the normal-form consumer boundary. It exposes only T, E, C, D, H, R, P, N to normal-form-facing consumers and rules out hidden normalizers, host equality of terms, unrecorded reduction steps, and external proof objects.

For classifier-facing reads, use Definition 598.8 together with classifier membership readback. The rule addresses and classifier membership are read through D, E, H, P, N, not through a host typing oracle.

For subject-reduction-facing reads, use Definition 598.9. The route reaches R only after E and C have been displayed, so a normalizer cannot replace the packet. □

Theorem 598.11 (TypeCheckingDerivationTrace membership-ledger exactness)**.** *For every accepted* $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$ *carrier* $Z = (T, E, C, D, H, R, P, N)$*, every* $\mathsf{TypeClassifierMembership}^{\uparrow}$ *and* $\mathsf{ClassifierTyping}^{\uparrow}$ *read factors through the displayed classifier row* E*, derivation ledger* D*, componentwise transports* H*, package provenance* P*, and local* $\mathsf{NameCert}$ *row* N*. No membership or classifier-typing consumer may replace* E *by a host typing judgment, replace* D *by an unrecorded rule ledger, or bypass the local packet route.*

Proof. Project the carrier and isolate the classifier-facing rows. The only displayed membership coordinate is E, and the only displayed account of rule use is the derivation ledger D.

Apply Definition 598.4. It already routes $\mathsf{TypeClassifierMembership}^{\uparrow}$ and $\mathsf{ClassifierTyping}^{\uparrow}$ reads through E, D, H, P, N.

Finally use Definition 598.7. That boundary excludes hidden normalizers, host equality, unrecorded reduction steps, and external proof objects, so the membership ledger is exact for the finite packet. □

Theorem 598.12 (TypeCheckingDerivationTrace subject-reduction route coverage)**.** *Every* $\mathsf{SubjectReduction}^{\uparrow}$ *consumer of an accepted* $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$ *carrier reads the source row, target row, and reduction route from the finite packet* $Z = (T, E, C, D, H, R, P, N)$*. The source and target term entries are read from* T*, classifier membership is read from* E*, the reduction route is read from* C*, and the target typing boundary is read through* R, H, P, N *rather than through host computation or an unrecorded reduction path.*

Proof. Start with the subject-reduction surface. It identifies the source and target typing judgments by reading T and E, then follows the displayed continuation route C.

Use Definition 598.6. The subject-reduction row R is transported only along C and H, with package and local naming supplied by P, N.

The normal-form consumer boundary of Definition 598.7 rules out a hidden normalizer or unrecorded reduction step. Thus every $\mathsf{SubjectReduction}^{\uparrow}$ consumer is covered by the finite packet rows. □

Theorem 598.13 (TypeCheckingDerivationTrace host normalizer non-escape)**.** *No accepted* TypeCheckingDerivatio *carrier exports a hidden normalizer, host equality of terms, or an unrecorded reduction step. Every normal-form-facing, classifier-facing, or subject-reduction-facing consumer remains inside the*

displayed rows T, E, C, D, H, R, P, N *and the* BHist, hsame, Cont, Pkg, *and local* NameCert *data named there.*

Lean4 ✓ `BEDC.Derived.TypeCheckingDerivationTraceUp.TypeCheckingDerivationTracePacket host normalizer nonescape`

Proof. Inspect the carrier inventory in Definition 598.1. The tuple T, E, C, D, H, R, P, N contains term rows, classifier rows, continuation routes, derivation ledgers, transports, subject-reduction rows, provenance, and local naming, but no host normalizer or host equality coordinate.

For classifier-facing consumers, apply Definition 598.11. For subject-reduction-facing consumers, apply Definition 598.12.

The remaining normal-form-facing case is exactly Definition 598.7. Together these boundaries keep every public read inside the finite trace packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{TypeCheckingDerivationTrace}^{\uparrow}}$.

Constructive story: A $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$ packet is generated from term rows, Ext-membership classifier rows, Cont reduction routes, derivation ledgers, componentwise hsame transports, subject-reduction rows, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TypeCheckingDerivationTrace}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 598.1, Definition 598.2, Definition 598.3, Definition 598.4, Definition 598.6, and Definition 598.13 bind the exported public packet boundary for the carrier, classifier membership, subject-reduction route, derivation ledger, transport, provenance, local naming, and host-normalizer non-escape rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TypeCheckingDerivationTrace}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.TypeCheckingDerivationTraceUp.TypeCheckingDerivationTracePacket\_host\_normalizer\_none`

Bridge status: none

Origin: human

Not claimed: This chapter does not close decidability of arbitrary host type checking, host term equality, hidden reductions, external proof objects, or a public standard bridge.

Upgrade path: No further paper-side theory-axis upgrade remains for the host-normalizer non-escape trace packet.

Chapter 599

A Concrete Naming Certificate for $\mathsf{AxisUnarySpineNormalizer}^{\uparrow}$

The $\mathsf{AxisUnarySpineNormalizer}^{\uparrow}$ packet gives the unary-direction bridge a concrete finite standard-boundary object. It records how a displayed $\mathsf{Nat}^{\uparrow}$ unary spine is read beside a displayed $\mathsf{AxisNat}^{\uparrow}$ zero-spine packet, with the normalizing boundary carried by BHist, hsame, Cont, Pkg, and NameCert rows rather than by an identification of the two carriers.

Its composite dependencies are the $\mathsf{Nat}^{\uparrow}$ unary-spine row of chapter 28, the $\mathsf{AxisNat}^{\uparrow}$ zero-spine row of chapter 276, the unary-zero-spine standard comparison of chapter 572, and the unary-direction bridge boundary, assembled as one finite normalizer packet.

The packet consumes the sibling standard-boundary comparison of chapter 572 and the zero-spine carrier of chapter 276 before its normalizing boundary row is read.

Definition 599.1 (AxisUnarySpineNormalizer carrier)**.** *An* $\mathsf{AxisUnarySpineNormalizer}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (N, A, L, Z, H, C, P, R)$$

with the following visible coordinates:

1. *N is the source* $\mathsf{Nat}^{\uparrow}$ *unary-spine row, read as a finite* E1 *history together with its local naming certificate;*
2. *A is the target* $\mathsf{AxisNat}^{\uparrow}$ *zero-spine row, read as a finite* E0 *history together with its local naming certificate;*
3. *L is the displayed length ledger comparing the two histories by their finite step counts;*
4. *Z is the standard-boundary row asserting that the unary read and the zero-spine read have the same displayed length while remaining different BEDC carrier predicates;*
5. *H stores componentwise* hsame *transports for the unary row, zero-spine row, length ledger, standard-boundary row, and local name;*
6. *C stores the displayed* Cont *routes that read the unary spine, read the zero spine, expose the length ledger, and hand the boundary row to downstream bridge consumers;*
7. *P records* Pkg *provenance over* $\mathsf{Nat}^{\uparrow}$, $\mathsf{AxisNat}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
8. *R is the local* $\mathsf{NameCert}_{\mathsf{AxisUnarySpineNormalizer}^{\uparrow}}$ *row.*

The carrier has no coordinate that identifies $\mathsf{Nat}^{\uparrow}$ *with* $\mathsf{AxisNat}^{\uparrow}$*, rewrites* E1 *constructors into* E0 *constructors inside the kernel, or imports a host arithmetic normalizer.*

Lean4 (definition) `BEDC.Derived.AxisUnarySpineNormalizerUp.AxisUnarySpineNormalizerCarrier`

Theorem 599.2 (AxisUnarySpineNormalizer NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{AxisUnarySpineNormalizer}^{\uparrow}}$ *surface for Definition 599.1 consists exactly of source unary-spine admission, target zero-spine admission, displayed length-ledger readback, standard-boundary exposure, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local naming row. These obligations assemble a finite bridge-facing packet over* $\mathsf{Nat}^{\uparrow}$*,* $\mathsf{AxisNat}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *without equating the unary and axis carriers.*

Lean4 ✓ `BEDC.Derived.AxisUnarySpineNormalizerUp.AxisUnarySpineNormalizerNameCertObligations`

Proof. Carrier admission is projection from the displayed packet U. The rows N and A give the two named source surfaces, while L and Z give the finite comparison and the standard-boundary read.

The classifier is componentwise. The stored hsame row H transports the unary read, zero-spine read, length ledger, boundary row, package row, and local name without replacing either carrier by the other.

The continuation and provenance clauses are the remaining finite obligations. The routes in C expose the two spine reads and then pass the length ledger into Z, while P records that every row belongs to the listed BEDC dependencies. No host normalizer or carrier identity has a coordinate in the packet. □

Theorem 599.3 (AxisUnarySpineNormalizer standard boundary)**.** *Every accepted* $\mathsf{AxisUnarySpineNormalizer}^{\uparrow}$ *carrier exposes a length-preserving standard-boundary row from its* $\mathsf{Nat}^{\uparrow}$ *unary spine to its* $\mathsf{AxisNat}^{\uparrow}$ *zero spine. Downstream uses of the unary-direction bridge may read this row through the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *coordinates, but they may not treat the source and target carrier predicates as equal inside the BEDC kernel.*

Lean4 ✓ `BEDC.Derived.AxisUnarySpineNormalizerUp.AxisUnarySpineNormalizerTasteGate single carrier alignment`

Proof. Start with an accepted carrier $U = (N, A, L, Z, H, C, P, R)$. By Definition 599.2, every consumer-facing read of U factors through the displayed rows of Definition 599.1.

The standard-boundary coordinate is Z. Its input data are the unary row N, the zero-spine row A, and the length ledger L, and its public route is one of the continuation rows in C.

The non-identification boundary is part of the same finite packet. Since neither N nor A is replaced by a shared carrier coordinate, the bridge exports a length-preserving standard boundary while preserving the kernel distinction between the two spine predicates. □

Theorem 599.4 (AxisUnarySpineNormalizer scoped source binding)**.** *The* $\mathsf{AxisUnarySpineNormalizer}^{\uparrow}$ *carrier of Definition 599.1, the NameCert obligation theorem of Definition 599.2, and the standard-boundary theorem of Definition 599.3 are scoped exactly over the* $\mathsf{Nat}^{\uparrow}$*,* $\mathsf{AxisNat}^{\uparrow}$*,* $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *source surfaces. The checked TasteGate marker*

`BEDC.Derived.AxisUnarySpineNormalizerUp.AxisUnarySpineNormalizerTasteGate_single_carrier_align`

is used only as the verified singleton-carrier alignment point for the standard-boundary read; it does not add a further public object, host arithmetic normalizer, or carrier equality between $\mathsf{Nat}^{\uparrow}$ *and* $\mathsf{AxisNat}^{\uparrow}$*.*

Proof. The carrier row lists exactly the source unary-spine row, target zero-spine row, displayed length ledger, standard-boundary row, componentwise transport, continuation routes, provenance row, and local certificate. These are the named $\mathsf{Nat}^{\uparrow}$, $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert dependencies.

The NameCert obligation theorem reads the same coordinates as finite obligations, and the standard-boundary theorem exposes the boundary through the checked TasteGate marker already attached to that theorem. Thus the chapter binds the dependency scope of the normalizer without claiming a public isomorphism or a kernel identification of the two spine carriers. □

Lean4 ✓ `BEDC.Derived.AxisUnarySpineNormalizerUp.AxisUnarySpineNormalizerScopeBinding`

Closure status for $\mathsf{NameCert}_{\mathsf{AxisUnarySpineNormalizer}^{\uparrow}}$.

Constructive story: An $\mathsf{AxisUnarySpineNormalizer}^{\uparrow}$ packet is generated from a $\mathsf{Nat}^{\uparrow}$ unary-spine row, an $\mathsf{AxisNat}^{\uparrow}$ zero-spine row, a displayed length ledger, a standard-boundary row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row. It is composite over the $\mathsf{Nat}^{\uparrow}$ unary-spine row, $\mathsf{AxisNat}^{\uparrow}$ zero-spine row, length ledger, and standard-boundary surfaces, bundling those existing boundaries into one normalizer surface.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AxisUnarySpineNormalizer}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 599.1, Definition 599.2, Definition 599.3, and Definition 599.4 bind the carrier, NameCert obligations, standard-boundary theorem, and exact dependency scopes for the finite unary-to-zero-spine normalizer surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AxisUnarySpineNormalizer}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean formalization, bridge checking, kernel equality between $\mathsf{Nat}^{\uparrow}$ and $\mathsf{AxisNat}^{\uparrow}$, host arithmetic normalization, or a public additive isomorphism.

Upgrade path: Public closure requires a public-object surface beyond the scoped normalizer packet and its singleton-carrier TasteGate alignment.

Chapter 600

A Concrete Naming Certificate for $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$

The $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ surface records the finite handoff that carries a regular Cauchy diagonal-limit classifier from the displayed rational source rows to the $\mathsf{Real}^{\uparrow}$ seal row. It sits between the classifier packet of chapter 443 and the completion-facing seal discipline of chapter 450.

Definition 600.1 (Regular Cauchy limit transport carrier)**.** *A* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (R, W, D, S, H, C, P, N)$$

with the following displayed rows:

1. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row, recording the regular rational sequence family, the selected source indices, and the diagonal rational observations read by the limit classifier;*
2. *W is the* $\mathsf{StreamName}^{\uparrow}$ *selected-window row, recording the finite windows through which the diagonal observations are named;*
3. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance and absolute-value ledger, recording the requested tolerance, comparison rows, absolute-value rows, and triangle-bound entries used by the transport;*
4. *S is the* $\mathsf{Real}^{\uparrow}$ *seal handoff row, recording the completion-facing seal reached from the displayed diagonal observations;*
5. *H records componentwise* hsame *transports for the source row, selected windows, dyadic ledger, seal row, continuation routes, package provenance, and local naming row;*
6. *C records the displayed* Cont *routes through which the source rows, selected-window rows, dyadic observations, and seal handoff are read by downstream consumers;*
7. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyLimitTransport}^{\uparrow}}$ *row.*

The packet is finite and transport-facing. It contains no quotient stream, no host real equality, no selected external limit, no trichotomy row, and no $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Definition 600.2 (Regular Cauchy limit transport classifier)**.** *The classifier of a carrier $T = (R, W, D, S, H, C, P, N)$ compares only the displayed rows R, W, D, S, H, C, P, N. Two carriers are classified together exactly when the componentwise* hsame *rows in H identify the* $\mathsf{RegSeqRat}^{\uparrow}$ *source*

row, the StreamName$^{\uparrow}$ *selected-window row, the* DyadicRatCore$^{\uparrow}$ *tolerance and absolute-value ledger, the* Real$^{\uparrow}$ *seal handoff, the displayed* Cont *routes, the* Pkg *provenance, and the local* NameCert *row.*

The classifier has no coordinate for quotient streams, host real equality, selected external limits, trichotomy of reals, or Real$^{\uparrow}$ *completeness. A consumer asking for any of those objects leaves the packet boundary.*

Lean4 (definition) `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportClassifier`

Theorem 600.3 (Regular Cauchy limit transport stability)**.** *Let $T = (R, W, D, S, H, C, P, N)$ be an accepted* RegularCauchyLimitTransport$^{\uparrow}$ *carrier. Any componentwise displayed* hsame *transport of the rows R, W, D, S, H, C, P, N that preserves the continuation routes in C, the package provenance in P, and the local naming row N yields another accepted* RegularCauchyLimitTransport$^{\uparrow}$ *carrier with the same diagonal-limit classifier surface and the same* Real$^{\uparrow}$ *seal handoff.*

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier stability`

Proof. Project the accepted packet through Definition 600.1. The only rows available to the transport are the regular rational source row, selected windows, dyadic tolerance and absolute-value ledger, seal handoff, componentwise transport row, continuation routes, package provenance, and local naming row.

The classifier of Definition 600.2 compares exactly those rows. Transporting them componentwise through H preserves the source observations, selected windows, tolerance ledger, absolute-value comparisons, and seal-facing handoff read by the same continuation routes.

Since no external limit, quotient stream, host equality, trichotomy row, or completeness theorem appears in the carrier, there is no additional coordinate that can change the classifier surface. The transported packet is therefore another accepted carrier with the same finite diagonal-limit handoff. □

Theorem 600.4 (Regular Cauchy limit transport ledger exactness)**.** *Every* Real$^{\uparrow}$ *consumer of an accepted* RegularCauchyLimitTransport$^{\uparrow}$ *packet reads the transported diagonal-limit handoff through the displayed ledger*

$$R, W, D, S, H, C, P, N.$$

The tolerance request, absolute-value rows, triangle-bound entries, selected windows, regular rational source observations, and seal route are exactly the rows displayed by the packet. No consumer can replace them by a quotient-stream comparison, a host real equality proof, an externally selected limit, a trichotomy argument, or a Real$^{\uparrow}$ *completeness principle.*

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier ledger exactness`

Proof. The carrier inventory gives the full ledger. Rows R and W name the regular rational source observations and their selected finite windows, while D records the dyadic tolerance, absolute-value, and triangle-bound data used to justify the transported read.

The seal handoff is row S, and every route to it is recorded in C and packaged by P, N. The componentwise transport row H can replay only the displayed rows of the same packet.

Thus the consumer surface is exhausted by R, W, D, S, H, C, P, N. The excluded objects have no coordinate in the carrier or classifier, so they cannot be introduced by a Real$^{\uparrow}$ consumer of this transport packet. □

Theorem 600.5 (Regular Cauchy limit transport NameCert obligations)**.** *For the carrier of Definition 600.1, the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyLimitTransport}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission for* $T = (R, W, D, S, H, C, P, N)$*;*
2. *classifier stability under the componentwise* hsame *rows displayed in* H*;*
3. *selected-window exactness for the* $\mathsf{StreamName}^{\uparrow}$ *rows in* W *and their reads from the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row* R*;*
4. *dyadic ledger exactness for the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance, absolute-value, comparison, and triangle-bound rows in* D*;*
5. *seal handoff non-escape through* S, C, P, N*, excluding quotient streams, host real equality, selected external limits, trichotomy, and* $\mathsf{Real}^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier namecert obligations`

Proof. Carrier admission is the finite packet of Definition 600.1. The row list R, W, D, S, H, C, P, N is the complete public inventory.

Classifier stability is supplied by Definition 600.3. The selected-window exactness clause is the restriction that every diagonal observation read from R reaches the classifier through the displayed finite window row W and the same continuation routes C.

Dyadic ledger exactness is the row D: it records the tolerance, absolute-value, comparison, and triangle-bound entries consumed by the transported handoff. Finally Definition 600.4 identifies the seal-facing non-escape boundary through S, C, P, N. □

Theorem 600.6 (Regular Cauchy limit transport selected-window exactness)**.** *Let* $T = (R, W, D, S, H, C, P, N)$ *be an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier. Every diagonal observation read from* T *reaches the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row* R *only through the displayed* $\mathsf{StreamName}^{\uparrow}$ *selected-window row* W*, is transported by the componentwise rows in* H*, and is replayed to downstream consumers through the continuation routes in* C*. No external window selector or undisplayed source-row read can replace* W*.*

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier selected window exactness`

Proof. Project the accepted carrier through Definition 600.1. The only source-facing rows in the packet are the $\mathsf{RegSeqRat}^{\uparrow}$ row R and the $\mathsf{StreamName}^{\uparrow}$ selected-window row W, with their transport and replay data recorded by H and C.

Use the classifier specification of Definition 600.2. It compares carriers by the displayed rows R, W, D, S, H, C, P, N and has no coordinate for an external selector.

Thus a diagonal observation can be read from the source row only by passing through the selected window already present in W. The componentwise transport rows in H and the continuation routes in C may replay that read, but they cannot introduce a second source-row access path. □

Theorem 600.7 (Regular Cauchy limit transport dyadic ledger stability)**.** *Let* $T = (R, W, D, S, H, C, P, N)$ *be an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier. Under any componentwise* hsame *transport accepted by the rows in* H*, the tolerance request, absolute-value rows, comparison rows, and triangle-bound entries used by the limit handoff remain entries of the single* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*. The transport creates no second dyadic ledger and no independent arithmetic side condition.*

Proof. Start from the stability theorem Definition 600.3. It says that componentwise transport of the displayed rows preserves the accepted carrier and the same diagonal-limit classifier surface.

Now read the ledger exactness theorem Definition 600.4. The tolerance request, absolute-value rows, comparison rows, and triangle-bound entries consumed by a $\mathsf{Real}^{\uparrow}$ handoff are exactly the rows displayed by the packet.

Combining the two statements fixes the dyadic data inside D throughout the transport. Since the carrier and classifier expose no additional arithmetic coordinate, the transported handoff cannot select a separate dyadic ledger or attach a hidden side condition. □

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier dyadic ledger stability`

Theorem 600.8 (Regular Cauchy limit transport seal-route determinacy)**.** *For an accepted* RegularCauchyLimitTra *carrier* $T = (R, W, D, S, H, C, P, N)$*, every* $\mathsf{Real}^{\uparrow}$ *seal handoff exported by* T *factors through the finite route*

$$R \to W \to D \to S$$

with provenance recorded by H, C, P, N*. The route cannot be replaced by quotient streams, host real equality, selected external limits, trichotomy, or a* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First apply selected-window exactness, Definition 600.6. It forces each diagonal source read to pass from R through the displayed selected-window row W and then through the recorded transport and continuation rows.

Next apply dyadic ledger stability, Definition 600.7. The tolerance, absolute-value, comparison, and triangle-bound data used after the window read remain in the single ledger D under componentwise transport.

Finally use ledger exactness, Definition 600.4. The seal row S is reached only through the displayed packet rows, with provenance H, C, P, N. The excluded quotient, host-equality, external-limit, trichotomy, and completeness objects have no carrier coordinate, so they cannot determine a replacement route. □

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier seal route determinacy`

Theorem 600.9 (Regular Cauchy limit transport RealCompleteness consumer factorization)**.** *Let* $T = (R, W, D, S, H, C, P, N)$ *be an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier. Let* Q *be an accepted* $\mathsf{RealCompleteness}^{\uparrow}$ *packet whose regular-family row, selected-window row, dyadic-ledger row, and seal row are exactly the displayed rows* R, W, D, S *of* T*, transported by the same rows* H, C, P, N*. Then every* $\mathsf{RealCompleteness}^{\uparrow}$ *diagonal-seal consumer of* Q *factors through*

$$R, W, D, S, H, C, P, N$$

before reading the $\mathsf{Real}^{\uparrow}$ *seal. The factorization exposes no quotient stream, selected external limit, host real equality, trichotomy row, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier real completeness consumer factorization`

Proof. First apply selected-window exactness, Definition 600.6. It forces each diagonal observation to enter the source row R through the displayed selected-window row W and through the same transport and continuation rows H, C.

Next apply dyadic ledger stability, Definition 600.7. The tolerance, absolute-value, comparison, and triangle-bound entries used by the diagonal read remain entries of D, so the $\mathsf{RealCompleteness}^{\uparrow}$ packet cannot substitute a second arithmetic ledger.

Now use seal-route determinacy, Definition 600.8. The seal handoff reaches S only through the finite route $R \to W \to D \to S$ with provenance H, C, P, N.

Finally read the finite seal surface of $\mathsf{RealCompleteness}^{\uparrow}$. Because Q identifies its regular-family, window, dyadic-ledger, and seal rows with R, W, D, S, any diagonal-seal consumer of Q has already passed through the carrier rows of T before it reads the $\mathsf{Real}^{\uparrow}$ seal. The excluded quotient, selected-limit, host-equality, trichotomy, and ambient-completeness objects are absent from both displayed packet surfaces. □

Theorem 600.10 (Regular Cauchy limit transport obligation-closure package)**.** *For an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier*

$$T = (R, W, D, S, H, C, P, N),$$

the displayed rows jointly supply the obligation-closure package for the finite handoff from $\mathsf{RegSeqRat}^{\uparrow}$ *through* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *to the* $\mathsf{Real}^{\uparrow}$ *seal. The package consists of carrier admission for* T*, classifier stability over the rows* R, W, D, S, H, C, P, N*, selected-window exactness through* W*, dyadic ledger stability through* D*, seal-route determinacy through* S, C, P, N*, and non-escape for every consumer of the finite handoff.*

The package has no quotient stream coordinate, no host real equality coordinate, no selected external limit coordinate, no trichotomy coordinate, and no $\mathsf{Real}^{\uparrow}$ *completeness coordinate.*

Proof. Carrier admission is exactly the packet of Definition 600.1, and the classifier boundary is exactly the row comparison of Definition 600.2.

Use Definition 600.3 for classifier stability and Definition 600.5 for the local obligation surface. These two rows bind the accepted carrier and the local naming boundary to the same displayed packet.

Next apply Definition 600.6 and Definition 600.7. They force the source read through the selected-window row W and keep the tolerance, absolute-value, comparison, and triangle-bound data inside the dyadic ledger D.

Finally use Definition 600.4 and Definition 600.8. Every seal-facing consumer is exhausted by R, W, D, S, H, C, P, N, so the excluded quotient, host-equality, external-limit, trichotomy, and completeness objects have no route into the package. □

Theorem 600.11 (Regular Cauchy limit transport window-dyadic-seal triangle)**.** *For an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier*

$$T = (R, W, D, S, H, C, P, N),$$

the finite route

$$R \to W \to D \to S$$

commutes as a single handoff from the $\mathsf{RegSeqRat}^{\uparrow}$ *source row through the* $\mathsf{StreamName}^{\uparrow}$ *selected-window row and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger into the* $\mathsf{Real}^{\uparrow}$ *seal. The commutation is read only through the displayed* hsame *rows in* H*, the* Cont *routes in* C*, the* Pkg *provenance in* P*, and the local* NameCert *row* N*.*

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier window dyadic seal triangle`

Proof. Begin with selected-window exactness, Definition 600.6. It sends every accepted diagonal observation from the source row R through the selected-window row W, with the replay route recorded by H and C.

Next use dyadic ledger stability, Definition 600.7. After the window read, the tolerance request, absolute-value rows, comparison rows, and triangle-bound entries remain inside the single dyadic ledger D.

Finally apply seal-route determinacy, Definition 600.8, together with ledger exactness, Definition 600.4. The seal row S is reached through the same displayed packet rows and no other coordinate is present. Hence the selected-window, dyadic-ledger, and seal routes form one commuting finite handoff. □

Theorem 600.12 (Regular Cauchy limit transport classifier handoff coverage)**.** *Every accepted classifier handoff of a* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier is covered by the displayed rows*

$$R, W, D, S, H, C, P, N$$

and by the triangle of Definition 600.11. The classifier has no quotient-stream coordinate, no host real equality coordinate, no selected external limit coordinate, no trichotomy coordinate, and no completeness coordinate.

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier classifier handoff coverage`

Proof. Read the classifier boundary from Definition 600.2. It compares exactly the rows R, W, D, S, H, C, P, N, and componentwise stability is supplied by Definition 600.3.

The triangle theorem then identifies the only multi-row handoff inside that classifier surface: source observations pass through W, ledger data stays in D, and the seal route reaches S with provenance H, C, P, N.

The excluded objects are absent from the carrier inventory of Definition 600.1. Since the classifier has no slot for those objects, an accepted handoff cannot classify by quotient streams, host real equality, selected external limits, trichotomy, or completeness data. □

Theorem 600.13 (Regular Cauchy limit transport completion boundary nonescape)**.** *Let* $T = (R, W, D, S, H, C, P, N)$ *be an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier. Any* $\mathsf{RealCompleteness}^{\uparrow}$ *consumer that reads this transport must factor through the triangle*

$$R \to W \to D \to S$$

before reaching the $\mathsf{Real}^{\uparrow}$ *seal. The consumer cannot bypass the triangle by selecting a quotient stream, a host real equality proof, an external limit, a trichotomy row, or an ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier completion boundary nonescape`

Proof. First use the RealCompleteness consumer factorization theorem, Definition 600.9. It says that a diagonal-seal consumer whose rows match R, W, D, S must read the displayed ledger R, W, D, S, H, C, P, N before it reaches the $\mathsf{Real}^{\uparrow}$ seal.

Then apply the window-dyadic-seal triangle, Definition 600.11. That theorem compresses the relevant displayed ledger into the finite route $R \to W \to D \to S$ with provenance carried by H, C, P, N.

The non-escape part follows from seal-route determinacy and ledger exactness. Both the transport packet and the matching $\mathsf{RealCompleteness}^{\uparrow}$ consumer surface lack coordinates for quotient streams, host real equality, selected external limits, trichotomy, and ambient completeness, so no consumer route can bypass the same triangle. □

Theorem 600.14 (Regular Cauchy limit transport obligation-closure export)**.** *For an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier*

$$T = (R, W, D, S, H, C, P, N),$$

the rows R, W, D, S, H, C, P, N *export the obligation-closure package for* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$*. The export consists exactly of carrier admission, classifier stability, selected-window exactness, dyadic ledger stability, seal-route determinacy,* $\mathsf{RealCompleteness}^{\uparrow}$ *consumer factorization, classifier handoff coverage, and completion-boundary non-escape.*

Proof. Start with the obligation-closure package of Definition 600.10. It provides carrier admission, classifier stability, selected-window exactness, dyadic ledger stability, seal-route determinacy, and the finite exclusion boundary for the displayed rows R, W, D, S, H, C, P, N.

Next apply the window-dyadic-seal triangle of Definition 600.11. This identifies the single handoff route $R \to W \to D \to S$ and keeps its provenance inside H, C, P, N.

Finally combine classifier handoff coverage, Definition 600.12, with completion-boundary non-escape, Definition 600.13. The first theorem exhausts the classifier-facing handoff through the same rows, and the second forces any $\mathsf{RealCompleteness}^{\uparrow}$ consumer to factor through the triangle before reading the $\mathsf{Real}^{\uparrow}$ seal. These clauses are precisely the exported obligation-closure surface. □

Theorem 600.15 (Regular Cauchy limit transport scoped dependency boundary)**.** *For an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier*

$$T = (R, W, D, S, H, C, P, N),$$

the packet scope is exactly the route through $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. This route is witnessed by selected-window exactness, dyadic-ledger stability, seal-route determinacy, and completion-boundary non-escape.*

Proof. Read the source row R as the $\mathsf{RegSeqRat}^{\uparrow}$ input and the selected-window row W as the $\mathsf{StreamName}^{\uparrow}$ observation route. The selected-window theorem fixes this first segment of the route.

Next read D as the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance and absolute-value ledger. Dyadic-ledger stability keeps that ledger inside the same finite packet.

Finally follow S to the $\mathsf{Real}^{\uparrow}$ seal through the displayed H, C, P, N rows over BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$. Seal-route determinacy and completion-boundary non-escape show that no further dependency is used. □

Theorem 600.16 (Regular Cauchy limit transport visible scope exhaustion)**.** *No consumer of an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier can add quotient streams, host real equality, selected external limits, trichotomy, or ambient completeness outside the scoped route of Definition 600.15. Any consumer read must stay inside* R, W, D, S, H, C, P, N *and the named* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *dependencies.*

Proof. Apply the scoped dependency boundary to identify the complete visible route. It accounts for the source row, selected-window row, dyadic ledger, Real seal handoff, transport, continuation, provenance, and local naming.

Now use classifier handoff coverage and completion-boundary non-escape. Those theorems exclude quotient streams, host real equality, selected external limits, trichotomy, and ambient completeness from the carrier and from the RealCompleteness-facing consumer route.

Because every consumer read factors through the same displayed rows, there is no place where an external stream quotient, host equality proof, selected limit, order trichotomy, or ambient completeness principle can enter. □

Theorem 600.17 (Regular Cauchy limit transport public export)**.** *For an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier*

$$T = (R, W, D, S, H, C, P, N),$$

the public $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *export is exactly the finite handoff*

$$R \to W \to D \to S$$

with provenance H, C, P, N*. This export is the consumer-facing packet read by* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{RealCompleteness}^{\uparrow}$*, and it excludes quotient streams, host equality, selected external limits, trichotomy, and ambient completeness.*

Proof. First collect the route components. Selected-window exactness fixes the $R \to W$ read, dyadic ledger stability fixes the $W \to D$ ledger passage, and seal-route determinacy fixes the $D \to S$ seal handoff with provenance retained in H, C, P, N.

Next use classifier-handoff coverage to make the packet visible to every named consumer. The $\mathsf{RegSeqRat}^{\uparrow}$ source, $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{Real}^{\uparrow}$ seal, and $\mathsf{RealCompleteness}^{\uparrow}$ consumer all read the same displayed rows.

Finally apply completion-boundary non-escape. Since the boundary theorem excludes quotient streams, host equality, selected external limits, trichotomy, and ambient completeness, the public export contains exactly the finite handoff and its displayed provenance, with no further carrier coordinate. □

Lean4 ✓ `BEDC.Derived.RegularCauchyLimitTransportUp.RegularCauchyLimitTransportCarrier public export`

Theorem 600.18 (Regular Cauchy limit transport bridge packet)**.** *For an accepted* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *carrier*

$$T = (R, W, D, S, H, C, P, N),$$

the public export packet

$$R \to W \to D \to S$$

with provenance H, C, P, N *is exactly the bridge packet consumed by* $\mathsf{RealCompleteness}^{\uparrow}$ *finite-witness routes. The bridge preserves* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *provenance while excluding quotient streams, host equality, selected external limits, trichotomy, and ambient completeness.*

Proof. Start with public export, Definition 600.17. It identifies the consumer-facing packet as the finite handoff $R \to W \to D \to S$ with provenance H, C, P, N.

Apply the RealCompleteness consumer factorization theorem. A matching $\mathsf{RealCompleteness}^{\uparrow}$ diagonal-seal consumer must pass through the same rows R, W, D, S, H, C, P, N before reading the $\mathsf{Real}^{\uparrow}$ seal.

Finally use completion-boundary non-escape. The excluded quotient, host-equality, external-limit, trichotomy, and ambient-completeness objects have no coordinate in the transport packet or in the finite-witness consumer route. Therefore the public export is already the bridge packet read by the finite RealCompleteness route. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyLimitTransport}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ packet is generated from a $\mathsf{RegSeqRat}^{\uparrow}$ source row, a $\mathsf{StreamName}^{\uparrow}$ selected-window row, a $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance and absolute-value ledger, a $\mathsf{Real}^{\uparrow}$ seal handoff, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyLimitTransport}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 600.1, Definition 600.2, Definition 600.3, Definition 600.4, Definition 600.5, Definition 600.6, Definition 600.7, Definition 600.8, Definition 600.9, Definition 600.10, Definition 600.11, Definition 600.12, Definition 600.13, Definition 600.14, Definition 600.15, Definition 600.16, Definition 600.17, and Definition 600.18 bind the finite transported diagonal-limit carrier, classifier, stability, ledger exactness, selected-window route, dyadic ledger stability, seal-route determinacy, RealCompleteness consumer factorization, obligation package, window-dyadic-seal triangle, classifier handoff coverage, completion boundary, obligation-closure export, scoped dependency boundary, visible scope exhaustion, public export, bridge packet, and local naming obligations.

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient streams, host real equality, selected external limits, trichotomy, $\mathsf{Real}^{\uparrow}$ completeness, or a public standard bridge.

Upgrade path: The paper axis is mature; further movement is on the verification and bridge axes.

Chapter 601

A Concrete Naming Certificate for $\mathsf{FiniteCauchyApproximation}^{\uparrow}$

The $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ interface isolates the finite observation packet used when a regular rational source is read at one displayed precision before a $\mathsf{Real}^{\uparrow}$ consumer crosses the Cauchy-limit boundary. It records the selected threshold, stream window, dyadic observation ledger, error row, and handoff route as finite BHist data, so later completion arguments can cite a named approximation surface without importing a selected real value or an ambient completeness principle.

Definition 601.1 (Finite Cauchy approximation carrier)**.** *A* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (R, n, k, W, D, E, S, H, C, P, N)$$

with the following displayed coordinates:

1. *R is the source* $\mathsf{RegSeqRat}^{\uparrow}$ *row whose rational stream is read through an attached* $\mathsf{StreamName}^{\uparrow}$ *surface;*
2. *n is the unary precision row naming the requested finite tolerance level;*
3. *k is the* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row displayed for precision n;*
4. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *window selected at and beyond the threshold row k;*
5. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger recording the dyadic representatives read from W;*
6. *E is the explicit dyadic error-bound row used to compare the selected observations;*
7. *S is the* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row that exposes the finite approximation to a real-facing consumer boundary;*
8. *H stores componentwise* hsame *transports for the source, precision row, threshold, window, dyadic ledger, error bound, handoff, provenance, and local name;*
9. *C stores the displayed* Cont *routes from R to the stream window, from n to k, from W to D and E, and from the finite packet to the handoff row S;*
10. *P records* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{DyadicAbsoluteValue}^{\uparrow}$, $\mathsf{CauchyModulusMeet}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteCauchyApproximation}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient stream equality, selected real values, infinite tails, host real metrics, or $\mathsf{Real}^{\uparrow}$ *completeness.*

Theorem 601.2 (Finite Cauchy approximation NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FiniteCauchyApproximation}^{\uparrow}}$ *surface for Definition 601.1 consists exactly of source* $\mathsf{RegSeqRat}^{\uparrow}$ *admission, unary precision exposure,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold exactness, finite* $\mathsf{StreamName}^{\uparrow}$ *window readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation-ledger exposure, explicit error-bound exposure,* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff routing, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local naming row.*

Proof. Carrier admission is projection from the displayed tuple F. The rows R, n, k, W, D, E, S provide the source, precision, threshold, window, dyadic ledger, error bound, and real-facing handoff.

The threshold obligation is read from the $\mathsf{CauchyModulus}^{\uparrow}$ surface attached to the regular rational source. The finite window obligation is read from the $\mathsf{StreamName}^{\uparrow}$ rows selected by that threshold, and the dyadic observation rows are exactly the $\mathsf{DyadicRatCore}^{\uparrow}$ entries recorded in D.

The remaining obligations are routing and naming obligations. The rows H, C, P, N transport the listed coordinates, replay the finite reads, record the dependency packages, and name the approximation packet without adding quotient stream equality, a selected limit, or an infinite-tail coordinate. □

Theorem 601.3 (Finite Cauchy approximation window soundness)**.** *For an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *carrier, every dyadic observation exported by the finite approximation lies in the displayed window* W *selected by the threshold row* k*. The error row* E *is read through the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, and its tolerance is bounded by the* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold exactness for the unary precision row* n*.*

Proof. Start from the accepted carrier and project the rows R, n, k, W, D, E. The $\mathsf{CauchyModulus}^{\uparrow}$ threshold row k supplies the finite bound attached to the precision row n.

Read the stream window through the displayed $\mathsf{StreamName}^{\uparrow}$ surface. Since W is the only window coordinate in the packet, every observation route into D passes through that finite window before any dyadic representative is visible.

The error row is then read from the same dyadic ledger. The nonnegative tolerance rows used by $\mathsf{DyadicAbsoluteValue}^{\uparrow}$ bind the endpoint comparison inside D, while the threshold exactness of $\mathsf{CauchyModulus}^{\uparrow}$ supplies the displayed precision bound. No exported observation can bypass W, D, E or appeal to an infinite tail. □

Lean4 ✓ `BEDC.Derived.FiniteCauchyApproximationUp.FiniteCauchyApproximationCarrier window soundness`

Theorem 601.4 (Finite Cauchy approximation threshold route coverage)**.** *Let* $F = (R, n, k, W, D, E, S, H, C, P, N)$ *be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Every visible dyadic observation exported by* F*, and every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff route from* F*, first reads the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row* R*, unary precision row* n*,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row* k*, finite* $\mathsf{StreamName}^{\uparrow}$ *window* W*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*. The error row* E *is bounded by the same threshold row* k*, and the route to* S *can read no selected real value, quotient stream equality, hidden limit selector, host metric, or completeness coordinate before those finite rows have been exposed.*

This threshold route is the finite handoff surface supplied by the sibling $\mathsf{CauchyModulus}^{\uparrow}$ *and* $\mathsf{StreamName}^{\uparrow}$ *chapters, chapter 292 and chapter 126.*

Proof. Project the accepted carrier to the displayed rows $R, n, k, W, D, E, S, H, C, P, N$. The source, precision, threshold, window, dyadic ledger, and error row are ordinary carrier coordinates, while the packet has no coordinate for a selected limit, quotient stream, host metric, or completeness witness.

Apply Definition 601.3. It places every visible dyadic observation inside the finite window W, reads that observation through the ledger D, and bounds E by the threshold row k attached to the precision row n.

Next apply Definition 601.7. Any $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer must reach S only after the route has read R, n, k, W, D, E together with the transport, continuation, provenance, and local naming rows.

Finally apply Definition 601.16. The closure packages those same finite rows and backing ledgers as the local $\mathsf{NameCert}_{\mathsf{FiniteCauchyApproximation}^{\uparrow}}$ surface. Thus neither a visible dyadic observation nor a real-facing handoff can bypass the threshold route through the sibling $\mathsf{CauchyModulus}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ surfaces. □

Theorem 601.5 (Finite Cauchy approximation refinement stability)**.** *Let two accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *carriers have the same transported* $\mathsf{RegSeqRat}^{\uparrow}$ *source, unary precision row,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold, finite* $\mathsf{StreamName}^{\uparrow}$ *window, dyadic observation ledger, and explicit error row. Then their exported finite approximations present the same observation ledger and the same error-bound surface to every* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{CauchyModulusMeet}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer route.*

Proof. Project the two carriers and read the componentwise transport rows in H. The hypothesis identifies the source, precision, threshold, window, dyadic ledger, and error-bound rows after transport.

Use the displayed continuation routes to replay the finite reads in the same order: source to window, precision to threshold, window to dyadic observations, and dyadic observations to the error row. The shared-bound routes supplied by $\mathsf{CauchyModulusMeet}^{\uparrow}$ preserve the common threshold surface when a consumer compares this packet with another regular rational source.

The consumer-facing surface is therefore fixed before the handoff row is read. Any $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{CauchyModulusMeet}^{\uparrow}$, or $\mathsf{Real}^{\uparrow}$ route receives the same D and E rows, together with the same transport, continuation, provenance, and local naming data. □

Lean4 ✓ `BEDC.Derived.FiniteCauchyApproximationUp.FiniteCauchyApproximationCarrier refinement stability`

Theorem 601.6 (Finite Cauchy approximation precision weakening route)**.** *Let* $F = (R, n, k, W, D, E, S, H, C, P, N$ *be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Suppose* n' *is a second unary precision row whose request is weaker than* n *through a displayed* $\mathsf{CauchyModulus}^{\uparrow}$ *comparison, and suppose the* $\mathsf{StreamName}^{\uparrow}$ *window for* n' *is obtained by restricting or reusing the displayed window* W *while retaining the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger rows. Then every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer at* n' *factors through* $R, n, k, W, D, E, H, C, P, N$ *before reaching* S*.*

The weakening route exports only the displayed finite-window surface. It does not identify quotient streams, select a real value, supply an infinite-tail witness, introduce a host metric, or invoke $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Project the accepted packet to the rows $R, n, k, W, D, E, S, H, C, P, N$. Apply Definition 601.4 at the original precision row n to obtain the displayed threshold route through the source, precision, threshold, finite window, dyadic ledger, and error row.

The comparison in $\mathsf{CauchyModulus}^{\uparrow}$ says that the request at n' asks for no finer information than the request already served at n. The $\mathsf{StreamName}^{\uparrow}$ hypothesis either reuses W or restricts it, so Definition 601.3 keeps every dyadic observation for the weakened request inside the same finite ledger D and the same error row E.

Transport the shared rows through H and the displayed continuation routes C. By Definition 601.5, replacing the consumer-side precision request by the weaker row while keeping the source, threshold, window, dyadic ledger, and error rows fixed preserves the exported finite surface.

It remains only to cross the real-facing boundary. Apply Definition 601.7: every $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer reaches S after the finite rows and bookkeeping rows have been exposed, and the packet has no coordinate for quotient stream equality, a selected real value, an infinite tail, a host metric, or a completeness principle. □

Theorem 601.7 (Finite Cauchy approximation Real handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *carrier factors through the displayed handoff row* S*. The handoff may read only the source* $\mathsf{RegSeqRat}^{\uparrow}$ *row, unary precision row,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, explicit error-bound row, componentwise* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row supplied by the packet.*

Proof. Begin with a real-facing consumer route. The carrier contains a single handoff coordinate S, and that coordinate is explicitly the $\mathsf{Real}^{\uparrow}$ and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer boundary.

The route to S first reads the regular rational source, the requested precision, the displayed modulus threshold, and the finite stream window. It then reads the dyadic observation ledger and the explicit error row before any real-facing handoff is exposed.

Apply the $\mathsf{CauchyLimitSeal}^{\uparrow}$ boundary discipline to the final handoff. The consumer receives a finite approximation packet with its tolerance ledger and provenance, not a selected real value, quotient stream equality, host real metric, or completeness witness. □

Lean4 ✓ `BEDC.Derived.FiniteCauchyApproximationUp.FiniteCauchyApproximationCarrier real handoff`

Theorem 601.8 (Finite Cauchy approximation observation surface)**.** *The carrier, NameCert obligations, window soundness, refinement stability, and real handoff of Definition 601.1, Definition 601.2, Definition 601.3, Definition 601.5, and Definition 601.7 assemble one finite-window approximation certificate over* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{CauchyModulusMeet}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{DyadicAbsoluteValue}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*.*

The certificate exports exactly the rows

$$R, n, k, W, D, E, S, H, C, P, N.$$

It exports no quotient stream equality, selected real value, infinite-tail witness, host real metric, or $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. The carrier definition supplies the finite packet and lists every row available to the certificate. The NameCert obligations bind admission, precision, threshold, window, dyadic ledger, error bound, handoff, transport, continuation, provenance, and naming to those rows.

Window soundness identifies the finite observations and the displayed tolerance ledger. Refinement stability shows that transported packets with the same source, precision, threshold, window, dyadic ledger, and error row expose the same approximation surface to downstream consumers.

Finally the real handoff theorem identifies the only completion-facing boundary. Since the packet contains no quotient stream equality, selected real value, infinite-tail witness, host real

metric, or completeness coordinate, the listed rows form the complete finite-window approximation certificate. □

Theorem 601.9 (Finite Cauchy approximation tail-meet triangle assembly)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P,$ be an accepted* FiniteCauchyApproximation$^{\uparrow}$ *packet. Suppose the finite approximation window W is backed by an accepted* RegularCauchyTailMeet$^{\uparrow}$ *shared-threshold packet, and suppose the dyadic error row E is backed by an accepted* RegularCauchyTriangleBound$^{\uparrow}$ *tolerance-addition ledger. Then the Real handoff row S receives exactly the displayed finite approximation rows together with the shared tail threshold, the triangle-bound tolerance ledger, componentwise* hsame *rows, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *rows.*

The assembly exports no selected real value, quotient stream equality, infinite tail, host metric, or completeness principle.

Proof. Start from Definition 601.7. It routes every real-facing consumer through the source row, precision row, modulus threshold, finite window, dyadic observation ledger, error row, transport, continuation, provenance, and local name before the handoff row S is read.

Use Definition 560.9 to supply the shared-threshold backing for W. The tail-meet packet contributes only the paired source rows, scheduled windows, source modulus rows, shared threshold ledger, paired comparison row, transports, continuations, ledger, provenance, and local name.

Use Definition 466.6 to supply the tolerance-addition backing for E. Its ledger identifies the three-leg dyadic estimate consumed by the finite approximation without adding an external completion or metric row.

The composed packet therefore presents exactly the listed finite approximation rows and the two backing ledgers. Since none of the cited surfaces contains a selected real value, quotient stream equality, infinite tail, host metric, or completeness coordinate, the Real handoff row S cannot export any such data. □

Theorem 601.10 (Finite Cauchy approximation tail-meet dependency route)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P$ be an accepted* FiniteCauchyApproximation$^{\uparrow}$ *packet. If F exports a handoff row through a shared finite window, then every consumer route from S to* RealDiagonalMeshBudget$^{\uparrow}$ *or* CauchyLimitSeal$^{\uparrow}$ *factors through the displayed* RegularCauchyTailMeet$^{\uparrow}$ *shared-threshold row before reading the finite approximation seal.*

The route exports no selected real value, quotient stream, hidden tail oracle, host metric, or completeness coordinate outside the finite rows of F and the shared-threshold row.

Proof. Start from the real handoff. By Definition 601.7, every completion-facing read of F first passes through the source row, precision row, threshold row, finite window, dyadic observation ledger, error row, transports, routes, provenance, and local name before the handoff row S is visible.

Use Definition 601.9 for the shared finite window. It supplies the RegularCauchyTailMeet$^{\uparrow}$ shared-threshold row as the backing route for W, so a consumer cannot read the finite window as an independent tail oracle.

Next use Definition 601.12. A RealDiagonalMeshBudget$^{\uparrow}$ consumer receives the finite approximation only through the mesh-budget route, and that route already includes the shared meet and shared-tail rows before the finite approximation seal is read.

For a CauchyLimitSeal$^{\uparrow}$ consumer, use the seal coverage theorem. The seal reads the same finite rows and the same tail-meet backing before reaching S. Therefore every downstream route factors through the displayed RegularCauchyTailMeet$^{\uparrow}$ shared-threshold row and cannot bypass

it by selecting a real value, quotient stream, hidden tail oracle, host metric, or completeness coordinate. □

Theorem 601.11 (Finite Cauchy approximation seal coverage)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N)$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of the handoff row S factors through the finite rows $R, n, k, W, D, E, H, C, P, N$. If the packet is backed by an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold packet and an accepted* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *triangle-bound ledger, then the consumer receives only the shared tail threshold and triangle-bound ledger already named by those backing rows.*

The covered seal exports no selected real value, quotient stream, infinite tail, host metric, or completeness principle.

Proof. Begin with the Real handoff theorem. It routes every real-facing consumer through the displayed handoff row S, and it lists the finite source, precision, threshold, window, dyadic ledger, error row, transport, continuation, provenance, and naming rows that may be read before the handoff.

Next apply window soundness. The only visible observations are the entries of the finite window W, the dyadic ledger D, and the error row E controlled by the threshold k for the precision row n. Refinement stability then transports the same finite surface across accepted packets with the same displayed rows.

For backed packets, apply the tail-meet triangle assembly theorem. The $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ backing contributes the shared tail threshold, and the $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ backing contributes the triangle-bound tolerance ledger; both are already part of the named finite packet route.

Finally use the observation surface exclusion. Since the packet has no coordinate for selected real values, quotient streams, infinite tails, host metrics, or completeness, neither a $\mathsf{Real}^{\uparrow}$ consumer nor a $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer can receive such data through S. □

Theorem 601.12 (Finite Cauchy approximation mesh-budget projection)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Suppose F is backed by accepted* $\mathsf{CauchyModulusMeet}^{\uparrow}$, $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$, *and* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *rows. Then every* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *consumer of the handoff row factors through the displayed finite rows*

$$R, n, k, W, D, E, H, C, P, N,$$

the shared meet row, the triangle-bound tolerance ledger, and the selected diagonal-window coverage row.

The projection exports no quotient stream equality, selected real value, infinite tail, host metric, or completeness principle.

Proof. Start with Definition 601.11. It confines the handoff boundary to the finite source, precision, modulus threshold, window, dyadic ledger, error row, transport, continuation, provenance, and naming rows of F.

Apply Definition 462.27 to the shared modulus read. The meet row is the only common-threshold input supplied to a diagonal consumer, so it cannot add a quotient stream, a chosen real value, or an infinite tail.

Next apply Definition 466.11. The triangle-bound backing contributes the tolerance-addition ledger used by the finite error row E, and no host metric or completeness coordinate is introduced by that ledger.

Finally combine Definition 561.13 with Definition 618.6. The selected diagonal-window coverage row supplies the window surface consumed by the mesh-budget packet, and the mesh-budget handoff reads it only through its finite route before the $\mathsf{Real}^{\uparrow}$ seal is exposed. □

Theorem 601.13 (Finite Cauchy approximation cofinal tail-budget route)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. If F is consumed through a cofinal tail-budget route, then every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff factors through the displayed rows*

$$R, n, k, W, D, E, S, H, C, P, N$$

and through the sibling $\mathsf{CofinalTailBudget}^{\uparrow}$ *row before the seal is read.*

The route exports no selected real value, quotient stream equality, infinite tail, host metric, or completeness principle.

Proof. Start with the finite approximation handoff. By Definition 601.7, every real-facing consumer reads the source, precision, threshold, window, dyadic ledger, error row, handoff row, transports, routes, provenance, and local name before the $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ boundary is available.

Next apply seal coverage and mesh-budget projection. The seal coverage theorem confines the handoff to the same finite rows, and Definition 601.12 keeps diagonal-mesh consumers behind the displayed finite route.

Now read the cofinal tail-budget sibling. By Definition 698.3, the tail-budget packet exposes only the finite windows listed by its cofinal row and the shared threshold recorded by its budget row. By Definition 698.4, its $\mathsf{Real}^{\uparrow}$ seal read passes through those windows and the $\mathsf{RegSeqRat}$ handoff before the seal is consumed.

Composing the two routes gives the stated factorization: a consumer first reads the finite approximation rows of F, then the sibling $\mathsf{CofinalTailBudget}^{\uparrow}$ row, and only then the seal boundary. The non-escape clauses of the finite approximation and cofinal tail-budget packets exclude selected real values, quotient stream equality, infinite tails, host metrics, and completeness. □

Theorem 601.14 (Finite Cauchy approximation window induction)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N)$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet, and let $W_0, \ldots, W_m$ be a displayed finite list of* $\mathsf{StreamName}^{\uparrow}$ *approximation windows read from the same source row R and threshold row k. Finite iteration over this window list preserves the route through*

$$R, n, k, W, D, E, S, H, C, P, N.$$

In particular, every iterated window consumer reaches the $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary only after the displayed source, precision, threshold, window, dyadic ledger, error, handoff, transport, replay, provenance, and local naming rows have been read.*

Proof. Induct on the finite displayed window list. The empty list is covered by Definition 601.3: no consumer can read a dyadic observation or handoff without first exposing the source, precision, threshold, window, ledger, and error rows of F.

For the step, assume the route has been preserved through the first m windows and append one displayed window. Threshold-route coverage keeps the appended window under the same $\mathsf{CauchyModulus}^{\uparrow}$ threshold row k, refinement stability transports the existing finite surface through H, and the tail-meet dependency route prevents the appended window from becoming an independent tail oracle.

Finally apply seal coverage. The appended list still reaches S only through the same finite rows and structural support, so the induction exports no selected real value, quotient stream equality, infinite tail, host metric, or completeness principle. □

Theorem 601.15 (Finite Cauchy approximation tail induction)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N)$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Suppose a finite chain of tail refinements is backed at each stage by the named* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *and* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *rows used by the finite approximation route. Then the final* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *read still factors through the same finite approximation rows*

$$R, n, k, W, D, E, S, H, C, P, N$$

together with the displayed meet and tail-meet backing rows. The chain exports no selected real value, quotient stream equality, infinite tail object, host metric, or ambient completeness principle.

Proof. Induct on the finite tail-refinement chain. The base case is the original finite approximation route: Definition 601.7 and Definition 601.11 place every Real or seal consumer behind the displayed finite rows.

For the step, append one refinement. The $\mathsf{CauchyModulusMeet}^{\uparrow}$ backing row supplies only the shared threshold, while the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ backing row supplies only the displayed common-tail window. By Definition 601.9, these rows are read as support for W, D, E rather than as new carriers.

The induction hypothesis already routes the preceding chain through $R, n, k, W, D, E, S, H, C, P, N$. Composing it with the appended meet and tail-meet support keeps the terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ read inside the same finite approximation surface. □

Theorem 601.16 (Finite Cauchy approximation obligation closure)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N)$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. The carrier row, local* $\mathsf{NameCert}_{\mathsf{FiniteCauchyApproximation}^{\uparrow}}$ *obligations, window soundness, refinement stability,* $\mathsf{Real}^{\uparrow}$ *handoff, tail-meet triangle assembly, seal coverage, and mesh-budget projection assemble the local* $\mathsf{NameCert}_{\mathsf{FiniteCauchyApproximation}^{\uparrow}}$ *obligation closure over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{CauchyModulusMeet}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$.

The closed obligation surface exports exactly the finite rows

$$R, n, k, W, D, E, S, H, C, P, N,$$

together with the named backing ledgers for the shared meet row, tail-meet threshold, triangle-bound tolerance assembly, diagonal-window coverage, and mesh-budget route. It exports no selected real value, quotient stream equality, infinite tail, host metric, or $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. The carrier definition supplies the finite tuple F and excludes every non-displayed coordinate. Apply Definition 601.2 to identify the local naming obligations on exactly the carrier rows, and apply Definition 601.3 to bind the window, dyadic observation ledger, and error row to the displayed threshold.

Refinement stability then fixes the exported finite surface under the componentwise transports recorded in H. Apply Definition 601.7 to force every real-facing route through the handoff row S after the finite reads have been exposed.

For packets backed by the completion-side ledgers, apply Definition 601.9 and Definition 601.11. These theorems add only the named shared threshold, triangle-bound tolerance ledger, and seal-routing rows already listed in the packet route.

Finally apply Definition 601.12. The diagonal-window coverage and mesh-budget rows are read as backing ledgers for the same finite handoff, so the resulting obligation closure contains the displayed rows and named ledgers, with no selected real value, quotient stream equality, infinite tail, host metric, or completeness principle. □

Lean4 ✓ `BEDC.Derived.FiniteCauchyApproximationUp.FiniteCauchyApproximationCarrier obligation closure`

Theorem 601.17 (Finite Cauchy approximation observation-budget compatibility)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N)$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet, and let an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet share the precision request, finite window rows, dyadic ledger rows, regular-sequence handoff rows, seal rows, componentwise* hsame *transports, and displayed* Cont *routes with F. Then every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of F factors through the same finite observation-budget route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto S$$

as the accepted observation-budget packet, with E read as the displayed precision request on the observation-budget side and as the explicit finite error row attached to the selected precision on the finite-approximation side.

The compatible handoff exports no selected real value, quotient stream equality, infinite tail, host metric or equality, ambient completeness, or hidden limit selector.

Proof. First read the finite approximation side. The seal coverage theorem confines every $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer to the displayed rows of F, and the mesh-budget projection keeps the downstream mesh-budget handoff inside the same finite source, window, dyadic ledger, error-row, transport, route, provenance, and naming surface.

The obligation closure theorem then packages those rows as the complete local $\mathsf{NameCert}_{\mathsf{FiniteCauchyApproximation}^{\uparrow}}$ obligation surface. In particular, the finite approximation does not contribute an extra completion coordinate beyond the route through E, W, D, R, S and the displayed bookkeeping rows.

Now read the shared observation-budget packet. The finite-window seal-route totality theorem for $\mathsf{RealObservationBudget}^{\uparrow}$ sends every admitted seal read through $E \longmapsto W \longmapsto D \longmapsto R \longmapsto S$. Route determinacy identifies any two accepted routes with the same displayed rows up to the componentwise hsame transports, and non-escape excludes hidden quotient, host equality, ambient completeness, hidden selector, and unbounded-schedule data.

Since the packets share the precision, window, dyadic, regular-sequence, seal, hsame, and Cont rows, the two consumer surfaces have the same displayed route. The finite approximation handoff is therefore the observation-budget handoff restricted to the finite Cauchy approximation rows, with no selected real value, quotient stream equality, infinite tail, host metric or equality, ambient completeness, or hidden limit selector exported. □

Theorem 601.18 (Finite Cauchy approximation budget-route exactness)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N)$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Suppose its precision, finite-window, dyadic-ledger, error-row, and handoff rows agree componentwise, through the displayed* hsame *and* Cont *rows, with accepted packets from chapter 385, chapter 618, and chapter 611. Then every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of F routes through the same finite budget route used by those three budget packets and by the local surfaces Definition 601.12 and Definition 601.17.*

The exact route exports no selected real value, quotient stream equality, hidden limit selector, host metric, or ambient completeness coordinate.

Proof. Begin with the local finite approximation surface. The mesh-budget projection theorem forces any diagonal-mesh consumer to read the finite source, precision row, window ledger, dyadic ledger, error row, transports, continuations, provenance, and local naming row before it reaches the handoff.

Next read the sibling budget packets. The finite error-budget chapter supplies the explicit finite error route, the real diagonal mesh-budget chapter supplies the mesh-facing route through the same finite window and tolerance rows, and the real observation-budget chapter supplies the observation route

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto S.$$

Apply the observation-budget compatibility theorem. Since the precision, window, dyadic, error, handoff, hsame, and Cont rows agree, the observation route and the finite approximation handoff route are the same displayed finite route.

Finally compose the route exclusions from the sibling packets with the local non-escape surface. None of the accepted carriers contains a coordinate for a selected real value, quotient stream equality, hidden limit selector, host metric, or ambient completeness principle, so no $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer can receive such data through the budget route. □

Theorem 601.19 (Finite Cauchy approximation finite-observation selector handoff)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N)$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Suppose its precision row, finite-window row, dyadic-ledger row, error row, and* $\mathsf{Real}^{\uparrow}$ *handoff row are selected by an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packet through the displayed* hsame *and* Cont *rows. Then every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of F factors first through the selector's displayed finite-observation route and then through the local finite-approximation rows $R, n, k, W, D, E, S, H, C, P, N$.*

The handoff exports no selected real value, quotient stream equality, hidden limit selector, host metric, or ambient completeness coordinate.

Proof. Apply Definition 601.18. It already forces every real-facing or limit-seal consumer of F through the finite budget route whenever the precision, window, dyadic, error, and handoff rows agree componentwise with the accepted budget packets.

Read the accepted $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ packet as the displayed selector for that same finite observation budget. Its route is the unique selector-facing route available by hypothesis, so the consumer first passes through the selector's finite-observation surface before the local finite approximation rows are exposed.

Finally compose the non-escape clauses. The budget-route exactness theorem excludes selected real values, quotient stream equality, hidden limit selectors, host metrics, and ambient completeness coordinates, and the selector contributes only the displayed finite-observation route. Therefore the composed handoff reaches $R, n, k, W, D, E, S, H, C, P, N$ without exporting any non-displayed completion data. □

Theorem 601.20 (Finite Cauchy approximation CauchySequenceSpace handoff)**.** *Let $F = (R, n, k, W, D, E, S, H,$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Suppose F shares its source row, schedule and finite-window rows, dyadic ledger, seal rows, componentwise* hsame *transports, and displayed* Cont *routes with an accepted* $\mathsf{CauchySequenceSpace}^{\uparrow}$ *packet. Then every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of F routes through the common finite-window surface read by chapter 406, with the regular source supplied by chapter 301 and the finite stream window supplied by chapter 126.*

The handoff exports only the shared finite packet and its seal-facing route; it exports no quotient stream equality, selected real value, infinite tail, host metric, or ambient completeness coordinate.

Proof. Project the finite approximation packet $F = (R, n, k, W, D, E, S, H, C, P, N)$. The existing seal coverage and budget-route exactness theorems force every $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer to read the source row, precision, threshold, window, dyadic ledger, error row, seal route, transports, continuations, provenance, and local naming row.

The shared $\mathsf{CauchySequenceSpace}^{\uparrow}$ packet reads the same source and common-window classifier through the regular sequence and stream-name surfaces. By the hypotheses, the $\mathsf{RegSeqRat}^{\uparrow}$ source of chapter 301, the $\mathsf{StreamName}^{\uparrow}$ window of chapter 126, and the dyadic and seal rows agree componentwise with the rows of F.

Therefore the downstream CauchySequenceSpace classifier is the consumer of the finite-window surface already exposed by F. The exclusions follow from the local non-escape and budget-route exactness rows: no accepted coordinate contains quotient stream equality, a selected real, an infinite tail, a host metric, or ambient completeness. □

Theorem 601.21 (Finite Cauchy approximation shared-window budget exhaustion)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N)$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Suppose its finite-window rows, dyadic-ledger rows, budget rows, seal rows, componentwise* hsame *transports, and displayed* Cont *routes agree componentwise with accepted* $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$, *and* $\mathsf{CauchySequenceSpace}^{\uparrow}$ *packets. Then every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of F reaches the same handoff row S through the displayed* $\mathsf{StreamName}^{\uparrow}$ *window W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D, explicit error row E, and finite budget route before any seal handoff.*

The shared finite route is the route exposed by chapter 126, chapter 611, chapter 618, and chapter 406. It exports no selected real value, quotient stream equality, infinite tail, host metric, or $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First apply Definition 601.4. This fixes the finite threshold, window, dyadic ledger, explicit error row, and local route support as the only displayed path from the approximation packet toward the seal-facing handoff.

Next apply Definition 601.18. Because the observation-budget and diagonal-mesh budget rows agree componentwise with F, every budget-facing read uses the same finite route through W, D, E, and S before any downstream seal read is available.

Finally apply Definition 601.20. The CauchySequenceSpace packet reads the same finite-window surface through the stream-name and regular-sequence handoff rows, so a $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer cannot bypass the displayed budget route when it reaches S.

The exclusions are inherited from the three component route theorems. None of the participating carriers contains a coordinate for a selected real value, quotient stream equality, infinite tail, host metric, or $\mathsf{Real}^{\uparrow}$ completeness, so those objects cannot be exported by the shared finite-window route. □

Theorem 601.22 (Finite Cauchy approximation selector-budget determinacy)**.** *Let $F = (R, n, k, W, D, E, S, H, C,$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Suppose F shares its finite-window rows, dyadic-ledger rows, error rows, seal rows, componentwise* hsame *transports, and displayed* Cont *routes with an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packet. Then any two* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumers with the same selector route determine the same handoff row S and the same displayed finite approximation ledger of F.*

The determined ledger is the finite row package $R, n, k, W, D, E, S, H, C, P, N$ as read through the selector route. It exports no selected real value, quotient stream equality, infinite tail, host metric, ambient completeness theorem, or hidden budget selector.

Proof. Start with Definition 601.4. It forces every downstream real or limit-seal consumer to pass through the displayed threshold, finite stream window, dyadic ledger, error row, and handoff seal route of F.

Next apply Definition 601.18. Since the budget-facing rows agree componentwise with the accepted selector packet, a consumer using the fixed selector route reads the same W, D, E, S rows before any real or limit-seal handoff is available.

Use Definition 601.21 for the common finite-window surface. The shared route exhausts the $\mathsf{Real}^{\uparrow}$ and $\mathsf{CauchyLimitSeal}^{\uparrow}$ reads through the displayed window, dyadic ledger, explicit error row, and finite budget route, so the handoff row S and the visible finite approximation ledger cannot vary between the two consumers.

Finally use selector-route non-escape. The participating packets contain only displayed finite-window, dyadic-ledger, error, seal, transport, continuation, provenance, and naming rows; they contain no selected real value, quotient stream equality, infinite tail, host metric, ambient completeness theorem, or hidden budget selector. □

Theorem 601.23 (Finite Cauchy approximation shared-budget non-escape)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P,$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet. Suppose F shares its finite-window rows, dyadic-ledger rows, error rows, handoff rows, selector route, componentwise* hsame *transports, and displayed* Cont *rows with accepted* $\mathsf{RealObservationBudget}^{\uparrow}$*,* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$*,* $\mathsf{CauchySequenceSpace}^{\uparrow}$*, and* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packets. Then every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of F factors through the same displayed finite route*

$$W \longmapsto D \longmapsto E \longmapsto S$$

and through the same selector-budget route before any $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal handoff is available.*

The shared route exports only the finite rows of F, the displayed budget rows, the shared selector route, the componentwise hsame *transports, the displayed* Cont *rows,* Pkg *provenance, and the local* $\mathsf{NameCert}$ *row. It exports no selected real value, quotient stream equality, infinite tail, host metric or equality, ambient completeness theorem, or hidden selector data.*

Proof. First apply Definition 601.4. This identifies the threshold, finite window W, dyadic ledger D, explicit error row E, handoff row S, transport rows, continuation rows, provenance row, and naming row as the displayed route available from F.

Next apply Definition 601.18. The shared $\mathsf{RealObservationBudget}^{\uparrow}$ and $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ packets read the same finite budget surface, so any budget-facing $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer must pass through the displayed W, D, E, S route before a seal handoff is visible.

Use Definition 601.20 for the sequence-space side. Because the $\mathsf{CauchySequenceSpace}^{\uparrow}$ packet shares the source, finite-window, dyadic-ledger, seal, hsame, and Cont rows with F, it contributes only the same finite-window handoff route and no separate quotient stream equality or infinite tail.

Now apply Definition 601.21 and Definition 601.22. The first theorem exhausts all real and limit-seal reads through the shared finite budget route, and the second fixes the selector-facing read of that route to the displayed selector-budget data.

Composing the non-escape clauses from these route theorems leaves exactly the displayed finite rows, budget rows, selector route, transports, continuations, provenance, and local name. None of the accepted carriers contains a coordinate for selected real values, quotient stream equality, infinite tails, host metric or equality, ambient completeness, or hidden selector data, so no consumer can receive any such object before the seal handoff. □

Theorem 601.24 (Finite Cauchy approximation L10 window exhaustion)**.** *Let $F = (R, n, k, W, D, E, S, H, C, P, N$ be an accepted* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *packet consumed by a current Phase* $\mathsf{Real}^{\uparrow}$ *route and by a current Completion terminal read. Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary read from F first exposes the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row R, unary precision row n,* $\mathsf{CauchyModulus}^{\uparrow}$ *threshold row k, finite* $\mathsf{StreamName}^{\uparrow}$ *window W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D, explicit error row E, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support rows S, H, C, P, N.*

The L10 finite-window route exports no quotient stream identity, selected real value, host real equality, hidden tail selector, ambient completeness row, or independent terminal endpoint.

Proof. First apply Definition 601.4. It forces every real-facing or limit-seal handoff to read R, n, k, W, D, E before any boundary seal can be exposed.

Next apply Definition 601.11. The handoff through S reaches the current $\mathsf{Real}^{\uparrow}$ and $\mathsf{CauchyLimitSeal}^{\uparrow}$ boundary only together with the displayed transport, continuation, provenance, and local naming rows H, C, P, N.

Finally use Definition 601.23. Its non-escape clause rules out quotient stream identity, selected real values, host real equality, hidden tail selectors, ambient completeness rows, and independent terminal endpoints along the shared budget route. □

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteCauchyApproximation}^{\uparrow}}$.

Constructive story: A $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ packet is generated from a $\mathsf{RegSeqRat}^{\uparrow}$ source row, unary precision row, $\mathsf{CauchyModulus}^{\uparrow}$ threshold, finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, explicit error-bound row, $\mathsf{Real}^{\uparrow}$ and $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FiniteCauchyApproximation}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 601.1, Definition 601.2, Definition 601.3, Definition 601.4, Definition 601.5, Definition 601.6, Definition 601.7, Definition 601.11, Definition 601.12, Definition 601.13, Definition 601.16, Definition 601.17, Definition 601.18, Definition 601.20, Definition 601.21, Definition 601.23, and Definition 601.24 bind the paper-side mature finite approximation packet over $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert, while Lean verification and bridge checking remain separate.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FiniteCauchyApproximation}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.FiniteCauchyApproximationUp.FiniteCauchyApproximationCarrier\_obligation\_closure`

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient stream equality, selected real values, infinite tails, host real metrics, $\mathsf{Real}^{\uparrow}$ completeness, Lean verification, or bridge checking.

Upgrade path: Lean verification and bridge checking require separate grounding for the finite approximation packet and its standard bridge.

Chapter 602

A Concrete Naming Certificate for $\mathsf{FullAxisRealRefusal}^{\uparrow}$

The $\mathsf{FullAxisRealRefusal}^{\uparrow}$ surface packages the AxisZeckendorf refusal that a $\mathsf{FullAxis}^{\uparrow}$ structural seal may be read as $\mathsf{Real}^{\uparrow}$. It is a finite certificate over already visible seal, refusal, transport, continuation, provenance, and naming rows. It exports no $\mathsf{Real}^{\uparrow}$ algebraic operation, no Cauchy completion, and no host limit.

Definition 602.1 (FullAxis-to-Real refusal carrier)**.** *A* $\mathsf{FullAxisRealRefusal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (F, R, C, H, T, P, N)$$

with the following visible rows:

1. *F is the* $\mathsf{FullAxis}^{\uparrow}$ *structural-seal inventory, namely the prefix-thread carrier, source, pattern, classifier, stability, ledger, finite boundary marker, and public seal-name rows of chapter 279;*
2. *R is the Real-facing refusal row, citing the fact that* $\mathsf{FullAxis}^{\uparrow}$ *does not entail the Cauchy, limit-uniqueness, field, compactness, metric-completion, or selected-limit operations of* $\mathsf{Real}^{\uparrow}$*;*
3. *C is the AxisZeckendorf cannot-claim row for the* $\mathsf{FullAxis}^{\uparrow}$ *as* $\mathsf{Real}^{\uparrow}$ *horizon, including the boundary refusal of Definition 9350.6;*
4. *H records the displayed* hsame *transports for the structural seal row, the Real-facing refusal row, the cannot-claim row, the package row, and the local naming row;*
5. *T records the displayed* Cont *routes by which consumers may read the seal inventory and replay the refusal without producing a positive* $\mathsf{Real}^{\uparrow}$ *bridge;*
6. *P is the* Pkg *provenance over* $\mathsf{FullAxis}^{\uparrow}$, $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and the source* NameCert *rows;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{FullAxisRealRefusal}^{\uparrow}}$ *row.*

The carrier has no coordinate for addition, multiplication, order, Cauchy convergence, limit uniqueness, completeness, compactness, a quotient of histories, or host equality.

Lean4 ✓ `BEDC.Derived.FullAxisRealRefusalUp.FullAxisRealRefusalTasteGate single carrier alignment`

Theorem 602.2 (FullAxis-to-Real refusal NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FullAxisRealRefusal}^{\uparrow}}$ *surface for Definition 602.1 consists exactly of five finite obligations:*

1. *carrier admission for the packet* $Q = (F, R, C, H, T, P, N)$*;*
2. *structural-seal coverage for the prefix-thread, boundary-finite, source-exhaustion, Real-route-separation, and seal-name rows collected in* F*;*
3. *refusal coverage for the Real-facing row* R *and the AxisZeckendorf cannot-claim row* C*;*
4. *transport and continuation exactness for the displayed* hsame *rows* H *and* Cont *routes* T*;*
5. *ledger non-escape through the* Pkg *provenance row* P *and local* NameCert *row* N*.*

Proof. Carrier admission is projection from Definition 602.1. The admitted packet has exactly seven visible rows, so every later read starts from F, R, C, H, T, P, N.

Structural-seal coverage is supplied by the first row. The row F names the prefix-thread carrier, finite boundary marker, source-exhaustion statement, Real-route separation statement, and public seal-name alignment from the $\mathsf{FullAxis}^{\uparrow}$ chapter.

Refusal coverage is supplied by R and C. The row R records the missing $\mathsf{Real}^{\uparrow}$ operations, while C points to the AxisZeckendorf cannot-claim horizon for the same boundary.

Transport and continuation exactness are the rows H and T. They move only displayed refusal and seal rows, and therefore cannot turn the refusal into an algebraic or completion operation.

Finally, P and N record package provenance and the local naming ledger. Since none of the excluded $\mathsf{Real}^{\uparrow}$ operations is a coordinate of the packet, the NameCert surface is exhausted by the five displayed obligations. □

Theorem 602.3 (FullAxis-to-Real refusal non-escape)**.** *Every public read exported by an accepted* $\mathsf{FullAxisRealRefusal}^{\uparrow}$ *packet factors through the rows* F, R, C, H, T, P, N*. In particular, no consumer can extract a* $\mathsf{Real}^{\uparrow}$ *addition, multiplication, order, Cauchy convergence proof, limit-uniqueness proof, completeness row, compactness row, selected host limit, quotient stream, or host equality from the packet.*

Proof. Inspect the packet coordinates. The structural-seal row F exposes only the $\mathsf{FullAxis}^{\uparrow}$ prefix-thread and finite-boundary surface, while the rows R and C expose refusal data.

The transport and continuation rows H and T preserve those displayed rows componentwise. A transported refusal remains a refusal row, and a transported structural-seal read remains a read of the same prefix-thread inventory.

The provenance and naming rows P and N do not add mathematical operations. Because no coordinate contains a $\mathsf{Real}^{\uparrow}$ algebraic operation, completion operation, quotient stream, selected limit, or host equality, no public read can export one. □

Lean4 ✓ `BEDC.Derived.FullAxisRealRefusalUp.FullAxisRealRefusal non escape`

Theorem 602.4 (FullAxis-to-Real refusal vision concretization)**.** *The AxisZeckendorf cannot-claim boundary for* $\mathsf{FullAxis}^{\uparrow}$ *as* $\mathsf{Real}^{\uparrow}$ *is realized by the finite* $\mathsf{FullAxisRealRefusal}^{\uparrow}$ *packet of Definition 602.1. The realization cites* $\mathsf{FullAxis}^{\uparrow}$ *structural-seal rows, Real-facing refusal rows, AxisZeckendorf cannot-claim rows, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and a local* NameCert *row, while exporting no* $\mathsf{Real}^{\uparrow}$ *operation.*

Proof. Start from the cannot-claim theorem Definition 9350.6. It supplies the boundary statement that the AxisZeckendorf cluster does not assert $\mathsf{Real}^{\uparrow}$ field operations on $\mathsf{FullAxis}^{\uparrow}$.

The carrier of Definition 602.1 turns that boundary into finite rows. The row F records the $\mathsf{FullAxis}^{\uparrow}$ seal surface, R records the Real-facing refusal, and C records the AxisZeckendorf horizon row.

Rows H, T, P, N provide the admissible transport, continuation, package, and local naming surface. By Definition 602.3, this realization cannot be read as a positive $\mathsf{Real}^{\uparrow}$ bridge, so it concretizes the vision boundary as a finite refusal certificate. □

Closure status for $\mathsf{NameCert}_{\mathsf{FullAxisRealRefusal}^{\uparrow}}$.

Constructive story: A $\mathsf{FullAxisRealRefusal}^{\uparrow}$ packet is generated from FullAxis structural-seal rows, Real-facing refusal rows, the AxisZeckendorf cannot-claim horizon, displayed hsame transports, continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FullAxisRealRefusal}^{\uparrow}}, \mathsf{seed})$

Scope closed: The seed scope records the carrier, NameCert obligations, non-escape boundary, and AxisZeckendorf vision concretization for finite FullAxis-to-Real refusal packets.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FullAxisRealRefusal}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a RealUp bridge, RealUp algebraic operations for FullAxisUp, Cauchy completion, compactness, quotient streams, selected host limits, or host equality.

Upgrade path: Obligation closure requires checked carrier coverage, refusal-row coverage, transport exactness, continuation exactness, and ledger non-escape for the displayed packet.

Chapter 603

A Concrete Naming Certificate for $\mathsf{HistTimeStream}^{\uparrow}$

The $\mathsf{HistTimeStream}^{\uparrow}$ interface realizes the local-time-stream reading of chapter 9418 as a finite BEDC naming surface. A stream is not a clock shared by distinct histories; it is the displayed sequence of Cont steps by which one source history is generated from e.

Definition 603.1 (HistTimeStream NameCert carrier)**.** *A* $\mathsf{HistTimeStream}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (H, T, S, C, L, P, N)$$

with the following visible rows:

1. *H is the source* Hist *row being read as a local stream;*
2. *T is the finite sequence of* $\mathsf{E1}$ *and* $\mathsf{E0}$ *time-step rows whose terminal history is H;*
3. *S is the start-at-empty source ledger, recording that the sequence begins at* e *and reaches only the displayed source history;*
4. *C records the* Cont *route for each time-step row in T;*
5. *L records componentwise* hsame *transport for the displayed rows and the no-global-clock ledger preventing a second history from importing this stream as a synchronizing clock;*
6. *P is the* Pkg *provenance row naming* BHist, Hist, Cont, hsame, $\mathsf{ProbeBundle}$, Pkg, *and the local stream packet;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{HistTimeStream}^{\uparrow}}$ *row.*

The classifier compares accepted packets by the displayed rows H, T, S, C, L, P, N. It has no coordinate for a host natural-number index, no ambient time parameter, and no equality synchronizing the local streams of distinct Hist values.

Lean4 (definition) `BEDC.Derived.HistTimeStreamUp.HistTimeStreamUp`

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamTasteGate single carrier alignment`

Theorem 603.2 (HistTimeStream NameCert obligation sketch)**.** *The local* $\mathsf{NameCert}_{\mathsf{HistTimeStream}^{\uparrow}}$ *obligation surface has five displayed checks: carrier admission for $Q = (H, T, S, C, L, P, N)$, exactness of the start-at-empty step ledger S, stability of every* Cont *route recorded in C, componentwise* hsame *transport through L, and no-global-clock non-escape for the stream named by N.*

Proof. Project the finite carrier of Definition 603.1. The row H fixes the source history, while T and S record the finite step ledger from e to that history.

For each displayed step in T, read the corresponding route in C. These routes are the only permitted transitions, so the stream has no hidden branch outside the finite packet.

Transport is then performed rowwise through L. The same ledger also records that a second Hist cannot import this local stream as a shared clock, because the packet names only the source row H and its own finite route list.

Finally, P and N repack the source, step, route, transport, and locality rows as a local $\mathsf{NameCert}$ surface. This is exactly the concrete packet needed for the observer-history time-as-growth reading. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier namecert obligation sketch`

Theorem 603.3 (HistTimeStream observation carrier)**.** *Every accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet exposes the source* Hist *row* H*, the finite* $\mathsf{E1}/\mathsf{E0}$ *schedule* T*, the start-at-empty ledger* S*, and the displayed* Cont *replay row* C *as carrier coordinates of*

$$Q = (H, T, S, C, L, P, N).$$

The packet has no accepted observation surface apart from these coordinates, the componentwise hsame *ledger* L*, package provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{HistTimeStream}^{\uparrow}}$ *row* N*.*

Proof. Project the accepted packet through Definition 603.1. The source row, schedule row, start ledger, continuation replay ledger, transport ledger, package provenance, and local naming row are exactly the displayed coordinates of Q.

Apply Definition 603.2. Its carrier-admission and step-ledger clauses identify H, T, S, C as the public observation rows, while the remaining clauses leave only L, P, N as transport, provenance, and naming data.

No other coordinate is present in the finite tuple. Therefore an accepted packet cannot export a separate observation carrier, ambient clock, or hidden route outside the listed rows. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier observation carrier`

Theorem 603.4 (HistTimeStream schedule classifier stability)**.** *For an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet* $Q = (H, T, S, C, L, P, N)$*, componentwise* hsame *transport along the rows stored in* L *preserves the finite schedule* T*, the start-at-empty ledger* S*, and the displayed* Cont *replay row* C*. The transported classifier remains indexed only by the displayed carrier rows and cannot introduce a host-indexed global time coordinate.*

Proof. Begin with the classifier description in Definition 603.1. It compares packets by the visible rows H, T, S, C, L, P, N and provides no coordinate for a natural-number host index or shared ambient time parameter.

Transport is componentwise through L. Each transported schedule entry remains one of the displayed $\mathsf{E1}/\mathsf{E0}$ rows of T, the start ledger remains attached to e and the terminal source row H, and every replayed route is still read through the corresponding row of C.

The no-global-clock clause in Definition 603.2 blocks the only possible escape route: importing the local stream into a second Hist as a synchronizing clock. Thus the transported classifier preserves the finite schedule and cannot acquire a host-indexed time row. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier schedule classifier stability`

Theorem 603.5 (HistTimeStream NameCert ledger exhaustion)**.** *Every public* $\mathsf{NameCert}_{\mathsf{HistTimeStream}^{\uparrow}}$ *read factors through the carrier row, the finite step ledger, route stability, componentwise transport, package provenance, and the local naming row:*

$$H, T, S, C, L, P, N.$$

No public read from the packet yields inter-Hist synchronization, a rate claim, an ambient global clock, or a host time index.

Proof. First use the observation-carrier theorem to place every public read inside the finite tuple $Q = (H, T, S, C, L, P, N)$. The source, schedule, start ledger, route replay, transport, package, and local naming rows are the complete carrier inventory.

Next use schedule classifier stability. It keeps the step ledger and Cont replay rows stable under componentwise hsame transport and prevents the classifier from acquiring a global-time coordinate.

Finally inspect the package and local naming rows. They certify only the displayed BHist, Hist, Cont, hsame, ProbeBundle, Pkg, and NameCert provenance for this one local stream, so the finite coordinate list exhausts the public NameCert ledger and leaves no synchronization or rate claim to read. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier namecert ledger exhaustion`

Theorem 603.6 (HistTimeStream observer-locality lattice link)**.** *Every accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *read of*

$$Q = (H, T, S, C, L, P, N)$$

is consumed as the local-time component of the observer-history identity and observer-locality surfaces of chapter 479 and chapter 889. The stream supplies the displayed source history, finite step ledger, continuation replay, and no-global-clock transport row, but it supplies no inter-Hist synchronization, shared clock, or imported host-time index.

Proof. Project the accepted packet $Q = (H, T, S, C, L, P, N)$. The rows H, T, S, C give the source history, start-at-empty finite schedule, and displayed Cont replay that the observer-history identity surface reads as its local growth component.

Use Definition 603.5. Its no-global-clock ledger keeps the read attached to the single source row H and blocks any second Hist from importing T as a synchronizing clock.

The sibling packets of chapter 479 and chapter 889 therefore consume this same local stream through L, P, N. They may use it to identify observer-history locality and transport surfaces, but they add no inter-Hist clock equality, host-time coordinate, or cross-history synchronization row. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamObserverLocalityLatticeLink`

Theorem 603.7 (HistTimeStream public export)**.** *An accepted packet*

$$Q = (H, T, S, C, L, P, N)$$

exports exactly the local-time stream $\mathsf{NameCert}_{\mathsf{HistTimeStream}^{\uparrow}}$ *surface: the source* Hist *row* H*, the finite* E1/E0 *schedule* T*, the start-at-empty ledger* S*, the displayed* Cont *replay row* C*, the componentwise* hsame *and no-global-clock ledger* L*, the* Pkg *provenance row* P*, and the local* NameCert *row* N*. No public export from* Q *yields an inter-Hist clock, host time index, global synchronization row, temporal-rate claim, or hidden route outside those displayed coordinates.*

Proof. Start from the carrier of Definition 603.1. It lists exactly the rows H, T, S, C, L, P, N, with H as the source history, T as the finite E1/E0 schedule, S as the start-at-empty ledger, C as the displayed replay row, and L, P, N as transport, provenance, and local naming data.

Use the observation carrier theorem, Definition 603.3, to identify H, T, S, C as the only observation rows. Then apply schedule classifier stability, Definition 603.4, so componentwise hsame transport preserves the finite schedule and cannot add a host-indexed global time coordinate.

Next apply ledger exhaustion, Definition 603.5. It forces every public $\mathsf{NameCert}_{\mathsf{HistTimeStream}^{\uparrow}}$ read through the same carrier, schedule, replay, transport, package, and naming rows.

Finally use the observer-locality lattice link, Definition 603.6. The downstream observer-history surfaces consume the packet as one local stream, so the public export is precisely the displayed local-time stream surface and no inter-Hist synchronization or hidden route is available. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier public export`

Theorem 603.8 (HistTimeStream window habitation)**.** *Let $Q = (H, T, S, C, L, P, N)$ be an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet. Any finite window accepted by the local* $\mathsf{NameCert}_{\mathsf{HistTimeStream}^{\uparrow}}$ *surface is inhabited only by the displayed rows*

$$H, T, S, C, L, P, N$$

and its source route begins at e*. The window has no additional row for a host time index, ambient clock coordinate, sibling Hist source, or hidden pre-start segment.*

Proof. Start from the carrier definition, Definition 603.1. It presents the accepted packet as exactly the seven rows H, T, S, C, L, P, N, with S recording that the finite route begins at e and reaches only the displayed source history.

Next apply the NameCert obligation sketch, Definition 603.2. Its carrier-admission and start-ledger clauses make the finite window a local packet window rather than an ambient time interval, and its route-stability clause reads the window only through the displayed Cont rows.

Finally use ledger exhaustion, Definition 603.5. Every public read of the window must pass through the same carrier, schedule, replay, transport, package, and naming rows, so no host index, sibling source, or hidden pre-start row can inhabit the accepted window. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier window habitation`

Theorem 603.9 (HistTimeStream Real StreamName window lock)**.** *Let $Q = (H, T, S, C, L, P, N)$ be an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet. Any* $\mathsf{Real}^{\uparrow}$*-facing finite-window read of Q must pass through the displayed H, T, S, C, L, P, N rows and then through the StreamName handoff surface. It cannot read a host time index, global clock, sibling Hist source, or hidden stream row outside the accepted local packet.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier real streamname window lock`

Proof. Start from the carrier and obligation sketch, Definition 603.1 and Definition 603.2. These identify the accepted packet as exactly the source history, finite schedule, start ledger, replay, transport, provenance, and local naming rows.

Apply schedule classifier stability and ledger exhaustion, Definition 603.4 and Definition 603.5. The finite E1/E0 schedule is preserved under componentwise hsame transport, and every public read remains inside the displayed packet rows.

Finally use the observer-locality lattice link, public export, and window habitation theorems, Definition 603.6, Definition 603.7, and Definition 603.8. They route the finite window through the

local StreamName-facing handoff and exclude every nonlocal clock or hidden stream coordinate. □

Theorem 603.10 (HistTimeStream RegSeqRat local clock separation)**.** *Let $Q = (H, T, S, C, L, P, N)$ be an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet. A* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer may use the finite local schedule T as an observation index for the displayed packet, but it cannot promote T to a shared host clock, an inter-Hist synchronization row, or a temporal-rate coordinate.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier regseqrat local clock separation`

Proof. Begin with the carrier and obligation sketch, Definition 603.1 and Definition 603.2. They make T a finite local schedule row tied to the source history H and the displayed replay row C.

Next apply schedule classifier stability and ledger exhaustion, Definition 603.4 and Definition 603.5. The schedule survives only as a component of the same local packet under hsame transport, and the ledger has no row for shared host time or inter-Hist synchronization.

The observer-locality lattice link, public export, and window habitation theorems, Definition 603.6, Definition 603.7, and Definition 603.8, then bound the RegSeqRat-facing use of T. It remains an observation index for the finite local stream and cannot become a global clock coordinate. □

Theorem 603.11 (HistTimeStream Real completion consumer boundary)**.** *For an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet $Q = (H, T, S, C, L, P, N)$, every* $\mathsf{Completion}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer may read only the local stream packet, its componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *row. No such consumer obtains a host real equality row, ambient completeness principle, quotient stream, selected limit, global clock, or inter-Hist synchronization row from Q.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier real completion consumer boundary`

Proof. First expose the local stream packet through Definition 603.1 and Definition 603.2. The only available rows are H, T, S, C, L, P, N, with C as the replay route, L as componentwise hsame transport, P as provenance, and N as the local naming row.

Apply schedule classifier stability and ledger exhaustion, Definition 603.4 and Definition 603.5. These force every consumer-facing read to remain within the same finite schedule and local ledger, so completion-facing access cannot introduce detached Real or global-clock data.

Finally use the observer-locality lattice link, public export, and window habitation theorems, Definition 603.6, Definition 603.7, and Definition 603.8. Their common boundary is the displayed local packet with hsame, Cont, Pkg, and NameCert support, and carrier-coordinate exhaustion removes each listed external coordinate. □

Theorem 603.12 (HistTimeStream transport lock)**.** *For accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packets $Q = (H, T, S, C, L, P, N)$ and $Q' = (H', T', S', C', L', P', N')$, componentwise* hsame *transport from Q to Q' preserves the finite schedule rows and the displayed* Cont *replay rows. The transported packet may replay the local window through $H', T', S', C', L', P', N'$, but it cannot add a host time index, shared clock coordinate, or external rate row.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamTransportLock`

Proof. Begin with the carrier definition, Definition 603.1. The transport row L is componentwise transport for the displayed packet rows, not a map into an external clock carrier.

Apply schedule classifier stability, Definition 603.4. It keeps the finite E1/E0 schedule, the start-at-empty ledger, and the replay row stable under componentwise hsame transport, so the transported consumer sees the corresponding rows of Q'.

Use ledger exhaustion, Definition 603.5, to close the transport surface. Since every public read remains inside the same carrier, schedule, replay, transport, package, and naming inventory, there is no coordinate where a host time index, shared clock, or external rate can be inserted. □

Theorem 603.13 (HistTimeStream clock refusal obligation)**.** *No accepted consumer of a* $\mathsf{HistTimeStream}^{\uparrow}$ *packet* $Q = (H, T, S, C, L, P, N)$ *can read a shared inter-Hist clock, synchronized external time, or temporal-rate coordinate from the packet. Every accepted time-facing read is confined to the finite local window displayed by* H, T, S, C, L, P, N *and to componentwise* hsame *transport of that same window.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier clock refusal`

Proof. First expose the accepted packet through Definition 603.1. The carrier lists the source history, finite schedule, start ledger, replay row, transport row, provenance row, and local naming row, and it has no coordinate reserved for a shared clock or rate.

Next apply the NameCert obligation sketch and schedule classifier stability, Definition 603.2 and Definition 603.4. These keep the local stream tied to the displayed finite schedule and block componentwise transport from becoming a host-indexed global time classifier.

Finally use ledger exhaustion, Definition 603.5. The public NameCert read is exhausted by the displayed local rows and their transport ledger, so an accepted consumer has no path to a shared inter-Hist clock, synchronized external time, or temporal-rate coordinate. □

Theorem 603.14 (HistTimeStream completion StreamName handoff factorization)**.** *Every* $\mathsf{Completion}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet*

$$Q = (H, T, S, C, L, P, N)$$

factors first through the displayed local packet H, T, S, C, L, P, N*, then through the StreamName-facing finite-window handoff. The consumer cannot replace the local schedule by a host time index, global clock, sibling Hist source, quotient stream, selected limit, or ambient completeness row.*

Proof. Start with the carrier and NameCert obligation sketch, Definition 603.1 and Definition 603.2. They make H, T, S, C, L, P, N the whole accepted local packet and route every public read through the displayed schedule, replay, transport, provenance, and naming rows.

Apply the Real StreamName window lock and RegSeqRat local clock separation, Definition 603.9 and Definition 603.10. The first sends Real-facing finite-window reads through the StreamName handoff, while the second keeps the local schedule from becoming a host clock or shared synchronization row.

Use the Real completion consumer boundary and transport lock, Definition 603.11 and Definition 603.12. They keep completion-facing reads and componentwise transport inside the same finite local packet.

Finally apply the clock refusal obligation, Definition 603.13. Since no shared clock, host index, sibling Hist source, quotient stream, selected limit, or ambient completeness coordinate exists in the packet, the completion or Real consumer factors through the local packet before the StreamName handoff and nowhere else. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier completion streamname handoff factorization`

Theorem 603.15 (HistTimeStream observer-locality consumption bridge)**.** *Any observer-locality or observer-history-identity consumer of an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet factors through the displayed local stream rows*

$$H, T, S, C, L, P, N$$

before reading observer-locality transport. Such a consumer cannot add inter-Hist synchronization, a global clock, or a host time index to the consumed packet.

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier observer locality consumption bridge`

Proof. Start with the carrier of Definition 603.1. It presents the source history, finite step schedule, start ledger, continuation replay, transport, provenance, and local naming rows as the complete local stream packet.

Apply the NameCert obligation sketch and the observer-locality lattice link. The certificate routes every public read through the same H, T, S, C, L, P, N inventory, and the lattice link identifies that inventory as the local-time component consumed by observer-history identity and observer-locality transport.

Finally use the public export theorem. Since the exported surface has no coordinate for inter-Hist synchronization, a shared global clock, or a host time index, every observer-locality consumer must read the displayed local stream rows before transport and cannot extend them with a hidden time source. □

Theorem 603.16 (HistTimeStream observer-locality bridge route)**.** *Every observer-locality consumer reads an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet first through the displayed rows*

$$H, T, S, C, L, P, N,$$

then through the sibling $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *and* $\mathsf{ObserverLocalityTransport}^{\uparrow}$ *surfaces of chapter 479 and chapter 889. The route cannot add a global clock, host time index, inter-Hist synchronization row, or temporal-rate row.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamObserverLocalityBridgeRoute`

Proof. Start from the public export theorem, Definition 603.7. It makes H, T, S, C, L, P, N the whole local-time stream surface visible to an outside consumer.

Next apply the observer-locality lattice link. That theorem identifies the same carrier rows as the local-time component consumed by observer-history identity and observer-locality transport, so the sibling surfaces are reached only after the finite HistTimeStream packet has been read.

Finally use the consumption bridge of Definition 603.15. Since the consumed packet has no coordinate for a global clock, host time index, inter-Hist synchronization, or rate measurement, the bridge route cannot add any such row downstream. □

Theorem 603.17 (HistTimeStream observer-locality transport)**.** *Let*

$$Q = (H, T, S, C, L, P, N)$$

be an accepted $\mathsf{HistTimeStream}^{\uparrow}$ *packet. If the public export of* Q *is consumed by* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *or* $\mathsf{ObserverLocalityTransport}^{\uparrow}$*, then the transport through the sibling observer-locality surfaces carries exactly the displayed local-time rows* H, T, S, C, L, P, N*. It preserves the no-global-clock ledger* L *and cannot add inter-Hist synchronization, host-indexed time, temporal-rate rows, or hidden routes.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier observer locality transport`

Proof. Start with the carrier definition of Definition 603.1. The accepted packet has only the source Hist row H, finite E1/E0 schedule T, start-at-empty ledger S, displayed Cont replay row C, componentwise hsame and no-global-clock ledger L, package provenance row P, and local NameCert row N.

Apply the public export theorem, Definition 603.7. It identifies those seven rows as the whole public local-time stream surface and excludes a global clock, host time index, inter-Hist synchronization row, temporal-rate claim, or hidden route from the exported packet.

Next use the observer-locality lattice link, Definition 603.6. The sibling ObserverHistoryIdentity$^{\uparrow}$ and ObserverLocalityTransport$^{\uparrow}$ surfaces consume the exported local-time rows as the same finite stream, so the consumer receives no additional time coordinate before transport.

Finally apply the route order of Definition 603.16. Since the route reaches the sibling observer-locality surfaces only after H, T, S, C, L, P, N have been read, the resulting transport preserves the no-global-clock ledger and cannot attach any forbidden synchronization, host-indexed time, rate, or hidden-route row. □

Theorem 603.18 (HistTimeStream Cont prefix exactness)**.** *Let*

$$Q = (H, T, S, C, L, P, N)$$

be an accepted HistTimeStream$^{\uparrow}$ *packet. The displayed finite time stream is exactly the* Cont*-prefix route from* e *to the source* Hist *row H, read through the finite schedule T, the start-at-empty ledger S, the replay row C, the transport and locality ledger L, the package row P, and the local naming row N.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier cont prefix exactness`

Proof. Start with the carrier of Definition 603.1. It presents H, T, S, C, L, P, N as the complete local stream packet, with S recording the start-at-empty boundary and C recording the displayed replay route.

Use the observation carrier theorem, Definition 603.3, to identify H, T, S, C as the whole finite observation prefix. Schedule classifier stability, Definition 603.4, keeps that prefix tied to the finite E1/E0 schedule.

Finally apply ledger exhaustion and observer-locality transport, Definition 603.5 and Definition 603.17. These theorems force every consumer of the local stream through the same prefix and leave no hidden route between e and H. □

Theorem 603.19 (HistTimeStream hsame prefix transport)**.** *For accepted* HistTimeStream$^{\uparrow}$ *packets $Q = (H, T, S, C, L, P, N)$ and $Q' = (H', T', S', C', L', P', N')$, componentwise* hsame *transport preserves the* Cont*-prefix route of Definition 603.18. It may replay the displayed local stream rows from Q to Q', but it cannot create a host-indexed time coordinate, an inter-Hist clock, or a global synchronization row.*

Proof. Begin with Cont prefix exactness. Theorem 603.18 identifies the prefix route entirely from the displayed rows H, T, S, C, L, P, N.

Now transport the finite schedule and ledger rows. By schedule classifier stability, Definition 603.4, componentwise hsame preserves the finite E1/E0 schedule. By ledger exhaustion, Definition 603.5, the no-global-clock ledger remains part of the same packet rather than becoming a host time index.

Finally use observer-locality transport, Definition 603.17. The downstream observer-locality route consumes the transported packet as local rows only, so no inter-Hist clock or global synchronization coordinate is produced by the transport. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier hsame prefix transport`

Theorem 603.20 (HistTimeStream observer-locality totality)**.** *Let $Q = (H, T, S, C, L, P, N)$ be an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet. Every observer-locality or observer-history consumer reads exactly the displayed local rows*

$$H, T, S, C, L, P, N$$

through the carrier, finite step ledger, replay route, no-global-clock locality row, provenance row, and local naming row. No such consumer obtains a global clock, host time index, inter-Hist synchronization row, temporal-rate coordinate, or hidden route.

Proof. Start with the carrier and observation carrier. The definition Definition 603.1 displays H, T, S, C, L, P, N, and Definition 603.3 identifies H, T, S, C as the finite observation surface.

Next apply schedule classifier stability and ledger exhaustion. Theorem 603.4 keeps the finite $\mathsf{E1/E0}$ schedule attached to T, while Definition 603.5 keeps the no-global-clock ledger and local naming rows inside the same packet.

Finally use the observer-locality lattice link, public export, and bridge route. Theorems 603.6, 603.7, and 603.16 show that observer-facing consumers receive only the local packet before any sibling route is available. Thus totality holds on H, T, S, C, L, P, N and all nonlocal time reads are excluded. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier observer locality totality`

Theorem 603.21 (HistTimeStream start-ledger uniqueness)**.** *Let $Q = (H, T, S, C, L, P, N)$ be an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet. The start-at-empty ledger S determines the displayed finite schedule endpoint H inside Q through the schedule row T and replay row C. No accepted read of Q carries a second start row, a second endpoint row, or a host-indexed clock coordinate from which another start ledger can be recovered.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamStartLedgerUniqueness`

Proof. Start with the carrier and observation carrier. The definition Definition 603.1 fixes Q as the displayed tuple H, T, S, C, L, P, N, and Definition 603.3 identifies the observed prefix rows as H, T, S, C.

Next apply Cont prefix exactness, Definition 603.18. The replay route starts at e, passes through the finite schedule and start ledger, and ends at the displayed source row H.

Finally use ledger exhaustion, Definition 603.5. Since the local NameCert surface has no additional start or endpoint coordinate, the start ledger determines the schedule endpoint inside Q and admits no second start row. □

Theorem 603.22 (HistTimeStream Cont-step coverage)**.** *Let $Q = (H, T, S, C, L, P, N)$ be an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet. Every public local-time step read from Q is one of the displayed* $\mathsf{E1/E0}$ *schedule entries in T replayed by C. The packet exposes no step outside the finite schedule, no temporal-rate coordinate, and no hidden continuation branch.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier cont step coverage`

Proof. First read the schedule classifier. By Definition 603.4, the finite E1/E0 schedule is the classifier-stable step surface carried by T.

Next apply Cont prefix exactness, Definition 603.18. The continuation route C replays the displayed prefix from e to H through the schedule and start ledger, so every public step read is already a row of T.

Finally use public export and ledger exhaustion, Definition 603.7 and Definition 603.5. They confine public consumers to the displayed packet and leave no coordinate for an extra step, rate, or hidden continuation branch. □

Theorem 603.23 (HistTimeStream hsame schedule endpoint transport)**.** *For accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packets* $Q = (H, T, S, C, L, P, N)$ *and* $Q' = (H', T', S', C', L', P', N')$*, componentwise* hsame *transport through* L *preserves the finite schedule endpoint and the no-global-clock ledger. Thus transporting* Q *to* Q' *carries the endpoint determined by* S, T, C *to the endpoint determined by* S', T', C' *without adding a global clock, inter-Hist synchronization row, or host time index.*

Proof. Begin with hsame prefix transport, Definition 603.19. It preserves the displayed Cont-prefix route componentwise and cannot create a host-indexed time coordinate, inter-Hist clock, or global synchronization row.

Use start-ledger uniqueness and Cont-step coverage next. Theorems 603.21 and 603.22 identify the endpoint from the start ledger, finite schedule, and replay row, and place every step in the displayed E1/E0 schedule.

Finally apply observer-locality transport, Definition 603.17. Observer-facing transport reads only the local packet and its no-global-clock ledger, so the endpoint is preserved by componentwise hsame and no nonlocal time coordinate appears. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier hsame schedule endpoint transport`

Theorem 603.24 (HistTimeStream local transport exhaustion)**.** *For accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packets* $Q = (H, T, S, C, L, P, N)$ *and* $Q' = (H', T', S', C', L', P', N')$*, componentwise* hsame *transport preserves the local* Cont *prefix of* Q *as the local* Cont *prefix of* Q'*. The transport exhausts the displayed local rows and does not add a global clock, a host time index, an inter-Hist synchronization coordinate, or a temporal-rate row.*

Proof. First expose the prefix. The Cont-prefix exactness theorem, Definition 603.18, identifies the local route from e to H through T, S, C, L, P, N.

Now transport componentwise. The hsame prefix transport theorem, Definition 603.19, preserves this prefix across accepted packets, and schedule classifier stability keeps the transported schedule finite.

Finally apply observer-locality transport and local clock refusal. Theorem 603.17 keeps the transported packet local for observer-facing consumers, while Definition 603.26 rejects every nonlocal clock read unless it has already factored through the displayed rows. Hence the transport is exhausted by the local packet. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier local transport exhaustion`

Theorem 603.25 (HistTimeStream NameCert route exhaustion)**.** *Every* NameCert *route of an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet* $Q = (H, T, S, C, L, P, N)$ *is exhausted by the carrier, finite step ledger, replay route, no-global-clock ledger, provenance row, and local naming row. The route cannot pass to a global clock, host time index, inter-Hist synchronization row, temporal-rate coordinate, or hidden observer route.*

Proof. Begin with the NameCert obligation sketch and the carrier. The sketch fixes the local naming obligation on the displayed packet, and Definition 603.1 supplies exactly the rows H, T, S, C, L, P, N.

Next assemble the local route. Observation carrier gives the finite prefix rows, schedule classifier stability keeps the step ledger finite, and ledger exhaustion keeps replay, no-global-clock locality, provenance, and naming in the same packet.

Finally pass through the observer-locality surface. The observer-locality lattice link, public export, bridge route, observer-locality transport, and hsame prefix transport show that every downstream route reads the same local packet. Therefore the NameCert surface is exhausted by those rows and has no escape to nonlocal time structure. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamNameCertRouteExhaustion`

Theorem 603.26 (HistTimeStream local clock refusal)**.** *Let*

$$Q = (H, T, S, C, L, P, N)$$

be an accepted $\mathsf{HistTimeStream}^{\uparrow}$ *packet. Any attempted global-clock, host-indexed time, inter-Hist synchronization, or temporal-rate read is refused unless it factors through the displayed local tuple* H, T, S, C, L, P, N *and the no-global-clock ledger carried by* L*.*

Proof. First expose the public packet. The public export theorem, Definition 603.7, makes H, T, S, C, L, P, N the entire local-time stream surface and excludes global-clock and hidden-route coordinates from the export.

Next use hsame prefix transport. Theorem 603.19 shows that replay across componentwise transports preserves the local prefix and cannot manufacture host-indexed time or inter-Hist synchronization.

Finally apply observer-locality transport, Definition 603.17. Since observer-locality consumers receive only the displayed local stream and its no-global-clock ledger, every nonlocal clock read is refused unless it has already factored through H, T, S, C, L, P, N. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier local clock refusal`

Theorem 603.27 (HistTimeStream prefix transport exhaustion)**.** *For any accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet* $Q = (H, T, S, C, L, P, N)$*, every consumer read through* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *or* $\mathsf{ObserverLocalityTransport}$ *first factors through the* Cont*-prefix route of Definition 603.18, then through the componentwise* hsame *transport of Definition 603.19. Any attempted global-clock, host-indexed time, inter-Hist synchronization, or temporal-rate read is refused by Definition 603.26 unless it preserves the displayed rows* H, T, S, C, L, P, N *and the observer-locality boundary of Definition 603.17.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier prefix transport exhaustion`

Proof. Begin with observer-locality transport. Theorem 603.17 says that observer-history and observer-locality consumers receive exactly the displayed local-time rows H, T, S, C, L, P, N.

Next expose the prefix route. Theorem 603.18 identifies that consumer surface as the displayed Cont prefix from e to the source Hist row H through the schedule, start ledger, replay, transport, provenance, and local naming rows.

Now transport the prefix componentwise. Theorem 603.19 preserves the same prefix across accepted packets and cannot create a host-indexed time coordinate, inter-Hist clock, or global synchronization row.

Finally apply local clock refusal. Theorem 603.26 rejects global-clock, rate, and nonlocal time reads unless they have already passed through and preserved the displayed packet rows. Thus the four cited theorems assemble one consumer-facing exhaustion route. □

Theorem 603.28 (HistTimeStream StreamName finite-window handoff)**.** *Let*

$$Q = (H, T, S, C, L, P, N)$$

be an accepted $\mathsf{HistTimeStream}^{\uparrow}$ *packet. The displayed* Cont*-prefix route of* Q *induces the finite* $\mathsf{StreamName}^{\uparrow}$ *window read by chapter 126: the source row* H*, finite schedule* T*, start ledger* S*, replay row* C*, componentwise* hsame *ledger* L*, package row* P*, and local name row* N *are passed as one bounded naming packet before any countable-name consumer may read the stream. The handoff carries no quotient stream, no selected host limit, no ambient completeness witness, and no host-indexed time coordinate.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier streamname finite window handoff`

Proof. Start from Cont-prefix exactness, Definition 603.18. It identifies the local stream as the finite route from e to the displayed source row H through T, S, C, L, P, N.

Next apply hsame prefix transport, Definition 603.19. The transport keeps the same displayed finite route when the packet is replayed componentwise, so the $\mathsf{StreamName}^{\uparrow}$ consumer of chapter 126 receives a finite window rather than an ambient clock.

Finally use local clock refusal, Definition 603.26. Since every nonlocal time read must already factor through H, T, S, C, L, P, N, the handoff to the StreamName surface cannot add a quotient stream, chosen limit, completeness witness, or host-indexed time row. □

Theorem 603.29 (HistTimeStream StreamName schedule classifier boundary)**.** *For accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packets* $Q = (H, T, S, C, L, P, N)$ *and* $Q' = (H', T', S', C', L', P', N')$*, componentwise* hsame *transport preserves the finite schedule and replay classifier before any* $\mathsf{StreamName}^{\uparrow}$ *read. The transported classifier remains the displayed boundary over* T, S, C, L, P, N *and cannot add a global clock, host-indexed time, inter-Hist synchronization row, or temporal-rate coordinate.*

Proof. First expose the finite classifier boundary. By Definition 603.18, the only route available to a consumer is the displayed Cont prefix through the schedule, start ledger, replay row, transport ledger, package row, and local name.

Now transport the packet. Theorem 603.19 preserves that prefix componentwise from Q to Q', so the schedule observed by chapter 126 is still the finite schedule carried by the HistTimeStream packet.

Finally apply local clock refusal, Definition 603.26. A global clock or host-indexed time row would have to appear before the StreamName read, but the refusal theorem permits only rows that already factor through the displayed local tuple. Therefore the schedule classifier boundary is stable under componentwise transport. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier streamname schedule classifier boundary`

Theorem 603.30 (HistTimeStream real-completion window nonescape)**.** *Any* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of the finite window induced by an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet factors through the* $\mathsf{HistTimeStream}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows of chapter 603, chapter 126, chapter 301, and chapter 38. The consumer receives only the displayed finite window and no quotient stream, selected host limit, ambient completeness object, host-indexed time, or cross-Hist clock.*

Proof. Begin with the HistTimeStream window. Theorem 603.18 supplies the finite Cont prefix, and Definition 603.28 identifies it as the window handed to the StreamName naming surface.

Next pass through the downstream rows. The StreamName chapter, chapter 126, supplies the countable-name surface; the RegSeqRat chapter, chapter 301, consumes such naming data as regular rational sequence input; and the Real chapter, chapter 38, reads the resulting real-number surface only after those rows have been traversed.

It remains to exclude escape data. The hsame prefix transport theorem, Definition 603.19, keeps the window componentwise local, while local clock refusal, Definition 603.26, blocks quotient streams, selected host limits, ambient completeness witnesses, host-indexed time, and cross-Hist clocks unless they already appear in H, T, S, C, L, P, N. They do not appear there, so the real-completion consumer remains inside the four displayed rows. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier real completion window nonescape`

Theorem 603.31 (HistTimeStream start-ledger totality)**.** *Let $Q = (H, T, S, C, L, P, N)$ be an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet. The local stream starts at* e*, reaches only the displayed source row H through the finite schedule T and start ledger S, and reads no external time index.*

Proof. Start with the carrier definition, Definition 603.1. It exposes H, T, S, C, L, P, N as the whole packet and places the start-at-empty ledger inside S.

Apply Cont prefix exactness, Definition 603.18. The displayed prefix runs from e to the source Hist row H through the finite schedule and replay rows, so no outside time index is available along the route.

Finally use the observer-locality bridge route, Definition 603.16. Downstream observer-history consumers receive the same local stream only after the displayed rows have been read, which preserves start-ledger totality for Q. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier start ledger totality`

Theorem 603.32 (HistTimeStream Cont replay determinacy)**.** *For accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packets $Q = (H, T, S, C, L, P, N)$ and $Q' = (H', T', S', C', L', P', N')$, the schedule row T and replay row C determine the local prefix route up to componentwise* hsame*. Under componentwise* hsame *transport from Q to Q', the replayed prefix remains the displayed route from* e *to the transported source row and cannot branch through a hidden clock row.*

Proof. Begin with Cont prefix exactness. Theorem 603.18 makes the local prefix a route determined by the displayed schedule, start ledger, replay row, locality row, provenance row, and local name.

Next apply hsame prefix transport, Definition 603.19. Componentwise hsame carries the displayed prefix from Q to Q' while preserving the local replay route.

Finally use the observer-locality bridge route. Since downstream observer-history and observer-locality consumers read only the transported local stream, the schedule and replay rows determine the consumer-facing prefix without adding an inter-Hist clock or hidden global time coordinate. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier cont replay determinacy`

Theorem 603.33 (HistTimeStream no-global-clock nonescape)**.** *Every observer-history consumer of an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet may read the displayed local stream H, T, S, C, L, P, N, but it cannot obtain inter-Hist synchronization, ambient clock equality, temporal-rate data, or a host time index from that packet.*

Proof. First expose the local stream through the carrier definition and Cont prefix exactness. These identify the observer-facing data as the finite prefix from e to H with schedule, replay, locality, provenance, and naming rows.

Now transport along componentwise hsame using Definition 603.19. The transported prefix remains local and does not create a host-indexed time coordinate or inter-Hist clock.

Finally apply the observer-locality bridge route, Definition 603.16. The sibling observer-history surfaces consume this packet only as a local stream, so ambient clock equality, temporal-rate data, and global synchronization remain outside the export. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier no global clock nonescape`

Theorem 603.34 (HistTimeStream source observation totality)**.** *Let $Q = (H, T, S, C, L, P, N)$ be an accepted* HistTimeStream$^{\uparrow}$ *packet. Before any observer-history, observer-locality,* StreamName$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*, or* Real$^{\uparrow}$ *consumer reads Q, the packet exposes exactly the source row H, finite schedule T, start ledger S, and replay row C through the displayed* Cont *prefix, with L, P, N recording only componentwise transport, package provenance, and local naming for that same finite observation.*

Proof. Start with the carrier definition, Definition 603.1. It displays H, T, S, C, L, P, N as the whole accepted packet and places the source observation, finite schedule, start ledger, and replay row in explicit coordinates.

Next apply Cont prefix exactness, Definition 603.18. The consumer route is the finite prefix from e to H through T, S, C, L, P, N, so no observer can read a source observation before these rows have been exposed.

Finally use the StreamName finite-window handoff and real-completion window nonescape, Definition 603.28 and Definition 603.30. These route every StreamName, RegSeqRat, and Real read through the same displayed finite window, so the source observation is total for all downstream consumers named in the statement. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier source observation totality`

Theorem 603.35 (HistTimeStream RegSeqRat reindex stability)**.** *For accepted* HistTimeStream$^{\uparrow}$ *packets $Q = (H, T, S, C, L, P, N)$ and $Q' = (H', T', S', C', L', P', N')$, componentwise* hsame *transport from Q to Q' preserves the finite window handed to* StreamName$^{\uparrow}$ *and therefore the regular rational sequence input read by* RegSeqRat$^{\uparrow}$*. The reindexed consumer sees only the transported rows $H', T', S', C', L', P', N'$ and cannot acquire a quotient stream, selected host limit, ambient completeness witness, host-indexed time, or cross-Hist clock.*

Proof. First expose the finite window by Cont prefix exactness and the StreamName handoff, Definition 603.18 and Definition 603.28. They identify the consumer-visible window as the displayed route through H, T, S, C, L, P, N before StreamName naming is read.

Now transport the packet componentwise. The hsame prefix transport theorem, Definition 603.19, carries the same finite route from Q to Q', so the StreamName surface receives the transported finite window rather than a newly chosen index source.

Finally pass to the RegSeqRat consumer. The real-completion window nonescape theorem, Definition 603.30, already routes RegSeqRat reads through HistTimeStream and StreamName; local clock refusal, Definition 603.26, blocks the listed escape data. Hence reindexing by componentwise hsame is stable for the RegSeqRat input. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier regseqrat reindex stability`
↪ variant `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier regseq reindex stability`

Theorem 603.36 (HistTimeStream Real readback ledger)**.** *Any* $\mathsf{Real}^{\uparrow}$ *readback of an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet factors through the HistTimeStream rows* H, T, S, C, L, P, N*, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window handoff, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-sequence consumer, and the* $\mathsf{Real}^{\uparrow}$ *row. The readback ledger cannot add quotient streams, selected host limits, ambient completeness objects, host-indexed time, or cross-Hist clock data.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier real readback ledger`

Proof. Begin with source observation totality, Definition 603.34. Every downstream read has already exposed the source row, finite schedule, start ledger, and replay row inside the displayed packet.

Next use RegSeqRat reindex stability, Definition 603.35. Componentwise hsame transport preserves the finite window handed to StreamName and then to RegSeqRat, so the regular-sequence input seen by a Real consumer remains tied to the HistTimeStream packet.

Finally apply real-completion window nonescape, Definition 603.30. It forces the Real readback through the HistTimeStream, StreamName, RegSeqRat, and Real rows named in the statement and excludes quotient streams, selected host limits, ambient completeness objects, host-indexed time, and cross-Hist clock data from the ledger. □

Theorem 603.37 (HistTimeStream StreamName window totality)**.** *Let* $Q = (H, T, S, C, L, P, N)$ *be an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet. Every* $\mathsf{StreamName}^{\uparrow}$*-facing consumer of* Q *reads exactly the displayed finite window rows* H, T, S, C, L, P, N *through the carrier, the finite* Cont *prefix, and the StreamName finite-window handoff. Such a consumer cannot obtain a quotient stream, host-indexed clock, hidden route, selected host limit, ambient completeness witness, or cross-Hist clock from the packet.*

Proof. Start with the carrier definition, Definition 603.1. It displays Q as precisely the seven rows H, T, S, C, L, P, N, with no coordinate for a quotient stream, hidden route, host-indexed clock, selected limit, or ambient completeness witness.

Next apply the StreamName finite-window handoff, Definition 603.28. It identifies the consumer-visible naming input as the bounded window induced by the displayed Cont prefix before any StreamName consumer reads the stream.

Finally use prefix transport exhaustion, Definition 603.27. Every observer-facing or naming-facing read has already passed through the finite prefix and componentwise hsame transport, and every attempted nonlocal time read is refused unless it preserves the displayed rows. Hence the StreamName-facing window is total and admits no hidden quotient, clock, route, limit, or completeness coordinate. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier streamname window totality`

Theorem 603.38 (HistTimeStream RegSeqRat Real window route)**.** *Let* $Q = (H, T, S, C, L, P, N)$ *be an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *read of the packet factors through* $\mathsf{HistTimeStream}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *in that order. The route reads only the finite window rows displayed by* Q *and cannot select a host limit, ambient completeness coordinate, quotient stream, host-indexed time, or cross-Hist clock.*

Proof. First apply StreamName window totality, Definition 603.37. It fixes the StreamName-facing input as the displayed finite window H, T, S, C, L, P, N and excludes hidden quotient, route, clock, limit, and completeness coordinates at the naming boundary.

Next use RegSeqRat reindex stability, Definition 603.35. The regular rational sequence consumer receives only the transported finite window handed through StreamName, so reindexing cannot choose a host limit or add an ambient completeness coordinate.

Finally apply real-completion window nonescape, Definition 603.30. It places each Real read after the HistTimeStream, StreamName, and RegSeqRat rows and blocks all listed escape data from the Real-facing route. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier regseq real window route`

Theorem 603.39 (HistTimeStream finite-window readback exhaustion)**.** *For an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet* $Q = (H, T, S, C, L, P, N)$*, the local source rows, StreamName window, RegSeqRat reindex stability, and Real readback ledger exhaust the finite-window readback obligations on the Real and Completion path. No further readback obligation remains outside the displayed local source rows, the StreamName window totality surface, the RegSeqRat route, and the Real ledger.*

Proof. Begin with StreamName window totality, Definition 603.37. It turns the local source rows of Q into the whole naming window available to a StreamName-facing consumer.

Next apply the RegSeqRat Real window route, Definition 603.38. This routes every RegSeqRat or Real read through HistTimeStream, StreamName, RegSeqRat, and Real in order, while preserving the finite window and excluding nonlocal escape data.

Finally use the Real readback ledger, Definition 603.36. The ledger records the same source rows, StreamName handoff, RegSeqRat input, and Real readback as the complete path, so the finite-window readback obligations for the Real and Completion path are exhausted by the three named surfaces. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier finite window readback exhaustion`

Theorem 603.40 (HistTimeStream NameCert root-unblock package)**.** *The* $\mathsf{HistTimeStream}^{\uparrow}$ *carrier exposure, finite schedule stability,* Cont*-prefix exactness, local-clock refusal,* $\mathsf{StreamName}^{\uparrow}$ *finite-window handoff,* $\mathsf{RegSeqRat}^{\uparrow}$ *reindex stability, and* $\mathsf{Real}^{\uparrow}$ *readback ledger form the root-unblock package for every downstream finite-window consumer of an accepted packet* $Q = (H, T, S, C, L, P, N)$*. The package exposes only the displayed local rows, componentwise* hsame *transport,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row, and it exports no quotient stream, selected host limit, ambient completeness witness, host-indexed time, or cross-Hist clock.*

Proof. Project the packet through the carrier, Definition 603.1. The rows H, T, S, C, L, P, N are the whole accepted surface, so the root consumer starts from the displayed source row, finite schedule, continuation routes, package row, and local naming row.

Next combine schedule stability, prefix exactness, and local-clock refusal. The stability and prefix theorems, Definition 603.4 and Definition 603.18, make the finite route from e through H, T, S, C, L, P, N the only consumer-visible prefix; Definition 603.26 blocks any host-indexed or cross-Hist clock read.

Finally attach the downstream readback surfaces. The StreamName handoff, RegSeqRat stability, and Real ledger, Definition 603.28, Definition 603.35, and Definition 603.36, consume the same finite window in order. Hence the listed rows are exactly the root-unblock package for finite-window consumers and no excluded host or quotient data is introduced. □

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier namecert root unblock package`

Theorem 603.41 (HistTimeStream local stream-prefix factorization)**.** *Every accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *consumer route factors first through the local prefix*

$$H, T, S, C, L, P, N$$

before any $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *read is available. The prefix is the displayed* Cont *route of the packet, not a hidden stream quotient, host clock, selected limit, or ambient completion coordinate.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier local stream prefix factorization`

Proof. Read the route from the carrier of Definition 603.1. The carrier has no coordinate outside the seven displayed rows, so any accepted consumer must begin by projecting those rows.

Apply Cont prefix exactness, Definition 603.18. It identifies the consumer path as the finite prefix ending in the displayed packet rows before a naming, sequence, or real-facing consumer can read the packet.

Use StreamName window totality and the RegSeqRat Real window route, Definition 603.37 and Definition 603.38. They place StreamName, RegSeqRat, and Real reads strictly after the local prefix and preserve the same rows throughout the downstream route. The absence of extra carrier coordinates gives the stated exclusions. □

Theorem 603.42 (HistTimeStream StreamName Real consumer route)**.** *The ordered downstream route*

$$\mathsf{HistTimeStream}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

preserves the no-global-clock ledger for the packet $Q = (H, T, S, C, L, P, N)$*. Along this route every read is through the local prefix, StreamName finite-window handoff, RegSeqRat reindex surface, and Real readback ledger, and the route excludes quotient streams, selected host limits, ambient completeness witnesses, host-indexed time, and cross-Hist clocks.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier streamname real consumer route`

Proof. First factor the consumer through the local prefix by Definition 603.41. The route has already exposed the finite HistTimeStream rows before any downstream naming or readback surface is used.

Next pass through StreamName and RegSeqRat. StreamName window totality, Definition 603.37, fixes the naming input as the same finite rows, and RegSeqRat reindex stability, Definition 603.35, keeps the regular rational sequence consumer tied to componentwise hsame transport of those rows.

Finally apply local-clock refusal and the Real readback ledger, Definition 603.26 and Definition 603.36. The refusal theorem preserves the no-global-clock ledger, while the Real ledger records the ordered HistTimeStream, StreamName, RegSeqRat, Real route and rules out every listed nonlocal or quotient datum. □

Theorem 603.43 (HistTimeStream StreamName tail scope)**.** *For an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet* $Q = (H, T, S, C, L, P, N)$*, every* $\mathsf{StreamName}^{\uparrow}$ *tail read induced by* Q *factors through the displayed finite rows*

$$H, T, S, C, L, P, N$$

and through the finite-window handoff of Definition 603.28. The tail read may consume only that bounded naming window and cannot add a quotient stream, host index, selected limit, ambient completeness witness, global clock, or cross-Hist time coordinate.

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier streamname tail scope`

Proof. Project Q through the carrier of Definition 603.1. The carrier exposes exactly the rows H, T, S, C, L, P, N, so a tail consumer has no source coordinate beyond the displayed packet.

Apply the local prefix factorization and the StreamName finite-window handoff, Definition 603.41 and Definition 603.28. Together they force every StreamName-facing tail read to pass through the finite Cont route before the naming surface is read.

Finally use real-completion window nonescape, the Real readback ledger, and the StreamName Real consumer route, Definition 603.30, Definition 603.36, and Definition 603.42. These downstream ledgers preserve the same finite rows and exclude quotient, host, limit, completeness, and clock data, so the StreamName tail scope is exactly the stated bounded window. □

Theorem 603.44 (HistTimeStream RegSeqRat window exactness)**.** *For an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet* $Q = (H, T, S, C, L, P, N)$*, every* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer of the induced downstream window receives exactly the local finite window together with the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity obligations already routed through componentwise* hsame *transport. It receives no selected host limit, quotient stream representative, ambient completeness witness, global clock, or Real completeness proof.*

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier regseqrat window exactness`

Proof. Start with the StreamName tail scope of Definition 603.43. It fixes the input to the RegSeqRat-facing consumer as the finite window already exposed by HistTimeStream and StreamName.

Next apply RegSeqRat reindex stability and the RegSeqRat Real window route, Definition 603.35 and Definition 603.38. These theorems identify the sequence-facing obligation as regular rational reindexing over the transported finite rows, not as a choice of a host limit or completion object.

The exclusion clauses follow from real-completion window nonescape, the Real readback ledger, and the StreamName Real consumer route, Definition 603.30, Definition 603.36, and Definition 603.42. Each cited route keeps the RegSeqRat window inside the same local rows and blocks every listed nonlocal datum. □

Theorem 603.45 (HistTimeStream Real readback scope lock)**.** *For an accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet* $Q = (H, T, S, C, L, P, N)$*, every* $\mathsf{Real}^{\uparrow}$ *readback on this consumer route must traverse*

$$\mathsf{HistTimeStream}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The readback may inspect only the certified real surface produced by the carrier, StreamName handoff, RegSeqRat window, and Real readback ledger. It cannot inspect Real completeness, a quotient class, a selected host limit, host-indexed time, global time, or any cross-Hist clock.

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier real readback scope lock`

Proof. First expose the packet through the carrier and local prefix factorization, Definition 603.1 and Definition 603.41. This places every downstream read after the finite HistTimeStream rows.

Then pass through the two intermediate consumers. The StreamName tail scope and RegSeqRat window exactness, Definition 603.43 and Definition 603.44, identify the only naming and rational-sequence surfaces that can be read before RealUp.

Finally apply the Real readback ledger and the StreamName Real consumer route, Definition 603.36 and Definition 603.42. Their route is the displayed HistTimeStream, StreamName, RegSeqRat, Real path, and their exclusions block Real completeness, quotient classes, host limits, host-indexed time, global time, and cross-Hist clocks from the readback scope. □

Theorem 603.46 (HistTimeStream regular witness-ledger route)**.** *Every accepted* $\mathsf{HistTimeStream}^{\uparrow}$ *packet consumed by a regular Cauchy modulus witness route first passes through the local finite window and then through the ordered downstream surface*

$$\mathsf{HistTimeStream}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The route displays the finite HistTimeStream rows, the StreamName tail window, the RegSeqRat regular readback, the regular Cauchy modulus witness ledger, and the RealUp seal rows in that order. It has no host clock, quotient stream, selected limit, ambient completeness coordinate, or cross-Hist time parameter.

Lean4 ✓ `BEDC.Derived.HistTimeStreamUp.HistTimeStreamCarrier regular witness ledger route`

Proof. First expose the accepted packet through the local carrier and finite-prefix route. The carrier and local prefix factorization place every downstream consumer after the displayed HistTimeStream rows.

Apply the StreamName tail scope, Definition 603.43. It fixes the naming input as the finite window already carried by the HistTimeStream packet and excludes host-clock or quotient-stream expansion.

Next apply RegSeqRat window exactness, Definition 603.44. The RegSeqRat consumer receives exactly that finite window together with its regular rational-sequence obligations, not a selected limit or ambient completion datum.

Finally combine the Real readback scope lock with the RegularCauchyModulusWitnessLedger consumer-totality theorem, Definition 603.45 and Definition 977.17. The Real-facing read must pass through the HistTimeStream, StreamName, RegSeqRat, witness-ledger, and Real seal rows, so the witness route remains a finite paper-side consumer route rather than an external completeness or host-clock assertion. □

Closure status for $\mathsf{NameCert}_{\mathsf{HistTimeStream}^{\uparrow}}$**.**

Constructive story: A $\mathsf{HistTimeStream}^{\uparrow}$ packet is generated by a source Hist row, a finite sequence of E1/E0 step rows, a start-at-empty ledger, displayed Cont routes, componentwise hsame transport, no-global-clock locality, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{HistTimeStream}^{\uparrow}}$, maturePackageClosed)

Scope closed: The bridge surface records the carrier, step-ledger exactness, route stability, componentwise hsame transport, no-global-clock locality, package provenance, local NameCert surface, public export, observer-locality consumption bridge, observer-locality bridge route, observer-locality transport theorem, Cont-prefix exactness, hsame prefix transport, and local-clock refusal for one Hist time stream.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{HistTimeStream}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not define inter-Hist synchronization, host-indexed time, temporal rates for analytic moduli, or Lean verification for the packet.

Upgrade path: No further paper-side closure grade remains; Lean verification and bridge checking are tracked only on the verification axis.

Chapter 604

A Concrete Naming Certificate for $\mathsf{TranscendentalSupplyInscription}^{\uparrow}$

The $\mathsf{TranscendentalSupplyInscription}^{\uparrow}$ surface turns the supply position and inscription point of chapter 9393 into a concrete BEDC packet. It records the named supply socket, the local inscription site, the finite GAP boundary at which a forward-binding belief is visible, and the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows that keep the object auditable. The packet names only the structural socket. It does not assert a positive predicate of the supply position, does not internalize induction, and does not add an axiom to the substrate.

The inscription-point row I is consumed from chapter 610 before the supply boundary is read, while this chapter adds the external supply socket and GAP boundary around that local inscription site.

Definition 604.1 (TranscendentalSupplyInscription carrier)**.** *A* $\mathsf{TranscendentalSupplyInscription}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$X = (T, S, I, G, H, C, P, N)$$

with the following displayed rows:

1. *T is the named transcendental supply position of Definition 9393.11, recorded only as an external socket and not as a substrate object;*
2. *S is the closed observational system in which a forward-binding belief is exposed as a BEDC-visible boundary;*
3. *I is the inscription point of Definition 9393.15, namely the local site at which the supply socket is read by S;*
4. *G is the GAP-boundary row that records the unavailable internal discharge of the forward-binding claim;*
5. *H records componentwise* hsame *transports for the supply-position name, closed-system row, inscription-point row, GAP boundary, package provenance, and local naming row;*
6. *C records the displayed* Cont *routes that read S, expose I, open the GAP boundary G, and keep T visible only as the far end of that boundary;*
7. *P is the* Pkg *provenance over* BHist, Gap, hsame, Cont, *and* $\mathsf{NameCert}$ *for the displayed socket;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{TranscendentalSupplyInscription}^{\uparrow}}$ *row.*

The carrier is exactly this finite supply-inscription socket. It has no row for a substrate-level induction rule, no internal witness for the universal claim marked by G, no selected content of T, no host equality test on supply positions, and no ambient completeness principle.

Lean4 (definition) `BEDC.Derived.TranscendentalSupplyInscriptionUp.TranscendentalSupplyInscriptionUp`
Lean4 ✓ `BEDC.Derived.TranscendentalSupplyInscriptionUp.TranscendentalSupplyInscriptionTasteGate`
`single carrier alignment`

Theorem 604.2 (TranscendentalSupplyInscription NameCert obligations)**.** *For the carrier of Definition 604.1, the local* $\mathsf{NameCert}_{\mathsf{TranscendentalSupplyInscription}^{\uparrow}}$ *surface consists of five finite rows:*

1. *carrier exposure: every accepted object exposes the tuple $X = (T, S, I, G, H, C, P, N)$ and no additional supply coordinate;*
2. *classifier transport: comparison transports the supply-position name, closed-system row, inscription-point row, GAP boundary, provenance row, and local naming row by the displayed* hsame *data;*
3. *inscription route: every consumer read of the local inscription point factors through S, then through I, and only then reaches the GAP boundary G;*
4. *package exactness: the provenance row P lists the full BEDC inventory needed for the socket and exposes no internal induction rule, selected supply content, host equality, trichotomy, or completeness datum;*
5. *supply boundary: the row T is readable only as the external position named at the far end of G, never as an object that can be consumed by a substrate derivation.*

Proof. Carrier exposure is projection from Definition 604.1. The supply name T, closed-system row S, inscription point I, GAP boundary G, transports, continuation routes, provenance, and local name are coordinates of one finite BHist packet.

Classifier transport is componentwise. The stored hsame rows in H compare exactly the displayed coordinates, and the Cont rows in C replay the same closed-system, inscription, GAP, provenance, and naming routes after transport.

For the inscription route, a consumer first reads the closed observational system S. The only local site then exposed is I, and the only boundary reached from I is the GAP row G that records the unavailable internal discharge.

Package exactness follows from the inventory of P. Since P names only the displayed BEDC rows, an internal induction rule, selected content of T, host equality test, trichotomy branch, or completeness principle would require an extra coordinate absent from X.

Finally, the supply boundary is the route S to I to G to the external position named by T. The packet therefore makes the socket auditable without turning the far end of the socket into a substrate object. □

Theorem 604.3 (TranscendentalSupplyInscription non-escape boundary)**.** *Every consumer of an accepted* $\mathsf{TranscendentalSupplyInscription}^{\uparrow}$ *packet factors through the finite route*

$$S \to I \to G \to H \to C \to P \to N.$$

The consumer may name T as the external supply position attached to the GAP boundary, but it cannot read T as internal mathematical content, an induction rule, a selected witness, host equality, or ambient completeness.

Proof. Project the accepted carrier $X = (T, S, I, G, H, C, P, N)$. The only closed-system coordinate is S, the only local inscription coordinate is I, and the only exposed unresolved boundary is G.

Apply Definition 604.2. Its inscription route sends every consumer through S and I before G, while its supply boundary permits T only as the named far end of that GAP boundary.

The package exactness row rules out the unavailable structure. Therefore every consumer remains inside the displayed packet and treats the supply position as an external socket endpoint rather than as an internally consumable rule or witness. □

Theorem 604.4 (TranscendentalSupplyInscription classifier transport)**.** *For every accepted* TranscendentalSupplyIn *carrier*

$$X = (T, S, I, G, H, C, P, N),$$

classifier comparison is transported only along the displayed hsame *row H and replayed only through the displayed* Cont *row C. The transport preserves the supply-position name, closed-system row, inscription-point row, GAP boundary, package row, and local* NameCert *row without adding substrate induction, selected supply content, host equality, or ambient completeness.*

Proof. Project the carrier. The compared rows are exactly T, S, I, G, H, C, P, N, and the only componentwise comparison row is H.

Apply the NameCert obligations. Their classifier-transport clause states that the supply-position name, closed-system row, inscription-point row, GAP boundary, provenance row, and local naming row are compared by the displayed hsame data and replayed by the displayed continuation routes.

The excluded objects follow from the carrier boundary. Since X contains no coordinate for substrate induction, selected supply content, host equality, or ambient completeness, classifier transport cannot acquire any of those objects during comparison. □

Theorem 604.5 (TranscendentalSupplyInscription package exactness)**.** *The* Pkg *row P of an accepted* TranscendentalSupplyInscription$^{\uparrow}$ *packet lists exactly the displayed* BHist, Gap, hsame, Cont, Pkg, NameCert, *and inscription-point rows needed to expose the route*

$$S \to I \to G \to T.$$

It does not package an internal induction rule, a selected witness of T, host equality on supply positions, trichotomy, or a completeness principle.

Proof. Read the package coordinate in the carrier definition. The row P names the finite BEDC inventory for the displayed socket and is attached to the same tuple $X = (T, S, I, G, H, C, P, N)$.

Use the package-exactness clause of Definition 604.2. It identifies P with the provenance over the socket rows rather than with an internal proof rule or a selected supply object.

Finally apply non-escape from Definition 604.3. Consumers can reach T only as the external supply position behind the GAP boundary, so the package cannot export host equality, trichotomy, completeness, or a substrate-level induction principle. □

Closure status for NameCert$_{\text{TranscendentalSupplyInscription}^{\uparrow}}$.

Constructive story: A TranscendentalSupplyInscription$^{\uparrow}$ packet is generated from a named supply-position socket, a closed observational system row, a local inscription-point row, a GAP boundary, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.TranscendentalSupplyInscriptionUp.taste gate`

Theory closure: TheoryGate(NameCert$_{\text{TranscendentalSupplyInscription}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 604.1, Definition 604.2, Definition 604.3, Definition 604.4, and Definition 604.5 bind the bridge-facing supply-boundary route through S, I, G, H, C, P, N for the same supply-inscription socket.

Formal verification: FormalStatus(NameCert$_{\text{TranscendentalSupplyInscription}\uparrow}$, axiomClean)
Lean target: `BEDC.Derived.TranscendentalSupplyInscriptionUp.TranscendentalSupplyInscriptionTasteGate\_single\_car`
Bridge status: none
Origin: ai
Not claimed: This chapter does not close mathematical induction, positive predicates of the supply position, selected supply content, host equality of supply positions, ambient completeness, or machine bridge checking.
Upgrade path: The theory axis is complete for the displayed supply-inscription socket; machine bridge checking remains the separate verification-axis route over BHist, Gap, hsame, Cont, Pkg, NameCert, and inscription-point rows.

Chapter 605

A Concrete Naming Certificate for $\mathsf{StationarySealUniqueness}^{\uparrow}$

The $\mathsf{StationarySealUniqueness}^{\uparrow}$ surface isolates the finite seal packet obtained when a stationary rational classifier is transported through the constant $\mathsf{StreamName}^{\uparrow}$ row, the finite $\mathsf{RegSeqRat}^{\uparrow}$ consumption row, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, and the $\mathsf{Real}^{\uparrow}$ finite-window boundary. It is a naming certificate for the four public readings of the same stationary seed, not a host-real equality assertion or a completeness principle.

As a concrete-instance dependency, $\mathsf{StationarySealUniqueness}^{\uparrow}$ is the four-reading finite-window specialization of chapter 701. It consumes the $\mathsf{Rat}^{\uparrow}$ seed classifier, constant $\mathsf{StreamName}^{\uparrow}$ row, stationary $\mathsf{RegSeqRat}^{\uparrow}$ diagonal row, $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, and $\mathsf{Real}^{\uparrow}$ finite-window classifier before exposing the same selected-window seal.

Definition 605.1 (Stationary seal uniqueness carrier)**.** *A* $\mathsf{StationarySealUniqueness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (Q, S, G, D, R, F, H, C, P, N)$$

with the following displayed rows:

1. *Q is the* $\mathsf{Rat}^{\uparrow}$ *stationary seed row, recording two rational history carriers and their transported* $\mathsf{RatHistoryClassifier}$ *row;*
2. *S is the constant* $\mathsf{StreamName}^{\uparrow}$ *row read from Q;*
3. *G is the finite* $\mathsf{RegSeqRat}^{\uparrow}$ *seal-consumption row that reads the same constant stream through a displayed observation window;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger for the finite window;*
5. *R is the* $\mathsf{Real}^{\uparrow}$ *finite-window classifier row obtained from the same stationary constant-stream data;*
6. *F records the selected finite window and the four public projections from U to D, S, G, R;*
7. *H stores componentwise* hsame *transports for the rational seed, stream row, regular-sequence seal row, dyadic ledger, real classifier row, window selector, continuation routes, package provenance, and local name;*
8. *C stores the displayed* Cont *routes from Q to S, from S to G, from S to D, and from D, S, G to the real-facing row R;*

9. *P records* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{StationarySealUniqueness}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient-real equality, selected host limits, non-stationary tails, ambient completeness, or an external comparison relation beyond the displayed four readings.

Theorem 605.2 (Stationary seal uniqueness NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{StationarySealUniqueness}^{\uparrow}}$ *surface for Definition 605.1 consists exactly of carrier admission for* $U = (Q, S, G, D, R, F, H, C, P, N)$*,* $\mathsf{Rat}^{\uparrow}$ *seed exposure, constant* $\mathsf{StreamName}^{\uparrow}$ *readback, finite* $\mathsf{RegSeqRat}^{\uparrow}$ *seal consumption,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation-ledger exposure,* $\mathsf{Real}^{\uparrow}$ *finite-window classifier exposure, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local naming row.*

Proof. Carrier admission is projection from the displayed packet U. The rows Q, S, G, D, R, F supply the rational seed, constant stream, regular-sequence seal consumption, dyadic ledger, real finite-window classifier, and selected window.

The stationary seed obligation is read from Q: it contains the two rational carriers and the RatHistoryClassifier row. The constant $\mathsf{StreamName}^{\uparrow}$ obligation is read from S by replaying the continuation route from Q to the constant stream.

The finite-window obligations are then forced by the packet order. Row G consumes the selected window as a $\mathsf{RegSeqRat}^{\uparrow}$ seal row, D records the dyadic observations read from that same window, and R exposes the real-facing classifier only after D, S, G have already been displayed.

The remaining data are routing and naming data. Rows H, C, P, N preserve the listed coordinates, replay the finite reads, record the dependency packages, and name the stationary seal packet without adding quotient-real equality, host completeness, or an external real comparison. □

Theorem 605.3 (Stationary seal four-row exhaustion)**.** *Let* $U = (Q, S, G, D, R, F, H, C, P, N)$ *be an accepted* $\mathsf{StationarySealUniqueness}^{\uparrow}$ *carrier. Every certified finite observation window exported by U has exactly the four public readings D, S, G, R: the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger, the constant* $\mathsf{StreamName}^{\uparrow}$ *classifier, the finite* $\mathsf{RegSeqRat}^{\uparrow}$ *seal-consumption row, and the* $\mathsf{Real}^{\uparrow}$ *finite-window classifier. These four readings are all transported from the same* $\mathsf{Rat}^{\uparrow}$ *seed row Q, and any two accepted seal packets with the same Q, F, H, C, P, N expose the same four-row public surface.*

Proof. Start from the accepted carrier and project the rows $Q, S, G, D, R, F, H, C, P, N$. The selected window is recorded in F, and the only continuation routes out of the stationary seed are the routes displayed in C.

Read the stream-facing boundary first. The route from Q to S exposes the constant $\mathsf{StreamName}^{\uparrow}$ classifier induced by the rational seed, so every later finite-window read is already tied to the same RatHistoryClassifier row.

Next read the two finite observation rows. The $\mathsf{RegSeqRat}^{\uparrow}$ row G consumes the selected constant-stream window, while the $\mathsf{DyadicRatCore}^{\uparrow}$ row D records the dyadic ledger for that same window. Since both rows are reached through the same selector F and the same continuation routes C, neither can introduce an independent seal coordinate.

Finally read the real-facing row R. The $\mathsf{Real}^{\uparrow}$ finite-window classifier receives only D, S, G together with the transport, provenance, and local name rows H, P, N. Thus the public surface of the seal is exhausted by D, S, G, R, and two carriers agreeing on Q, F, H, C, P, N replay the same four readings. □

Closure status for $\mathsf{NameCert}_{\mathsf{StationarySealUniqueness}^{\uparrow}}$ **.**

Constructive story: A StationarySealUniqueness$^{\uparrow}$ packet is generated from a stationary Rat$^{\uparrow}$ seed classifier, a constant StreamName$^{\uparrow}$ row, a finite RegSeqRat$^{\uparrow}$ seal-consumption row, a DyadicRatCore$^{\uparrow}$ observation ledger, a Real$^{\uparrow}$ finite-window classifier, a selected-window projection row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\mathsf{StationarySealUniqueness}^{\uparrow}}$, seed)

Scope closed: Definition 605.1, Definition 605.2, and Definition 605.3 bind the stationary finite-window carrier, local naming obligations, and four-reading exhaustion surface over Rat$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, and Real$^{\uparrow}$.

Formal verification: FormalStatus(NameCert$_{\mathsf{StationarySealUniqueness}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient-real equality, selected host limits, non-stationary tails, ambient completeness, Lean verification, or a public standard bridge.

Upgrade path: Obligation closure requires checked carrier admission, stationary seed exposure, constant-stream readback, finite seal consumption, dyadic ledger exactness, real finite-window exposure, and four-reading exhaustion for the same displayed packet.

Chapter 606

A Finite Value-Preservation Certificate for $\mathsf{ZeckendorfCarryValue}^{\uparrow}$

The $\mathsf{ZeckendorfCarryValue}^{\uparrow}$ surface packages the Fibonacci value reading of the displayed Zeckendorf carry as a finite $\mathsf{NameCert}$ packet. It keeps the carry classifier separate from history sameness: the packet records the source and target windows, the carry row, the two Fibonacci value rows, the equality-of-value check, and the visible provenance needed by consumers.

The dependency anchors are $\mathsf{ZCarry}^{\uparrow}$, $\mathsf{ZeckendorfNormal}^{\uparrow}$, BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, and the displayed words of Definition 278.2.

Definition 606.1 (Zeckendorf carry-value carrier)**.** *A* $\mathsf{ZeckendorfCarryValue}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$V = (h, k, G, N_h, N_k, F, H, C, P, N)$$

with the following visible rows:

1. $h =$ `word_011` *is the displayed source carry window;*
2. $k =$ `word_100` *is the displayed target carry window;*
3. G *is the local carry row* $\mathsf{ZCarry}(h, k)$ *inherited from* $\mathsf{ZCarry}^{\uparrow}$*;*
4. N_h *records the source normality boundary, namely that* h *is rejected by the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *normal-form classifier;*
5. N_k *records the target normality boundary, namely that* k *is accepted by the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *normal-form classifier;*
6. F *records the finite Fibonacci value calculation for the two displayed windows and the equality of those two values;*
7. H *records the negative history-sameness boundary* $\neg\mathsf{hsame}(h, k)$ *together with the displayed same-side transports allowed for consumers;*
8. C *records the* Cont *routes from the carry row to the value calculation and from the value calculation to the public read;*
9. P *is the* Pkg *provenance over* BHist, $\mathsf{ZCarry}^{\uparrow}$, $\mathsf{ZeckendorfNormal}^{\uparrow}$, hsame, *and the finite Fibonacci value rows;*
10. N *is the local* $\mathsf{NameCert}_{\mathsf{ZeckendorfCarryValue}^{\uparrow}}$ *row.*

The classifier compares accepted packets through the carry row, the two value rows, and the listed provenance. It does not identify h and k by hsame*, install a kernel rewrite, or export a host-level quotient of histories.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryValueUp.ZeckendorfCarryValueTasteGate single carrier alignment`

Theorem 606.2 (Zeckendorf carry-value non-hsame boundary)**.** *For every accepted* $\mathsf{ZeckendorfCarryValue}^{\uparrow}$ *packet* $V = (h, k, G, N_h, N_k, F, H, C, P, N)$*, the value-preservation row and the history-sameness boundary occupy distinct coordinates. The row F states that the displayed Fibonacci value of h equals the displayed Fibonacci value of k, while H records* $\neg\mathsf{hsame}(h, k)$*. Thus value preservation is a finite classifier-facing calculation, not a kernel identification of the two histories.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryValueUp.ZeckendorfCarryValueNonHsameBoundary`

Proof. Project the carry row G and the normality rows N_h, N_k. They fix the displayed source as `word_011` and the displayed target as `word_100` with the same orientation as the $\mathsf{ZCarry}^{\uparrow}$ packet.

Next project the value row F. It reads the finite Fibonacci value calculation for exactly those two displayed words and records equality of the computed values.

Finally project the boundary row H. Since H records the negative hsame fact for the same source and target, the equality in F cannot be read as a history-sameness witness. The public read therefore separates value preservation from kernel history identification. □

Theorem 606.3 (Zeckendorf carry-value NameCert package)**.** *The rows of Definition 606.1 form a finite* $\mathsf{NameCert}_{\mathsf{ZeckendorfCarryValue}^{\uparrow}}$ *package. Its obligations are carrier habitation, carry-generator orientation, source and target normality boundaries, finite Fibonacci value calculation, non-*hsame *separation, continuation routing, package provenance, and the local naming row. Every consumer-visible value-preservation read factors through*

$$h, k, G, N_h, N_k, F, H, C, P, N.$$

No quotient stream, host arithmetic oracle, global normalization procedure, kernel rewrite, or source-target hsame *proof is exported.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryValueUp.ZeckendorfCarryValueCarrier namecert package`

Proof. Carrier habitation is the displayed packet of Definition 606.1. The packet stores the two windows, the carry row, the normality boundary rows, the value calculation, and the provenance rows in a single finite history surface.

The carry-generator orientation is read from G, while N_h and N_k supply the source rejection and target admission rows. These coordinates determine which finite words are sent to the value calculation.

The value-preservation read is then routed through F and C. The row F stores the two displayed Fibonacci value computations and their equality check, and C records that consumers reach the public value row only along the carrier route.

The non-escape clauses are the remaining projections. The row H prevents the value equality from becoming $\mathsf{hsame}(h, k)$, while P and N account for provenance and naming. Since none of the excluded objects is a coordinate of the packet, no consumer can extract it from the package. □

Theorem 606.4 (Zeckendorf carry-value exactness obligation)**.** *For every accepted* $\mathsf{ZeckendorfCarryValue}^{\uparrow}$ *packet*

$$V = (h, k, G, N_h, N_k, F, H, C, P, N),$$

the value-row exactness obligation is exactly the finite Fibonacci value row F over the displayed carry packet `word_011` $\to$ `word_100`*. The row is read only after G, N_h, N_k identify the carry source, target, and normality boundaries, and it is exported only through H, C, P, N. It records equality of the two displayed Fibonacci values without identifying the histories by* hsame*.*

Proof. Project the accepted carrier of Definition 606.1. The rows h, k, G, N_h, N_k fix the source as `word_011`, the target as `word_100`, the displayed carry row, and the two normality boundary rows.

Now read the value coordinate. By Definition 606.3, the row F is the finite Fibonacci calculation attached to exactly those two displayed words, and the public value read factors through $h, k, G, N_h, N_k, F, H, C, P, N$.

Finally apply the non-hsame boundary from Definition 606.2. The value equality in F and the negative history-sameness row in H remain distinct coordinates, so exactness of the value row does not produce $\mathsf{hsame}(h, k)$. □

Theorem 606.5 (Zeckendorf carry-value vision realization)**.** *The finite packet $V = (h, k, G, N_h, N_k, F, H, C, P, N)$ realizes the Fibonacci value-preservation reading of the displayed carry row as a concrete* ZeckendorfCarryValue$^{\uparrow}$ *NameCert surface. It extends the carry classifier by adding the value row F and its consumer route, while preserving the boundary that carry-relatedness and history sameness are different judgments.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryValueUp.ZeckendorfCarryValueCarrier value public read`
Lean4 ✓ `BEDC.Derived.ZeckendorfCarryValueUp.ZeckendorfCarryValueVisionRealization`

Proof. Start from the displayed ZCarry$^{\uparrow}$ carrier. Its source, target, carry row, source rejection, target admission, and non-hsame boundary provide the rows h, k, G, N_h, N_k, H.

Add the finite value row F for the two displayed words and route it through C. This supplies a consumer-facing value-preservation check without changing the carry generator or the normal-form classifier.

Package the resulting rows with P and N. The package exposes value preservation only through the finite NameCert surface, so the existing separation between carry-relatedness and history sameness remains part of the public contract. □

Theorem 606.6 (Zeckendorf carry-value classifier dependency)**.** *Every accepted* ZeckendorfCarryValue$^{\uparrow}$ *packet consumes the carry row, source and target windows, normality boundary rows, and non-*hsame *separation supplied by the carry classifier of chapter 567 before it adds the Fibonacci value row. The value-preservation surface is therefore a finite row over the* ZCarry$^{\uparrow}$ *classifier, not a replacement for that classifier.*

Proof. Project the carrier $V = (h, k, G, N_h, N_k, F, H, C, P, N)$ from Definition 606.1. The rows h, k, G, N_h, N_k, H are the carry-side data: the two displayed windows, the carry row, the source and target normality boundaries, and the public separation from hsame.

Use the local non-hsame boundary and NameCert package, Definition 606.2 and Definition 606.3. They keep the value surface tied to the carry classifier while preventing the finite value equality from becoming a source-target history-sameness proof.

The additional row is F, routed through C and recorded with P and N. Thus the accepted packet first cites the sibling carry classifier of chapter 567 and then appends the finite Fibonacci value-preservation row over that cited carrier. □

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryValueUp.ZeckendorfCarryValueUp classifier dependency rows`

Theorem 606.7 (Zeckendorf carry-value scoped public route)**.** *Every public carry-value read exported by* ZeckendorfCarryValue$^{\uparrow}$ *passes through* ZCarry$^{\uparrow}$, ZeckendorfNormal$^{\uparrow}$, *the displayed source and target word rows, the Fibonacci value row, the non-*hsame *boundary,* Cont *replay,* Pkg *provenance, and local* NameCert *rows. The exported surface is value preservation for the displayed carry packet, not kernel history identification, quotient arithmetic, a global normalizer, or a host-level numerical oracle.*

Proof. Project the carrier of Definition 606.1. The rows h, k, G, N_h, N_k fix the displayed words, the ZCarry$^{\uparrow}$ carry row, and the ZeckendorfNormal$^{\uparrow}$ source and target normality boundaries before the value row is read.

Next apply value-row exactness and the classifier dependency route, Definition 606.4 and Definition 606.6. They keep the Fibonacci equality in F over the carry classifier rather than as a replacement for the classifier.

Finally apply the non-hsame boundary and the NameCert package, Definition 606.2 and Definition 606.3. The rows H, C, P, N export value preservation only through the finite public route, so no kernel history identification, quotient arithmetic, global normalizer, or host-level numerical oracle is introduced. □

Closure status for NameCert$_{\text{ZeckendorfCarryValue}^{\uparrow}}$.

Constructive story: A ZeckendorfCarryValue$^{\uparrow}$ packet records the displayed carry from `word_011` to `word_100`, the finite Fibonacci value equality for those two words, the normality boundary rows, and the non-hsame separation row in one finite BHist certificate.

Theory closure: TheoryGate(NameCert$_{\text{ZeckendorfCarryValue}^{\uparrow}}$, publicClosed)

Scope closed: Definition 606.1, Definition 606.2, Definition 606.3, Definition 606.4, Definition 606.5, Definition 606.6, and Definition 606.7 bind the finite value-preservation public route over ZCarry$^{\uparrow}$, ZeckendorfNormal$^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus(NameCert$_{\text{ZeckendorfCarryValue}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ZeckendorfCarryValueUp.ZeckendorfCarryValueTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a Lean implementation, a bridge certificate, a global Zeckendorf normalizer, uniqueness of numerical interpretation, a kernel rewrite, or source-target hsame.

Upgrade path: Bridged closure requires a bridge theorem connecting the public carry-value packet to the standard Zeckendorf value-preservation interface.

Chapter 607

A Concrete Naming Certificate for $\mathsf{ObservationConservationLedger}^{\uparrow}$

The $\mathsf{ObservationConservationLedger}^{\uparrow}$ interface names the finite monotone ledger packet that realises closed observation inside the BEDC kernel vocabulary. It binds observation states to displayed BHist records, uses hsame to transport old records into later states, routes every allowed read through Cont, records provenance through Pkg, and marks every non-recorded universal demand as a Gap row. The packet is a concrete NameCert carrier for the conservation side of closed observation; it is not an induction principle, not a universal quantifier over all future observations, and not an external oracle for unseen records.

The ledger consumes the observer-history comparison surface of chapter 477: old records are preserved only by transporting the displayed earlier record rows into the later observation state. That preservation row is the dependency edge read by the inscription-event packet of chapter 519, where an accepted inscription can cite the finite record that already survived the ledger transition rather than a host memory store or an unrecorded event.

Definition 607.1 (ObservationConservationLedger carrier)**.** *An* $\mathsf{ObservationConservationLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (O_t, O_{t+1}, R_t, R_{t+1}, A, G, H, C, P, N)$$

with the following visible coordinates:

1. O_t *and* O_{t+1} *are the earlier and later observation-state rows;*
2. R_t *is the finite ledger of records already visible at* O_t*;*
3. R_{t+1} *is the finite ledger visible at* O_{t+1}*;*
4. A *is the admission row saying which finite records are appended between the two states;*
5. G *is the* Gap *row assigned to any universal or future-facing assertion not witnessed by* R_t*,* R_{t+1}*, or* A*;*
6. H *records componentwise* hsame *transport for the earlier observation state, later observation state, old records, appended records, and* Gap *rows;*
7. C *records the visible* Cont *routes by which ledger consumers read old records, appended records, transport rows, and non-escape rows;*

8. *P is the* Pkg *provenance row for the observation-state, record-ledger, admission,* Gap, hsame, *and* Cont *coordinates;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{ObservationConservationLedger}^{\uparrow}}$ *row.*

The carrier exports only the two observation-state rows, the two finite record ledgers, the displayed admission row, the Gap *row, transport, continuation, package, and local naming rows. It contains no route for deleting old records, rewriting old records, manufacturing a universal record, or reading a witness absent from the displayed finite ledgers.*

Lean4 (definition) `BEDC.Derived.ObservationConservationLedgerUp.ObservationConservationLedgerCarrier`

Theorem 607.2 (ObservationConservationLedger NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ObservationConservationL}}$ *surface consists exactly of five finite obligations:*

1. *carrier habitation by the finite packet of Definition 607.1;*

2. *old-record preservation from R_t into R_{t+1} through the displayed admission row A;*

3. *appended-record visibility for every record admitted by A;*

4. *componentwise* hsame *and* Cont *stability for the observation-state rows, record-ledger rows, admission rows, and* Gap *rows;*

5. *provenance and naming closure through P and N, forcing every consumer read to remain inside the displayed finite packet.*

No obligation exports a universal quantifier over future observations, an induction principle, a deletion route for old records, or an oracle for unseen witnesses.

Lean4 ✓ `BEDC.Derived.ObservationConservationLedgerUp.ObservationConservationLedgerCarrier namecert obligations`

Proof. Carrier habitation is exactly Definition 607.1. The two observation states, both record ledgers, the admission row, the Gap row, transport, continuation, package, and naming rows are all displayed coordinates of one finite packet.

Old-record preservation is read by comparing R_t with R_{t+1} through A. The admission row can append finite records, and the transport row H moves the earlier ledger componentwise into the later packet without changing its visible record identities.

Appended-record visibility is supplied by the same admission row. Any newly admitted record must appear in R_{t+1} and must be routed through C, P, and N before a consumer can read it.

The remaining demands are non-escape demands. If a consumer asks for a universal or future-facing assertion not witnessed by the displayed rows, the request is assigned to G rather than accepted as a record, so the local NameCert surface contains exactly the listed finite obligations. □

Theorem 607.3 (ObservationConservationLedger non-escape)**.** *Every consumer of an accepted* $\mathsf{ObservationConservationLedger}^{\uparrow}$ *carrier reads only the displayed rows $O_t, O_{t+1}, R_t, R_{t+1}, A, G, H, C, P, N$. A consumer may recover preserved old records, newly appended finite records, componentwise transports, continuation routes, provenance, and the local naming row. It cannot recover an unrecorded witness, a deletion or alteration of an old record, a universal assertion over all future observations, or an induction principle.*

Lean4 ✓ `BEDC.Derived.ObservationConservationLedgerUp.ObservationConservationLedgerCarrier gap read nonescape`

Proof. Inspect the carrier of Definition 607.1. Its only record coordinates are the finite ledgers R_t and R_{t+1} together with the finite admission row A.

Apply the NameCert obligation surface of Definition 607.2. Old records persist through H, appended records become visible through A, and every legal consumer read is routed through C, P, and N.

It remains to rule out non-displayed reads. A request for a universal or future-facing assertion has no witness coordinate in R_t, R_{t+1}, or A, so it is routed to the Gap row G. Since G is a tag rather than an accepted record, the carrier has no route from closed observation to an unrecorded witness, record deletion, universal closure, or induction. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObservationConservationLedger}^{\uparrow}}$.

Constructive story: An $\mathsf{ObservationConservationLedger}^{\uparrow}$ packet is generated by two observation-state rows, two finite record ledgers, a finite admission row, a Gap non-escape row, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObservationConservationLedger}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: Definition 607.1, Definition 607.2, and Definition 607.3 bind the BHist carrier row, hsame transport, Cont replay, Pkg provenance, Gap non-escape row, and local NameCert obligations for the finite monotone observation ledger packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObservationConservationLedger}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ObservationConservationLedgerUp.ObservationConservationLedgerCarrier\_namecert\_obligat`

Bridge status: none

Origin: human

Not claimed: This chapter does not close induction, universal quantification over future observations, infinite observation streams, or any oracle for records absent from the displayed finite ledgers.

Upgrade path: Bridged closure requires an explicit standard bridge for the monotone finite observation ledger.

Chapter 608

A Concrete Naming Certificate for $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$

The $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$ interface packages the displayed Zeckendorf carry witness as a finite naming certificate. It records the source non-normal row, the target normal row, the Fibonacci-value ledger, the non-hsame boundary, displayed transports, continuation routes, package provenance, and a local naming row. The packet therefore separates normalization-by-carry from history sameness while keeping value preservation as an explicit ledger row.

The source non-normal row and target normal row are read through chapter 278, while the carry witness row is read through chapter 544. The value ledger and non-hsame boundary are therefore sibling-carried rows, not standalone local data.

Definition 608.1 (Zeckendorf carry-normalization carrier)**.** *A* $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (h, k, W, V, H, C, P, N)$$

with the following visible coordinates:

1. *h is the displayed source history row with public carry window* `word_011`*;*
2. *k is the displayed target history row with public carry window* `word_100`*;*
3. *W is the Zeckendorf carry witness row, reading* $\mathsf{ZCarry}(h, k)$ *through the local generator;*
4. *V is the Fibonacci-value ledger row, recording that the value read from h and the value read from k are the same displayed Fibonacci sum;*
5. *H records the non-*hsame *boundary between h and k together with the componentwise* hsame *transports that preserve the source row, target row, carry witness, value ledger, package row, and local naming row;*
6. *C stores the finite* Cont *routes by which consumers read the source non-normal row, target normal row, carry row, value ledger, boundary row, package provenance, and local naming row;*
7. *P is the* Pkg *provenance over* BHist, $\mathsf{ZeckendorfNormal}^{\uparrow}$, $\mathsf{ZCarry}^{\uparrow}$, *Fibonacci-value ledgers,* hsame, Cont, *and local* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ZeckendorfCarryNormalization}^{\uparrow}}$ *row.*

The carrier exports only the displayed carry packet and its finite value ledger. It contains no source-target hsame *proof, no global normalization algorithm, no arithmetic model outside the Fibonacci rows, and no kernel rewrite rule.*

Lean4 (definition) `BEDC.Derived.ZeckendorfCarryNormalizationUp.ZeckendorfCarryNormalizationCarrier`

Theorem 608.2 (Zeckendorf carry-normalization NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ZeckendorfCarryNormalizat}}$ *surface for Definition 608.1 consists of five finite obligations:*

1. *carrier admission for the finite packet* $Z = (h, k, W, V, H, C, P, N)$*;*
2. *source and target normality, stating that* h *is rejected by the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *normal-form classifier and* k *is accepted by it;*
3. *value-ledger exactness, stating that* V *is the unique public Fibonacci-value row exported by the packet;*
4. *carry-is-not-*hsame *preservation, stating that the carry witness* W *does not supply* $\mathsf{hsame}(h, k)$ *and that all displayed transports preserve that boundary;*
5. *local naming, stating that* P *and* N *name exactly the displayed carrier rows and no additional normalization object.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryNormalizationUp.ZeckendorfCarryNormalizationCarrier namecert obligations`

Proof. Carrier admission is projection of the tuple in Definition 608.1. The source row, target row, carry witness, value ledger, boundary-and-transport row, continuation routes, package provenance, and local naming row are all displayed coordinates of one finite BHist packet.

The normality clause reads the source and target sides through C and the normal-form rows named by P. The source window is the non-normal `word_011` row, while the target window is the normal `word_100` row.

The value and boundary clauses are separate projections. The row V records the Fibonacci-value equality of the two displayed sums, while H records that the carry witness is not an $\mathsf{hsame}(h, k)$ proof and transports only the named components.

Finally, the package and local naming rows repack the same finite surface. Since no coordinate names a global normalizer, source-target hsame proof, or kernel rewrite rule, the five obligations exhaust the local NameCert surface. □

Theorem 608.3 (Zeckendorf carry-normalization value ledger)**.** *For an accepted* $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$ *carrier*

$$Z = (h, k, W, V, H, C, P, N),$$

every public claim that the source and target carry rows have the same Fibonacci value factors through the displayed ledger V*. The ledger boundary is exact:* V *may be used to read equality of the two Fibonacci sums, but it cannot be repacked as* $\mathsf{hsame}(h, k)$*, as a kernel rewrite, or as a global normalization procedure.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryNormalizationUp.ZeckendorfCarryNormalizationCarrier value ledger`

Proof. Read the accepted packet through the carrier definition. The only coordinate that mentions Fibonacci value is V, and the continuation routes in C expose that coordinate as a finite ledger row.

The carry witness W supplies the local $\mathsf{ZCarry}(h, k)$ edge, while the row H keeps the non-hsame boundary visible under componentwise transport. Thus a consumer can combine W and V to

read value-preserving carry normalization, but the consumer still lacks a source-target $\mathsf{hsame}(h, k)$ witness.

The package provenance P and local naming row N name exactly this packet. They do not add a global normalizer or a kernel rewrite coordinate, so every public value-preservation read remains inside the displayed ledger boundary. □

Theorem 608.4 (Zeckendorf carry-normalization carry and Nat dependency)**.** *For an accepted* $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$ *packet*

$$Z = (h, k, W, V, H, C, P, N),$$

the value ledger V is readable only after the local carry row certified by chapter 558 and the unary Fibonacci-index discipline of chapter 28 have been consumed. Thus V is a sibling-dependent ledger row, not an isolated kernel-only row.

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryNormalizationUp.ZeckendorfCarryNormalizationCarrier axis nat dependency`

Proof. Project $Z = (h, k, W, V, H, C, P, N)$ from Definition 608.1. The row W is the local carry witness, while V is the row that records equality of the displayed Fibonacci sums.

Read W through the Zeckendorf carry sibling of chapter 558. The source and target windows h, k are indexed as unary Nat positions, so the Fibonacci indexing discipline is read through chapter 28 before the sums named by V are meaningful.

Finally apply Definition 608.3. Since every public value-preservation read factors through V after the carry edge and Nat-index rows have been fixed, V records a sibling-dependent ledger rather than a detached kernel-only certificate. □

Theorem 608.5 (Zeckendorf carry-normalization source-target totality)**.** *For an accepted* ZeckendorfCarryNormaliz *packet*

$$Z = (h, k, W, V, H, C, P, N),$$

the visible source and target normality surface is total for the displayed carry move: the source row h is exposed as the public non-normal `word_011` *row, the target row k is exposed as the public normal* `word_100` *row, and every consumer route that reads the local carry edge W also reads those two source-target normality rows through the same finite packet.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryNormalizationUp.ZeckendorfCarryNormalizationCarrier source target window totality`

Proof. Begin with the carrier definition Definition 608.1. The rows h, k, and W are coordinates of the same finite packet Z, with h displaying the non-normal carry window and k displaying the normal target window.

Apply the NameCert obligation theorem Definition 608.2. Its source and target normality clause makes the two classifier reads part of the admitted certificate surface, while its carrier-admission clause keeps the carry edge W tied to those same rows.

Finally use the value ledger theorem Definition 608.3. Since public value-preservation reads remain inside V and the displayed packet, no consumer can read the carry edge as a detached operation without also seeing the source and target normality rows. □

Theorem 608.6 (Zeckendorf carry-normalization boundary transport)**.** *For an accepted* ZeckendorfCarryNormalizat *packet*

$$Z = (h, k, W, V, H, C, P, N),$$

*the carry-is-not-*hsame *boundary is preserved by the displayed transport rows H and continuation routes C. Transporting the source row, target row, carry witness, Fibonacci-value ledger, provenance row, or local name along those routes never produces an* hsame(h, k) *proof and never turns the carry witness into a kernel rewrite rule.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryNormalizationUp.ZeckendorfCarryNormalizationCarrier boundary transport`

Proof. Project the packet through Definition 608.1. The row H contains the non-hsame boundary together with the componentwise transports, while C records only the finite continuation routes by which consumers read the displayed rows.

The boundary clause of Definition 608.2 states that W does not supply hsame(h, k) and that all displayed transports preserve that boundary. The value ledger theorem Definition 608.3 keeps equality of Fibonacci values confined to V.

Therefore transport through H and C may preserve source, target, carry, value, package, and naming rows, but it cannot create source-target history sameness or a kernel rewrite coordinate. □

Theorem 608.7 (Zeckendorf carry-normalization local naming exhaustion)**.** *For an accepted* ZeckendorfCarryNormalization$^{\uparrow}$ *packet*

$$Z = (h, k, W, V, H, C, P, N),$$

the provenance row P and local NameCert *row N are exhausted by the displayed packet rows h, k, W, V, H, C, P, N. They name the source non-normal row, target normal row, carry witness, Fibonacci-value ledger, non-*hsame *boundary, transport and continuation routes, and no global normalizer, source-target* hsame *proof, ambient arithmetic model, or kernel rewrite rule.*

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryNormalizationUp.ZeckendorfCarryNormalizationCarrier local name window exhaustion`

Proof. Read P and N through the carrier definition Definition 608.1. Both rows are part of the same finite packet as the source, target, carry, value, boundary, transport, and continuation data.

The local naming clause of Definition 608.2 says that P and N name exactly the displayed carrier rows and no additional normalization object. The value ledger theorem Definition 608.3 further confines all public value-preservation reads to V.

Thus the naming surface is exhausted by Z itself. Any consumer of P or N receives the displayed carry-normalization packet and none of the excluded global or kernel-level objects. □

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryNormalizationUp.ZeckendorfCarryNormalizationCarrier local naming exhaustion`

Theorem 608.8 (Zeckendorf carry-normalization bridged export)**.** *The public* ZeckendorfCarryNormalization$^{\uparrow}$ *route exports only the finite Nat/carry rows already displayed by Definition 608.1. A bridge-facing consumer may read the source non-normal row h, target normal row k, carry witness W, value ledger V, boundary row H, continuation row C, provenance row P, and local name N, but it receives no source-target host equality, global normalization theorem, or kernel rewrite rule.*

Proof. Start from the public carrier and local naming exhaustion theorems, Definition 608.1 and Definition 608.7. They expose exactly the rows h, k, W, V, H, C, P, N and state that the local name is exhausted by those rows.

Next use the public route theorems. The NameCert obligations of Definition 608.2 bind carrier admission, source-target normality, the value ledger, the non-hsame boundary, and local naming. The Nat/carry dependency theorem Definition 608.4 keeps the value ledger downstream of the displayed carry row and Nat-index discipline.

Finally apply the value ledger and boundary transport theorems, Definition 608.3 and Definition 608.6. They keep public value preservation inside V and keep transport from creating $\mathsf{hsame}(h, k)$ or a rewrite coordinate. Thus the bridge-facing surface is exactly the finite Nat/carry route already displayed by the chapter. □

Lean4 ✓ `BEDC.Derived.ZeckendorfCarryNormalizationUp.ZeckendorfCarryNormalizationCarrier bridged export`

Theorem 608.9 (Zeckendorf carry-normalization mature package)**.** *The* $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$ *carrier, NameCert obligations, value ledger, Nat/carry dependency route, source-target totality, boundary transport, local naming exhaustion, and bridged export assemble one mature finite Nat/carry package. The package exposes the displayed source row h, target row k, carry witness W, value ledger V, boundary row H, continuation row C, provenance row P, and local name N as the complete public surface. It still exports no source-target* hsame*, global normalization theorem, ambient arithmetic model, or kernel rewrite rule.*

Proof. Start with the carrier and NameCert obligation rows of Definition 608.1 and Definition 608.2. They admit exactly the finite packet $Z = (h, k, W, V, H, C, P, N)$ and bind source-target normality, value exactness, boundary preservation, and local naming to that packet.

Next use the value ledger, Nat/carry dependency, and source-target totality rows. Theorems 608.3, 608.4, and 608.5 keep value preservation downstream of the displayed carry row, Nat indexing discipline, and visible source-target windows.

Finally apply boundary transport, local naming exhaustion, and bridged export. Theorems 608.6, 608.7, and 608.8 preserve the non-hsame boundary and expose only the finite Nat/carry route. Hence the assembled package is mature on the paper theory axis without adding the excluded global or kernel-level objects. □

Closure status for $\mathsf{NameCert}_{\mathsf{ZeckendorfCarryNormalization}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$ packet is generated from a source non-normal row, target normal row, carry witness row, Fibonacci-value ledger row, non-hsame boundary row, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ZeckendorfCarryNormalization}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 608.1, Definition 608.2, Definition 608.3, Definition 608.4, and Definition 608.5 bind the displayed carrier, NameCert obligations, value ledger, and Nat/carry sibling dependency route as the scoped finite carry-normalization surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ZeckendorfCarryNormalization}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close source-target hsame, global normalization, kernel rewrite rules, or a checked Lean certificate.

Upgrade path: No further theory-axis upgrade is claimed; only Lean bridge verification remains outside the paper package.

Chapter 609

A Concrete Naming Certificate for $\mathsf{ObserverCoordinateFrame}^{\uparrow}$

The $\mathsf{ObserverCoordinateFrame}^{\uparrow}$ surface names the local coordinate-frame packet that a conscious observer may use without appealing to a global observer frame. It is a finite consumer of the conscious-observer-state row of chapter 578 and the observer-locality-cell row of chapter 513, then adds $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, and $\mathsf{MaxCausalRate}^{\uparrow}$ rows without forming an ambient chart over all observers.

Definition 609.1 (Observer-coordinate-frame carrier)**.** *An* $\mathsf{ObserverCoordinateFrame}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (S, L, M, C, B, H, R, P, N)$$

with the following displayed rows:

1. *S is an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *row naming the observer-state surface at which the frame is read;*
2. *L is an accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *row naming the locality cell through which nearby observer records are coordinated;*
3. *M is an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *row displaying the finite collection of observer histories available to the frame;*
4. *C is a finite family of* $\mathsf{CrossHistCausal}^{\uparrow}$ *rows over selected pairs in M and the locality-cell anchors in L;*
5. *B is an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *row bounding the displayed cross-Hist causal reads without adding a metric tensor or global clock;*
6. *H is the componentwise* hsame *transport ledger for S, L, M, C, B and for the package and naming rows;*
7. *R is the* Cont *route ledger by which a consumer reads local coordinates through S, L, M, C, B, H;*
8. *P is the* Pkg *provenance over* $\mathsf{ConsciousObserverState}^{\uparrow}$, $\mathsf{ObserverLocalityCell}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverCoordinateFrame}^{\uparrow}}$ *row.*

The classifier compares two carriers only by the displayed rows and their hsame *and* Cont *ledgers. It has no coordinate for a god's-eye observer, a single global chart, a shared external time scalar, a host spacetime manifold, or an observer-independent event object.*

Theorem 609.2 (ObserverCoordinateFrame NameCert obligations)**.** *For the carrier of Definition 609.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverCoordinateFrame}^{\uparrow}}$ *surface consists exactly of five finite obligations: carrier exposure for the rows* $S, L, M, C, B, H, R, P, N$*; observer-state anchoring through* S*; locality-cell and multi-Hist anchoring through* L *and* M*; causal and bound routing through* C *and* B*; and non-escape from global observer frames, shared clocks, host manifolds, metric tensors, observer-independent events, quotients of histories, and unrecorded histories.*

Lean4 ✓ `BEDC.Derived.ObserverCoordinateFrameUp.ObserverCoordinateFrameUp taste gate boundary`

Proof. Carrier exposure is projection from the finite tuple $F = (S, L, M, C, B, H, R, P, N)$.

Observer-state anchoring is read from S. Locality-cell and multi-Hist anchoring are read from L and M, so every frame coordinate begins inside the displayed observer state and its listed local comparison surface.

The causal and bound obligations are then read from C and B. The family C supplies only selected $\mathsf{CrossHistCausal}^{\uparrow}$ rows over the visible configuration, while B supplies the finite $\mathsf{MaxCausalRate}^{\uparrow}$ bound row for those reads.

Finally inspect the remaining coordinates. The transport ledger H, route ledger R, package row P, and local name row N can replay only the displayed finite rows, so no global frame, shared clock, host manifold, metric tensor, observer-independent event, quotient, or hidden history is exported. □

Theorem 609.3 (ObserverCoordinateFrame locality soundness)**.** *Every accepted* $\mathsf{ObserverCoordinateFrame}^{\uparrow}$ *packet is local to the conscious observer state* S*, the locality cell* L*, and the finite multi-Hist configuration* M*. A consumer may read selected cross-Hist causal rows and their maximum-rate bound through* C *and* B*, transported by* H *and routed by* R*, but the consumer cannot read a coordinate outside the displayed locality-cell and multi-Hist rows.*

Proof. Project the accepted packet as $F = (S, L, M, C, B, H, R, P, N)$. The observer-state row S fixes the state at which the frame is read, while L and M fix the locality-cell and multi-Hist surfaces available at that state.

The selected causal reads in C are anchored in those rows. The bound row B is a finite $\mathsf{MaxCausalRate}^{\uparrow}$ consumer of the same cross-Hist surface, not a metric or global-chart object.

Transport and continuation replay through H and R preserve the same finite rows. Since no coordinate outside $S, L, M, C, B, H, R, P, N$ is exposed, every accepted frame remains locality-cell sound. □

Theorem 609.4 (ObserverCoordinateFrame non-global-frame boundary)**.** *An accepted* $\mathsf{ObserverCoordinateFrame}^{\uparrow}$ *carrier exports only conscious-observer-state, observer-locality-cell, multi-Hist configuration, cross-Hist causal, maximum-bound,* hsame *transport,* Cont *route, package, and local* NameCert *rows. It exports no god's-eye observer, no global coordinate frame, no shared external time scalar, no host spacetime manifold, no metric tensor, no observer-independent event object, no quotient of histories, and no unrecorded remote history.*

Proof. Use the carrier inventory of Definition 609.1. Every public read of the frame is one of the rows $S, L, M, C, B, H, R, P, N$.

The positive frame data is therefore local: S supplies the present conscious-observer state, L supplies the locality cell, M supplies the finite history configuration, C supplies selected cross-Hist causal rows, and B supplies the finite bound row.

The remaining rows H, R, P, N transport, route, package, and name those same coordinates. None of them contains a god's-eye observer, global chart, shared time scalar, manifold, metric,

observer-independent event, quotient, or hidden remote history, so none of those objects can be projected from the packet. □

Falsifiable prediction: An accepted ObserverCoordinateFrameUp packet cannot export a global observer frame, shared external time scalar, host spacetime manifold, metric tensor, observer-independent event object, quotient of histories, or unrecorded remote history while preserving the displayed local-frame carrier rows.

Independence witness: consciousobserverstate, observerlocalitycell, multihistconfig, crosshistcausal, maxcausalrate: no sibling is bijective to $\mathsf{ObserverCoordinateFrame}^{\uparrow}$ because this carrier simultaneously stores observer-state, locality-cell, multi-Hist configuration, selected cross-Hist causal rows, a maximum causal-rate bound, transport, route, provenance, and local naming rows; each sibling supplies only one face of that local-frame packet.

The Lean TasteGate namespace is the natural home for the `Nontrivial` and `FieldFaithful` instances for this displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverCoordinateFrame}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverCoordinateFrame}^{\uparrow}$ packet is generated from a conscious-observer-state row, an observer-locality-cell row, a multi-Hist configuration row, selected cross-Hist causal rows, a maximum-causal-bound row, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverCoordinateFrame}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 609.1, Definition 609.2, Definition 609.3, Definition 609.4, and the checked TasteGate boundary bind the finite local-frame scope over $\mathsf{ConsciousObserverState}^{\uparrow}$, $\mathsf{ObserverLocalityCell}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverCoordinateFrame}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ObserverCoordinateFrameUp.ObserverCoordinateFrameUp\_taste\_gate\_boundary`
Lean4 ✓ `BEDC.Derived.ObserverCoordinateFrameUp.taste gate`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close bridge status, god's-eye observer, global coordinate frame, shared external time scalar, host spacetime manifold, metric tensor, observer-independent event object, quotient of histories, or unrecorded remote-history read.

Upgrade path: The paper theory axis is mature over the displayed local-frame rows; machine bridge checking remains the formal-axis route beyond the existing audit-clean TasteGate boundary.

Chapter 610

A Concrete Naming Certificate for $\mathsf{InscriptionPoint}^{\uparrow}$

The $\mathsf{InscriptionPoint}^{\uparrow}$ surface realizes the local carrier promised by Definition 9393.15. It packages an individual inscription site as finite BEDC data: one accepted history, one visible gap socket, one supply-socket ledger row, one inscription-event row, transport and continuation routes, package provenance, and a local naming row. The packet does not treat the supply as a substrate-internal rule; it records only the finite site at which the supply is ledgered for downstream consumers.

The inscription point consumes the supply ledger of chapter 528, the induction-socket handoff of chapter 498, and the event row of chapter 519 before packaging the local site. These dependencies are the concrete rows named by S, T, I, not external supply, induction, or event principles.

Definition 610.1 (InscriptionPoint carrier)**.** *An* $\mathsf{InscriptionPoint}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$J = (H, G, S, T, I, L, R, C, P, N)$$

with the following displayed rows:

1. *H is the accepted* BHist *row naming the local observational history;*
2. *G is the* Gap *row governed by* $\mathsf{FiniteTraceGapSocket}^{\uparrow}$*, recording the finite trace boundary at which no substrate-internal supply rule is provided;*
3. *S is the* $\mathsf{SupplySocketLedger}^{\uparrow}$ *row classifying the requested supply as an inscription-novelty socket rather than as a hidden derivation rule;*
4. *T is the* $\mathsf{TranscendentalInductionSocket}^{\uparrow}$ *handoff row, naming the forward-binding induction socket that the local history may consume without internalizing its far end;*
5. *I is the* $\mathsf{InscriptionEvent}^{\uparrow}$ *row that records the public event by which the site becomes readable as an accepted local inscription;*
6. *L is the local ledger row tying H, G, S, T, I to the same inscription point;*
7. *R records componentwise* hsame *comparisons for H, G, S, T, I, L, package provenance, and the local naming row;*
8. *C records the displayed* Cont *routes by which consumers may read the history, gap socket, supply ledger, induction handoff, inscription event, and ledger row;*
9. *P is the* Pkg *row naming* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, $\mathsf{FiniteTraceGapSocket}^{\uparrow}$, $\mathsf{TranscendentalInductionSoc}$ $\mathsf{SupplySocketLedger}^{\uparrow}$*, and* $\mathsf{InscriptionEvent}^{\uparrow}$*;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{InscriptionPoint}^{\uparrow}}$ *row.*

The classifier for accepted carriers compares only these displayed rows and their transported continuations. It contains no positive predicate for the far end of the supply, no universal induction rule, no private subject predicate, and no hidden source selector.

Lean4 (definition) `BEDC.Derived.InscriptionPointUp.InscriptionPointUp`
Lean4 ✓ `BEDC.Derived.InscriptionPointUp.InscriptionPointTasteGate single carrier alignment`

Theorem 610.2 (InscriptionPoint NameCert obligations)**.** *For the carrier of Definition 610.1, the local* $\mathsf{NameCert}_{\mathsf{InscriptionPoint}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission: every accepted inscription point exposes exactly $J = (H, G, S, T, I, L, R, C, P, N)$;*
2. *history locality: every consumer read begins at the displayed* BHist *row H;*
3. *gap and supply exactness: G is the finite trace socket, S is the supply-socket ledger, and T is the transcendental-induction handoff row consumed at that socket;*
4. *event and transport stability: the inscription event I, local ledger L, componentwise* hsame *row R, and* Cont *routes C preserve the same finite packet for downstream reads;*
5. *non-escape: the packet exports no substrate-internal supply rule, private subject primitive, hidden source selector, or positive predicate about the far end of the supply.*

Proof. Carrier admission is projection from the displayed tuple in Definition 610.1. The accepted history, gap socket, supply ledger, handoff row, inscription event, local ledger, transport row, continuation routes, package provenance, and local naming row are all finite coordinates.

History locality reads the first coordinate H. Every downstream route in C begins from the displayed history row and then reaches the gap, ledger, handoff, event, and naming rows through the same packet.

Gap and supply exactness are recorded by G, S, T. The finite trace gap is classified before the supply ledger is consumed, and the transcendental-induction handoff is named as a handoff rather than as an internal derivation principle.

Event and transport stability use I, L, R, C. The inscription event makes the local site publicly readable, the ledger ties the rows to the same point, and the hsame and Cont rows replay the same finite packet after transport.

The non-escape clause is the inventory boundary. Since J has no coordinate for a closed supply rule, private subject primitive, hidden source selector, or positive far-end predicate, no local $\mathsf{NameCert}_{\mathsf{InscriptionPoint}^{\uparrow}}$ projection can export one. □

Theorem 610.3 (InscriptionPoint gap handoff)**.** *For an accepted* $\mathsf{InscriptionPoint}^{\uparrow}$ *carrier $J = (H, G, S, T, I, L, R, C, P, N)$, every consumer read of the local inscription point factors through the finite trace gap row G, the supply-socket ledger row S, the transcendental-induction handoff row T, and the inscription-event row I before it reaches the local* NameCert *row N.*

Proof. Start with the carrier coordinates of Definition 610.1. The rows G, S, T, I, N are displayed in the same finite BHist packet, and C records the permitted routes among them.

Apply the gap and supply exactness clause of Definition 610.2. It fixes G as the finite trace socket, S as the supply-socket ledger, and T as the forward-binding handoff row attached to that socket.

Apply the event and transport stability clause. The inscription event I and ledger L keep the local point readable through the same hsame and Cont routes, so the NameCert row cannot be consumed through a route that bypasses the gap and handoff rows. □

Theorem 610.4 (InscriptionPoint non-escape)**.** *No consumer of an accepted* $\mathsf{InscriptionPoint}^{\uparrow}$ *packet can extract a substrate-internal rule for the supply, a private subject primitive, a hidden source selector, a global observer frame, or a positive predicate about the far end of the transcendental supply. Every consumer read factors through*

$$H, G, S, T, I, L, R, C, P, N.$$

Proof. Inspect the carrier inventory in Definition 610.1. The exported rows are exactly the local history, finite trace gap, supply ledger, handoff row, inscription event, ledger, transport row, continuation routes, package provenance, and naming row.

Definition 610.2 supplies the non-escape clause for these rows. The classifier may compare the displayed packet and its transports, but it has no coordinate that evaluates the supply as a rule inside the substrate.

Definition 610.3 fixes the route shape for downstream reads. Since every read passes through the finite gap, ledger, handoff, and event rows before the local name is consumed, there is no projection target for a private subject primitive, hidden selector, global observer frame, or positive far-end predicate. □

Theorem 610.5 (InscriptionPoint socket surface through the canonical carrier)**.** *Every supply-socket read of an accepted* $\mathsf{InscriptionPoint}^{\uparrow}$ *carrier factors through the canonical rows*

$$H, G, S, T, I, L, R, C, P, N.$$

The socket and Gap *portion is supplied by* G, S, T*, the public event portion by* I, L*, and transport and provenance by* R, C, P, N*. The canonical carrier already absorbs the* O, S, A, G, H, C, P, N *socket surface: it exports no internally supplied theorem, hidden receiver, private source predicate, selected witness, quotient equality, or completed supply principle.*

Proof. Definition 610.1 fixes the accepted carrier as the displayed tuple $J = (H, G, S, T, I, L, R, C, P, N)$. Its socket-facing rows are not external receivers; they are the finite trace gap, supply-socket ledger, and transcendental-induction handoff rows named by G, S, T.

Definition 610.2 gives the NameCert inventory. Gap and supply exactness identify G, S, T as the only socket and handoff portion, while event and transport stability identify I, L, R, C as the public event and replay surface for the same packet.

Definition 610.3 forces every consumer read through G, S, T, I before the local $\mathsf{NameCert}$ row is consumed. Definition 610.4 supplies the boundary: the carrier has no coordinate for an internally supplied theorem, hidden receiver, private source predicate, selected witness, quotient equality, or completed supply principle.

Thus any read formerly expressible as O, S, A, G, H, C, P, N is read inside the canonical rows. Observation, socket, actuality, gap, transport, continuation, provenance, and naming are accounted for by $H, G, S, T, I, L, R, C, P, N$, with no additional exported theorem or hidden supply surface. □

Theorem 610.6 (InscriptionPoint bridge-facing preservation)**.** *The standard bridge-facing read of an accepted* $\mathsf{InscriptionPoint}^{\uparrow}$ *carrier preserves exactly*

$$H, G, S, T, I, L, R, C, P, N$$

through the existing finite gap, supply-ledger, induction-handoff, and inscription-event rows. The bridge-facing surface has no additional coordinate beyond the carrier of Definition 610.1, the NameCert obligations of Definition 610.2, the gap handoff of Definition 610.3, the non-escape boundary of Definition 610.4, and the canonical-carrier socket surface of Definition 610.5.

Proof. The carrier definition fixes $H, G, S, T, I, L, R, C, P, N$ as the only displayed rows. The finite gap, supply ledger, induction handoff, and inscription event are not reconstructed by a bridge read; they are the existing coordinates G, S, T, I.

The NameCert obligations preserve the same tuple under classifier, exactness, transport, continuation, provenance, and local naming reads. Gap handoff then forces every consumer route through G, S, T, I before the local NameCert row is consumed.

The non-escape and canonical-carrier socket theorems remove the remaining alternatives. Since the packet has no hidden supply rule, far-end predicate, private subject primitive, selected witness, quotient equality, or completed supply coordinate, a bridge-facing read can only preserve the displayed rows already present in $H, G, S, T, I, L, R, C, P, N$. □

Closure status for $\mathsf{NameCert}_{\mathsf{InscriptionPoint}^{\uparrow}}$.

Constructive story: An $\mathsf{InscriptionPoint}^{\uparrow}$ packet is generated from one accepted BHist row, a finite trace gap socket, a supply-socket ledger row, a transcendental-induction handoff row, an inscription-event row, a local ledger, componentwise hsame transport, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{InscriptionPoint}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 610.1, Definition 610.2, Definition 610.3, Definition 610.4, and Definition 610.5 bind the finite inscription-point carrier, classifier, gap handoff, non-escape surface, finite packet boundary, and public export surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{InscriptionPoint}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.InscriptionPointUp.InscriptionPointTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: ai

Lean4 ✓ `BEDC.Derived.InscriptionPointUp.taste gate`

Not claimed: This chapter does not close bridge checking, a substrate-internal supply rule, private subject primitive, hidden source selector, global observer frame, positive far-end predicate, or standard bridge for $\mathsf{InscriptionPoint}^{\uparrow}$.

Upgrade path: No further paper-axis closure grade remains; only bridge checking remains on the formal and bridge axes.

Chapter 611

A Concrete Naming Certificate for $\mathsf{RealObservationBudget}^{\uparrow}$

The $\mathsf{RealObservationBudget}^{\uparrow}$ interface records the finite observation packet that a completion-facing consumer may inspect before a $\mathsf{Real}^{\uparrow}$ seal is reached. It keeps the precision request, stream windows, dyadic readbacks and radii, regular-sequence handoff rows, real-seal rows, transports, routes, provenance, and local naming row inside one BHist surface. It does not export quotient stream equality, host real equality, ambient completeness, hidden limit selection, or an unbounded observation schedule.

This budget packet is a consumer of chapter 126, chapter 291, chapter 301, and chapter 38. Its substantive dependency path is finite window selection, dyadic readback and radius rows, regular-sequence handoff, and the real-seal boundary.

Whenever a completion-facing $\mathsf{Real}^{\uparrow}$ consumer asks for a synchronized diagonal read, this finite observation route also consumes the diagonal selector surface of chapter 853. The $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ sibling supplies the finite precision, mesh, and comparison budget that $\mathsf{RealObservationBudget}^{\uparrow}$ repackages as observation windows, dyadic readbacks, $\mathsf{RegSeqRat}^{\uparrow}$ handoff rows, and $\mathsf{Real}^{\uparrow}$ seal rows.

Definition 611.1 (Real observation budget carrier)**.** *A* $\mathsf{RealObservationBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (E, W, D, R, S, H, C, P, N)$$

with the following displayed coordinates:

1. *E is the unary precision request row naming the finite tolerance level visible to the consumer;*
2. *W is the finite family of* $\mathsf{StreamName}^{\uparrow}$ *window rows selected for that request;*
3. *D records the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readbacks together with the displayed dyadic radii attached to the windows in W;*
4. *R stores the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows that expose the regular rational sources feeding the observation budget;*
5. *S stores the* $\mathsf{Real}^{\uparrow}$ *seal rows that mark the boundary at which completion-facing consumers receive the finite packet;*
6. *H stores componentwise* hsame *transports for the precision request, windows, dyadic readbacks and radii, regular-sequence rows, seal rows, provenance, and local name;*

7. *C stores the displayed* Cont *routes from E to W, from W to D, from D to R, and from R to S;*
8. *P records* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RealObservationBudget}^{\uparrow}}$ *row.*

The carrier is finite. It has no coordinate for quotient stream equality, host real equality, ambient completeness, hidden limit selection, or an unbounded observation schedule.

Theorem 611.2 (Real observation budget NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RealObservationBudget}^{\uparrow}}$ *surface for Definition 611.1 consists exactly of carrier admission, unary precision exposure, finite* $\mathsf{StreamName}^{\uparrow}$ *window coverage,* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback and radius exposure,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff routing,* $\mathsf{Real}^{\uparrow}$ *seal-boundary exposure, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and the local naming row.*

Proof. Carrier admission is projection from the displayed packet B. The rows E, W, D, R, S provide the precision request, finite windows, dyadic readbacks and radii, regular-sequence handoffs, and real-seal boundary.

The window and dyadic obligations are read directly from W and D. The regular-sequence handoff rows in R expose only the rational-source data already routed through those finite observations.

The remaining obligations are the transport, route, provenance, and naming rows H, C, P, N. Since the carrier has no coordinate for quotient stream equality, host real equality, ambient completeness, hidden limit selection, or an unbounded schedule, the listed rows exhaust the local naming certificate. □

Theorem 611.3 (Real observation budget window coverage)**.** *For an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *carrier, every dyadic readback and displayed radius exported by D is covered by one of the finite* $\mathsf{StreamName}^{\uparrow}$ *windows in W, and every such window is selected by the unary precision request row E through the displayed routes in C.*

Lean4 ✓ `BEDC.Derived.RealObservationBudgetUp.RealObservationBudgetWindowCoverage`

Proof. Project the accepted packet B and read the precision row E, window family W, dyadic ledger D, transports H, and continuation routes C.

The route from E to W selects the finite windows visible to the budget. The route from W to D is the only displayed path by which a dyadic readback or radius enters the packet.

Transport rows in H preserve the same precision, window, readback, and radius coordinates when the packet is repacked for a consumer. Therefore every exported dyadic observation is covered by W and no observation can be imported from an unbounded stream schedule. □

Theorem 611.4 (Real observation budget regular-sequence handoff)**.** *For an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *carrier, each* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row in R is reached only after the unary precision request, finite stream windows, and dyadic readbacks and radii have been read. A downstream* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer receives the handoff through the finite route*

$$E, W, D, H, C, P, N.$$

Proof. Begin with the carrier projection. The displayed order of the observation route places R after the precision request, stream windows, and dyadic ledger.

Use window coverage to bind every dyadic readback and radius to the finite windows selected from E. The continuation route from D to R then supplies the only path from the observation budget to the regular rational source rows.

The transport and provenance rows repack the same route for consumers. No handoff row can bypass E, W, D, H, C, P, N or appeal to quotient stream equality, hidden limit choice, or host real comparison. □

Theorem 611.5 (Real observation budget seal boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *completion-facing consumer of an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *carrier factors through the seal rows* S*. The seal rows may read only the precision request* E*, finite windows* W*, dyadic readbacks and radii* D*, regular-sequence handoffs* R*, transports* H*, routes* C*, provenance* P*, and local naming row* N *supplied by the packet.*

Proof. Project the accepted packet and inspect the consumer-facing coordinates. The carrier contains a single real-facing boundary coordinate, namely the seal family S.

Apply the regular-sequence handoff theorem to force any route into S through E, W, D, R, H, C, P, N. The seal rows therefore receive only the finite observations, their radii, the regular rational handoffs, and the bookkeeping rows displayed by the packet.

Since S is reached after those rows and no other real-facing coordinate exists, a completion consumer cannot read a selected completed real, a host equality test, an ambient completeness principle, or a hidden infinite schedule from the budget. □

Theorem 611.6 (Real observation budget non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *carrier factors through the finite rows*

$$E, W, D, R, S, H, C, P, N.$$

The consumer may inspect exactly the unary precision request, finite $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *readbacks and radii,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows,* $\mathsf{Real}^{\uparrow}$ *seal rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row. It cannot inspect quotient stream equality, host real equality, ambient completeness, hidden limit selection, or an unbounded observation schedule.*

Lean4 ✓ `BEDC.Derived.RealObservationBudgetUp.RealObservationBudgetUp nonescape`

Proof. Start from the finite carrier of Definition 611.1. The displayed rows of B are exactly $E, W, D, R, S, H, C, P, N$.

Apply the local NameCert obligations to identify those rows as the complete naming surface. Window coverage binds the dyadic readbacks and radii to the finite windows selected by the precision request.

The regular-sequence handoff theorem routes source-facing access through the same finite observations. The seal-boundary theorem then routes every completion-facing consumer through S without exposing any unlisted analytic object.

Thus the observation budget is a finite BEDC packet. Its consumers can use the displayed rows, but the carrier gives them no route to quotient streams, host real equality, ambient completeness, hidden limit selection, or unbounded observation schedules. □

Theorem 611.7 (Real observation budget obligation package)**.** *The* $\mathsf{RealObservationBudget}^{\uparrow}$ *obligation package is the finite surface*

$$B = (E, W, D, R, S, H, C, P, N)$$

over BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. It packages carrier admission, unary precision exposure, finite window coverage, dyadic readback and radius exposure,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff routing,* $\mathsf{Real}^{\uparrow}$ *seal-boundary exposure, componentwise transport, displayed route replay, provenance, and the local naming row, with no quotient stream equality, host real equality, ambient completeness, hidden limit selection, or unbounded observation schedule.*

Proof. Start from the carrier and the local NameCert obligation theorem. Definition 611.1 supplies exactly $E, W, D, R, S, H, C, P, N$, and Definition 611.2 reads those rows as the local naming surface.

The window, dyadic, regular-rational, and real-facing clauses are already separated by the existing obligation rows. Definition 611.3 binds D to the finite windows W, Definition 611.4 routes R through the finite observation route, and Definition 611.5 marks S as the completion-facing boundary.

Finally apply non-escape. Definition 611.6 rules out every unlisted analytic object, so the obligation package is exhausted by the finite BEDC surface displayed above. □

Theorem 611.8 (Real observation budget transport stability)**.** *Classifier transport for the* $\mathsf{RealObservationBudget}^{\uparrow}$ *obligation package preserves the same precision request, finite window family, dyadic readbacks and radii, regular-sequence handoff rows, real-seal boundary rows, provenance, and local name. Thus any transported package remains a finite observation-budget surface over the same* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Project the two classified budget packets to their displayed coordinates. The transport ledger H is componentwise: it transports the precision request, window rows, dyadic ledger, handoff rows, seal rows, provenance, and local name without changing the shape of the packet.

Use the displayed routes C to replay the observation order after transport. The route from E to W, from W to D, from D to R, and from R to S is part of the same finite package, so transported consumers still read the same obligation surface.

The non-escape theorem excludes hidden replacement data during transport. No transported package can insert quotient stream equality, host real equality, ambient completeness, hidden limit selection, or an unbounded schedule because none of those rows exists in the source package. □

Theorem 611.9 (Real observation budget consumer exactness)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of a* $\mathsf{RealObservationBudget}^{\uparrow}$ *obligation package reads exactly the finite packet rows required by the observation budget:* $E, W, D, R, S, H, C, P, N$*. The* $\mathsf{RegSeqRat}^{\uparrow}$ *side factors through the handoff rows* R*, the* $\mathsf{Real}^{\uparrow}$ *side factors through the seal rows* S*, and both sides remain inside the obligation package of Definition 611.7.*

Proof. First read the source-facing route. Definition 611.4 forces every regular-sequence handoff through the precision request, finite windows, dyadic readbacks and radii, transports, routes, provenance, and local naming row.

Next read the completion-facing route. Definition 611.5 sends every $\mathsf{Real}^{\uparrow}$ consumer through the seal rows S, and those seal rows are reached only after E, W, D, R, H, C, P, N have been displayed.

Combine these routes with transport stability and non-escape. The transported package keeps the same finite rows, and Definition 611.6 blocks any consumer from reading quotient stream equality, host real equality, ambient completeness, hidden limit selection, or an unbounded observation schedule outside the package. □

Theorem 611.10 (Real observation budget prefix pullback determinacy)**.** *Let* $B = (E, W, D, R, S, H, C, P, N)$ *be an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet. Any* $\mathsf{Real}^{\uparrow}$*- or* $\mathsf{CauchyLimitSeal}^{\uparrow}$*-facing prefix pullback that reads the same unary precision row* E *and the same finite* $\mathsf{StreamName}^{\uparrow}$ *window family*

W determines the same dyadic readback ledger D, the same $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows R, the same* $\mathsf{Real}^{\uparrow}$ *seal rows S, and the same consumer route through H, C, P, N. Thus prefix pullbacks through the displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *surfaces cannot split into different finite consumer routes once E and W have been fixed.*

Proof. Project the accepted packet to the carrier of Definition 611.1. The prefix pullback is therefore read against the displayed rows $E, W, D, R, S, H, C, P, N$, with no extra analytic coordinate available to the consumer.

Use window coverage first. Definition 611.3 binds every dyadic readback and displayed radius in D to the finite windows W selected by E, so two pullbacks with the same E and W must read the same dyadic ledger.

Next pass through the downstream rows. Definition 611.4 binds the $\mathsf{RegSeqRat}^{\uparrow}$ handoff R to D, and Definition 611.5 binds the $\mathsf{Real}^{\uparrow}$ seal S to that handoff boundary.

Finally apply consumer exactness and non-escape. Definition 611.9 forces the route through H, C, P, N, while Definition 611.6 rules out quotient stream equality, host real equality, hidden limit selection, and unbounded schedules as alternate sources of a different route. □

Theorem 611.11 (Real observation budget StreamName–RegSeq–Real exit)**.** *Every completion-facing consumer of an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet reaches the* $\mathsf{Real}^{\uparrow}$ *seal only through the finite chain consisting of the* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *readbacks and radii,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows, and displayed seal rows. Along this route the consumer receives the packet coordinates $E, W, D, R, S, H, C, P, N$ and introduces no quotient stream equality, host real equality, hidden limit selector, or unbounded observation schedule.*

Proof. Start with the finite packet of Definition 611.1. The $\mathsf{StreamName}^{\uparrow}$ dependency is the selected window family W, and Definition 611.3 binds every $\mathsf{DyadicRatCore}^{\uparrow}$ readback and displayed radius in D to one of those finite windows selected by the precision row E.

Next pass through the rational handoff. Definition 611.4 sends every $\mathsf{RegSeqRat}^{\uparrow}$ consumer row through the already displayed E, W, D route together with the transport, continuation, provenance, and local naming rows H, C, P, N.

Now read the completion boundary. Definition 611.5 makes the seal rows S the only $\mathsf{Real}^{\uparrow}$ boundary reachable by a completion-facing consumer, and those rows may read only the finite observation and handoff surface already exposed by $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{RegSeqRat}^{\uparrow}$.

Finally apply non-escape. Definition 611.6 exhausts the downstream consumer surface by $E, W, D, R, S, H, C, P, N$, so the exit route cannot import quotient stream equality, host real equality, hidden limit selection, or an unbounded observation schedule from outside the displayed packet. □

Theorem 611.12 (Real observation budget request totality)**.** *Every accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *budget request carries a finite unary precision row E, a finite selected* $\mathsf{StreamName}^{\uparrow}$ *window family W, and matching* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback and radius rows D. These rows are routed by the displayed* Cont *coordinate C, so each accepted request exposes a finite path*

$$E \longmapsto W \longmapsto D$$

inside the same packet $B = (E, W, D, R, S, H, C, P, N)$.

Proof. Project the accepted carrier to its displayed rows. The carrier definition supplies the precision row E, the finite window family W, the dyadic ledger D, and the continuation coordinate C as components of one finite BHist packet.

Use window coverage for the request-facing content. Definition 611.3 says that every dyadic readback and displayed radius exported by D is covered by one of the finite windows in W, and that those windows are selected by E through the routes in C.

Finally apply non-escape. Since Definition 611.6 leaves no coordinate for quotient stream equality, host real equality, hidden limit selection, or an unbounded schedule, an accepted request cannot obtain its readback or radius rows from outside the displayed finite route. □

Theorem 611.13 (Real observation budget route determinacy)**.** *Let two accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *consumer routes display the same rows* $E, W, D, R, S, H, C, P, N$*. Then they determine the same* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *observation-budget surface up to the componentwise* hsame *transports displayed in* H*.*

Proof. Begin with the request and dyadic part. Request totality identifies the finite path from E through W to D, and window coverage fixes the dyadic readbacks and radii as the observations selected by those windows.

Pass to the rational-source handoff. Definition 611.4 routes the $\mathsf{RegSeqRat}^{\uparrow}$ surface through the same E, W, D, H, C, P, N rows, so two routes with the same displayed packet have the same handoff surface after the hsame transports in H are applied.

Pass to the completion-facing boundary. Definition 611.5 forces every $\mathsf{Real}^{\uparrow}$ consumer through the seal rows S, and transport stability preserves those seal rows with the same provenance and local name. Non-escape rules out any hidden selector that could separate the two displayed routes. □

Theorem 611.14 (Real observation budget diagonal Cauchy handoff totality)**.** *Every synchronized diagonal completion read of an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet first consumes the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *precision row, mesh row, and comparison row, and only then factors through the finite observation route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto S \longmapsto H \longmapsto C \longmapsto P \longmapsto N.$$

The exposed surface consists only of finite windows, dyadic readbacks and radii, $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows, and* $\mathsf{Real}^{\uparrow}$ *seal rows, with the structural transport, route, provenance, and local naming rows attached. The handoff exports no quotient stream equality, host real equality, ambient completeness principle, hidden limit selection, or unbounded schedule.*

Proof. Begin with request totality and window coverage. Definition 611.12 places every accepted precision request on the displayed route through E, W, D, and Definition 611.3 makes the dyadic readbacks and radii finite window data.

Next attach the completion-facing handoff. Definition 611.4 routes the rational source through the $\mathsf{RegSeqRat}^{\uparrow}$ rows, and Definition 611.5 sends the resulting completion read through the $\mathsf{Real}^{\uparrow}$ seal rows.

Finally use route determinacy with the synchronized diagonal sibling. Definition 611.13 fixes the displayed route once $E, W, D, R, S, H, C, P, N$ are fixed, while the $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ sibling of chapter 853 supplies exactly the finite precision, mesh, and comparison rows for the diagonal budget. Non-escape then refuses quotient stream equality, host real equality, ambient completeness, hidden limit selection, and unbounded schedules outside the displayed handoff. □

Theorem 611.15 (Real observation budget TasteGate-visible surface)**.** *Any* $\mathsf{ChapterTasteGate}$ *witness for this AI-origin* $\mathsf{RealObservationBudget}^{\uparrow}$ *chapter may inspect only the finite packet rows* $E, W, D, R, S, H, C, P, N$ *over* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. It may not read quotient streams, host real equality, ambient completeness, hidden limit selection, or an unbounded schedule.*

Proof. Read the chapter origin and the carrier together. The chapter is AI-origin, and Definition 611.1 gives the complete carrier as the finite packet $B = (E, W, D, R, S, H, C, P, N)$ over the listed BEDC rows.

The request-totality and route-determinacy theorems identify the visible surface available to consumers. The first binds each accepted request to E, W, D through the displayed Cont route, while the second shows that the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ surfaces are determined by the same packet up to the displayed hsame transports.

Apply the ground-compiler alignment and non-escape results. Definition 611.16 restricts $\mathsf{ChapterTasteGate}$ consumption to displayed rows, and Definition 611.6 excludes quotient streams, host real equality, ambient completeness, hidden limit selection, and unbounded schedules from the packet. □

Theorem 611.16 (Real observation budget TasteGate ground-compiler alignment)**.** *For an AI-origin* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet*

$$B = (E, W, D, R, S, H, C, P, N),$$

the rows $E, W, D, R, S, H, C, P, N$ *are exactly the single-carrier* $\mathsf{ChapterTasteGate}$ *surface available to the chapter. The precision request, finite windows, dyadic readbacks and radii, regular-sequence handoff rows, real-seal rows, transports, continuation routes, provenance, and local name must be consumed through the ground-compiler event-flow and no-hidden-input discipline of chapter 9207. In particular, a consumer may not replace those rows by hidden prompt state, a host-side limit selector, an unlisted compiler fact, quotient stream equality, host real equality, ambient completeness, or an unbounded observation schedule.*

Proof. Start from the carrier definition and the local NameCert surface. Definition 611.1 exposes exactly $E, W, D, R, S, H, C, P, N$, while Definition 611.2 reads those coordinates as the whole local certificate.

The ground-compiler boundary is then a consumption rule for the same finite packet. The event-flow and no-hidden-input discipline of chapter 9207 permits only displayed, recognized rows to enter the compiler-facing read, so the $\mathsf{ChapterTasteGate}$ row cannot import an extra semantic channel.

Finally apply non-escape. Definition 611.6 already rules out quotient stream equality, host real equality, ambient completeness, hidden limit selection, and unbounded schedules; the ground-compiler reading adds that hidden prompt state and unnamed compiler facts are not admissible input rows either. □

Theorem 611.17 (Real observation budget finite-window seal-route totality)**.** *Every admitted* $\mathsf{Real}^{\uparrow}$ *seal read of an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet is reached by the finite route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto S.$$

The route is carried with componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RealObservationBudget}^{\uparrow}}$ *row. There is no admitted seal read that bypasses the precision request, finite window coverage, dyadic ledger, regular-sequence handoff, or displayed provenance rows.*

Proof. First use window coverage. Definition 611.3 sends every exported dyadic readback and radius through the precision request E, the finite window family W, and the dyadic ledger D.

Next use the regular-sequence handoff theorem. Definition 611.4 places the handoff rows R downstream of E, W, D and carries the same transport, route, provenance, and naming data.

Finally apply the real-seal boundary theorem. Definition 611.5 makes S the only completion-facing boundary, and transport stability keeps the same hsame, Cont, Pkg, and NameCert rows attached to the route. □

Theorem 611.18 (Real observation budget obligation closure readiness)**.** *The* $\mathsf{RealObservationBudget}^{\uparrow}$ *paper-side obligation package consists of the carrier admission of* $B = (E, W, D, R, S, H, C, P, N)$*, the local* NameCert *obligations, finite window coverage,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff routing,* $\mathsf{Real}^{\uparrow}$ *seal-boundary routing, non-escape, transport stability, consumer exactness,* ChapterTasteGate *ground-compiler alignment, and finite-window seal-route totality. This package is precisely the obligation surface required before a later closure claim may promote the AI-origin observation budget beyond seed status.*

Proof. Begin with the carrier and NameCert rows. Definition 611.7 assembles carrier admission, local naming, window, handoff, seal, transport, route, provenance, and non-escape obligations into one finite surface.

Add the consumer-facing rows. Definition 611.8 preserves the same packet under classifier transport, and Definition 611.9 says the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers read exactly that packet.

Add the AI-origin readiness rows. Definition 611.16 ties the single-carrier ChapterTasteGate surface to ground-compiler event-flow and no-hidden-input consumption, while Definition 611.17 makes every admitted seal read pass through E, W, D, R, S with the displayed transport and provenance rows. □

Theorem 611.19 (Real observation budget classifier exactness)**.** *For an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet*

$$B = (E, W, D, R, S, H, C, P, N),$$

the classifier is exact on the displayed rows $E, W, D, R, S, H, C, P, N$*. Two consumer reads agree at the observation-budget classifier exactly when they agree on the visible precision request* E*, finite window family* W*, dyadic readback and radius rows* D*, regular-sequence handoff rows* R*, real-seal rows* S*, componentwise transports* H*, displayed routes* C*, provenance* P*, and local* NameCert *row* N*. The comparison does not inspect hidden prompt state, host real equality, quotient stream equality, ambient completeness, or an unlisted compiler fact.*

Proof. Start with the carrier definition and the local NameCert obligation surface. These expose precisely the rows $E, W, D, R, S, H, C, P, N$ and give no coordinate for a hidden classifier input.

Use consumer exactness and transport stability. Consumer exactness confines the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ reads to the displayed packet, while transport stability preserves the same componentwise rows under hsame replay.

Finally apply the ground-compiler alignment and non-escape theorems. Ground-compiler alignment forbids prompt-state or unnamed compiler facts from entering the classifier, and non-escape excludes quotient stream equality, host real equality, ambient completeness, hidden limit selection, and unbounded schedules. □

Theorem 611.20 (Real observation budget finite-route coverage)**.** *Every admitted seal read of an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet*

$$B = (E, W, D, R, S, H, C, P, N)$$

is covered by the finite route

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto S.$$

The route carries the same componentwise transport row H, displayed route row C, package provenance P, and local NameCert *row N. No seal read is admitted directly from E, W, D, or R, and no seal read bypasses the displayed finite-window and regular-sequence handoff rows.*

Proof. First read the precision and finite-window obligations. Window coverage sends each dyadic readback and radius through E, W, D before any regular-sequence handoff is available.

Next apply the regular-sequence handoff theorem. It places R downstream of the precision, window, and dyadic rows, with the same transport, route, provenance, and local naming data attached.

The real-seal boundary then makes S the only completion-facing row. Since non-escape permits no hidden seal coordinate, every admitted seal read follows the displayed route $E \longmapsto W \longmapsto D \longmapsto R \longmapsto S$. □

Theorem 611.21 (Real observation budget root-unblock package)**.** *The root-unblock package exposed by* $\mathsf{RealObservationBudget}^{\uparrow}$ *over*

$$B = (E, W, D, R, S, H, C, P, N)$$

consists exactly of carrier admission, local NameCert *obligations, non-escape, finite-route determinacy through $E \longmapsto W \longmapsto D \longmapsto R \longmapsto S$, classifier exactness on displayed rows, and* ChapterTasteGate *ground-compiler alignment. This package is the paper-side surface available to downstream* $\mathsf{Real}^{\uparrow}$ *completion consumers, without claiming a checked TasteGate target.*

Proof. Begin with carrier admission and local naming. The carrier definition and NameCert obligation theorem give the complete finite packet $B = (E, W, D, R, S, H, C, P, N)$.

Add the route and classifier obligations. Finite-route coverage forces each seal read through E, W, D, R, S, and classifier exactness restricts comparison to the same displayed rows.

Finally add non-escape and ground-compiler alignment. These two results prevent hidden prompt state, unlisted compiler facts, quotient stream equality, host real equality, ambient completeness, and unbounded schedules from acting as completion inputs, while leaving the TasteGate Lean target as a separate verification obligation. □

Theorem 611.22 (Real observation budget TasteGate-cited obligation)**.** *Any promotion of the AI-origin* $\mathsf{RealObservationBudget}^{\uparrow}$ *chapter beyond seed closure must consume the real* ChapterTasteGate *declaration* `BEDC.Derived.RealObservationBudgetUp.taste_gate`*. The resolving declaration records the TasteGate citation for the finite carrier rows $E, W, D, R, S, H, C, P, N$ while the remaining observation-budget obligations stay on their paper-side rows.*

Lean4 ✓ `BEDC.Derived.RealObservationBudgetUp.taste gate`

Proof. Read the origin row in the closure status together with the carrier definition. The chapter is AI-origin, and the only displayed observation-budget packet is $B = (E, W, D, R, S, H, C, P, N)$.

Apply the TasteGate-visible surface and ground-compiler alignment theorems. They say that a ChapterTasteGate consumer may inspect only the displayed observation-budget rows under the ground-compiler event-flow and no-hidden-input discipline.

The paper-Lean name channel is stricter than the paper theorem site. The named Lean declaration supplies the TasteGate citation, while the observation-budget carrier, window, handoff, seal, transport, classifier, and non-escape obligations remain distinct from that citation. □

Theorem 611.23 (Real observation budget AI-origin obligation package)**.** *The AI-origin obligation package for* $\mathsf{RealObservationBudget}^{\uparrow}$ *is the finite packet consisting of carrier admission, finite window coverage,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal boundary, non-escape, transport stability, consumer exactness, and ground-compiler alignment over* $E, W, D, R, S, H, C, P, N$*. This package is the whole observation-budget surface carried alongside the resolving TasteGate declaration.*

Proof. Start with the carrier and local NameCert obligations. They expose the precision request, finite windows, dyadic readback and radius rows, regular-sequence handoff rows, real-seal rows, transport, routes, provenance, and local name.

Add the analytic-facing obligations. Window coverage, the $\mathsf{RegSeqRat}^{\uparrow}$ handoff, and the $\mathsf{Real}^{\uparrow}$ seal boundary place every completion-facing read on the finite route through E, W, D, R, S.

Finally apply non-escape, transport stability, consumer exactness, and ground-compiler alignment. These results preserve the same row set under hsame transport, exhaust the consumer read, and prevent hidden prompt state, quotient stream equality, host real equality, or ambient completeness from entering the AI-origin package. □

Theorem 611.24 (Real observation budget seed-to-obligation readiness)**.** *The* $\mathsf{RealObservationBudget}^{\uparrow}$ *chapter carries an obligation-closure ledger once the TasteGate target is present and the finite rows* $E, W, D, R, S, H, C, P, N$ *are the sole admissible carrier surface. The paper-side obligations display the observation request, window, dyadic, regular-sequence, real-seal, transport, route, provenance, and naming rows without asserting scoped closure or Lean verification for those rows.*

Proof. Use Definition 611.23 to assemble the finite obligation package. It gives exactly the rows $E, W, D, R, S, H, C, P, N$ and the named coverage, handoff, seal, non-escape, transport, consumer, and compiler-alignment obligations.

Use Definition 611.22 for the AI-origin gate. It requires the real TasteGate declaration before the paper can cite a checked TasteGate target.

Thus the obligation boundary has two ingredients: the finite row surface remains exhaustive, and the TasteGate target resolves. Together they record the paper-side obligation ledger while keeping the remaining proof and verification axes separate. □

Theorem 611.25 (Real observation budget finite-window ledger resolution)**.** *For an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *carrier*

$$B = (E, W, D, R, S, H, C, P, N),$$

every finite-window ledger read used by a $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer is resolved by* E, W, D *together with* H, C, P, N *before* R *or* S *is consumed. No such read may use quotient stream equality, host real equality, ambient completeness, hidden limit selection, or an unbounded schedule.*

Proof. First read the request and window side. Request totality exposes the finite path from E to W and then to D, while window coverage binds every dyadic readback and displayed radius to the windows selected by the unary precision row.

Next use the consumer-facing handoff theorems. The regular-sequence handoff places R downstream of E, W, D, H, C, P, N, and the real-seal boundary places S downstream of the same finite route.

Finally apply classifier exactness and non-escape. Classifier exactness confines comparison to the displayed packet rows, and non-escape excludes quotient stream equality, host real equality, ambient completeness, hidden limit selection, and unbounded schedules from the ledger. □

Theorem 611.26 (Real observation budget window-request totalization)**.** *For an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *carrier*

$$B = (E, W, D, R, S, H, C, P, N),$$

every admitted $\mathsf{StreamName}^{\uparrow}$ *window in* W*, every* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback in* D*, and every displayed dyadic radius in* D *is selected by the unary precision request* E *through the displayed* Cont *route*

$$E \longmapsto W \longmapsto D.$$

If such a row is consumed by a $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *reader, the same finite request route continues through* R *and* S *with the stored* hsame*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{RealObservationBudget}^{\uparrow}}$ *rows.*

Proof. Start with the carrier definition. Definition 611.1 gives the only displayed packet rows $E, W, D, R, S, H, C, P, N$, and the continuation coordinate C records the route from the precision request to windows and then to dyadic readbacks and radii.

Use the window and handoff theorems. Definition 611.3 binds every dyadic readback and radius in D to a finite window in W selected by E, while Definition 611.4 sends every regular-rational read through the same request, window, and dyadic rows.

Finally apply finite-route coverage and non-escape. Definition 611.20 extends the route to S for admitted seal reads, and Definition 611.6 prevents any window, readback, radius, handoff, or seal row from being supplied by an unlisted schedule or host-side selector. □

Theorem 611.27 (Real observation budget seal-ledger exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read admitted by an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *carrier factors through the finite ledger rows*

$$E, W, D, R, S, H, C, P, N.$$

The seal ledger has no row for host real equality, hidden limit selection, ambient completeness, quotient stream equality, or an unbounded observation schedule.

Proof. Project the finite packet from Definition 611.1. The only real-facing coordinate is S, and the only rows attached to it are the request, window, dyadic, handoff, transport, route, provenance, and local naming rows.

Apply the seal boundary and route-totality results. Definition 611.5 makes S the completion-facing boundary, while Definition 611.17 and Definition 611.20 force every admitted seal read through $E \longmapsto W \longmapsto D \longmapsto R \longmapsto S$.

Use non-escape for the exhaustion claim. Since Definition 611.6 excludes host real equality, hidden limit selection, ambient completeness, quotient stream equality, and unbounded schedules from the carrier, the displayed rows exhaust the seal ledger. □

Theorem 611.28 (Real observation budget NameCert field saturation)**.** *The carrier field, classifier field, componentwise transport field, displayed route field, provenance field, and local* $\mathsf{NameCert}_{\mathsf{RealObservationBudget}}$ *field of an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet exhaust the paper-side obligation surface. A downstream* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer can request only the rows* $E, W, D, R, S, H, C, P, N$ *and their displayed classifier, transport, route, provenance, and naming evidence.*

Proof. First read the local certificate. Definition 611.2 identifies carrier admission, local naming, window coverage, handoff routing, seal-boundary routing, transport, route replay, and provenance as the complete local $\mathsf{NameCert}$ surface.

Next add classifier and transport exactness. Definition 611.19 confines classifier comparison to the displayed rows, and Definition 611.8 preserves the same rows under componentwise hsame replay.

Finally combine finite-route coverage with the AI-origin obligation package. Definition 611.20 routes each seal read through the finite ledger, and Definition 611.23 packages exactly these carrier, classifier, transport, route, provenance, and naming fields before any TasteGate citation is available. □

Theorem 611.29 (Real observation budget TasteGate target consumption)**.** *Any* RealObservationBudget$^{\uparrow}$ *closure claim beyond seed status must consume the resolving* ChapterTasteGate *carrier-alignment theorem named* `BEDC.Derived.RealObservationBudgetUp.RealObservationBudgetTasteGate_single_carrie` *The resolving marker is the TasteGate carrier-alignment theorem for the displayed packet*

$$E, W, D, R, S, H, C, P, N.$$

The checked TasteGate marker does not discharge the remaining observation-budget rows, and no downstream Real$^{\uparrow}$ *or* RegSeqRat$^{\uparrow}$ *consumer may treat prose, host equality, quotient stream equality, hidden limit selection, ambient completeness, or an unbounded observation schedule as a substitute for those obligations.*

Lean4 ✓ `BEDC.Derived.RealObservationBudgetUp.RealObservationBudgetTasteGate single carrier alignment`

Proof. Read the AI-origin row together with the carrier definition. The chapter declares its origin as AI, and Definition 611.1 gives the only carrier packet $B = (E, W, D, R, S, H, C, P, N)$.

Use the TasteGate-visible surface and the ground-compiler alignment theorem. Definition 611.16 says the ChapterTasteGate read is confined to the displayed rows under ground-compiler event-flow and no-hidden-input discipline.

Finally apply the paper-Lean marker rule. The resolving theorem named `BEDC.Derived.RealObservationBudg` supplies the TasteGate citation required for the AI-origin chapter to record its paper-side obligation surface, while the remaining carrier, window, handoff, seal, transport, classifier, and non-escape proofs stay on their separate obligation rows. □

Falsifiable prediction: A counterexample to the observation-budget route is an accepted RealObservationBudget$^{\uparrow}$ seal read reaching S without passing through the displayed rows E, W, D, R, H, C, P, N.

Independence witness: real-observation-budget, observationbudgetlimiter, regular-cauchy-tail-budget, cauchy-seal-budget-synchronizer, finite-observation-budget-selector: none is bijective to RealObservationBudget$^{\uparrow}$ because the observation-budget packet carries the joint field rows $E, W, D, R, S, H, C, P, N$, while each sibling omits at least one request, window, dyadic, regular handoff, seal, transport, route, provenance, or local naming field needed by this carrier.

Theorem 611.30 (Real observation budget field-faithful commitment)**.** *Any Lean TasteGate file that discharges the AI-origin* RealObservationBudget$^{\uparrow}$ *carrier-alignment surface must supply explicit* `Nontrivial RealObservationBudgetUp` *and* `FieldFaithful RealObservationBudgetUp` *instances over the displayed fields*

$$E, W, D, R, S, H, C, P, N.$$

The commitment is a companion obligation for the chapter template: the checked TasteGate carrier-alignment target may record the displayed carrier, but it does not by itself make the carrier non-trivial or field-faithful.

Proof. Read the AI-origin row and the carrier definition. The chapter is explicitly AI-origin, and Definition 611.1 displays the whole observation-budget packet as the fields $E, W, D, R, S, H, C, P, N$.

Use the TasteGate target-consumption theorem only as a boundary. Definition 611.29 says the resolving carrier-alignment target is consumed by closure claims, but it also keeps the remaining observation-budget obligations separate from that marker.

Therefore a non-vacuous TasteGate discharge must carry the two companion instances on the same displayed fields. Without `Nontrivial RealObservationBudgetUp`, the carrier could collapse to a one-object reading; without `FieldFaithful RealObservationBudgetUp`, the fields could be ignored while the chapter still names the carrier. □

Theorem 611.31 (Real observation budget RegSeqRat RealUp consumer factorization)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer admitted by an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *carrier factors through the finite route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto S$$

with the displayed hsame *row* H*,* Cont *row* C*,* Pkg *row* P*, and local* $\mathsf{NameCert}_{\mathsf{RealObservationBudget}^{\uparrow}}$ *row* N*. The factorization has no read channel for quotient stream equality, host real equality, ambient completeness, hidden limit selection, or an unbounded schedule.*

Proof. First compose the request and window coverage. Definition 611.26 and Definition 611.3 route each admitted dyadic readback and radius through E, W, D.

Next attach the consumer handoff rows. Definition 611.4 places $\mathsf{RegSeqRat}^{\uparrow}$ consumption at R, while Definition 611.5 and Definition 611.27 place $\mathsf{Real}^{\uparrow}$ consumption at the seal row S.

Transport stability then preserves the same evidence rows. Definition 611.8 keeps the componentwise hsame, displayed Cont, Pkg provenance, and local $\mathsf{NameCert}$ data attached to the route.

Finally use non-escape and classifier exactness. Definition 611.6 and Definition 611.19 exclude quotient stream equality, host real equality, ambient completeness, hidden limit selection, and unbounded schedules from every admitted consumer read. □

Theorem 611.32 (Real observation budget L10 gate handoff exactness)**.** *Every admitted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet exposes the L10 phase handoff exactly through the finite route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto S,$$

where W *is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window surface,* D *is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback and radius surface,* R *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff surface, and* S *is the* $\mathsf{Real}^{\uparrow}$ *seal boundary. No* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer admitted by the packet may bypass this route by quotient stream equality, host real equality, hidden limit selection, ambient completeness, or an unbounded observation schedule. Thus the L10 gate is a finite BEDC route over* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*.*

Proof. Start with the observation route. Definition 611.3 binds every dyadic readback and radius in D to the finite $\mathsf{StreamName}^{\uparrow}$ windows W selected by the request row E.

Attach the rational handoff and the completion boundary. Definition 611.4 places the $\mathsf{RegSeqRat}^{\uparrow}$ consumer surface at R downstream of E, W, D, and Definition 611.5 makes S the only $\mathsf{Real}^{\uparrow}$ seal boundary reachable from that handoff.

Now use the consumer factorization theorem. Definition 611.31 says every admitted $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer factors through

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto S$$

with the displayed hsame, Cont, Pkg, and local NameCert rows.

Finally read the TasteGate target as a boundary condition, not as an extra analytic channel. Definition 611.29 keeps the checked target attached to the displayed packet and does not add quotient stream equality, host real equality, hidden limit selection, ambient completeness, or an unbounded observation schedule. The L10 handoff is therefore exactly the finite BEDC route over BHist, hsame, Cont, Pkg, NameCert, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$. □

Theorem 611.33 (Real observation budget finite-window seal lock)**.** *Let $B = (E, W, D, R, S, H, C, P, N)$ be an accepted* RealObservationBudget$^{\uparrow}$ *packet. Every* Real$^{\uparrow}$ *seal read admitted through S first passes through the finite* StreamName$^{\uparrow}$ *windows W selected by E, then through the* DyadicRatCore$^{\uparrow}$ *readback and radius rows D, and then through the* RegSeqRat$^{\uparrow}$ *handoff row R. The rows H, C, P, N preserve the same packet while transport, continuation replay, provenance, and local naming are consumed. Thus the seal boundary is a reusable finite-window consumer boundary for* RegSeqRat$^{\uparrow}$ *and* Real$^{\uparrow}$*, with no channel for quotient stream equality, host real equality, ambient completeness, hidden limit selection, or an unbounded observation schedule.*

Proof. Begin with the displayed packet. By Definition 611.1, the only rows of an accepted RealObservationBudget$^{\uparrow}$ carrier are $E, W, D, R, S, H, C, P, N$.

Build the finite observation spine. Definition 611.3 places every admitted dyadic readback and radius row behind the finite StreamName$^{\uparrow}$ windows selected by E, and Definition 611.4 places the RegSeqRat$^{\uparrow}$ handoff at R after those rows.

Lock the completion-facing end of the route. Definition 611.5 makes S the Real$^{\uparrow}$ seal boundary reached from that handoff, while Definition 611.32 identifies the whole L10 route as

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto S.$$

The remaining rows do not create another analytic read. They preserve the same packet as componentwise hsame transport, displayed Cont replay, Pkg provenance, and local NameCert naming. Hence every seal read through S is locked to the finite-window route, and the excluded quotient, host equality, completeness, limit-selection, and unbounded-schedule channels have no coordinate in B. □

Theorem 611.34 (Real observation budget diagonal selector source lock)**.** *Let $B = (E, W, D, R, S, H, C, P, N)$ be an accepted* RealObservationBudget$^{\uparrow}$ *packet. Suppose a completion-facing consumer is synchronized with an accepted* CauchyDiagonalBudget$^{\uparrow}$ *route. Then the consumer can read the diagonal selector only through the displayed rows $E, W, D, R, S, H, C, P, N$ together with the* CauchyDiagonalBudget$^{\uparrow}$ *precision row, mesh row, and comparison row. The packet provides no read channel for a host-selected limit, quotient stream, ambient completeness witness, or hidden selector input.*

Proof. Project the finite carrier. By Definition 611.1, the only rows of B are $E, W, D, R, S, H, C, P, N$.

Use the observation route already forced by the local budget. Window coverage binds finite reads to E, W, D, the RegSeqRat$^{\uparrow}$ handoff binds rational-name consumption to R, and the Real$^{\uparrow}$ seal boundary binds completion-facing reads to S.

Now attach the synchronized diagonal sibling. The CauchyDiagonalBudget$^{\uparrow}$ route supplies the finite selector surface through its precision, mesh, and comparison rows, and the L10 handoff exactness of Definition 611.32 repackages those reads through E, W, D, R, S.

Finally apply non-escape at the seal boundary. Since neither the carrier nor the synchronized finite selector surface contains a host-selected limit, quotient stream, ambient completeness witness, or hidden selector input, the completion-facing consumer has no channel outside the displayed rows and the diagonal precision, mesh, and comparison rows. □

Theorem 611.35 (Real observation budget L10 four-face pullback)**.** *Let $B = (E, W, D, R, S, H, C, P, N)$ be an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet. Suppose the diagonal-selector row synchronized with B is consumed by a completion-facing consumer or by a* $\mathsf{Real}^{\uparrow}$ *consumer. Then the consumer route factors through the finite four-face packet*

$$\mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$$

and the only supporting rows used by the factorization are the displayed BHist *observations, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *data attached to B and to those four faces.*

Consequently the combined observation-budget and diagonal-selector route has no channel for quotient stream equality, selected host limits, host real equality, countable-choice selectors, ambient completeness, metric-completeness rows, or a duplicate diagonal-budget face.

Proof. Project the carrier first. By Definition 611.1, the accepted packet exposes only the rows $E, W, D, R, S, H, C, P, N$, so any consumer read attached to B must begin with those displayed observation-budget coordinates.

Use the L10 handoff already forced by the local packet. Definition 611.32 identifies the observation-budget handoff as the finite route through E, W, D, R, S, with the displayed BHist, hsame, Cont, Pkg, and local NameCert support and with no hidden analytic route.

Now attach the diagonal selector. Definition 611.34 says that a completion-facing synchronized selector can only be read through the displayed packet rows together with the finite precision, mesh, and comparison rows of the $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ route.

Finally pass to the Real L10 terminal surface. Definition 38.454 places any diagonal-budget row owned by a terminal $\mathsf{Real}^{\uparrow}$ read on the same finite packet over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, while Definition 38.457 identifies that packet as the exact terminal boundary. The listed quotient, host-limit, host-equality, choice, completeness, metric-completeness, and duplicate-budget rows therefore have no coordinate in the combined consumer route. □

Theorem 611.36 (Real observation budget closure-axis obligation ledger)**.** *The obligation ledger for* $\mathsf{RealObservationBudget}^{\uparrow}$ *consists of carrier admission for $B = (E, W, D, R, S, H, C, P, N)$, the local* NameCert *obligations, classifier exactness,* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer factorization, non-escape, and* ChapterTasteGate *target consumption. These rows record the paper-side obligation surface without asserting scoped closure or Lean verification.*

Proof. Assemble the carrier and local certificate rows from Definition 611.1 and Definition 611.2. These rows give the finite packet and its local naming obligations.

Add the consumer and classifier obligations. Definition 611.19 confines comparison to the displayed rows, and Definition 611.31 supplies the finite $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ route.

Close the paper-side ledger with non-escape and TasteGate target consumption. Definition 611.6 rules out hidden analytic input, while Definition 611.29 keeps Lean-side checking separate from the obligation rows recorded here. □

Lean4 ✓ `BEDC.Derived.RealObservationBudgetUp.RealObservationBudgetUp StdBridge`

Closure status for $\mathsf{NameCert}_{\mathsf{RealObservationBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{RealObservationBudget}^{\uparrow}$ packet is generated from a unary precision request, finite $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{DyadicRatCore}^{\uparrow}$ readbacks and radii, $\mathsf{RegSeqRat}^{\uparrow}$ handoff rows, $\mathsf{Real}^{\uparrow}$ seal rows, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RealObservationBudget}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 611.1, Definition 611.2, Definition 611.3, Definition 611.4, Definition 611.5, Definition 611.7, Definition 611.18, and Definition 611.29 scope the finite observation-budget carrier, precision windows, dyadic

readbacks, RegSeqRat$^{\uparrow}$ handoffs, Real$^{\uparrow}$ seal boundary, TasteGate instance `BEDC.Derived.RealObservationBudgetUp.taste_gate`, and TasteGate carrier-alignment theorem over BHist, hsame, Cont, Pkg, NameCert, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$.

Formal verification: FormalStatus(NameCert$_{\text{RealObservationBudget}\uparrow}$, bridgeChecked)

Lean target: `BEDC.Derived.RealObservationBudgetUp.RealObservationBudgetUp\_StdBridge`

Bridge status: bridgeChecked

Origin: ai

Not claimed: This chapter does not close quotient stream equality, host real equality, ambient completeness, hidden limit selection, unbounded observation schedules, or bridge checking.

Upgrade path: No further formal-axis upgrade remains: the standard bridge for the observation-budget packet is checked.

Chapter 612

A Concrete Naming Certificate for $\mathsf{CauchyDiagonalFusion}^{\uparrow}$

The $\mathsf{CauchyDiagonalFusion}^{\uparrow}$ packet is the finite naming certificate that joins the observation-budget route, the regular Cauchy witness schedule, and the schedule-fusion row before the $\mathsf{Real}^{\uparrow}$ diagonal seal is read. It presents one completion-facing handoff over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$, $\mathsf{RealScheduleFusion}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, while withholding quotient streams, host real equality, selected limits, and ambient completeness.

This fusion packet consumes the modulus-indexed witness-window route of chapter 593: the row W is not an independent schedule oracle, but the sibling witness-schedule carrier transported into the diagonal fusion route before the dyadic readback and $\mathsf{Real}^{\uparrow}$ seal are available.

Definition 612.1 (Cauchy diagonal fusion carrier)**.** *A* $\mathsf{CauchyDiagonalFusion}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (E, B, W, S, D, R, L, H, C, P, N)$$

with the following displayed rows:

1. *E is the precision request row whose tolerance selects the diagonal observation;*
2. *B is the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row exposing the finite stream windows, dyadic readbacks, regular-sequence handoffs, and real-seal boundary for E;*
3. *W is the* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *row exposing the modulus-indexed witness window used by the diagonal read;*
4. *S is the* $\mathsf{RealScheduleFusion}^{\uparrow}$ *row that locks the schedule, window ledger, regular-rational readback, and seal handoff into one route;*
5. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row consumed by both the observation budget and the witness schedule;*
6. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row reached after the dyadic readback and before the real seal;*
7. *L is the* $\mathsf{Real}^{\uparrow}$ *diagonal seal row exported to completion-facing consumers;*
8. *H records componentwise* hsame *transports for E, B, W, S, D, R, L and the structural rows;*
9. *C records the displayed* Cont *routes from precision request to observation budget, witness schedule, schedule fusion, dyadic readback, regular-rational handoff, and diagonal seal;*
10. *P is the* Pkg *provenance over the listed rows,* BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyDiagonalFusion}^{\uparrow}}$ *row.*
The carrier has no coordinate for quotient stream equality, host real equality, a selected completed limit, an unbounded schedule, or an ambient completeness principle.

Lean4 (definition) `BEDC.Derived.CauchyDiagonalFusionUp.CauchyDiagonalFusionUp`

Theorem 612.2 (Cauchy diagonal fusion NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CauchyDiagonalFusion}^{\uparrow}}$ *surface consists exactly of carrier admission for $F = (E, B, W, S, D, R, L, H, C, P, N)$, precision request exposure,* $\mathsf{RealObservationBudget}^{\uparrow}$ *observation routing,* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *witness-window routing,* $\mathsf{RealScheduleFusion}^{\uparrow}$ *schedule locking,* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback exposure,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff routing,* $\mathsf{Real}^{\uparrow}$ *diagonal seal exposure, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and the local naming row.*

Proof. Project the carrier of Definition 612.1. The rows E, B, W, S, D, R, L are the only mathematical coordinates, and H, C, P, N are the only transport, route, package, and naming coordinates.

The observation row B, witness row W, and schedule-fusion row S are read before any seal consumer reaches L. Thus the local certificate is assembled from the same finite route rather than from a host completion object.

Since quotient streams, host equality, selected limits, unbounded schedules, and ambient completeness have no row in F, no local NameCert projection can export them. □

Theorem 612.3 (Cauchy diagonal fusion schedule lock)**.** *For an accepted* $\mathsf{CauchyDiagonalFusion}^{\uparrow}$ *carrier, every precision request routed through E reaches the same* $\mathsf{RealObservationBudget}^{\uparrow}$ *row B,* $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ *row W, and* $\mathsf{RealScheduleFusion}^{\uparrow}$ *row S before reading the dyadic row D. The schedule fusion therefore fixes the finite window ledger and regular-rational readback used by the diagonal route.*

Proof. Start with the precision request row E. The displayed continuations in C send this request to B, W, S before D is available.

The transport row H carries the same observation budget, witness schedule, and schedule-fusion rows componentwise. Therefore a transported precision request cannot select a second window family or a second schedule after the diagonal route has begun. □

Theorem 612.4 (Cauchy diagonal fusion RealUp seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *diagonal seal read exported by an accepted* $\mathsf{CauchyDiagonalFusion}^{\uparrow}$ *packet factors through the finite route*

$$E \longmapsto B \longmapsto W \longmapsto S \longmapsto D \longmapsto R \longmapsto L.$$

The seal receives only the precision request, observation-budget row, witness-schedule row, schedule-fusion row, dyadic readback, regular-rational handoff, transports, routes, provenance, and local naming data.

Proof. Apply the schedule-lock theorem to place every seal-facing request after E, B, W, S, D. The dyadic readback is therefore already tied to the displayed observation budget and witness schedule.

The regular-rational handoff row R is the only source-facing row between the dyadic readback and the seal. The continuation route then reaches L with H, C, P, N as visible structural data.

No further analytic object is present in the carrier, so the seal handoff cannot bypass the finite diagonal route. □

Theorem 612.5 (Cauchy diagonal fusion non-escape)**.** *An accepted* $\mathsf{CauchyDiagonalFusion}^{\uparrow}$ *packet exports only the rows* $E, B, W, S, D, R, L, H, C, P, N$ *of Definition 612.1. It exports no quotient stream, no host real equality, no selected completed limit, no unbounded schedule, and no ambient completeness principle.*

Proof. Inspect the carrier rows. The route-visible data are the precision request, observation budget, witness schedule, schedule fusion, dyadic readback, regular-rational handoff, and diagonal seal, together with the structural rows H, C, P, N.

The NameCert obligation theorem identifies this list as the local naming surface. The schedule-lock theorem and seal-handoff theorem then force every downstream read to pass through that surface.

Because the excluded objects are not coordinates and are not produced by the displayed continuations, no consumer can recover them from the packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyDiagonalFusion}^{\uparrow}}$**.**

Constructive story: A $\mathsf{CauchyDiagonalFusion}^{\uparrow}$ packet is generated from finite BHist rows for a precision request, observation-budget row, witness-schedule row, schedule-fusion row, dyadic readback, regular-rational handoff, and $\mathsf{Real}^{\uparrow}$ diagonal seal. The diagonal route is assembled bottom-up by Cont: the request reaches budget, witness, and schedule rows before the dyadic and seal rows can be read. Componentwise hsame keeps those route coordinates stable, and Pkg records the Real-observation, witness-schedule, dyadic, regular-rational, and seal dependencies. The fusion names one finite diagonal path, not an ambient completion theorem or selected limit.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyDiagonalFusion}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the diagonal-fusion carrier, NameCert obligations, schedule lock, RealUp seal handoff, and non-escape theorem for $\mathsf{CauchyDiagonalFusion}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CauchyDiagonalFusion}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim quotient stream equality, host real equality, selected completed limits, unbounded schedules, choice selectors, or ambient completeness.

Upgrade path: Obligation closure requires Lean encodings of the diagonal carrier, schedule-lock theorem, seal-handoff route, and non-escape boundary.

Chapter 613

A Concrete Naming Certificate for $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$

The $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ packet records the finite route by which a transported stationary $\mathsf{Rat}^{\uparrow}$ classifier is read as a $\mathsf{Real}^{\uparrow}$ observation window. It keeps the rational seed, constant $\mathsf{StreamName}^{\uparrow}$ row, $\mathsf{RegSeqRat}^{\uparrow}$ seal-consumption row, $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, real finite-window row, transport table, continuation routes, provenance, and local naming row in one finite boundary packet. It does not export quotient stream equality, selected limit data, host real equality, or an unbounded completion principle.

Definition 613.1 (Stationary diagonal window route carrier)**.** *A* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (Q, S, G, D, R, H, C, P, N)$$

with the following displayed coordinates:

1. *Q is the transported stationary* $\mathsf{Rat}^{\uparrow}$ *seed row, including the two rational history carriers and their* $\mathsf{RatHistoryClassifier}$ *row;*
2. *S is the constant* $\mathsf{StreamName}^{\uparrow}$ *window row induced by Q;*
3. *G is the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite seal-consumption row for the same window;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger read from that window;*
5. *R is the* $\mathsf{Real}^{\uparrow}$ *finite-window classifier row reached from S, G, D;*
6. *H stores componentwise* hsame *transports for Q, S, G, D, R, P, N;*
7. *C stores the displayed* Cont *routes from Q to S, from S to G, from S to D, and from D, S, G to R;*
8. *P records* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}}$ *row.*

The carrier is a finite route packet for stationary window reads. It contains no coordinate for quotient streams, selected real limits, host real equality, non-stationary tails, or ambient completeness.

Theorem 613.2 (Stationary diagonal window route NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{StationaryDiagonalWind}}$ *surface for Definition 613.1 consists exactly of carrier admission for* $W = (Q, S, G, D, R, H, C, P, N)$*, stationary* $\mathsf{Rat}^{\uparrow}$ *seed exposure, constant* $\mathsf{StreamName}^{\uparrow}$ *window exposure,* $\mathsf{RegSeqRat}^{\uparrow}$ *seal-consumption exposure,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger exposure,* $\mathsf{Real}^{\uparrow}$ *finite-window classifier exposure, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and the local naming row.*

Proof. Carrier admission is projection from the displayed tuple W. The rows Q, S, G, D, R expose the stationary rational seed, constant stream window, regular-sequence seal row, dyadic observation ledger, and real-facing finite-window classifier.

The route obligations are read from C. They force every stream, regular-sequence, dyadic, and real-facing read to pass through the constant window induced by the same rational seed row Q.

The transport, provenance, and naming obligations are the rows H, P, N. Since the carrier has no coordinate for quotient streams, selected real limits, host equality, non-stationary tails, or ambient completeness, these displayed rows exhaust the local naming surface. □

Lean4 ✓ `BEDC.Derived.StationaryDiagonalWindowRouteUp.StationaryDiagonalWindowRoutePacket namecert obligations`

Theorem 613.3 (Stationary diagonal window route non-escape)**.** *Every transported stationary* $\mathsf{Real}^{\uparrow}$ *finite-window read exported by an accepted* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ *carrier factors through the finite rows*

$$Q, S, G, D, R, H, C, P, N.$$

The consumer may inspect the $\mathsf{Rat}^{\uparrow}$ *seed classifier, constant* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *seal-consumption row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *finite-window classifier,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row, and nothing else.*

Proof. Project the accepted carrier and inspect its consumer-facing rows. The only route out of the stationary rational seed is the displayed continuation from Q to the constant stream window S.

The regular-sequence and dyadic reads are then forced by the routes from S to G and from S to D. The real-facing finite-window row R receives only those rows together with the transport, provenance, and naming rows.

Thus any certified finite observation of the transported stationary diagonal is exhausted by the displayed route packet. No quotient stream comparison, selected limit, host real equality, non-stationary tail, or ambient completeness datum can escape from the carrier. □

Theorem 613.4 (Stationary diagonal window route classifier stability)**.** *Let* $W = (Q, S, G, D, R, H, C, P, N)$ *and* $W' = (Q', S', G', D', R', H', C', P', N')$ *be accepted* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ *carriers. If the component rows* Q, S, G, D, R, P, N *and* $Q', S', G', D', R', P', N'$ *are related by the displayed* hsame *transports stored in* H *and* H'*, then every classifier-visible comparison of the two route packets is componentwise: it compares the transported* $\mathsf{Rat}^{\uparrow}$ *seed rows, constant* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *seal-consumption rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledgers,* $\mathsf{Real}^{\uparrow}$ *finite-window rows, provenance rows, and local* NameCert *rows through those transports and through no other object.*

Proof. Project the two carriers with Definition 613.1. Their classifier-visible coordinates are exactly the displayed rows $Q, S, G, D, R, H, C, P, N$ and $Q', S', G', D', R', H', C', P', N'$.

Use the local NameCert obligations of Definition 613.2. They require all stationary seed exposure, constant-window exposure, seal consumption, dyadic ledger exposure, real finite-window exposure, transport, route replay, provenance, and naming reads to pass through the displayed packet rows.

Finally apply Definition 613.3. Since no quotient stream equality, selected limit, host real equality, non-stationary tail, or ambient completeness coordinate is present, the classifier stability claim is exhausted by componentwise hsame comparison of the named rows. □

Theorem 613.5 (Stationary diagonal window route constant-window exactness)**.** *For an accepted* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ *carrier* $W = (Q, S, G, D, R, H, C, P, N)$*, the* $\mathsf{StreamName}^{\uparrow}$ *window row* S *is exactly the constant window induced by the transported stationary* $\mathsf{Rat}^{\uparrow}$ *seed row* Q*. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *read through* G*, every* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger read through* D*, and every* $\mathsf{Real}^{\uparrow}$ *finite-window read through* R *consumes that same constant window and does not select a non-stationary tail.*

Proof. Begin with the carrier definition. The row Q is the transported stationary rational seed, and S is declared as the constant $\mathsf{StreamName}^{\uparrow}$ window induced by that seed.

Read the route row C. The route obligations in Definition 613.2 force the route from Q to S, from S to G, from S to D, and from D, S, G to R.

The non-escape theorem then rules out any alternate source for the window. A consumer cannot replace the constant window by quotient stream equality, a selected limit, host real equality, a non-stationary tail, or ambient completeness data, so the window consumed by G, D, R is the one induced by Q. □

Theorem 613.6 (Stationary diagonal window route sibling dependency)**.** *For an accepted* StationaryDiagonalWindo *carrier* $W = (Q, S, G, D, R, H, C, P, N)$*, the route is the route-level consumer of the sibling stationary-window boundary in chapter 626 and the transported stationary seed surface in chapter 475. It retains the sibling rows needed by the downstream regular-Cauchy window fusion consumer of chapter 693 while omitting any second classifier row, quotient stream, host real equality, non-stationary tail, or completeness principle.*

Proof. Project the accepted carrier W. Its displayed rows expose the transported stationary seed Q, the constant stream window S, the seal row G, the dyadic ledger D, the finite real-window row R, the component transports H, the continuation routes C, provenance P, and naming N.

Compare these rows with the stationary-window carrier. The sibling stationary-window boundary supplies the same constant-window shape at the Q and S rows, while the transported stationary diagonal surface supplies the seed table consumed before any real-facing read.

Apply Definition 613.5. It identifies the shared Q to S to G, D to R route as a constant-window route induced by the transported stationary seed.

The rows G, D, R, H, C, P, N are therefore the route-level material retained for the regular-Cauchy window fusion consumer. By Definition 613.3, no second classifier row, quotient stream, host real equality, non-stationary tail, or completeness principle is exported from the packet. □

Theorem 613.7 (Stationary diagonal window route seal-consumption handoff)**.** *An accepted* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ *carrier* $W = (Q, S, G, D, R, H, C, P, N)$ *hands the* $\mathsf{RegSeqRat}^{\uparrow}$ *seal-consumption row* G *to the* $\mathsf{Real}^{\uparrow}$ *finite-window row* R *only through the displayed route packet. The handoff consumes* $Q, S, G, D, R, H, C, P, N$*: the stationary* $\mathsf{Rat}^{\uparrow}$ *seed, constant* $\mathsf{StreamName}^{\uparrow}$ *window, seal-consumption row, dyadic ledger, real window row, componentwise transports, continuation routes, package provenance, and local naming row.*

Proof. First project the accepted packet and isolate the handoff rows. The carrier supplies G as the regular-sequence seal-consumption row and R as the real-facing finite-window classifier row.

Next follow the displayed continuation routes. The NameCert obligations route Q to S, route S to G and D, and route D, S, G to R, with H supplying the componentwise transports and P, N supplying provenance and local naming.

The handoff has no further analytic coordinate. By non-escape, it cannot consume quotient streams, selected limits, host real equality, non-stationary tails, or ambient completeness, so the $\mathsf{RegSeqRat}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$ handoff is exactly the finite packet $Q, S, G, D, R, H, C, P, N$. □

Theorem 613.8 (Stationary diagonal window route stationary seed exposure)**.** *For an accepted* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ *carrier* $W = (Q, S, G, D, R, H, C, P, N)$*, the first readable analytic row is the transported stationary* $\mathsf{Rat}^{\uparrow}$ *seed row* Q*. The rows for* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *become readable only after the displayed continuation route from* Q *to the constant window row* S *has been exposed in* C*.*

Proof. Project the carrier of Definition 613.1. Its first coordinate is the transported stationary rational seed row Q, while the later analytic coordinates are S, G, D, R.

Now read the route coordinate C. The NameCert obligations in Definition 613.2 display the route from Q to S before any route to G, D, R is available.

The non-escape theorem supplies the boundary check. Since no quotient stream, selected real limit, host equality, non-stationary tail, or ambient completeness coordinate is present, a consumer cannot read a stream, regular-sequence, dyadic, or real row before passing through the stationary seed route in C. □

Theorem 613.9 (Stationary diagonal window route constant-window routing)**.** *For an accepted* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ *carrier* $W = (Q, S, G, D, R, H, C, P, N)$*, the row* S *is the only constant* $\mathsf{StreamName}^{\uparrow}$ *window induced by the transported stationary seed* Q *inside the packet. The rows* G *and* D *are reachable only through the displayed packet coordinates* S, H, C, P, N*, and the finite real-facing row* R *consumes them only through the same route surface.*

Proof. The carrier definition identifies S as the constant stream window induced by Q. No second stream-window coordinate occurs in the tuple $W = (Q, S, G, D, R, H, C, P, N)$.

The route coordinate C then fixes the downstream access pattern. The only displayed routes out of the stream row are from S to the seal-consumption row G and from S to the dyadic ledger row D, with H carrying componentwise transport and P, N carrying provenance and naming.

Finally apply Definition 613.5. It rules out any non-stationary tail or alternate window source for the reads through G, D, R, so the constant window route is exactly the one carried by S, H, C, P, N. □

Theorem 613.10 (Stationary diagonal window route dyadic ledger exposure)**.** *Every* $\mathsf{Real}^{\uparrow}$ *finite-window read* R *exported by an accepted* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ *carrier consumes the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D *and the* $\mathsf{RegSeqRat}^{\uparrow}$ *seal row* G *through the displayed route*

$$Q, S, G, D, R, H, C, P, N.$$

The read exports no quotient stream, selected real limit, host equality, non-stationary tail, or ambient completeness datum.

Proof. Begin with the handoff theorem Definition 613.7. It says that the regular-sequence seal row G reaches the real finite-window row R only through the finite route packet.

The dyadic ledger coordinate is tied to the same route. By Definition 613.2, the route row C displays S to D and D, S, G to R, while H, P, N provide transport, provenance, and local naming.

The non-escape theorem completes the exposure claim. The carrier has no coordinate from which a quotient stream, selected limit, host equality, non-stationary tail, or ambient completeness principle could be exported, so the real finite-window read is exactly the displayed dyadic-ledger and seal-consumption route. □

Theorem 613.11 (Stationary diagonal window route public export)**.** *For an accepted* StationaryDiagonalWindowRo *carrier*

$$W = (Q, S, G, D, R, H, C, P, N),$$

the rows $Q, S, G, D, R, H, C, P, N$ form the public $\mathsf{Real}^{\uparrow}$*-and-completion handoff from a transported stationary* $\mathsf{Rat}^{\uparrow}$ *seed through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and the* $\mathsf{Real}^{\uparrow}$ *finite-window classifier. Any consumer of the public export factors through that finite packet before reading a real-facing or completion-facing boundary.*

Proof. Start with the row inventory. The NameCert obligations of Definition 613.2 identify $Q, S, G, D, R, H, C, P, N$ as the carrier, stationary seed, constant window, seal-consumption, dyadic ledger, finite real-window, transport, route, provenance, and local naming surface.

Next route the stationary seed through the stream window. By Definition 613.5, the row S is exactly the constant $\mathsf{StreamName}^{\uparrow}$ window induced by Q, and every downstream G, D, R read consumes that same window.

Now attach the real-and-completion handoff. The seal-consumption handoff of Definition 613.7 sends G to R only through the displayed packet, while the dyadic ledger exposure of Definition 613.10 forces the D row into the same route.

Finally apply non-escape. Definition 613.3 excludes quotient streams, selected limits, host equality, non-stationary tails, and ambient completeness from the carrier, so any public real-facing or completion-facing consumer must factor through the finite rows $Q, S, G, D, R, H, C, P, N$. □

Theorem 613.12 (Stationary diagonal window route formal target)**.** *The public export of Definition 613.11 is the formal target for* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$*: every accepted carrier*

$$W = (Q, S, G, D, R, H, C, P, N)$$

exposes the stationary $\mathsf{Rat}^{\uparrow}$ *seed, constant* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *seal row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *finite-window row,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *row as the complete consumer surface.*

Proof. Start with the public export theorem. It identifies $Q, S, G, D, R, H, C, P, N$ as the finite real-facing and completion-facing handoff from the transported stationary rational seed through the stream, regular-sequence, dyadic, and real rows.

The dyadic ledger exposure theorem supplies the ledger side of the target surface. It forces every $\mathsf{Real}^{\uparrow}$ finite-window read to consume the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger D together with the $\mathsf{RegSeqRat}^{\uparrow}$ seal row G through the displayed route.

The seal-consumption handoff supplies the regular-sequence side. It places G on the same finite route to R, with H, C, P, N carrying transport, continuation, provenance, and local naming.

Finally apply non-escape. Since the carrier exports no quotient stream, selected limit, host real equality, non-stationary tail, or ambient completeness coordinate, these displayed rows form the complete consumer surface for the later Lean target. □

Closure status for $\mathsf{NameCert}_{\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}}$**.**

Constructive story: A $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ packet is generated from a transported stationary $\mathsf{Rat}^{\uparrow}$ seed row, a constant $\mathsf{StreamName}^{\uparrow}$ window row, a $\mathsf{RegSeqRat}^{\uparrow}$ seal-consumption row, a $\mathsf{DyadicRatCore}^{\uparrow}$ observation

ledger, a Real$^{\uparrow}$ finite-window classifier, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{StationaryDiagonalWindowRoute}^{\uparrow}}$, publicClosed)

Scope closed: Definition 613.1, Definition 613.2, Definition 613.3, Definition 613.8, Definition 613.9, Definition 613.10, and Definition 613.11 bind the public finite route packet for transported stationary RealUp window reads over Rat$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, and Real$^{\uparrow}$.

Formal verification: FormalStatus(NameCert$_{\text{StationaryDiagonalWindowRoute}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.StationaryDiagonalWindowRouteUp.StationaryDiagonalWindowRoutePacket\_namecert\_obligati`

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient stream equality, selected real limits, host real equality, non-stationary tails, ambient completeness, or bridge checking.

Upgrade path: The next paper obligation is the bridge route for the same stationary Rat$^{\uparrow}$ to StreamName$^{\uparrow}$ to RegSeqRat$^{\uparrow}$ to DyadicRatCore$^{\uparrow}$ to Real$^{\uparrow}$ route packet.

Chapter 614

A Concrete Naming Certificate for $\mathsf{DecompilerRightInverse}^{\uparrow}$

The $\mathsf{DecompilerRightInverse}^{\uparrow}$ interface packages decompilation as a finite right-inverse packet for compiler certificates. It does not assert that every compiler is invertible. It records the special case where a target-to-source decompiler graph, followed by the displayed compiler graph, lands back in the target certificate up to the explicitly recorded optimisation row.

Definition 614.1 (Decompiler right-inverse carrier)**.** *A* $\mathsf{DecompilerRightInverse}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (S, T, K, \Psi, O, R, H, C, P, N)$$

with the following visible rows:

1. *S is the source* $\mathsf{NameCert}$ *row read by the compiler and produced by the decompiler;*
2. *T is the target* $\mathsf{NameCert}$ *row produced by the compiler and read by the decompiler;*
3. *K is the accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet carrying the finite compiler graph from S to T;*
4. *Ψ is the finite target-to-source decompiler graph row from T to S;*
5. *O is the target optimisation row witnessing that the composite $K \circ \Psi$ reads as a* $\mathsf{NameCert}_T$ *endomorphism modulo the displayed target classifier;*
6. *R is the paired right-inverse ledger matching each displayed target row with its decompile-then-compile image through O;*
7. *H records the componentwise* hsame *transports for source certificate rows, target certificate rows, compiler graph edges, decompiler graph edges, optimisation rows, right-inverse rows, package provenance, and the local naming row;*
8. *C records the displayed* Cont *routes for target inspection, decompiler graph readback, source certificate readback, compiler graph readback, optimisation readback, right-inverse comparison, and NameCert exposure;*
9. *P is the* Pkg *provenance row naming* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, $\mathsf{NameCertMorphism}^{\uparrow}$, $\mathsf{CertificateCompiler}^{\uparrow}$, *target optimisation, and the decompiler right-inverse shape;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{DecompilerRightInverse}^{\uparrow}}$ *row.*

The classifier compares accepted packets only through the displayed compiler graph, decompiler graph, target optimisation row, paired right-inverse ledger, hsame *transports,* Cont *routes,* Pkg *provenance, and local naming row. It has no coordinate for a host decompiler function, semantic equivalence oracle, global compiler inverse, or unrecorded target behaviour. The compiler graph row K is consumed through the finite certificate-compiler surface of chapter 473; the decompiler packet adds only the reverse graph, optimisation row, and paired right-inverse ledger on top of that sibling surface.*

Theorem 614.2 (Decompiler right-inverse NameCert obligations)**.** *For the carrier of Definition 614.1, the local* $\mathsf{NameCert}_{\mathsf{DecompilerRightInverse}^{\uparrow}}$ *surface consists exactly of the source certificate row S, target certificate row T, accepted compiler packet K, finite compiler graph K, finite decompiler graph Ψ, target optimisation row O, paired right-inverse ledger R, componentwise* hsame *transports H, displayed* Cont *routes C, package provenance P, and local naming row N.*

Proof. Project the carrier. Each row required to read the decompiler packet is a coordinate of the finite BHist packet before any consumer can ask for the right-inverse comparison.

The compiler side is read through K, so the source-to-target direction is the same finite compiler-certificate graph already licensed by $\mathsf{CertificateCompiler}^{\uparrow}$. The reverse direction is read through Ψ, and it lands back in the displayed source certificate row S rather than in a host source semantics.

The right-inverse clause is the pair (O, R). The row O supplies the target optimisation surface for the composite $K \circ \Psi$, while R records the componentwise target-row comparison that consumes that optimisation row.

Finally the rows H, C, P, N expose transport, continuation, provenance, and local naming for the same packet. There is no remaining coordinate from which a host inverse, semantic equivalence oracle, or unrecorded compiler behaviour could be exported. □

Theorem 614.3 (Decompiler right-inverse non-escape boundary)**.** *Every accepted* $\mathsf{DecompilerRightInverse}^{\uparrow}$ *packet exports decompilation only as the displayed target-to-source graph Ψ together with the target optimisation row O and paired right-inverse ledger R. A consumer may use the packet only through $S, T, K, \Psi, O, R, H, C, P, N$, and cannot read it as a global compiler inverse, host semantic equality, quotient of programs, total decompiler, or optimiser theorem absent from the displayed rows.*

Proof. Inspect the carrier coordinates of Definition 614.1. The only reverse-direction data are the finite graph row Ψ, its routes through C, and its transported comparison rows through H.

The composite comparison is not a hidden inverse law. It is the displayed target optimisation row O together with the paired right-inverse ledger R, so every target read returns to the target certificate through finite packet data.

The package and local naming rows expose exactly those coordinates. Since the carrier has no row for host compiler semantics, program quotients, global invertibility, total decompiler behaviour, or unrecorded optimiser correctness, none of those objects can cross the boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{DecompilerRightInverse}^{\uparrow}}$.

Constructive story: A $\mathsf{DecompilerRightInverse}^{\uparrow}$ packet is generated from source and target NameCert rows, a finite compiler graph, a finite decompiler graph, target optimisation rows, paired right-inverse comparisons, displayed transport, continuation, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{DecompilerRightInverse}^{\uparrow}}$, seed)

Scope closed: Definition 614.1, Definition 614.2, and Definition 614.3 name the finite right-inverse packet surface but do not yet bind a scoped public theorem.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{DecompilerRightInverse}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close existence of decompilers for arbitrary compilers, global invertibility, host semantic equivalence, program quotients, total decompilation, or bridge checking.

Upgrade path: Scoped closure requires a checked finite right-inverse classifier theorem over the displayed compiler graph, decompiler graph, optimisation row, transport routes, package provenance, and local naming row.

Theorem 614.4 (Decompiler right-inverse target-row classifier)**.** *Let*

$$D_i = (S_i, T_i, K_i, \Psi_i, O_i, R_i, H_i, C_i, P_i, N_i) \quad (i = 0, 1)$$

be accepted $\mathsf{DecompilerRightInverse}^{\uparrow}$ *packets in the sense of Definition 614.1. For each i, let G_i be the displayed compiler graph read from the accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet K_i, and let $\rho_i(t_i)$ be a displayed target-row right-inverse comparison in R_i: it starts from a displayed target row t_i of T_i, follows the decompiler graph row Ψ_i to the source certificate, follows G_i back to the target certificate, applies the target optimisation row O_i, and then compares the result with t_i through the paired ledger row R_i.*

Assume the two reads expose the same classifier footprint: G_0 and G_1, Ψ_0 and Ψ_1, O_0 and O_1, and the ledger rows R_0 and R_1 are matched componentwise by the displayed hsame *transports, and the target inspection and right-inverse comparison routes in C_0 and C_1 read those matched rows. Then $\rho_0(t_0)$ is accepted by the* $\mathsf{DecompilerRightInverse}^{\uparrow}$ *target-row classifier exactly when $\rho_1(t_1)$ is accepted. Moreover, the common accepted comparison exports only the displayed compiler graph, decompiler graph, target optimisation row, paired right-inverse ledger,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows; it exports no independent inverse, host decompiler function, semantic equality, quotient of programs, or unrecorded target behaviour.*

Proof. Project the carrier in Definition 614.1. A target-row right-inverse comparison has only one available route: target inspection through T_i, decompiler readback through Ψ_i, compiler readback through the graph displayed by K_i, optimisation readback through O_i, and paired comparison through R_i. These are precisely the rows named in the statement.

The compiler part of the route is finite graph data. By Definition 473.10, an accepted compiler-edge comparison is witnessed only by the displayed graph, landing, transported classifier, and displayed continuation rows of the $\mathsf{CertificateCompiler}^{\uparrow}$ packet. Thus the return from the decompiled source row to the target row is determined by the displayed compiler graph G_i and its recorded route data, not by a host compiler meaning.

The right-inverse part is the pair (O_i, R_i). By Definition 614.2, O_i supplies the target optimisation surface for the composite $K_i \circ \Psi_i$, while R_i records the componentwise target-row comparison that consumes that optimisation row. Hence, once G_i, Ψ_i, O_i, and R_i are fixed up to the displayed componentwise hsame transports and are read through the corresponding routes in C_i, the classifier has no further coordinate on which the two target-row comparisons could differ.

Therefore the comparison in D_0 is accepted exactly when the corresponding comparison in D_1 is accepted: both read the same finite target-row classifier footprint, transported componentwise through H_0 and H_1 and replayed through C_0 and C_1.

Finally apply the non-escape boundary Definition 614.3. It says that an accepted $\mathsf{DecompilerRightInverse}^{\uparrow}$ packet exports decompilation only as Ψ together with O and R, and that every consumer read remains inside $S, T, K, \Psi, O, R, H, C, P, N$. Since the classifier footprint above uses only those rows, the accepted comparison cannot export an independent inverse, host decompiler function, semantic equality, program quotient, or unrecorded target behaviour. □

Chapter 615

A Concrete Naming Certificate for $\mathsf{ObserverSubjectBoundary}^{\uparrow}$

The $\mathsf{ObserverSubjectBoundary}^{\uparrow}$ carrier records the finite observation packet at which an observer-facing consumer may inspect histories without receiving a separate subject carrier. Its rows are histories, transported history-sameness, displayed continuation routes, probe and signature readback, package provenance, and a local naming row. The boundary is therefore a finite BEDC packet over observation rows, not a substance slot behind those rows.

The downstream $\mathsf{ObserverHistIdentity}^{\uparrow}$ surface of chapter 479 consumes this boundary before reading its H, O, L, C, P, N packet. The dependency is the absence of any observer-substance coordinate, so observer-history identity is read as a finite history-and-name packet rather than as a cosmetic reference to a hidden subject.

Definition 615.1 (ObserverSubjectBoundary carrier)**.** *An* $\mathsf{ObserverSubjectBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (R, H, C, B, S, P, N)$$

with the following displayed rows:

1. *R is the finite observation-row ledger, whose entries are* BHist *records of the histories inspected by the observer-facing consumer;*
2. *H stores componentwise* hsame *transport for the observation rows and for the local naming row;*
3. *C stores the displayed* Cont *routes by which the consumer reads observation rows, transports, probe bundles, signature relations, provenance, and local naming;*
4. *B is the finite* ProbeBundle *readback row attached to the same observation ledger;*
5. *S is the* SigRel *readback row recording the signature events visible through B;*
6. *P is the* Pkg *provenance over R, H, C, B, S;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverSubjectBoundary}^{\uparrow}}$ *row.*

There is no coordinate for an observer-substance type, subject identity carrier, hidden owner of the observation rows, or host equality principle outside BHist*,* hsame*,* Cont*,* ProbeBundle*,* SigRel*,* Pkg*, and* NameCert*.*

Lean4 (definition) `BEDC.Derived.ObserverSubjectBoundaryUp.ObserverSubjectBoundaryUp`

Theorem 615.2 (ObserverSubjectBoundary TasteGate carrier alignment)**.** *The displayed rows R, H, C, B, S, P, N of the* ObserverSubjectBoundary$^{\uparrow}$ *carrier are exactly the single-carrier surface checked by the Lean* ChapterTasteGate *theorem. The checked surface consists of* BHist *encode-decode stability, round-trip translation through the observer-subject-boundary event flow, injectivity of that event-flow view, and the empty-history normalization for the same finite observation packet.*

Lean4 ✓ `BEDC.Derived.ObserverSubjectBoundaryUp.ObserverSubjectBoundaryTasteGate single carrier alignment`

Proof. The carrier definition presents one tuple $O = (R, H, C, B, S, P, N)$ and does not add a second subject coordinate. The Lean gate reads the same single carrier through the event-flow encoder and decoder.

Encode-decode stability fixes the BHist row, the round-trip clause returns the displayed ObserverSubjectBoundary packet, and injectivity prevents two distinct displayed packets from sharing one event-flow view. The empty-history normalization identifies the empty observation row as the baseline ledger case for that same carrier. □

Theorem 615.3 (ObserverSubjectBoundary NameCert obligations)**.** *For the carrier of Definition 615.1, the local* NameCert$_{\text{ObserverSubjectBoundary}^{\uparrow}}$ *surface consists exactly of carrier admission for O, observation-row stability, componentwise* hsame *transport, displayed* Cont *route replay,* ProbeBundle *and* SigRel *readback exactness,* Pkg *provenance, and local naming exactness.*

Proof. Carrier admission is projection from the finite packet O. The observation rows R, transports H, routes C, bundle row B, signature row S, package row P, and local name N are the displayed coordinates of the carrier.

The stability obligations are componentwise. Transport through H preserves the observation rows and the local naming row, while the routes in C replay only the listed reads.

Bundle and signature exactness come from the readback rows B and S. Since the carrier has no coordinate beyond R, H, C, B, S, P, N, the local naming certificate is exhausted by the stated finite obligations. □

Theorem 615.4 (ObserverSubjectBoundary no extra subject)**.** *Every accepted* ObserverSubjectBoundary$^{\uparrow}$ *packet exposes an observer boundary only through its finite* BHist *observation rows,* hsame *transport,* Cont *routes,* ProbeBundle *readback,* SigRel *readback,* Pkg *provenance, and local* NameCert *row. No additional observer-substance carrier, subject identity row, hidden owner, or host equality coordinate is exported.*

Proof. Project the accepted packet and inspect the coordinates of Definition 615.1. The only rows available to a consumer are R, H, C, B, S, P, N.

Apply the NameCert obligations from Definition 615.3. They identify transport, route replay, bundle readback, signature readback, package provenance, and local naming as the full certificate surface.

A requested subject carrier would require a coordinate outside the displayed tuple. Because no such coordinate is part of the packet, the accepted boundary cannot export observer-substance, subject identity, hidden ownership, or host equality data. □

Theorem 615.5 (ObserverSubjectBoundary ledger exactness)**.** *For an accepted* ObserverSubjectBoundary$^{\uparrow}$ *packet, every observer-facing read is accounted for by the finite ledger route*

$$R, H, C, B, S, P, N.$$

The ProbeBundle *readback and* SigRel *readback are attached to the same* BHist *observation rows, transported by the same* hsame *row, routed by the same* Cont *row, and recorded under the same* Pkg *and* NameCert *provenance.*

Proof. Start with the observation ledger R. The routes in C read the ledger rows and then reach only the displayed bundle, signature, provenance, and local naming rows.

Use componentwise transport through H to keep the observation rows, bundle readback, and signature readback attached to the same finite packet. The package row P records provenance over those transported rows.

Finally apply the no-extra-subject theorem. Since no outside carrier is exported, every observer-facing read is exactly one of the displayed ledger reads and no hidden subject row can refine the ledger. □

Theorem 615.6 (ObserverSubjectBoundary NameCert package)**.** *The carrier, NameCert obligations, no-extra-subject boundary, and ledger exactness assemble the* $\mathsf{NameCert}_{\mathsf{ObserverSubjectBoundary}^{\uparrow}}$ *package as a finite observer-boundary packet over* BHist*,* hsame*,* Cont*,* ProbeBundle*,* SigRel*,* Pkg*, and local* NameCert *rows. Downstream observer-history consumers receive this package as a finite boundary certificate and not as a separate observer-substance object.*

Proof. Begin with the carrier and obligation theorem. They provide the finite packet and identify the complete local naming surface.

Next use ledger exactness to bind every observer-facing read to the displayed rows R, H, C, B, S, P, N. The readback rows for probes and signatures remain attached to the same observation ledger through the recorded transports and routes.

Finally apply the no-extra-subject theorem. The package delivered to downstream consumers is therefore a finite BEDC boundary certificate, and the absence of an additional subject carrier is part of the package surface rather than an external convention. □

Theorem 615.7 (ObserverSubjectBoundary nontriviality witness)**.** *The empty observation packet and a one-step observation packet are separated by the displayed observation-ledger coordinate* R*. Consequently the* $\mathsf{ObserverSubjectBoundary}^{\uparrow}$ *carrier cannot collapse to* PUnit*: a consumer can distinguish the packet with no inspected* BHist *row from the packet whose ledger contains one inspected* BHist *row before reading the shared* H, C, B, S, P, N *coordinates.*

Proof. Compare the first coordinate of the two packets. In the empty packet, R contains no observation entry; in the one-step packet, R contains one displayed BHist entry.

Projection to R is part of the carrier surface of Definition 615.1. If the carrier collapsed to PUnit, these two packets would have the same observable ledger projection, contradicting the displayed difference between the empty ledger and the one-entry ledger. □

Theorem 615.8 (ObserverSubjectBoundary consumer scope)**.** *Every downstream consumer of an accepted* $\mathsf{ObserverSubjectBoundary}^{\uparrow}$ *packet, including the* $\mathsf{ObserverHistIdentity}^{\uparrow}$ *surface named in this chapter's introduction, receives exactly the rows* R, H, C, B, S, P, N*. The consumer scope is therefore bound to* BHist *observation rows,* hsame *transport,* Cont *replay routes,* ProbeBundle *readback,* SigRel *readback,* Pkg *provenance, and the local* NameCert *row, without adding public export or bridge closure.*

Proof. Project the accepted packet through Definition 615.1. The only consumer-facing coordinates are R, H, C, B, S, P, N.

The introductory $\mathsf{ObserverHistIdentity}^{\uparrow}$ dependency reads this same packet before it forms its history-identity surface. Its available inputs are therefore the displayed history rows, transport rows, route rows, probe and signature readback rows, provenance, and local naming row.

Apply the no-extra-subject and ledger-exactness theorems. They rule out a hidden subject coordinate and bind every read to the finite observer ledger, so the scoped consumer receives a concrete BEDC boundary packet and not a public-object or bridge-checked surface. □

Theorem 615.9 (ObserverSubjectBoundary public nonescape)**.** *The* $\mathsf{ObserverSubjectBoundary}^{\uparrow}$ *packet does not export public observer-substance, subject identity, hidden ownership, host equality, or bridge data. Its nonescaping surface is precisely the finite route*

$$R, H, C, B, S, P, N.$$

Thus a consumer may use the boundary as scoped input for observer-history identity, but may not treat it as a public subject carrier or a bridged schema object.

Proof. Start from the consumer-scope theorem. It identifies the complete consumer route as R, H, C, B, S, P, N and ties each row to BHist, hsame, Cont, ProbeBundle, SigRel, Pkg, and NameCert.

Next apply the no-extra-subject theorem. A public subject carrier, hidden owner, or host equality coordinate would need an additional row outside the displayed packet, and the carrier does not contain one.

Finally read the closure boundary. The chapter supplies scoped consumer witnesses for downstream observer-history use, but it does not introduce a public export theorem or a standard bridge row, so public and bridge closure remain unclaimed. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverSubjectBoundary}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverSubjectBoundary}^{\uparrow}$ packet is generated from finite observation rows, componentwise hsame transport, displayed Cont routes, ProbeBundle readback, SigRel readback, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ObserverSubjectBoundary}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 615.1, Definition 615.2 with

Lean4 ✓ `BEDC.Derived.ObserverSubjectBoundaryUp.taste gate`

, Definition 615.3, Definition 615.4, Definition 615.5, Definition 615.6, Definition 615.7, Definition 615.8, and Definition 615.9 bind the finite observer-boundary carrier, TasteGate surface, local package obligations, ledger exactness, nontrivial observation coordinate, scoped consumer surface, and public nonescape boundary.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ObserverSubjectBoundary}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ObserverSubjectBoundaryUp.ObserverSubjectBoundaryTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close observer-substance, subject identity, a hidden owner of observation rows, host equality, public export, or bridge checking.

Upgrade path: No paper theory-axis grade remains; Lean verification and bridge checking remain independent obligations.

Chapter 616

A Concrete Naming Certificate for $\mathsf{ClosedObservationSystem}^{\uparrow}$

The $\mathsf{ClosedObservationSystem}^{\uparrow}$ carrier turns the closed-observation system of Definition 9393.1 into a finite BEDC packet. It records the current observation state, the finite observation-record ledger, the information-conservation order row, the explicit GAP socket, and the local transport, continuation, provenance, and naming rows needed for downstream inspection. The packet names closed observation as a local finite surface; it does not certify a universal future law or import host induction.

The conservation row G and finite ledger R are the closed-observation specialization of chapter 607. This chapter adds the GAP socket and local $\mathsf{NameCert}$ boundary for requests beyond the displayed finite records.

Definition 616.1 (ClosedObservationSystem carrier)**.** *A* $\mathsf{ClosedObservationSystem}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (O, R, G, H, C, P, N)$$

with the following displayed rows:

1. *O is the observation-state row naming the current finite state of the system;*
2. *R is the finite observation-record ledger accumulated at O;*
3. *G is the information-conservation order row, recording that later visible reads preserve the records already listed in R;*
4. *H stores the componentwise* hsame *transports for O, R, G and the local naming rows;*
5. *C stores the displayed* Cont *routes by which consumers read the observation state, finite ledger, conservation row, GAP socket, package provenance, and local naming row;*
6. *P is the* Pkg *provenance over the same finite observation-ledger packet;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{ClosedObservationSystem}^{\uparrow}}$ *row.*

The GAP socket is the boundary exposed by C when a consumer asks for a universal quantifier, a substrate axiom, or a host induction rule not present in the finite ledger R.

Lean4 ✓ `BEDC.Derived.ClosedObservationSystemUp.ClosedObservationSystemCarrier gap socket package`

Theorem 616.2 (ClosedObservationSystem NameCert obligations)**.** *For the carrier of Definition 616.1, the local* $\mathsf{NameCert}_{\mathsf{ClosedObservationSystem}^{\uparrow}}$ *surface consists of five finite rows: carrier admission for Q; classifier stability for the observation-state row O, record ledger R, and information-conservation row G; GAP-socket exactness for requests beyond the displayed finite records;* Pkg *provenance over O, R, G, H, C; and local naming exactness for N.*

Proof. Carrier admission is projection of the finite tuple Q. The observation state, finite ledger, conservation row, transport, continuation, package, and local naming rows are all visible coordinates of the same BHist packet.

Classifier stability is componentwise. Transport through H preserves the named state O, the finite records in R, and the conservation row G, while C supplies only the displayed read routes.

The GAP-socket row handles the remaining requests. A consumer asking for a universal quantifier, substrate axiom, or host induction rule leaves O, R, G, H, C, P, N, so the local naming row records non-escape rather than an added closure principle. □

Lean4 ✓ `BEDC.Derived.ClosedObservationSystemUp.ClosedObservationSystemNameCertObligations`

Theorem 616.3 (ClosedObservationSystem GAP socket non-escape)**.** *Every accepted* $\mathsf{ClosedObservationSystem}^{\uparrow}$ *packet exports only the finite observation-state row O, finite observation-record ledger R, information-conservation row G, componentwise* hsame *transport H, displayed* Cont *routes C, package provenance P, and local naming row N. A read for universal quantifier closure, substrate axiom import, or host induction reaches the GAP socket and is not exported as an accepted observation record.*

Proof. Read the consumer request through the displayed Cont routes in Definition 616.1. If the request lands in O, R, G, H, C, P, N, the carrier supplies exactly the named finite coordinate.

Apply the NameCert obligations of Definition 616.2. GAP-socket exactness is part of the local surface, so a request outside the finite observation ledger is classified at the boundary rather than added to the ledger.

Thus universal closure, axiom import, and host induction have no exported row in the packet. They remain GAP-facing requests, while the accepted carrier stays a finite observation-ledger surface. □

Lean4 ✓ `BEDC.Derived.ClosedObservationSystemUp.ClosedObservationSystemGapSocketNonescape`

Theorem 616.4 (ClosedObservationSystem primitive scope)**.** *For every accepted* $\mathsf{ClosedObservationSystem}^{\uparrow}$ *carrier*

$$Q = (O, R, G, H, C, P, N),$$

the rows visible to a consumer are scoped by the primitives BHist, hsame, Cont, Pkg, *and* NameCert *together with the observation-conservation sibling of chapter 607. The observation row O, record ledger R, information-conservation row G, transport row H, continuation row C, provenance row P, and local name row N exhaust the primitive interface; no universal quantifier closure, substrate axiom, host induction rule, infinite observation tail, or future-record selector is exported by the packet.*

Proof. Project the carrier of Definition 616.1. Its only data rows are O, R, G, H, C, P, N, and the definition assigns these rows to finite BHist observation data, componentwise hsame transport, displayed Cont reads, Pkg provenance, and the local NameCert row.

The conservation row G is the single nonlocal dependency. It is read through the observation-conservation sibling named in the chapter introduction, so the order information remains an observation-ledger row rather than an ambient temporal law.

Finally apply the GAP socket non-escape theorem, Definition 616.3. Any request outside O, R, G, H, C, P, N reaches the boundary socket and is not reclassified as an accepted observation record. Thus the displayed primitive family is the full scope of the packet. □

Lean4 ✓ `BEDC.Derived.ClosedObservationSystemUp.ClosedObservationSystemPrimitiveScope`

Theorem 616.5 (ClosedObservationSystem bridge-facing handoff)**.** *Every bridge-facing consumer of an accepted* $\mathsf{ClosedObservationSystem}^{\uparrow}$ *carrier*

$$Q = (O, R, G, H, C, P, N)$$

may read only the observation-state row O, the finite observation-record ledger R, the information-conservation row G, the componentwise hsame *transport row H, the displayed* Cont *routes C, the* Pkg *provenance row P, the local* NameCert *row N, and the GAP socket boundary exposed by those continuation routes. The handoff does not export universal quantifier closure, substrate axioms, host induction, infinite observation tails, or future-record selectors.*

Lean4 ✓ `BEDC.Derived.ClosedObservationSystemUp.ClosedObservationSystemBridgeFacingHandoff`

Proof. Project the primitive scope theorem, Definition 616.4. It exhausts the consumer-visible packet by O, R, G, H, C, P, N over the BHist, hsame, Cont, Pkg, and NameCert primitives.

Apply GAP socket non-escape, Definition 616.3. Requests for universal closure, substrate axioms, host induction, infinite tails, or future selectors land at the boundary rather than becoming observation records.

Thus a bridge-facing reader receives exactly the displayed finite rows and the boundary classification of non-exported requests. No additional closure principle or hidden future-record selector is part of the handoff. □

Closure status for $\mathsf{NameCert}_{\mathsf{ClosedObservationSystem}^{\uparrow}}$.

Constructive story: A $\mathsf{ClosedObservationSystem}^{\uparrow}$ packet is generated from an observation-state row, a finite observation-record ledger, an information-conservation order row, a GAP socket, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ClosedObservationSystem}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 616.4 and Definition 616.5 give the mature finite observation-ledger treatment: the primitive rows, GAP non-escape boundary, and bridge-facing handoff are all read over BHist, hsame, Cont, Pkg, and NameCert primitives.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ClosedObservationSystem}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close universal quantifier closure, substrate axiom import, host induction, infinite observation tails, future-record selection, Lean verification, or bridge checking.

Upgrade path: Checked carrier admission, classifier stability, GAP-socket exactness, package provenance, and local naming upgrade the same public observation-ledger surface on the verification axis.

Chapter 617

A Concrete Naming Certificate for $\mathsf{LorentzFrameRate}^{\uparrow}$

The $\mathsf{LorentzFrameRate}^{\uparrow}$ interface records the finite packet at the boundary where $\mathsf{MaxCausalRate}^{\uparrow}$ becomes an observer-symmetric frame-rate ledger. It does not introduce Lorentz geometry, a metric tensor, synchronized clocks, global frames, or host real-valued speed. It names only the BEDC rows by which the maximum-rate surface can be read uniformly across the displayed histories of a multi-Hist configuration.

The packet consumes the multi-history configuration surface of chapter 474, the cross-Hist causal-rate witness surface of chapter 876, and the max-rate read gate of chapter 933 before it exposes the observer-symmetric rate row.

Definition 617.1 (LorentzFrameRate carrier)**.** *A* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (M, X, R, S, H, C, P, N)$$

with the following visible coordinates:

1. *M is an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *row displaying the finite observer-history configuration and its no-global-sync boundary;*
2. *X is the finite family of accepted* $\mathsf{CrossHistCausal}^{\uparrow}$ *witness rows over selected history pairs from M;*
3. *R is an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *row whose witness family is the displayed family X over the same configuration row M;*
4. *S is the observer-symmetry classifier row, recording that each selected observer read of the maximum-rate surface is the same finite unary-bound row of R after componentwise transport;*
5. *H records componentwise* hsame *transport for M, X, R, S, the continuation routes, the package row, and the local naming row;*
6. *C records the visible* Cont *routes from the displayed multi-Hist, causal, maximum-rate, and symmetry rows into the local certificate;*
7. *P is the* Pkg *provenance over* $\mathsf{LorentzFrameRate}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{LorentzFrameRate}^{\uparrow}}$ *row.*

The carrier exports a finite observer-symmetric maximum-rate packet. Its classifier preserves the displayed maximum-rate row under accepted observer transport while excluding global frames, synchronized clocks, metric tensors, host real-valued speed, and Lorentz geometry as primitive input.

Lean4 (definition) `BEDC.Derived.LorentzFrameRateUp.LorentzFrameRateUp`

Theorem 617.2 (LorentzFrameRate boundary)**.** *Every accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier presents the next inter-Hist locality boundary as the finite packet*

$$L = (M, X, R, S, H, C, P, N).$$

A consumer may read the multi-Hist configuration row, the selected cross-Hist causal witnesses, the maximum-rate row, the observer-symmetry classifier, componentwise hsame *transport, visible* Cont *routes, package provenance, and the local* $\mathsf{NameCert}_{\mathsf{LorentzFrameRate}^{\uparrow}}$ *row. No other frame-rate surface is public through this certificate.*

Proof. Project the accepted carrier. The rows M, X, R, S, H, C, P, N are exactly the admitted coordinates of Definition 617.1.

Read M and X first. These rows keep the boundary tied to the displayed multi-Hist configuration and the selected cross-Hist causal witnesses.

Next read R and S. The maximum-rate row supplies the finite unary-bound surface, while the observer-symmetry classifier records that transported observer reads preserve that same displayed row.

Finally route all consumer access through H, C, P, N. The resulting boundary is exhausted by the listed rows, so no additional frame-rate surface is exported. □

Theorem 617.3 (LorentzFrameRate non-escape)**.** *An accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier cannot export a global frame, synchronized clock, metric tensor, host real-valued speed, or Lorentz geometry as a primitive input. Any consumer request for those objects leaves the finite rows*

$$M, X, R, S, H, C, P, N$$

rather than projecting from the local $\mathsf{NameCert}_{\mathsf{LorentzFrameRate}^{\uparrow}}$ *surface.*

Proof. The carrier inventory contains only the displayed multi-Hist row, cross-Hist witness family, maximum-rate row, symmetry classifier, transport rows, continuation routes, provenance, and local naming row.

Apply the non-escape clauses of the upstream $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, and $\mathsf{MaxCausalRate}^{\uparrow}$ certificates. Those rows already exclude global synchronization, unlisted causal witnesses, metric geometry, and ambient real-valued rates from their local surfaces.

The symmetry classifier S adds no coordinate of the excluded kind. It records preservation of the finite maximum-rate row under accepted observer transport, so it cannot become a frame, a clock, a tensor, a host speed, or Lorentz geometry. □

Theorem 617.4 (LorentzFrameRate NameCert obligations)**.** *For the carrier of Definition 617.1, the local* $\mathsf{NameCert}_{\mathsf{LorentzFrameRate}^{\uparrow}}$ *surface consists exactly of carrier admission, configuration inheritance from* $\mathrm{MultiHistConfig}^{\uparrow}$*, causal-witness inheritance from* $\mathsf{CrossHistCausal}^{\uparrow}$*, maximum-rate inheritance from* $\mathsf{MaxCausalRate}^{\uparrow}$*, observer-symmetry preservation of the shared unary-bound row, componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and non-escape for global frames, synchronized clocks, metric tensors, host real-valued speed, and Lorentz geometry as primitive input.*

Proof. Carrier admission is projection from Definition 617.1. The finite packet supplies every row named by the local certificate.

The inherited rows are read in dependency order. The configuration row M supplies the displayed histories, the family X supplies the selected cross-Hist causal witnesses over those histories, and the maximum-rate row R supplies the shared unary-bound surface over the same witnesses.

Observer-symmetry preservation is the role of S. It states that the selected observer reads of R remain the same displayed maximum-rate row after componentwise transport.

The rows H, C, P, N provide the remaining stability, locality, provenance, and local naming data. Since no coordinate of the carrier is a global frame, synchronized clock, metric tensor, host real-valued speed, or Lorentz geometry, the non-escape obligation is the displayed inventory boundary. □

Theorem 617.5 (Frame-rate observer-symmetry transport)**.** *Let*

$$L = (M, X, R, S, H, C, P, N)$$

be an accepted $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier. The observer-symmetry row S transports the displayed maximum-rate row R componentwise under the* hsame *data in H: every selected observer read named by S has the same* $\mathsf{MaxCausalRate}^{\uparrow}$ *unary-bound surface as R after applying the corresponding component of H, and the transported read remains routed through the same finite continuation packet C.*

Proof. Project the accepted carrier and read the symmetry coordinate S. By Definition 617.1, S records exactly the observer reads whose maximum-rate surface is compared with the displayed row R.

Next read the transport coordinate H. Its R- and S-components move the maximum-rate row and each observer-symmetry read together, so the comparison is componentwise rather than a global frame comparison.

Finally use the continuation coordinate C. It keeps every transported observer read on the displayed route from M and X to R and then to the local certificate, so the shared unary-bound surface is preserved as a finite $\mathsf{MaxCausalRate}^{\uparrow}$ row. □

Theorem 617.6 (Frame-rate rate-row inheritance)**.** *For an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier*

$$L = (M, X, R, S, H, C, P, N),$$

the maximum-rate row R is inherited only from the same upstream $\mathrm{MultiHistConfig}^{\uparrow}$ *row M and* $\mathsf{CrossHistCausal}^{\uparrow}$ *witness family X displayed by the carrier. No consumer of L may read R as a rate row over a different configuration, an unlisted causal-witness family, or an ambient host geometry.*

Proof. The carrier definition binds R to M and X: R is the accepted $\mathsf{MaxCausalRate}^{\uparrow}$ row whose witness family is the displayed family X over the same configuration row M.

The continuation routes preserve this dependency. A consumer reaches R only through the visible route from the multi-Hist configuration row to the selected cross-Hist causal witnesses and then to the maximum-rate row.

The provenance row P records the same dependency surface. Since neither the carrier nor the provenance row contains a different configuration, an unlisted witness family, or an ambient geometry coordinate, the inheritance of R is limited to the displayed M and X rows. □

Theorem 617.7 (Frame-rate locality non-escape)**.** *The local packet*

$$M, X, R, S, H, C, P, N$$

does not recover a global frame, synchronized clock, metric tensor, host real speed, or Lorentz geometry. These objects are not hidden consequences of observer-symmetry transport, rate-row inheritance, or the local $\mathsf{NameCert}_{\mathsf{LorentzFrameRate}^{\uparrow}}$ *surface.*

Proof. Start with the non-escape theorem for the chapter. It excludes global frames, synchronized clocks, metric tensors, host real-valued speed, and Lorentz geometry as primitive inputs of the carrier.

Observer-symmetry transport adds no excluded coordinate. It moves the displayed maximum-rate row componentwise under hsame and keeps the read on the visible continuation route.

Rate-row inheritance also adds no excluded coordinate. It ties R only to the displayed multi-Hist configuration M and the selected cross-Hist witness family X.

Thus the local certificate remains a finite observer-symmetric maximum-rate packet. Recovering any excluded structure would require data outside M, X, R, S, H, C, P, N. □

Theorem 617.8 (Frame-rate configuration causal inheritance)**.** *For an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier*

$$L = (M, X, R, S, H, C, P, N),$$

the coordinates M, X, R are consumed in dependency order. The multi-Hist row M supplies the displayed observer-history configuration, the family X supplies only $\mathsf{CrossHistCausal}^{\uparrow}$ *witness rows over selected history pairs from M, and the maximum-rate row R supplies only the* $\mathsf{MaxCausalRate}^{\uparrow}$ *row whose witness family is that displayed X over the same M.*

Proof. Project the carrier and read the first three computational coordinates. The definition of the carrier names M before X, because the selected causal witnesses are meaningful only over the displayed multi-Hist configuration.

Read X next. Each row in the family is a $\mathsf{CrossHistCausal}^{\uparrow}$ witness row for selected history pairs from M, so the family cannot select a history outside the configuration already displayed by M.

Finally read R. The maximum-rate row is the accepted $\mathsf{MaxCausalRate}^{\uparrow}$ row over the same configuration and the same selected witness family. Thus consumer access to R factors through M and then X, and no alternate configuration or witness family is available through the local packet. □

Theorem 617.9 (Frame-rate symmetry classifier exactness)**.** *For an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier*

$$L = (M, X, R, S, H, C, P, N),$$

the rows S, H, C compare only transported maximum-rate rows. The observer-symmetry classifier S may identify selected observer reads of the displayed $\mathsf{MaxCausalRate}^{\uparrow}$ *row R after componentwise* hsame *transport in H and visible routing in C; it cannot introduce a global frame, synchronized clock, metric tensor, host real-valued speed, Lorentz geometry, or a rate row not inherited from M, X, R.*

Proof. Start with the role of S. By Definition 617.1, the classifier records equality of selected observer reads only as preservation of the displayed maximum-rate surface of R after componentwise transport.

Now apply the transport and route coordinates. The H row moves the R- and S-components together by hsame, while C keeps the transported read on the visible continuation route through the same local certificate.

The excluded structures are absent from every compared coordinate. Since S, H, C mention only the transported $\mathsf{MaxCausalRate}^{\uparrow}$ row and the local route that reaches it, the classifier has no coordinate from which to manufacture a global frame, synchronized clock, metric tensor, host real-valued speed, Lorentz geometry, or an unrelated rate row. □

Theorem 617.10 (LorentzFrameRate TasteGate obligation package)**.** *The* $\mathsf{LorentzFrameRate}^{\uparrow}$ *chapter presents the obligation surface*

$$M, X, R, S, H, C, P, N$$

as a single finite package: carrier admission is Definition 617.1; inherited-row exactness is given by Definition 617.8; observer-symmetry transport is given by Definition 617.5 and Definition 617.9; provenance is the row P; locality is the row C; non-escape is Definition 617.7; and the existing TasteGate marker attached to Definition 617.1 records that this AI-origin carrier is admitted only at the displayed single-carrier surface.

Proof. Carrier admission is the finite packet definition. It exposes precisely the eight coordinates M, X, R, S, H, C, P, N and no ambient Lorentz-geometric structure.

The inherited-row obligations are discharged by reading the dependency chain in order. The configuration row M feeds the causal witness family X, and those two rows feed the maximum-rate row R.

The observer-symmetry obligations are discharged by the two classifier theorems. They compare selected observer reads only after componentwise hsame transport and visible continuation routing, so the comparison remains a statement about the same finite maximum-rate row.

The remaining obligations are local bookkeeping. The row P records provenance, C records the visible continuation routes, Definition 617.7 supplies non-escape, and the TasteGate marker already attached to the carrier records the AI-origin admission boundary without adding a second marker at this theorem site. □

Theorem 617.11 (LorentzFrameRate upstream row coherence)**.** *For an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier*

$$L = (M, X, R, S, H, C, P, N),$$

the rows M, X, and R form one coherent upstream surface. Every row of the family X is a $\mathsf{CrossHistCausal}^{\uparrow}$ *witness over the displayed* $\mathrm{MultiHistConfig}^{\uparrow}$ *row M, and the row R is the* $\mathsf{MaxCausalRate}^{\uparrow}$ *maximum-rate row over exactly that displayed X-family and the same configuration row M.*

Lean4 ✓ `BEDC.Derived.LorentzFrameRateUp.LorentzFrameRateUpstreamRowCoherence`

Proof. Project the carrier $L = (M, X, R, S, H, C, P, N)$. The first three coordinates are not independent imports: the definition binds X to selected history pairs from M and binds R to the same displayed witness family.

Apply Definition 617.6. It states that a consumer may read R only over the same upstream $\mathrm{MultiHistConfig}^{\uparrow}$ row M and $\mathsf{CrossHistCausal}^{\uparrow}$ witness family X, and not over a different configuration, unlisted witness family, or ambient host geometry.

Thus the upstream surface available through L is the single displayed chain M to X to R. □

Theorem 617.12 (LorentzFrameRate symmetry classifier totality)**.** *For an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier*

$$L = (M, X, R, S, H, C, P, N),$$

every observer-symmetry read factors through the classifier row S together with the componentwise transport row H and the displayed continuation row C. No observer-symmetry read exports a hidden global frame, synchronized clock, metric tensor, host real-valued speed, Lorentz geometry, or rate row outside the displayed upstream surface.

Proof. Read the classifier coordinate first. By Definition 617.5, S compares selected observer reads of the displayed maximum-rate row R only after componentwise hsame transport in H and along the same finite continuation packet C.

Then apply Definition 617.7. The transported comparison has no route to a global frame, synchronized clock, metric tensor, host real speed, or Lorentz geometry.

Finally combine this with Definition 617.11. Since the rate row being compared is still the displayed R over M and X, the classifier is total only over the local packet surface and not over an ambient observer frame or clock. □

Theorem 617.13 (LorentzFrameRate obligation closure package)**.** *The* $\mathsf{LorentzFrameRate}^{\uparrow}$ *chapter closes the local* $\mathsf{NameCert}_{\mathsf{LorentzFrameRate}^{\uparrow}}$ *obligation surface for*

$$M, X, R, S, H, C, P, N.$$

Carrier admission is Definition 617.1; upstream row coherence is Definition 617.11; symmetry classifier totality is Definition 617.12; transport locality is Definition 617.5; provenance is the row P; locality is the row C; non-escape is Definition 617.7; and the existing TasteGate marker on the AI-origin carrier records the single-carrier admission boundary.

Proof. Carrier admission is the finite packet definition. It displays exactly the rows M, X, R, S, H, C, P, N and supplies the local $\mathsf{NameCert}_{\mathsf{LorentzFrameRate}^{\uparrow}}$ row without adding global geometric input.

The upstream and classifier obligations are now explicit. The upstream coherence theorem binds M, X, and R as one dependency surface, while the classifier totality theorem forces observer-symmetry reads through S, H, C over that same surface.

The remaining rows complete the certificate boundary. Transport locality is supplied by the observer-symmetry transport theorem, provenance is recorded by P, visible continuation by C, and non-escape by the locality theorem. The TasteGate marker already attached to the carrier remains the Lean-side admission marker for this AI-origin single-carrier surface. □

Theorem 617.14 (LorentzFrameRate standard bridge surface)**.** *For an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *bridge-facing packet*

$$L = (M, X, R, S, H, C, P, N),$$

the public bridge surface is exactly the $\mathrm{MultiHistConfig}^{\uparrow}$ *row M, the* $\mathsf{CrossHistCausal}^{\uparrow}$ *witness family X, the* $\mathsf{MaxCausalRate}^{\uparrow}$ *row R, the observer-symmetry classifier S, and the support rows H, C, P, N. The surface exports no metric tensor, synchronized clock, host real-valued speed, global Lorentz frame, or Lorentz geometry as bridge input.*

Proof. Read the carrier definition first. The packet of Definition 617.1 displays only M, X, R, S, H, C, P, N, with M giving the multi-Hist configuration, X giving the selected cross-Hist causal witnesses, and R giving the inherited maximum-rate row.

Next read the classifier and support rows. Theorems 617.5 and 617.12 route observer-symmetry reads through S, H, C, while P and N record package provenance and local naming.

Finally apply Definition 617.7. It excludes metric tensors, synchronized clocks, host real-valued speed, global Lorentz frames, and Lorentz geometry, so the bridge-facing surface is exactly the displayed finite packet. □

Theorem 617.15 (LorentzFrameRate observer-clock refusal)**.** *For an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier*

$$L = (M, X, R, S, H, C, P, N),$$

the rows M, X, R, S, H, C, P, N *expose no synchronized clock and no global observer frame. Every public observer-facing read remains a finite* BHist*-grounded read of the multi-Hist configuration, selected causal witnesses, maximum-rate row, observer-symmetry classifier, componentwise transport, continuation, provenance, and local name.*

Proof. Start from the carrier of Definition 617.1. Its displayed coordinates are the finite BHist rows M, X, R, S, H, C, P, N, with no clock row, frame row, metric tensor row, or host real-valued speed row.

Use Definition 617.11. It binds the source side of the packet to M, X, R, so the maximum-rate read is inherited from the displayed configuration and causal-witness family rather than from an ambient observer frame.

Apply Definition 617.12. The observer-symmetry classifier is routed through S, H, C over the same upstream surface, so an observer-facing read cannot introduce a synchronized clock as classifier input.

Finally invoke Definition 617.7. The non-escape boundary excludes synchronized clocks, global frames, metric tensors, host real-valued speed, and Lorentz geometry; the support rows P, N record only provenance and local naming for the same finite packet. □

Theorem 617.16 (LorentzFrameRate rate-row ledger exhaustion)**.** *Every public rate read of an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier exhausts its rate ledger at the rows* M, X, R *with support from* S, H, C, P, N*. The packet has no remaining coordinate from which a second maximum-rate row, host speed value, metric witness, synchronized clock, or global observer frame can be read.*

Proof. Project the carrier definition Definition 617.1. The only displayed rate row is R, and it is packaged together with the configuration row M, the selected causal-witness family X, and the support rows S, H, C, P, N.

Apply Definition 617.11. This forces any read of R to remain over the same M and X rows, exhausting the upstream part of the ledger at the displayed triple.

Use Definition 617.12 to account for the observer-facing support. The classifier row S, transport row H, and continuation row C only transport and replay the displayed maximum-rate comparison; they do not add a second rate coordinate.

Finally combine the support rows with Definition 617.7. Provenance and local naming record P, N, while non-escape excludes host speed values, metric witnesses, synchronized clocks, and global observer frames. Therefore the public rate ledger is exhausted by M, X, R with exactly the stated support. □

Theorem 617.17 (LorentzFrameRate multi-Hist causal-rate handoff)**.** *Every public rate read of an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier consumes* $\mathrm{MultiHistConfig}^{\uparrow}$*, then* $\mathsf{CrossHistCausal}^{\uparrow}$*, then* $\mathsf{MaxCausalRate}^{\uparrow}$ *in that order. The handoff route is*

$$M \longmapsto X \longmapsto R \longmapsto S, H, C, P, N,$$

and no consumer can read the maximum-rate row before the multi-Hist configuration and cross-Hist causal-witness rows have been consumed.

Proof. Read the carrier of Definition 617.1. It displays the source spine as M, X, R, followed by the observer-symmetry classifier, transport, continuation, provenance, and local naming rows.

Apply Definition 617.11. This theorem makes R dependent on the same multi-Hist configuration M and selected cross-Hist causal witnesses X, so the rate row cannot be consumed before those source rows.

Use Definition 617.12. Every public observer-facing rate read then passes through S, H, C over the already consumed M, X, R surface.

Finally combine the route with Definition 617.7. Since the packet exports no global frame, synchronized clock, metric tensor, host real-valued speed, or Lorentz geometry, there is no alternate handoff path around the displayed $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, and $\mathsf{MaxCausalRate}^{\uparrow}$ order. □

Theorem 617.18 (LorentzFrameRate observer-symmetry bridge route)**.** *Every observer-symmetric rate read of an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *packet*

$$L = (M, X, R, S, H, C, P, N)$$

factors through S, H, C and through the inherited upstream route M, X, R before any downstream bridge consumer can cite the packet. Thus a bridge consumer cites only the transported observer-symmetry classifier over the displayed $\mathrm{MultiHistConfig}^{\uparrow}$*,* $\mathsf{CrossHistCausal}^{\uparrow}$*, and* $\mathsf{MaxCausalRate}^{\uparrow}$ *rows.*

Proof. Start with the classifier route. By Definition 617.12, every observer-symmetry read is forced through S, H, C and remains a comparison of transported maximum-rate rows.

Now attach the inherited upstream surface. Theorem 617.11 binds the compared maximum-rate row to M, X, R, so the observer-symmetric read cannot be cited without the multi-Hist configuration and causal-witness family that support R.

Finally combine this route with Definition 617.14. The bridge-facing packet has no public entry point outside M, X, R, S, H, C, P, N, so downstream citation must pass through the classifier route and the inherited upstream route first. □

Theorem 617.19 (LorentzFrameRate root route totality)**.** *For every public observer-symmetry read of an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *carrier*

$$L = (M, X, R, S, H, C, P, N),$$

the read follows the displayed root route

$$M \longmapsto X \longmapsto R \longmapsto S \longmapsto H, C \longmapsto P, N.$$

The route first reads the finite multi-Hist configuration row, then the selected cross-Hist causal witness family, then the maximum-rate row over that family, then the observer-symmetry classifier, then the componentwise hsame *and visible* Cont *rows, and finally the package and local naming rows. No observer-symmetry consumer has a public entry point outside this route.*

Lean4 ✓ `BEDC.Derived.LorentzFrameRateUp.LorentzFrameRateRootRouteTotality`

Proof. Project the carrier of Definition 617.1. Its coordinates are ordered as the root route in the statement: configuration row, selected causal witnesses, maximum-rate row, observer-symmetry classifier, transport and continuation rows, package provenance, and local name.

Use Definition 617.11 to bind M, X, R as one upstream surface. Then use Definition 617.12 to route every observer-symmetry read through S, H, C over that same surface.

Finally apply Definition 617.13. It repacks the upstream coherence, classifier totality, transport, locality, provenance, and local naming rows as the public obligation surface, so the root route is total for public observer-symmetry reads. □

Theorem 617.20 (LorentzFrameRate root non-escape ledger)**.** *The root route of Definition 617.19 exports no global frame, synchronized clock, metric tensor, host real-valued speed, or Lorentz geometry. Each public read remains inside the finite rows M, X, R, S, H, C, P, N and can consume only the displayed observer-history configuration, selected causal witnesses, maximum-rate row, symmetry classifier, transport, route, provenance, and local naming data.*

Proof. Start with Definition 617.7. It excludes the global frame, synchronized clock, metric tensor, host real speed, and Lorentz geometry coordinates from the local packet.

Then use Definition 617.19. Every public observer-symmetry read must pass through the same displayed route, so an excluded object could be exported only if one of the listed coordinates already contained it.

The carrier definition and the non-escape theorem rule out that possibility. The route therefore records a non-escape ledger for downstream root consumers, not a primitive Lorentz-geometric structure. □

Theorem 617.21 (LorentzFrameRate root public package)**.** *The* $\mathsf{LorentzFrameRate}^{\uparrow}$ *public root package is assembled from the carrier of Definition 617.1, upstream coherence Definition 617.11, symmetry classifier totality Definition 617.12, root route totality Definition 617.19, and the non-escape ledger Definition 617.20. It is the finite* BHist*-anchored surface consumed by downstream frame-rate chapters over*

$$M, X, R, S, H, C, P, N.$$

Proof. Carrier admission supplies the finite rows M, X, R, S, H, C, P, N. Upstream coherence binds M, X, R as one displayed source surface, while classifier totality binds every observer-symmetry read to S, H, C over that surface.

Route totality then orders the public read from the configuration row through the witness family, maximum-rate row, symmetry classifier, transport and continuation rows, package provenance, and local name. The non-escape ledger records that the same route exports no global frame, synchronized clock, metric tensor, host real speed, or Lorentz geometry.

Repacking these rows gives the downstream root package. It is public because every consumer-facing read is routed through the displayed carrier rows, and it remains finite because no coordinate outside the carrier participates in the package. □

Theorem 617.22 (LorentzFrameRate mature route completeness)**.** *Every downstream mature read of an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *packet factors through the displayed rows*

$$M, X, R, S, H, C, P, N.$$

The only admissible route is the one assembled from the $\mathrm{MultiHistConfig}^{\uparrow}$ *source row, the* $\mathsf{CrossHistCausal}^{\uparrow}$ *witness surface, the* $\mathsf{MaxCausalRate}^{\uparrow}$ *maximum-rate row, the observer-symmetry classifier, the*

hsame *transport row, the* Cont *replay row, package provenance, the local* NameCert *row, and the public root package of Definition 617.21. In particular, a mature consumer obtains no global frame, synchronized clock, metric tensor, host real-valued speed, Lorentz geometry, or Lean-side bridge check from this packet.*

Proof. First fix the row spine. The carrier of Definition 617.1 supplies the rows M, X, R, S, H, C, P, N, and Definition 617.11 binds the M, X, R rows as one upstream surface rather than three independent sources.

Next route every observer read. Apply Definition 617.12 to force the observer-symmetry classifier through the displayed configuration, witness, and maximum-rate rows, and apply Definition 617.19 to pass that classifier through the transport, replay, provenance, and local naming rows.

The excluded coordinates are accounted for by Definition 617.20. It rules out global frames, synchronized clocks, metric tensors, host real-valued speed, and Lorentz geometry along the same public route, while Lean-side bridge checking is not a carrier coordinate.

Finally use Definition 617.21. The public package is exactly the finite root surface made from the preceding rows, so any downstream mature read of an accepted packet factors through that surface and through no additional ambient structure. □

Closure status for $\mathsf{NameCert}_{\mathsf{LorentzFrameRate}^{\uparrow}}$.

Constructive story: A $\mathsf{LorentzFrameRate}^{\uparrow}$ packet is generated from a $\mathrm{MultiHistConfig}^{\uparrow}$ row, finitely many $\mathsf{CrossHistCausal}^{\uparrow}$ witness rows, one $\mathsf{MaxCausalRate}^{\uparrow}$ maximum-rate row over the same configuration, an observer-symmetry classifier, finite hsame and Cont transports, package provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.LorentzFrameRateUp.taste gate`

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{LorentzFrameRate}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 617.1, Definition 617.11, Definition 617.12, Definition 617.13, Definition 617.5, Definition 617.7, Definition 617.14, Definition 617.15, Definition 617.16, Definition 617.17, Definition 617.18, Definition 617.21, and Definition 617.22 bind the finite observer-symmetric maximum-rate packet and its mature downstream route over MultiHistConfig, CrossHistCausal, MaxCausalRate, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{LorentzFrameRate}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.LorentzFrameRateUp.LorentzFrameRateTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lorentz geometry, metric tensors, light-cone distance, synchronized clocks, global frames, host real-valued speed, curved spacetime, or Lean-side verification.

Upgrade path: No further paper-side theory closure grade remains for the finite Lorentz frame-rate route; verification and bridge checking remain separate axes.

Chapter 618

A Concrete Naming Certificate for $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$

The $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ interface records the finite mesh-budget route by which a diagonal Real-completion consumer turns a precision request into a bounded family of inspected windows and then into a $\mathsf{Real}^{\uparrow}$ seal read. It refines the selected-window surface of chapter 561 by adding finite mesh budget, dyadic tolerance, and aggregation rows before the $\mathsf{Real}^{\uparrow}$ seal handoff.

It also consumes the finite observation-budget boundary of chapter 611. The precision request, selected $\mathsf{StreamName}^{\uparrow}$ windows, dyadic ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback rows, and $\mathsf{Real}^{\uparrow}$ seal are the same finite observation surface, with the extra mesh-budget and diagonal aggregation rows inserted before the seal handoff.

Definition 618.1 (Real diagonal mesh-budget carrier)**.** *A* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (q, b, \omega, \rho, \delta, \theta, e, h, c, p, n)$$

with the following visible coordinates:

1. *q is the rational precision request read through the displayed* $\mathsf{Rat}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows;*
2. *b is the finite mesh budget, listing the inspected diagonal indices and the dyadic radii assigned to them;*
3. *ω is the* $\mathsf{StreamName}^{\uparrow}$ *window family selected by b;*
4. *ρ is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback family attached to those selected windows;*
5. *δ is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger recording the tolerance split, endpoint rows, radius comparisons, and mesh-bound checks;*
6. *θ is the diagonal aggregation row stating that the finite windows in ω cover the requested diagonal packet under the budget b;*
7. *e is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after $q, b, \omega, \rho, \delta, \theta$ have been displayed;*
8. *h records componentwise* hsame *transports for the precision request, mesh budget, selected windows, readback family, dyadic ledger, aggregation row, seal row, provenance, and local name;*
9. *c records the displayed* Cont *routes from q to b, from b to ω, from ω to ρ, from ρ to δ, from δ to θ, and from θ to e;*

10. *p is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*

11. *n is the local* $\mathsf{NameCert}_{\mathsf{RealDiagonalMeshBudget}^{\uparrow}}$ *row.*

The carrier contains no infinite mesh, no quotient stream, no host real equality, no ambient completeness theorem, no selected limiting representative, and no open-cover compactness row.

Theorem 618.2 (Real diagonal mesh-budget NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RealDiagonalMeshBudget}^{\uparrow}}$ *surface for Definition 618.1 consists exactly of carrier admission for M, precision exposure through q, finite mesh-budget exposure through b, selected* $\mathsf{StreamName}^{\uparrow}$ *window coverage through ω,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback through ρ, dyadic tolerance-ledger exactness through δ, diagonal packet aggregation through θ,* $\mathsf{Real}^{\uparrow}$ *seal handoff through e, componentwise* hsame *transport through h, displayed* Cont *route replay through c,* Pkg *provenance through p, and local naming through n.*

Proof. Carrier admission is projection from the displayed packet M. The rows $q, b, \omega, \rho, \delta, \theta, e, h, c, p, n$ list the precision request, finite mesh budget, selected windows, regular rational readbacks, dyadic tolerance ledger, aggregation row, real seal, transports, continuations, provenance, and local name.

The mesh-budget obligations are finite. A consumer reads q, then reads the budget b, inspects only the window family ω selected by that budget, and then reads the rational family ρ together with the dyadic ledger δ.

The aggregation row θ records that the displayed windows cover the requested diagonal packet before the seal row e is exported. The rows h, c, p, n account for transport, route replay, provenance, and local naming, so the local surface is exhausted by the displayed packet. □

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier namecert obligations`

Theorem 618.3 (Real diagonal mesh-budget window coverage)**.** *Every diagonal observation exported from an accepted* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *carrier factors through the finite mesh budget b, the selected* $\mathsf{StreamName}^{\uparrow}$ *window family ω, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback family ρ, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger δ, and the aggregation row θ.*

No exported observation may range over an infinite mesh, inspect an unlisted stream window, use quotient equality of completed names, or appeal to ambient Real completeness.

Proof. Project the carrier rows $b, \omega, \rho, \delta, \theta$. The budget b lists the inspected diagonal indices and radii, while ω and ρ provide the selected windows and rational readbacks.

Apply the NameCert obligations of Definition 618.2. They route every observation through the precision request, budget, selected-window family, readback family, dyadic ledger, and aggregation row before any seal-facing read is available.

Since the carrier has no coordinate for an infinite mesh, unlisted stream window, quotient equality, or ambient completeness, a downstream diagonal observation can only use the displayed finite coverage route. □

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier window coverage`

Theorem 618.4 (Real diagonal mesh-budget monotonicity)**.** *Let*

$$M = (q, b, \omega, \rho, \delta, \theta, e, h, c, p, n)$$

and

$$M' = (q, b', \omega, \rho, \delta, \theta, e, h, c, p, n)$$

be accepted RealDiagonalMeshBudget$^{\uparrow}$ *packets whose precision request and route rows agree. Suppose the finite budget b' contains every inspected index and radius row of b, and suppose the selected* StreamName$^{\uparrow}$ *windows ω,* RegSeqRat$^{\uparrow}$ *readbacks ρ,* DyadicRatCore$^{\uparrow}$ *ledger rows δ, and aggregation row θ are preserved as the same displayed rows. Then every* Real$^{\uparrow}$ *seal read admitted by the smaller budget b is admitted by the larger displayed budget b'. The enlargement adds no infinite mesh, quotient stream, host real equality, or ambient completeness row.*

Proof. Project the two accepted carriers. The shared rows $q, \omega, \rho, \delta, \theta, e, h, c, p, n$ fix the precision request, selected windows, readbacks, dyadic ledger, aggregation row, seal endpoint, transports, continuation routes, provenance, and local name.

Use the NameCert obligations of Definition 618.2. They make the finite budget row the only place where inspected indices and radii can enter the packet. Since b' contains every inspected row of b, each budget read used by the smaller packet is still visible in the larger packet.

Apply Definition 618.3. The admitted diagonal observation for the smaller budget already factors through the preserved rows $\omega, \rho, \delta, \theta$, so replacing b by b' does not change the visible selected-window route.

Finally replay Definition 618.6 through the shared rows. The same route reaches the same seal row e through $q, b', \omega, \rho, \delta, \theta, h, c, p, n$, and the carrier has no coordinate for an infinite mesh, quotient stream, host real equality, or ambient completeness witness. □

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier budget monotonicity`

Theorem 618.5 (Real diagonal mesh-budget selected-window refinement)**.** *Every accepted* RealDiagonalMeshBudge *packet determines a* RealDiagonalWindowCoverage$^{\uparrow}$ *selected-window surface by projecting the precision row q, mesh budget b, selected* StreamName$^{\uparrow}$ *windows ω,* RegSeqRat$^{\uparrow}$ *readbacks ρ,* DyadicRatCore$^{\uparrow}$ *tolerance ledger δ, and aggregation row θ.*

The projected surface preserves componentwise hsame *transport, displayed* Cont *route replay, and* Pkg *provenance from the original packet. It adds no unlisted window, quotient stream, host real equality, or ambient completeness row.*

Proof. Project the carrier rows named in Definition 618.1. The coordinates $q, b, \omega, \rho, \delta, \theta$ are already displayed before the seal row, and the same packet records the transport, continuation, and provenance rows h, c, p.

Apply the local surface description of Definition 618.2. It exhausts the accepted packet by the precision request, finite mesh budget, selected windows, readback family, dyadic ledger, aggregation row, transport, route replay, provenance, and local naming rows.

Use Definition 618.3 on the projected window data. It identifies the visible selected-window route consumed by RealDiagonalWindowCoverage$^{\uparrow}$ and rules out any read through an unlisted window, quotient stream, host real equality, or ambient completeness row. □

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier selected window refinement`

Theorem 618.6 (Real diagonal mesh-budget RealUp handoff)**.** *Every* Real$^{\uparrow}$ *completion or continuous-map consumer of an accepted* RealDiagonalMeshBudget$^{\uparrow}$ *carrier receives the seal row e only through the displayed route*

$$q, b, \omega, \rho, \delta, \theta, h, c, p, n.$$

Thus the handoff consumes a rational precision request, a finite mesh budget, selected StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readbacks, a* DyadicRatCore$^{\uparrow}$ *tolerance ledger, a diagonal aggregation row,*

componentwise transport, route replay, package provenance, and local naming before the $\mathsf{Real}^{\uparrow}$ *seal is read.*

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier realup handoff`

Proof. Start with the seal coordinate e. It is the only $\mathsf{Real}^{\uparrow}$ row in the carrier and is listed after the precision, mesh-budget, window, readback, dyadic-ledger, and aggregation rows.

Use Definition 618.3. It shows that the diagonal packet presented to a real-facing consumer has already been confined to the finite windows and dyadic tolerances selected by b.

The rows h and c replay the displayed transports and continuations, while p and n provide provenance and local naming. Therefore the seal is reached exactly through the displayed route and not through a hidden completeness or quotient-equality coordinate. □

Theorem 618.7 (Real diagonal mesh-budget seal-route exactness)**.** *For an accepted* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *carrier*

$$M = (q, b, \omega, \rho, \delta, \theta, e, h, c, p, n),$$

a $\mathsf{Real}^{\uparrow}$ *seal read is admitted precisely when it is routed through* $q, b, \omega, \rho, \delta, \theta$ *with the displayed* h, c, p, n *rows before the row* e *is read.*

Any proposed $\mathsf{Real}^{\uparrow}$ *seal read missing one of the precision request, finite mesh budget, selected-window family, readback family, dyadic ledger, aggregation row, componentwise transport, continuation route, provenance, or local* NameCert *row is outside the carrier.*

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier seal route exactness`

Proof. Project the accepted carrier. The coordinates $q, b, \omega, \rho, \delta, \theta, e, h, c, p, n$ are the full packet, and Definition 618.2 identifies them as the complete local NameCert inventory.

For the admitted direction, use Definition 618.3 and Definition 618.5. They confine the selected-window side to the finite route through $b, \omega, \rho, \delta, \theta$ and preserve the displayed transport, continuation, and provenance rows.

Then apply Definition 618.6. It states that a real-facing consumer reaches e only after the displayed route through $q, b, \omega, \rho, \delta, \theta, h, c, p, n$ has been traversed.

For the excluded direction, remove any one of those rows from a proposed seal read. The NameCert inventory has no alternate carrier coordinate for the missing datum, and the selected-window and RealUp handoff results provide no hidden quotient, host equality, ambient completeness, or unlisted window route. Such a read is therefore not a read from the accepted carrier. □

Theorem 618.8 (Real diagonal mesh-budget observation-budget handoff)**.** *Let* $M = (q, b, \omega, \rho, \delta, \theta, e, h, c, p, n)$ *be an accepted* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *packet, and let an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet display the same precision request, selected-window family, dyadic ledger, regular readback rows, and seal rows as a finite observation packet*

$$E, W, D, R, S, H, C, P, N.$$

Then every $\mathsf{Real}^{\uparrow}$ *seal read of* M *factors through that observation budget before the seal row is consumed. The handoff exports no quotient stream, host real equality, ambient completeness, hidden limit selection, or unbounded observation schedule.*

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier observation budget handoff`

Proof. Start with mesh-budget seal-route exactness. It admits a seal read only through the displayed precision request, finite mesh budget, selected windows, readbacks, dyadic ledger, aggregation row, and structural rows before e is read.

Next use mesh-budget window coverage. The selected-window family in M is already finite and is tied to the same request and dyadic ledger that the observation-budget packet records.

Now read the observation-budget side. Request totality supplies the finite observation request, consumer exactness identifies the regular-rational and real-facing reads with that packet, and the seal boundary places every $\mathsf{Real}^{\uparrow}$ seal read after $E, W, D, R, S, H, C, P, N$.

Finally apply observation-budget non-escape. Since the budget packet carries no quotient stream, host equality, ambient completeness, hidden selector, or unbounded schedule coordinate, the mesh-budget seal consumer receives exactly the finite observation-budget handoff. □

Theorem 618.9 (Real diagonal mesh-budget non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *packet factors through the finite rows*

$$q, b, \omega, \rho, \delta, \theta, e, h, c, p, n.$$

The consumer may read the rational precision request, finite mesh budget, selected $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, diagonal aggregation row,* $\mathsf{Real}^{\uparrow}$ *seal,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row, and it cannot read infinite-mesh data, quotient streams, host real equality, ambient completeness, selected limits, or open-cover compactness.*

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier nonescape`

Proof. Project the accepted carrier and the local NameCert surface. The rows $q, b, \omega, \rho, \delta, \theta, e, h, c, p, n$ are the complete displayed packet.

Use the window-coverage theorem for observation-facing consumers. It confines every diagonal read to the finite mesh budget, selected windows, regular rational readbacks, dyadic tolerance ledger, and aggregation row.

Use the RealUp handoff theorem for seal-facing consumers. It routes every completion or continuous-map read through $q, b, \omega, \rho, \delta, \theta, h, c, p, n$ before e is consumed.

No remaining carrier coordinate exists beyond those rows. Hence no downstream consumer can extract infinite-mesh data, quotient streams, host real equality, ambient completeness, selected limits, or open-cover compactness from the packet. □

Theorem 618.10 (Real diagonal mesh-budget obligation closure package)**.** *The carrier of Definition 618.1, the NameCert obligations of Definition 618.2, finite window coverage from Definition 618.3, selected-window refinement from Definition 618.5, RealUp handoff from Definition 618.6, seal-route exactness from Definition 618.7, and non-escape from Definition 618.9 constitute the finite mesh-budget obligation package over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert.

The package binds a rational precision request to a finite mesh budget, selected StreamName windows, regular rational readbacks, dyadic tolerance rows, diagonal aggregation, the RealUp seal row, componentwise transports, displayed continuations, provenance, and local naming.

Proof. The carrier theorem fixes the packet $M = (q, b, \omega, \rho, \delta, \theta, e, h, c, p, n)$ and lists the only rows available to a mesh-budget consumer. The NameCert obligation theorem binds admission, precision exposure, finite budget exposure, selected-window coverage, readback, dyadic exactness, aggregation, seal handoff, transport, route replay, provenance, and local naming to that packet.

Apply finite window coverage and selected-window refinement. These results identify the visible route through $b, \omega, \rho, \delta, \theta$ and show that the same rows project to the selected-window surface without adding an unlisted window or a quotient stream.

Apply the RealUp handoff theorem, seal-route exactness, and then non-escape. The seal row e is consumed only after the precision, budget, selected windows, readbacks, dyadic ledger, aggregation row, transports, routes, provenance, and local name have been displayed.

No infinite mesh selection, quotient reals, host real equality, or ambient completeness row exists in the carrier. Therefore the cited rows form the complete finite mesh-budget obligation package and nothing stronger. □

Theorem 618.11 (Real diagonal mesh-budget scoped route)**.** *Every accepted* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *consumer route is scoped by the finite packet rows*

$$q, b, \omega, \rho, \delta, \theta, e, h, c, p, n$$

over $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. A consumer may read the rational precision request, mesh budget, selected windows, rational readbacks, dyadic tolerance ledger, aggregation row, seal row, componentwise transports, displayed continuation routes, package provenance, and local naming row, and nothing outside that finite route.*

Proof. Project the carrier of Definition 618.1. Its displayed coordinates are exactly $q, b, \omega, \rho, \delta, \theta, e, h, c, p, n$.

Apply Definition 618.10. The cited package binds the precision request, finite mesh budget, selected windows, rational readbacks, dyadic ledger, aggregation row, seal row, transports, routes, provenance, and local naming into one mesh-budget surface.

The dependency names in p are precisely $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$. Since the carrier has no further row, every accepted consumer route is scoped by that finite packet. □

Theorem 618.12 (Real diagonal mesh-budget consumer scope exhaustion)**.** *The NameCert obligations of Definition 618.2, finite window coverage of Definition 618.3, selected-window refinement of Definition 618.5, RealUp handoff of Definition 618.6, non-escape of Definition 618.9, and obligation-closure package of Definition 618.10 exhaust the scoped mesh-budget surface for* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$*.*

The exhausted surface excludes infinite mesh data, quotient streams, host real equality, ambient completeness, selected limits, and open-cover compactness.

Proof. Start with Definition 618.11. It confines every accepted consumer route to $q, b, \omega, \rho, \delta, \theta, e, h, c, p, n$ and to the named rational, stream, regular-sequence, dyadic, diagonal-window, real, history, transport, continuation, package, and naming surfaces.

The NameCert obligations and finite window coverage account for precision, budget, selected-window, readback, dyadic, and aggregation reads. Selected-window refinement accounts for the handoff to $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$.

RealUp handoff accounts for the seal-facing route, non-escape removes unlisted analytic data, and the obligation-closure package repacks those rows as one finite mesh-budget packet. Thus the scoped surface is exhausted and cannot supply infinite mesh data, quotient streams, host real equality, ambient completeness, selected limits, or open-cover compactness. □

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier consumer scope exhaustion`

Theorem 618.13 (Real diagonal mesh-budget formal target surface)**.** *Let*

$$M = (q, b, \omega, \rho, \delta, \theta, e, h, c, p, n)$$

be an accepted $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *packet. The later finite formal target consumed by Real-completion Lean work is exactly the route through the rational precision request* q*, the finite mesh budget* b*, the selected* $\mathsf{StreamName}^{\uparrow}$ *window family* ω*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback family* ρ*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* δ*, the* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *aggregation row* θ*, the* $\mathsf{RealObservationBudget}^{\uparrow}$ *handoff, the* $\mathsf{Real}^{\uparrow}$ *seal row* e*, componentwise* hsame *transports* h*, displayed* Cont *routes* c*,* Pkg *provenance* p*, and the local* $\mathsf{NameCert}_{\mathsf{RealDiagonalMeshBudget}^{\uparrow}}$ *row* n*.*

It exports no infinite mesh, quotient stream, host real equality, selected limit, open-cover compactness, or ambient Real completeness.

Proof. Project the accepted packet M. The carrier definition supplies exactly the rows $q, b, \omega, \rho, \delta, \theta, e, h, c, p, n$, with no coordinate outside that finite list.

Use Definition 618.2 to identify the local admission, precision, mesh-budget, selected-window, readback, tolerance-ledger, aggregation, seal, transport, route, provenance, and naming obligations. Then use Definition 618.3 to confine every diagonal observation to the selected windows, regular readbacks, dyadic ledger, and aggregation row.

Apply Definition 618.8 for the observation-budget boundary and Definition 618.6 for the seal-facing boundary. These two results place the finite observation packet before the $\mathsf{Real}^{\uparrow}$ seal without introducing quotient streams, host real equality, or ambient completeness.

Finally apply Definition 618.12. Carrier inspection then leaves only the displayed precision request, budget, selected windows, readbacks, tolerance ledger, aggregation, observation handoff, seal, transports, continuations, provenance, and local NameCert row as the formal target surface. □

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier formal target surface`

Theorem 618.14 (Real diagonal mesh-budget common-refinement seal)**.** *Let an accepted* $\mathsf{RealDiagonalMeshBudget}$ *packet have selected windows and dyadic ledger rows that agree, as displayed routes, with a* $\mathsf{CauchySharedTailModulus}$ *shared-threshold route and a* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *seal-source route. Then every* $\mathsf{Real}^{\uparrow}$ *or completion-facing seal consumer factors through one finite pullback surface whose coordinates are the* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, diagonal aggregation row, shared threshold, Real seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows.*

This is a correspondence of displayed finite routes. It is not a claim of host equality of reals, equality of quotient streams, equality of selected limits, ambient completeness, or choice data.

Proof. Start with the local mesh-budget route. By Definition 618.11, every accepted consumer route is confined to $q, b, \omega, \rho, \delta, \theta, e, h, c, p, n$ and to the rational, stream-window, regular-readback, dyadic-ledger, diagonal-window, Real-seal, transport, continuation, package, and naming surfaces. By Definition 618.12, these rows exhaust the mesh-budget surface.

Next read the shared-tail route. Apply Definition 983.3: the two tail requests pass through the same shared threshold before either window or readback is consumed. Apply Definition 983.4: the Real seal is exposed only after the shared threshold, dyadic ledger, paired windows, paired readbacks, transport, continuation, package, and naming rows have been displayed.

Now synchronize the diagonal-limit source. Apply Definition 646.69. It fixes the diagonal source, triangle row, dyadic ledger, window ledger, regular readback, Real seal, hsame transports,

Cont routes, Pkg provenance, and local NameCert row before any seal-facing read can consume the packet.

The hypothesis says that the selected mesh-budget windows and dyadic ledger agree with both adjacent routes as displayed rows. Pull the three route descriptions back along those shared coordinates. The only remaining rows are the selected StreamName$^{\uparrow}$ windows, RegSeqRat$^{\uparrow}$ readbacks, DyadicRatCore$^{\uparrow}$ ledger, diagonal aggregation, shared threshold, Real seal, BHist, hsame, Cont, Pkg, and NameCert rows.

Coordinate exhaustion gives the conclusion. Since none of the three packets exports host real equality, quotient-stream equality, selected-limit equality, ambient completeness, or choice data, the common refinement is exactly a finite route correspondence and nothing stronger. □

Lean4 ✓ `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier common refinement seal`

Theorem 618.15 (Real diagonal mesh-budget terminal budget refinement)**.** *Let an accepted* RealDiagonalMeshBudget$^{\uparrow}$ *packet have selected mesh windows and dyadic ledger rows that agree with a* CauchySharedTailModulus$^{\uparrow}$ *route and a* DiagonalLimitCompatibility$^{\uparrow}$ *route as displayed rows. Then every terminal* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *seal consumer for those routes is forced through the same finite budget-refinement packet: the selected mesh windows, regular readbacks, dyadic ledger, diagonal aggregation row, shared-tail threshold, Real seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. The terminal consumer cannot introduce a selected limit, quotient stream, host real equality, or ambient completeness row.*

Proof. Begin with the local mesh-budget route. Definition 618.11 confines every accepted consumer route to the displayed precision request, finite budget, selected windows, readbacks, dyadic ledger, aggregation, Real seal, transport, continuation, provenance, and local naming rows.

Use consumer-scope exhaustion next. By Definition 618.12, those rows exhaust the mesh-budget surface, so a terminal seal consumer has no mesh-side coordinate beyond the finite packet.

Now attach the downstream budget and common-refinement surfaces. Definition 618.8 places the finite observation-budget handoff before the Real seal, and Definition 618.14 pulls the mesh-budget, shared-tail, and diagonal-limit routes back to one finite refinement surface.

Finally synchronize the two adjacent routes. Definition 983.3 keeps the shared-tail threshold attached to the same windows and readbacks, while Definition 646.69 fixes the diagonal seal source before any seal-facing read is consumed.

The terminal consumer therefore reaches only the finite budget-refinement packet named in the statement. Since the cited routes export no selected limit, quotient stream, host real equality, or ambient completeness coordinate, none can be introduced at the terminal Real$^{\uparrow}$ or Completion$^{\uparrow}$ seal. □

Theorem 618.16 (Real diagonal mesh-budget terminal route readback)**.** *Let an accepted* RealDiagonalMeshBudget$^{\uparrow}$ *packet have selected mesh windows and dyadic ledger rows that agree, as displayed routes, with a* CauchySharedTailModulus$^{\uparrow}$ *route and a* DiagonalLimitCompatibility$^{\uparrow}$ *route. Then a terminal* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *seal read for this triple is admitted if and only if it factors through the finite budget-refinement packet consisting of the selected* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readbacks,* DyadicRatCore$^{\uparrow}$ *ledger, diagonal aggregation row, shared-tail threshold,* RealObservationBudget$^{\uparrow}$ *handoff,* Real$^{\uparrow}$ *seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Equivalently, the terminal Real$^{\uparrow}$ *and* Completion$^{\uparrow}$ *consumer surface is exactly the finite route displayed by the mesh-budget packet together with the shared-tail and diagonal-limit routes. It*

contains no additional selected limit, quotient stream, host real equality, ambient completeness, or choice coordinate.

Proof. For the forward implication, apply Definition 618.15. Any terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal consumer is forced through the selected mesh windows, regular readbacks, dyadic ledger, diagonal aggregation, shared-tail threshold, Real seal, BHist, hsame, Cont, Pkg, and NameCert rows. Then apply Definition 618.8 to insert the $\mathsf{RealObservationBudget}^{\uparrow}$ handoff in the displayed order before the Real seal.

For the readback implication, begin with a route that factors through the stated finite packet. Use Definition 618.7 to read the $\mathsf{Real}^{\uparrow}$ seal only from the selected windows, regular readbacks, dyadic ledger, diagonal aggregation, transport, continuation, package, and naming rows. Use Definition 618.14 to identify the same finite packet as the common refinement of the mesh-budget, shared-tail, and diagonal-limit routes.

The adjacent route synchronizations keep this readback terminal. By Definition 983.3, the shared-tail threshold is attached to the same windows and readbacks. By Definition 646.69, the diagonal-limit source reaches the seal only through the displayed diagonal aggregation, dyadic ledger, window, readback, hsame, Cont, Pkg, and NameCert rows.

It remains to exclude hidden coordinates. Apply Definition 618.12: the accepted carrier has no consumer row beyond the precision request, mesh budget, selected windows, regular readbacks, dyadic ledger, aggregation, observation handoff, Real seal, transports, continuations, provenance, and local naming row. Thus a route through the finite packet is an admitted terminal read, and the missing selected-limit, quotient-stream, host-equality, ambient-completeness, and choice coordinates cannot be supplied by the terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealDiagonalMeshBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ packet is generated from a rational precision request, a finite mesh budget, selected stream windows, regular rational readbacks, a dyadic tolerance ledger, a diagonal aggregation row, a real-seal row, componentwise transports, continuation routes, package provenance, and local naming.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RealDiagonalMeshBudget}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 618.1, Definition 618.2, Definition 618.3, Definition 618.5, Definition 618.6, Definition 618.7, Definition 618.9, Definition 618.11, Definition 618.12, Definition 618.13, and Definition 618.14 bind the carrier, NameCert obligations, selected-window coverage, selected-window refinement, RealUp handoff, non-escape, scoped consumer route, formal target surface, common-refinement seal route, and displayed BHist, hsame, Cont, Pkg, and NameCert rows from precision request through selected diagonal windows to the RealUp seal.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RealDiagonalMeshBudget}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.RealDiagonalMeshBudgetUp.RealDiagonalMeshBudgetCarrier\_consumer\_scope\_exhaustion`

Bridge status: none

Origin: human

Not claimed: This chapter does not close RealUp completeness, uniqueness of completed limits, quotient equality of streams, host real equality, continuous-map theorems, open-cover compactness, Lean verification, or bridge checking.

Upgrade path: No further paper-axis theory upgrade remains; formal verification and bridge checking remain separate over the same finite diagonal mesh packet.

Chapter 619

A Concrete Naming Certificate for $\mathsf{FiniteNetMinimumFold}^{\uparrow}$

The $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ interface packages the finite rational lower-bound fold used by compact-uniform-modulus consumers. It reads a nonempty $\mathsf{ProbeBundle}$ of positive $\mathsf{Rat}^{\uparrow}$ half-radius ledgers, folds them through the $\mathsf{TotalOrder}^{\uparrow}$ finite-minimum route, and returns a single precision history whose classifier-stable lower-bound certificate is visible to the downstream $\mathsf{UniformModulus}^{\uparrow}$ handoff.

The fold is the finite rational lower-bound row consumed by chapter 388 and chapter 369. Those consumers read only the displayed $\mathsf{ProbeBundle}$, $\mathsf{Rat}^{\uparrow}$ half-radius, $\mathsf{TotalOrder}^{\uparrow}$ selector, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, so the handoff exposes no host minimum, open-cover selector, or external modulus coordinate.

Definition 619.1 (FiniteNetMinimumFold carrier)**.** *A* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (P, R, M, L, H, C, Q, N)$$

with the following visible rows:

1. *P is a nonempty* $\mathsf{ProbeBundle}$ *row indexing the compact finite-net probes;*
2. *R assigns to each bundled probe a positive* $\mathsf{Rat}^{\uparrow}$ *half-radius ledger;*
3. *M is the primitive-recursive accumulator history produced by folding the bundled radius ledgers through the* $\mathsf{TotalOrder}^{\uparrow}$ *finite-minimum selector;*
4. *L stores the lower-bound certificates saying that M is below every radius ledger in R after the displayed classifier transports;*
5. *H records componentwise* hsame *transports for probe membership, radius histories, accumulator rows, and lower-bound rows;*
6. *C records the* Cont *routes for bundle recursion, rational order readback, accumulator comparison, and downstream precision handoff;*
7. *Q records* Pkg *provenance over* $\mathsf{ProbeBundle}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{TotalOrder}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteNetMinimumFold}^{\uparrow}}$ *row.*

The classifier compares accepted packets only after transporting the bundle spine, each positive rational half-radius row, the accumulator history, and the lower-bound certificates to a common finite-net surface. The carrier has no coordinate for an external minimum operator, a selected probe representative, host-order trichotomy, or a modulus chosen outside the displayed recursion.

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.TasteGate.FiniteNetMinimumFoldTasteGate single carrier alignment`

Theorem 619.2 (FiniteNetMinimumFold NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FiniteNetMinimumFold}^{\uparrow}}$ *surface for the carrier of Definition 619.1 consists exactly of five finite obligations:*

1. *carrier admission for the displayed packet* $F = (P, R, M, L, H, C, Q, N)$*;*
2. *classifier transport of bundle membership, positive rational radius rows, accumulator rows, and lower-bound certificates to a common finite-net surface;*
3. *primitive-recursion stability for the fold over the nonempty* ProbeBundle *spine;*
4. *rational lower-bound exactness for every bundled radius ledger stored in* R*;*
5. *ledger rows for rational order readback,* Cont *routes,* Pkg *provenance, and the local naming certificate.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket namecert obligations`

Proof. Project the carrier. The displayed rows contain precisely the nonempty bundle spine, its positive rational half-radius ledgers, the fold accumulator, the lower-bound certificates, transports, continuations, provenance, and local name.

Use the $\mathsf{TotalOrder}^{\uparrow}$ finite-minimum selector at each recursive step over P. The accumulator is initialized from the nonempty bundle data and then compared with the next bundled half-radius ledger, so each recursive branch produces either the previous lower-bound row transported forward or the newly read rational row.

The componentwise transports in H and the continuation routes in C preserve bundle membership, rational positivity, and order readback. Therefore the five obligations exhaust the local certificate surface, and no external selector or host-order principle is available. □

Theorem 619.3 (FiniteNetMinimumFold radius ledger admission)**.** *For an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *carrier*

$$F = (P, R, M, L, H, C, Q, N),$$

the positive $\mathsf{Rat}^{\uparrow}$ *half-radius ledger* R *is admitted only through the nonempty* ProbeBundle *row* P *and the displayed* $\mathsf{TotalOrder}^{\uparrow}$ *fold rows that build* M *and* L*. No radius ledger enters through a host compactness selector, an external enumeration, or a host minimum.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket radius ledger admission`

Proof. Project the carrier and the NameCert obligations. The packet admits radius data as the row R indexed by the nonempty bundle P, and the fold rows M, L are the only rows that compare those radius ledgers.

Apply the lower-bound certificate Definition 619.8. It reads every bundled half-radius ledger through the same finite fold and records the resulting lower-bound evidence in L.

Use nonempty probe exhaustion and selector stability, Definition 619.11 and Definition 619.16. They keep the admitted radius rows inside the displayed bundle recursion and transport surface, so no host compactness selector, external enumeration, or host minimum can introduce another radius ledger. □

Theorem 619.4 (FiniteNetMinimumFold compact-modulus cover input exactness)**.** *Every* CompactModulusCover$^{\uparrow}$ *input consumed through an accepted* FiniteNetMinimumFold$^{\uparrow}$ *packet enters only through*

$$P, R, H, C, Q, N$$

and the fold rows M, L generated from those inputs. The compact-cover consumer has no additional input channel for an unbundled probe, a separate compactness witness, a selected probe representative, or an external modulus row.

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket compactmoduluscover input exactness`

Proof. Start with the compact-cover consumer theorem Definition 619.17. It lists the only rows visible to CompactModulusCover$^{\uparrow}$ consumers: P, R, M, L, H, C, Q, N.

Apply radius ledger admission to locate the input radius rows. They enter through P and R before the fold produces M and L.

Finally use nonempty probe exhaustion and order-selector transport. Theorems 619.11 and 619.12 show that the compact-cover input surface is replayed through H, C with provenance Q, N, and no unbundled probe or external modulus row is available. □

Theorem 619.5 (FiniteNetMinimumFold compact-metric probe consumption)**.** *For an accepted* FiniteNetMinimumFold$^{\uparrow}$ *packet supplied by a* CompactMetric$^{\uparrow}$ *finite-net witness, every bundled probe and positive half-radius row consumed by the fold is one of the displayed* ProbeBundle *rows of the compact metric certificate. The accumulator M and lower-bound row L are therefore available to the* UniformModulus$^{\uparrow}$ *handoff without host compactness, selected representatives, or open-cover compactness.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket compactmetric probe consumption`

Proof. Project the accepted fold carrier $F = (P, R, M, L, H, C, Q, N)$. The compact metric witness supplies the finite-net bundle through the displayed ProbeBundle row P and the positive half-radius ledgers through R.

Use compact-modulus input exactness, Definition 619.4. It confines the consumed compact-cover input to P, R, H, C, Q, N before the fold rows M, L are generated.

Apply the lower-bound certificate Definition 619.8. The fold produces the accumulator M and certificate L from the displayed bundle and radius rows.

Finally use output exhaustion, Definition 619.7. The UniformModulus$^{\uparrow}$ boundary receives exactly M with lower-bound row L, and the carrier has no channel for host compactness, selected representatives, or open-cover compactness. □

Theorem 619.6 (Finite-net fold compact-uniform modulus consumption)**.** *Every accepted* FiniteNetMinimumFold$^{\uparrow}$ *packet consumed by a* CompactUniformContinuity$^{\uparrow}$ *route supplies exactly the finite* ProbeBundle *centers, positive* Rat$^{\uparrow}$ *radius rows, certified lower-bound fold,* hsame *transports,* Cont *replay,* Pkg *provenance, and local* NameCert *rows needed to produce a* UniformModulus$^{\uparrow}$ *ledger. The consuming route exports no host finite minimum, selected point oracle, open-cover compactness, quotient real equality, or ambient completeness datum.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket root compact cover readback`

Proof. Start with the local carrier and obligation rows, Definition 619.1 and Definition 619.2. They expose the finite bundle P, positive radius ledger R, accumulator M, lower-bound row L, transports H, routes C, provenance Q, and local name N as the whole fold surface.

Apply compact-metric probe consumption and uniform-modulus output exhaustion, Definition 619.5 and Definition 619.7. These identify the centers and radius rows read by the compact-uniform route, then deliver exactly the accumulator M with certificate L to the $\mathsf{UniformModulus}^{\uparrow}$ ledger.

The sibling compact-uniform and uniform-modulus chapters, chapter 388 and chapter 369, consume the same finite handoff, while chapter 37 supplies the rational positivity boundary for the radius rows. Since the fold carrier has no coordinate for host minima, point oracles, open-cover compactness, quotient real equality, or ambient completeness, none of those objects is exported by the route. □

Theorem 619.7 (FiniteNetMinimumFold uniform-modulus output exhaustion)**.** *Every* $\mathsf{UniformModulus}^{\uparrow}$ *output obtained from an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *carrier receives exactly the accumulator precision row M with lower-bound certificate L. The output receives no host minimum, no compactness selector, no selected probe representative, and no external modulus row beyond the displayed finite fold packet.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket uniformmodulus output exhaustion`

Proof. Project the carrier and apply the uniform-modulus handoff Definition 619.10. The handoff delivers the precision history M together with the lower-bound certificate L.

Use modulus consumer exactness Definition 619.13. It identifies M as the exact precision history read by the $\mathsf{UniformModulus}^{\uparrow}$ consumer and L as the only admissibility certificate for bundled pointwise-modulus rows.

Apply the compact-cover consumer theorem to close the output boundary. Because every downstream read factors through P, R, M, L, H, C, Q, N, the output cannot contain a host minimum, compactness selector, selected probe representative, or external modulus row. □

Theorem 619.8 (FiniteNetMinimumFold lower-bound certificate)**.** *For an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *carrier*

$$F = (P, R, M, L, H, C, Q, N),$$

the accumulator history M is certified below every positive $\mathsf{Rat}^{\uparrow}$ *half-radius ledger assigned by R to a bundled probe of P. The certificate is the finite row L, transported through H and read by C; it is not a host-level minimum and does not depend on a selected enumeration outside the* ProbeBundle *recursion.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket lower bound certificate`

Proof. Read the nonempty ProbeBundle row P and the radius assignment row R. Primitive recursion over P produces the accumulator M by repeatedly applying the rational finite-minimum selector to the current accumulator and the next radius ledger.

At the base probe, the lower-bound row is the positive rational radius ledger itself. At each successor probe, the $\mathsf{TotalOrder}^{\uparrow}$ readback compares the current accumulator with the next radius ledger and records the selected lower-bound branch in L.

Transport stability follows from H, and the consumer-facing read is through C. Since the carrier contains no external enumeration, no selected probe representative, and no host-order trichotomy, the only exported lower-bound evidence is the finite certificate row L. □

Theorem 619.9 (FiniteNetMinimumFold positive precision obligation)**.** *For an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *carrier*

$$F = (P, R, M, L, H, C, Q, N),$$

the accumulator M is not only certified below every bundled half-radius ledger by L; it is itself a positive $\mathsf{Rat}^{\uparrow}$ *precision history transported through H and read by C. This positivity and admissibility are part of the displayed finite fold packet, not consequences of a host minimum, host-order trichotomy, or an external rational selector.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket positive precision obligation`

Proof. Use the nonempty ProbeBundle row P. Its base probe supplies an initial bundled radius, and the radius assignment row R records that radius as a positive $\mathsf{Rat}^{\uparrow}$ half-radius ledger.

Run the primitive-recursive fold over the remaining probes. At each recursive step, the $\mathsf{TotalOrder}^{\uparrow}$ selector compares the current accumulator with the next bundled positive $\mathsf{Rat}^{\uparrow}$ row and chooses one of those two already positive rows.

The componentwise transports in H preserve the accumulator as a positive $\mathsf{Rat}^{\uparrow}$ history under classifier movement, and the routes in C replay the same row to downstream consumers. Thus M is an admissible positive precision history as well as a lower-bound certificate.

Because the carrier has no coordinate for a host minimum or host-order trichotomy, the positivity of M is obtained only by this finite row selection and transport. □

Theorem 619.10 (FiniteNetMinimumFold uniform-modulus handoff)**.** *Let a compact-uniform-continuity consumer provide a positive tolerance history ε, a nonempty finite-net* ProbeBundle *P, and positive half-radius ledgers R subordinate to the pointwise* $\mathsf{ContinuousMap}^{\uparrow}$ *or* $\mathsf{CFun}^{\uparrow}$ *modulus reads. An accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *packet*

$$F = (P, R, M, L, H, C, Q, N)$$

hands off the precision history M to the $\mathsf{UniformModulus}^{\uparrow}$ *consumer with the lower-bound certificate L below every bundled half-radius ledger. The handoff exposes the same* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows and exposes no independent compactness, choice, or host-function-extensionality datum.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket uniform modulus handoff`

Proof. Start with the finite-net data supplied by the compact certificate. The bundle row P and radius row R identify the exact half-radius ledgers needed by the local pointwise-modulus reads.

Apply Definition 619.8. It supplies a single accumulator history M and a finite certificate L proving that M is below every bundled half-radius ledger after the displayed transports.

The $\mathsf{UniformModulus}^{\uparrow}$ consumer then reads M as its precision history and uses L to enter whichever bundled pointwise-modulus row the compact cover supplies for the source point. The package rows Q, N and the routes H, C keep the handoff inside the BEDC ledger surface, so no compactness selector, host function extensionality, or external minimum is exported. □

Theorem 619.11 (FiniteNetMinimumFold nonempty probe exhaustion)**.** *For an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *carrier*

$$F = (P, R, M, L, H, C, Q, N),$$

every probe consumed by the accumulator history M is a member of the nonempty ProbeBundle *row P, and every member of P is consumed exactly once by the primitive-recursive fold that builds M.*

The exhaustion certificate is internal to the displayed bundle recursion, radius ledger R, transport row H, continuation row C, and local NameCert *row N.*

Proof. Start with the nonempty ProbeBundle row P. Its constructors supply the initial probe for the fold and the finite successor spine for the remaining probes.

Run primitive recursion over that spine. At the base probe, the accumulator reads the corresponding positive $\mathsf{Rat}^{\uparrow}$ half-radius ledger from R and records the first lower-bound row in L.

At each successor probe, the recursion extends the accumulator by exactly the next bundled radius ledger. The $\mathsf{TotalOrder}^{\uparrow}$ finite-minimum route compares the current accumulator with that ledger and records the selected branch without introducing an unbundled probe.

The transports in H and routes in C replay the same membership and radius rows under classifier movement. Thus the fold consumes precisely the bundle P, with no missing bundled probe and no probe outside P. □

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket nonempty probe exhaustion`

Theorem 619.12 (FiniteNetMinimumFold order-selector transport)**.** *For an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *carrier $F = (P, R, M, L, H, C, Q, N)$, the* $\mathsf{TotalOrder}^{\uparrow}$ *selector used at each fold step is stable under the displayed componentwise* hsame *transports. If two transported presentations of the same bundled half-radius ledgers in R are compared through the routes in C, the selected accumulator branch and the lower-bound certificate row in L transport to the same* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *classifier surface.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket order selector transport`

Proof. Read the fold step determined by a bundled probe in P. The step compares the current accumulator row with the next positive $\mathsf{Rat}^{\uparrow}$ half-radius ledger from R.

Transport both compared rows through the corresponding component of H. The rational comparison is then read through the displayed $\mathsf{TotalOrder}^{\uparrow}$ route in C, so the selector sees the same ordered pair on the transported surface.

If the selector keeps the accumulator branch, the transported lower-bound row is the previous certificate transported forward. If the selector chooses the new radius branch, the transported lower-bound row is the radius ledger transported through the same component of H.

In both cases the selected branch and its certificate remain inside M and L. Therefore order selection is stable under the displayed classifier transport and exports no host-order trichotomy. □

Theorem 619.13 (FiniteNetMinimumFold modulus consumer exactness)**.** *Let a* $\mathsf{UniformModulus}^{\uparrow}$ *consumer read an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *packet*

$$F = (P, R, M, L, H, C, Q, N)$$

through the handoff of Definition 619.10. The precision history delivered to the consumer is exactly M, and the only justification that M is admissible for every bundled pointwise-modulus row is the finite lower-bound certificate L transported by H and replayed by C. No separate compactness witness, selected probe representative, host minimum, or external modulus row is exported.

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket modulus consumer exactness`

Proof. Project the handoff packet. The consumer receives the nonempty probe bundle P, half-radius ledger R, accumulator M, lower-bound certificate L, transports H, routes C, provenance Q, and local name N.

Apply Definition 619.11. It shows that every bundled pointwise-modulus row has been consumed by the same primitive-recursive fold that produced M.

Apply Definition 619.12. It shows that the order selector and lower-bound row survive the displayed classifier transports, so the consumer reads the same accumulator and the same certificate after transport.

Finally use Definition 619.10. The $\mathsf{UniformModulus}^{\uparrow}$ consumer therefore receives exactly M with certificate L, and the carrier has no remaining coordinate from which a separate compactness witness, selected probe, host minimum, or external modulus could be read. □

Theorem 619.14 (FiniteNetMinimumFold terminal readback)**.** *For any terminal consumer read of an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *packet*

$$F = (P, R, M, L, H, C, Q, N),$$

the delivered fold result is exactly the accumulator precision history M together with the lower-bound certificate L, transported through H and replayed through C with provenance Q and local name N. This terminal readback is equivalent to the displayed finite fold surface P, R, H, C, Q, N producing M, L; it is not a host minimum, an external compactness witness, or a selected representative outside the packet.

Proof. Start with the lower-bound certificate of Definition 619.8. It identifies L as the internal certificate that the accumulator selected by the finite fold is a lower bound for the bundled pointwise-modulus rows.

Use the positive precision obligation of Definition 619.9. This makes the accumulator row M an admissible positive precision history, so the terminal consumer does not need a separate positivity or compactness row.

Next apply the uniform-modulus handoff Definition 619.10. The handoff carries the displayed packet through P, R, M, L, H, C, Q, N, with transports and routes preserving the same fold result.

Finally use modulus consumer exactness Definition 619.13. It says that the consumer receives exactly M and that L is the only admissibility certificate for the bundled rows. Hence the terminal readback is precisely the finite fold surface, with no host minimum or selected representative outside the accepted packet. □

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket terminal readback`

Theorem 619.15 (FiniteNetMinimumFold selector totality)**.** *For every accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *carrier*

$$F = (P, R, M, L, H, C, Q, N),$$

every nonempty finite probe ledger P exposes a selected lower-bound row through the displayed fold. The selected row is the accumulator M with lower-bound certificate L, read through the positive radius assignment R and the finite bundle recursion, not through an external selector or host minimum.

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket selector totality`

Proof. Start with the nonempty probe exhaustion theorem Definition 619.11. It shows that the primitive-recursive fold consumes exactly the bundled probes in P.

Use the lower-bound certificate of Definition 619.8. At the base probe, the selected row is the positive radius ledger read from R; at each successor probe, the fold compares the current accumulator with the next radius row and records the selected lower-bound branch in L.

The positive precision obligation Definition 619.9 makes the selected accumulator M an admissible positive $\mathsf{Rat}^{\uparrow}$ precision history. Thus every nonempty probe ledger exposes a selected lower-bound row through the displayed fold alone. □

Theorem 619.16 (FiniteNetMinimumFold selector stability)**.** *For an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *carrier* $F = (P, R, M, L, H, C, Q, N)$*, componentwise* hsame *transport preserves the selected accumulator row* M *and its lower-bound certificate* L*. After transporting bundle membership, positive radius rows, accumulator rows, and lower-bound rows through* H *and replaying them through* C*, the selected row remains the same* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *classifier surface.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket selector stability`

Proof. Project the componentwise transport row H and the continuation routes C. They move the bundle spine, positive rational radius rows, accumulator row, and lower-bound row together.

Apply the order-selector transport theorem Definition 619.12. Each fold step compares the transported accumulator with the transported next radius row and preserves the selected branch and lower-bound certificate.

Use Definition 619.15 to identify the transported selected row with the displayed accumulator M and certificate L. The modulus consumer exactness theorem then confirms that no external selector, host minimum, or separate compactness witness is read after transport. □

Theorem 619.17 (FiniteNetMinimumFold compact-cover consumer)**.** *Every* $\mathsf{CompactMetric}^{\uparrow}$*,* $\mathsf{UniformModulus}^{\uparrow}$*, or* $\mathsf{CompactModulusCover}^{\uparrow}$ *consumer of an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *packet can read the selected lower-bound row only through the nonempty finite net* P*, positive precision ledgers* R*, fold accumulator* M*, lower-bound certificate* L*, componentwise transport* H*, continuation routes* C*, package provenance* Q*, and local* NameCert *row* N*. The consumer receives no separate compactness witness, selected probe representative, host minimum, or external modulus row.*

Proof. Begin with the uniform-modulus handoff Definition 619.10. It places compact-uniform-continuity consumers behind the finite-net row P, positive radius row R, accumulator M, and lower-bound certificate L.

Apply nonempty probe exhaustion and selector totality, Definition 619.11 and Definition 619.15. They show that the selected lower-bound row is produced by the displayed fold over the finite net and not by an unrecorded probe representative.

Use selector stability and modulus consumer exactness, Definition 619.16 and Definition 619.13. These transport the same selected row through H, C and deliver exactly M with certificate L to $\mathsf{UniformModulus}^{\uparrow}$ and to compact-cover consumers that depend on that route.

The package row Q and local name N record the provenance of the finite packet. Since the carrier contains no host minimum, separate compactness witness, selected probe representative, or external modulus row, no $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{UniformModulus}^{\uparrow}$, or $\mathsf{CompactModulusCover}^{\uparrow}$ consumer can read one from this packet. □

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket compact cover consumer`

Theorem 619.18 (FiniteNetMinimumFold compact-cover consumer completeness)**.** *An accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *packet supplies exactly the fold rows needed by* $\mathsf{CompactModulusCover}^{\uparrow}$*,* $\mathsf{CompactMetric}^{\uparrow}$*,* $\mathsf{UniformModulus}^{\uparrow}$*,* $\mathsf{Rat}^{\uparrow}$*, and* $\mathsf{TotalOrder}^{\uparrow}$ *consumers. The supplied surface is the nonempty finite-net bundle* P*, positive rational half-radius ledger* R*, primitive-recursive accumulator* M*, lower-bound certificate* L*, componentwise transport row* H*, continuation row* C*, package provenance* Q*, and local naming row* N*.*

The packet exports no open-cover compactness theorem, no choice-selected minimizer, no host-level minimum, no selected probe representative, and no external modulus row beyond the displayed finite fold.

Proof. Start with the carrier and local obligations, Definition 619.1 and Definition 619.2. They display the nonempty bundle, rational radius ledgers, accumulator, lower-bound certificates, transports, continuations, provenance, and local naming row.

Apply the lower-bound and positive-precision theorems, Definition 619.8 and Definition 619.9. These identify M as the positive $\mathsf{Rat}^{\uparrow}$ precision row and L as the finite certificate below every bundled radius.

Use nonempty probe exhaustion, order-selector transport, and modulus consumer exactness. Theorems 619.11, 619.12, and 619.13 show that the $\mathsf{TotalOrder}^{\uparrow}$ fold consumes exactly the bundle rows and transports the selected accumulator to downstream consumers.

Finally apply the uniform-modulus handoff and compact-cover consumer theorem. They route $\mathsf{CompactModulusCover}^{\uparrow}$, $\mathsf{CompactMetric}^{\uparrow}$, and $\mathsf{UniformModulus}^{\uparrow}$ consumers through the same finite rows P, R, M, L, H, C, Q, N. Since the carrier has no coordinate for open-cover compactness, a choice-selected minimizer, a host minimum, a selected probe representative, or an external modulus, none of those objects can be exported. □

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket compact cover consumer completeness`

Theorem 619.19 (FiniteNetMinimumFold UniformModulus CompactMetric handoff gate)**.** *Any* $\mathsf{UniformModulus}^{\uparrow}$ *route that consumes a* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net witness through an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *packet must pass through the nonempty* $\mathsf{ProbeBundle}$ *row* P*, the positive* $\mathsf{Rat}^{\uparrow}$ *radius ledger* R*, the accumulator* M*, the lower-bound certificate* L*, transports* H*, routes* C*, provenance* Q*, and local* $\mathsf{NameCert}$ *row* N*. The route receives no open-cover compactness theorem, no selected-probe representative, and no external compactness selector outside the displayed finite fold packet.*

Proof. First use compact-metric probe consumption. It places every bundled probe and positive half-radius row supplied by the compact metric witness inside P and R, then obtains M and L from the finite fold rather than from open-cover compactness.

Next apply uniform-modulus output exhaustion. The $\mathsf{UniformModulus}^{\uparrow}$ consumer receives exactly the accumulator precision row M with lower-bound certificate L, transported and replayed through the displayed rows.

Finally use compact-cover consumer completeness. It assembles the consumer-facing surface as P, R, M, L, H, C, Q, N for $\mathsf{CompactModulusCover}^{\uparrow}$, $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{UniformModulus}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, and $\mathsf{TotalOrder}^{\uparrow}$ consumers. Since that theorem also excludes open-cover compactness, choice-selected minimizers, selected probe representatives, host minima, and external modulus rows, the handoff gate is exactly the finite fold packet. □

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket uniformmodulus compactmetric handoff gate`

Theorem 619.20 (FiniteNetMinimumFold compact-modulus attainment)**.** *Let a compact-uniform-continuity consumer read an accepted* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net witness through an accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *packet*

$$F = (P, R, M, L, H, C, Q, N).$$

Its public UniformModulus$^{\uparrow}$ *precision is obtained exactly by composing the* CompactMetric$^{\uparrow}$ *finite-net probe rows in P, the* CompactUniformContinuity$^{\uparrow}$ *local pointwise modulus rows indexed by those probes, the positive* Rat$^{\uparrow}$ *half-radius rows in R, the* TotalOrder$^{\uparrow}$ *finite lower-bound selection that produces M, L, and the accepted* FiniteNetMinimumFold$^{\uparrow}$ *transport, replay, provenance, and local naming rows. The consumer receives no host compactness selector, no selected-point oracle, no open-cover compactness theorem, no quotient real equality, and no modulus coordinate outside the displayed finite packet.*

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket compact modulus attainment`

Proof. First use compact-metric probe consumption, Definition 619.5. It confines the compact metric input to the displayed finite-net probes P and positive half-radius rows R.

Next apply the uniform-modulus handoff and the handoff gate, Definition 619.10 and Definition 619.19. These place the compact-uniform-continuity consumer behind the same finite packet and deliver the accumulator precision M with lower-bound certificate L to the UniformModulus$^{\uparrow}$ surface.

The finite selection step is controlled by selector totality, selector stability, and the lower-bound certificate, Definition 619.15, Definition 619.16, and Definition 619.8. Together they show that the TotalOrder$^{\uparrow}$ route chooses a lower-bound row from the displayed positive Rat$^{\uparrow}$ ledgers and transports that row through H, C.

Finally use compact-cover consumer completeness, Definition 619.18. It identifies the exact consumer-facing surface for CompactModulusCover$^{\uparrow}$, CompactMetric$^{\uparrow}$, UniformModulus$^{\uparrow}$, Rat$^{\uparrow}$, and TotalOrder$^{\uparrow}$ consumers, so the attained public modulus precision is precisely the finite-net fold result rather than an external compactness or choice artifact. □

Theorem 619.21 (FiniteNetMinimumFold compact-uniform pointwise-radius chain)**.** *A* CompactUniformContinuit *consumer obtains its public* UniformModulus$^{\uparrow}$ *precision from an accepted* FiniteNetMinimumFold$^{\uparrow}$ *packet exactly through the chain of* CompactMetric$^{\uparrow}$ *finite-net probes,* CompactUniformContinuity$^{\uparrow}$ *pointwise modulus rows, positive* Rat$^{\uparrow}$ *radius rows, the* TotalOrder$^{\uparrow}$ *finite lower-bound fold, and the* FiniteNetMinimumFold$^{\uparrow}$ *transport, replay, provenance, and local naming rows. For a packet*

$$F = (P, R, M, L, H, C, Q, N),$$

the delivered precision is the accumulator row M with lower-bound certificate L, transported by H, replayed by C, packaged by Q, and named by N; no compactness selector, selected point oracle, external modulus row, host minimum, or quotient real equality is read outside this chain.

Proof. Start from compact-modulus attainment, Definition 619.20. It already identifies the public modulus precision with the finite-net probes, pointwise modulus rows, positive radius rows, finite lower-bound selection, and the displayed packet rows P, R, M, L, H, C, Q, N.

Use selector totality and selector stability, Definition 619.15 and Definition 619.16. These two rows make M, L the selected lower-bound surface of the finite TotalOrder$^{\uparrow}$ fold and preserve that surface under the displayed hsame transports and Cont replays.

Finally apply compact-cover consumer completeness, Definition 619.18. It says that CompactModulusCover$^{\uparrow}$, CompactMetric$^{\uparrow}$, UniformModulus$^{\uparrow}$, Rat$^{\uparrow}$, and TotalOrder$^{\uparrow}$ consumers see exactly the finite fold packet. Therefore the CompactUniformContinuity$^{\uparrow}$ pointwise-radius chain ends at the public UniformModulus$^{\uparrow}$ precision and has no route to any excluded external selector or equality datum. □

Lean4 ✓ `BEDC.Derived.FiniteNetMinimumFoldUp.FiniteNetMinimumFoldPacket compact uniform pointwise radius chain`

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteNetMinimumFold}^{\uparrow}}$.

Constructive story: A $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ packet is generated from a nonempty ProbeBundle, positive $\mathsf{Rat}^{\uparrow}$ half-radius ledgers, a primitive-recursive accumulator, lower-bound certificates, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FiniteNetMinimumFold}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The public surface consists of the ProbeBundle carrier, $\mathsf{Rat}^{\uparrow}$ half-radius ledgers, $\mathsf{TotalOrder}^{\uparrow}$ selector route, BHist histories, hsame transports, Cont routes, Pkg provenance, local NameCert obligations, rational lower-bound certificate, positive precision obligation, uniform-modulus handoff, nonempty probe exhaustion, order-selector transport, modulus consumer exactness, compact-cover consumer export, and Definition 619.18 for the finite-net fold packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FiniteNetMinimumFold}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close the full compact-uniform-continuity theorem, a public compactness bridge, host-level minima, selected probe representatives, or Lean verification.

Upgrade path: No further paper-axis theory step remains for this finite-net fold packet; formal verification and bridge checking remain separate verification-axis work.

Chapter 620

A Concrete Naming Certificate for KernelMorphismUp

The KernelMorphismUp surface turns a compiler graph between two certified kernels into a finite packet whose rows can be inspected without importing a host category of programs. It sits between classifier morphisms and compiler certificates: the source and target rows supply the carrier data, the graph row supplies the displayed edge relation, and the certificate rows record exactly the carrier-preserving and classifier-preserving obligations needed by a later compiler or decompiler chapter.

Definition 620.1 (KernelMorphism carrier)**.** *A* KernelMorphismUp *carrier is a finite* BHist *packet*

$$K = (S, T, G, E, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the source* NameCert *carrier row;*
2. *T is the target* NameCert *carrier row;*
3. *G is the finite compiler-graph row relating accepted source histories to accepted target histories;*
4. *E is the edge-admission row recording that every displayed graph edge starts in S and lands in T;*
5. *L is the classifier-lift row recording that every source-classified input has a displayed target edge;*
6. *H records componentwise* hsame *transport for S, T, G, E, L and the local naming row;*
7. *C records the displayed* Cont *routes by which consumers read the source, target, graph, admission, and lift rows;*
8. *P is the* Pkg *provenance row over the same finite morphism packet;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{KernelMorphismUp}}$ *row.*

The local classifier compares two accepted carriers only through the displayed source row, target row, graph row, edge-admission row, classifier-lift row, transport rows, continuation routes, package provenance, and local naming row.

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier source graph edge readback`

Theorem 620.2 (KernelMorphism NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{KernelMorphismUp}}$ *surface for Definition 620.1 has five finite obligations: expose the carrier* $K = (S, T, G, E, L, H, C, P, N)$*; admit only graph edges recorded by* E *as source-to-target carrier edges; lift source classifier membership only through the displayed row* L*; transport graph, edge, and lift comparisons through* H *and* C*; and exclude any export of a host compiler semantics, quotient of programs, ambient category law, or undisplayed target object.*

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier namecert obligations`

Proof. Carrier exposure is projection from the finite tuple. The source, target, graph, edge-admission, classifier-lift, transport, continuation, package, and local naming rows are all displayed coordinates.

The admission and lift obligations are read from E and L. The edge row prevents a graph edge from leaving the source-target pair, while the lift row records the only route from source classifier membership to a target graph edge.

Transport and non-escape follow from the inventory of the same packet. Since no coordinate carries host compiler semantics, a quotient of programs, an ambient category proof, or an undisplayed target object, the certificate surface remains the finite NameCert morphism packet. □

Theorem 620.3 (KernelMorphism edge-admission obligation)**.** *For every accepted* KernelMorphismUp *carrier*

$$K = (S, T, G, E, L, H, C, P, N),$$

edge admission is exactly the displayed source-to-target row E *of the packet. A graph edge in* G *is accepted only when* E *records its source endpoint in the carrier row* S *and its target endpoint in the carrier row* T*, with the route transported through* H*, replayed through* C*, and named by the local* NameCert *row* N*.*

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier edge lift transport`

Proof. Project the carrier through Definition 620.1. The graph row G and edge-admission row E are separate displayed coordinates, and E is the only coordinate that records source-to-target admission for graph edges.

Use Definition 620.2. Its admission clause says that only graph edges recorded by E as source-to-target carrier edges are admitted by the local certificate surface.

The transport and route rows H and C preserve the same displayed coordinates, while P and N record provenance and local naming. No host compiler edge or undisplayed target object is available to admit an edge outside E. □

Theorem 620.4 (KernelMorphism classifier-lift obligation)**.** *For every accepted* KernelMorphismUp *carrier*

$$K = (S, T, G, E, L, H, C, P, N),$$

classifier lift is exactly the displayed row L*. A source-classified input may be exported to a target graph edge only by reading* S*, then* L*, then the corresponding graph and admission rows* G *and* E*, with componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* NameCert *row attached to the same packet.*

Proof. Start with the carrier definition. The source classifier information is read from S, while the lift route from a classified source input to a target edge is the displayed row L.

Apply Definition 620.2. Its lift clause identifies L as the only route from source classifier membership to a displayed target graph edge.

The rows G and E then certify that the lifted result is a graph edge admitted between S and T. Transport, continuation, package provenance, and local naming keep the lift inside $K = (S, T, G, E, L, H, C, P, N)$ and do not add a compiler-correctness theorem. □

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier classifier lift obligation`

Theorem 620.5 (KernelMorphism transport-stability obligation)**.** *For every accepted* KernelMorphismUp *carrier*

$$K = (S, T, G, E, L, H, C, P, N),$$

componentwise transport along H and replay along C preserves the same edge-admission and classifier-lift obligations. A transported packet remains readable only through $S, T, G, E, L, H, C, P, N$, so graph edges, admitted endpoints, and lifted classifier inputs stay on the displayed finite morphism surface.

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier transport stability obligation`

Proof. Read the transport rows from the carrier. The row H relates the source, target, graph, edge-admission, classifier-lift, continuation, package, and naming coordinates componentwise, and C replays the same routes after transport.

Use Definition 620.2 for the transported packet. Edge admission still passes through E, and classifier lift still passes through L, because those are the rows named by the certificate surface.

The package and local naming rows P, N close the transported surface as the same finite morphism packet. No ambient compiler semantics, quotient of programs, inverse data, or undisplayed target object is introduced by the transport. □

Theorem 620.6 (KernelMorphism composition surface)**.** *Given accepted* KernelMorphismUp *carriers*

$$K_1 = (S, M, G_1, E_1, L_1, H_1, C_1, P_1, N_1)$$

and

$$K_2 = (M, T, G_2, E_2, L_2, H_2, C_2, P_2, N_2),$$

the displayed composite surface is the finite packet whose source row is S, middle row is read only as the shared target-source row M, target row is T, graph row is the finite relational composite of G_1 and G_2, and obligation rows are obtained by chaining E_1, E_2 and L_1, L_2 through the displayed hsame*,* Cont*,* Pkg*, and local* NameCert *rows. The statement supplies a composition surface only; it does not assert an ambient compiler category or global associativity theorem.*

Proof. Project the two carriers. The first packet exposes a source-to-middle graph and the second exposes a middle-to-target graph, with the same middle row visible as a named coordinate.

Build the composite graph by finite relational composition: a source row is related to a target row exactly when a displayed middle row is named by the two graph rows. The edge-admission rows chain source-to-middle and middle-to-target carrier admission, and the classifier-lift rows chain source classification through the middle row to the target row.

Finally repack the chained obligations through the displayed transport, continuation, package, and naming rows. Because the construction reads only K_1 and K_2, it supplies no ambient associativity law beyond the finite composition surface. □

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier composition surface`

Theorem 620.7 (KernelMorphism non-escape)**.** *Every consumer read exported by an accepted* KernelMorphismUp *carrier factors through* $S, T, G, E, L, H, C, P, N$*. A read asking for compiler semantics, an optimization proof, decompiler inverse data, quotient program equality, or a target object not named by* T *is recorded as outside the morphism packet and is not exported as NameCert evidence.*

Proof. Read the request through the displayed continuation route C. If it asks for the source row, target row, graph row, edge-admission row, classifier-lift row, transport row, package provenance, or local naming row, the carrier supplies exactly that coordinate.

All other requests leave the carrier inventory. The NameCert obligations allow graph and classifier evidence only through E and L, so a request for host compiler semantics, optimization, decompilation, quotient equality, or an undisplayed target object has no certificate row from which it can be exported. □

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier non escape`

Theorem 620.8 (KernelMorphism public export)**.** *The public export of an accepted* KernelMorphismUp *carrier is the finite NameCert morphism packet consisting of source carrier row* S*, target carrier row* T*, compiler-graph row* G*, edge-admission row* E*, classifier-lift row* L*, componentwise* hsame *transport* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local naming row* N*. Downstream* CertificateCompiler$^{\uparrow}$*, pipeline-stage, and decompiler-right-inverse consumers may cite this packet as their morphism input, but they receive no compiler correctness theorem beyond these rows.*

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismTasteGate single carrier alignment`

Proof. Start with the carrier definition. It lists exactly the rows named in the public export, and the local classifier restricts comparison to those rows.

Use the NameCert obligation theorem to expose carrier admission, graph edge admission, classifier lift, transport, package provenance, and local naming. The non-escape theorem rules out hidden semantics and inverse data, so the exported object is only the finite morphism packet.

The downstream handoff is therefore a reuse of the same named rows. The first compiler-certificate consumer is chapter 473: it may read the source, target, graph, edge, lift, transport, route, provenance, and local naming rows only as its displayed morphism input. Compiler, pipeline, and decompiler certificates can read the morphism packet as input, but any stronger correctness or inverse claim must be supplied by their own certificate surfaces. □

Theorem 620.9 (KernelMorphism CertificateCompiler handoff)**.** *Any* CertificateCompiler$^{\uparrow}$*, pipeline-stage, or decompiler-right-inverse consumer of an accepted* KernelMorphismUp *carrier must first read the source row* S*, target row* T*, graph row* G*, edge-admission row* E*, classifier-lift row* L*, transports* H*, routes* C*, provenance* P*, and local name* N*. The compiler-facing consumer receives these rows as its morphism input and receives no compiler correctness theorem, inverse proof, quotient program equality, or undisplayed target object.*

Proof. Start with the local NameCert obligations. Definition 620.2 reads carrier admission, graph evidence, classifier accountability, transport, route, provenance, and local naming from the displayed packet.

Next use the edge-admission and classifier-lift obligations. They bind graph edges to the accepted source and target rows, and they expose the classifier lift only through the row L rather than through a host compiler fact.

Finally compose non-escape with public export. Definition 620.7 excludes compiler semantics, inverse data, quotient program equality, and unnamed targets, while Definition 620.8 presents $S, T, G, E, L, H, C, P, N$ as the public morphism packet. Therefore the CertificateCompiler-facing read is exactly that finite input surface and no stronger theorem is transferred. □

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier certificate compiler handoff`

Theorem 620.10 (KernelMorphism composite compiler handoff boundary)**.** *Given composable accepted* KernelMorphismUp *carriers*

$$K_1 = (S, M, G_1, E_1, L_1, H_1, C_1, P_1, N_1)$$

and

$$K_2 = (M, T, G_2, E_2, L_2, H_2, C_2, P_2, N_2),$$

any CertificateCompiler$^{\uparrow}$*, pipeline-stage, or decompiler-right-inverse consumer of the displayed composite must read the chained source row S, middle row M, target row T, composite graph, edge-admission rows, classifier-lift rows, transports, routes, provenance, and local names before obtaining a compiler-facing morphism input. The consumer receives no ambient compiler correctness theorem, quotient program equality, inverse proof, or category law from the composite packet.*

Proof. Start with the composition surface. Definition 620.6 projects K_1 and K_2, identifies M as the shared middle row, composes G_1 with G_2 through displayed middle witnesses, and chains the admission and classifier-lift rows.

The chained rows are still local NameCert rows. Edge admission is read from E_1, E_2, classifier lift is read from L_1, L_2, and the componentwise transports, routes, provenance, and local names are exactly the displayed H_i, C_i, P_i, N_i rows.

Apply public export and the existing compiler handoff to the repacked composite. Definition 620.8 exposes only the finite morphism packet, and Definition 620.9 makes that packet the input surface for compiler, pipeline, and decompiler-facing consumers.

Finally use non-escape. Definition 620.7 blocks compiler semantics, quotient program equality, inverse data, and unnamed target objects, while the composition theorem itself asserts no ambient category law. Hence the composite handoff supplies the chained finite input and nothing stronger. □

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier composite compiler handoff boundary`

Theorem 620.11 (KernelMorphism scoped consumer packet)**.** *Every accepted* KernelMorphismUp *consumer route factors through the single packet*

$$K = (S, T, G, E, L, H, C, P, N).$$

Edge admission is read from E, classifier lift is read from L, transport and replay pass through H and C, finite composition passes through displayed middle rows of composable packets, and the non-escape boundary excludes host compiler semantics, quotient program equality, inverse data, and ambient category laws.

Proof. Start with the carrier and public export theorems. They identify the consumer-facing object with the finite rows $S, T, G, E, L, H, C, P, N$, so every accepted read begins inside the same packet.

Use edge-admission and classifier-lift obligations. The row E supplies the only source-to-target admission for graph edges, and L supplies the only route from source classifier membership to a displayed target graph edge.

Transport-stability keeps these rows readable through H and C. For composable routes, the composition-surface theorem chains through the displayed middle row and repacks the composite graph, admission, and lift data into the same finite packet shape.

Finally apply non-escape and public export. They rule out host compiler semantics, quotient program equality, inverse data, and ambient category laws, leaving downstream consumers with exactly the scoped morphism packet. □

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier scoped consumer packet`

Theorem 620.12 (KernelMorphism source-target scope)**.** *For every accepted* KernelMorphismUp *carrier*

$$K = (S, T, G, E, L, H, C, P, N),$$

the source-target scope is exactly the finite BHist *route that reads S as the source* NameCert *carrier row, T as the target* NameCert *carrier row, G as the displayed graph row, E as the source-to-target admission row, and L as the classifier-lift row, with componentwise* hsame *transport through H, displayed* Cont *replay through C, package provenance through P, and local naming through N. No source or target object outside the displayed rows is in scope.*

Proof. Project the carrier rows in Definition 620.1. The source row S, target row T, graph row G, edge-admission row E, and classifier-lift row L are explicit coordinates of the same finite BHist packet.

Use the NameCert obligation theorem for the public route. Edge admission is read from E, classifier lift is read from L, and both reads are transported through H and replayed through C.

The package and local naming rows P, N record that the same finite packet is being consumed. Since no carrier coordinate names an external source object, external target object, host compiler semantics, or quotient program equality, the source-target scope is exhausted by $S, T, G, E, L, H, C, P, N$. □

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier source target scope`

Theorem 620.13 (KernelMorphism composition scope)**.** *Given accepted* KernelMorphismUp *carriers*

$$K_1 = (S, M, G_1, E_1, L_1, H_1, C_1, P_1, N_1)$$

and

$$K_2 = (M, T, G_2, E_2, L_2, H_2, C_2, P_2, N_2),$$

the scoped composite reads only the displayed middle row M, the two graph rows G_1, G_2, the two edge-admission ledgers E_1, E_2, and the two classifier-lift ledgers L_1, L_2, together with the displayed hsame, Cont, Pkg, *and local* NameCert *rows of the two packets. It does not import an ambient category law, hidden associativity proof, external middle object, or compiler semantics.*

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier composition scope`

Proof. Start from the two displayed carriers. The only shared row available to connect them is the middle row M, occurring as the target row of K_1 and the source row of K_2.

Build the composite read by chaining G_1 with G_2 through that displayed middle row. The edge-admission side chains E_1 and E_2, and the classifier-lift side chains L_1 and L_2.

The transport, continuation, package, and local naming rows are then read componentwise from both packets. Because the construction never leaves those rows, it supplies only a scoped composition surface and no ambient category or compiler-correctness theorem. □

Theorem 620.14 (KernelMorphism NameCert scope)**.** *The scoped* $\mathsf{NameCert}_{\mathsf{KernelMorphismUp}}$ *consumer packet is the finite surface consisting of carrier exposure for* $K = (S, T, G, E, L, H, C, P, N)$*, edge admission through* E*, classifier lift through* L*, transport and replay through* H *and* C*, composition through displayed middle rows and the two edge/lift ledgers of composable packets, and non-escape from host compiler semantics, quotient program equality, inverse data, undisplayed target objects, and ambient category laws.*

Proof. Carrier exposure comes from Definition 620.1. The rows $S, T, G, E, L, H, C, P, N$ are the only rows a consumer can inspect.

Use source-target scope for the local read. It binds source, target, graph, admission, lift, transport, route, package, and naming data into one finite packet.

Use composition scope for composable reads. The only additional data consumed are displayed middle rows and the two edge/lift ledgers belonging to the two displayed packets.

Finally use the non-escape and public export theorems. They exclude host compiler semantics, quotient program equality, inverse data, undisplayed target objects, and ambient category laws, so the scoped consumer receives exactly the NameCert packet described above. □

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier namecert scope`

Theorem 620.15 (KernelMorphism scoped edge-lift consumer)**.** *Every consumer route through an accepted* KernelMorphismUp *packet*

$$K = (S, T, G, E, L, H, C, P, N)$$

that asks for a target graph edge must first read the source and target rows S, T*, then edge admission through* E*, then classifier lift through* L*. The same read is transported through* H*, replayed through* C*, recorded through* P*, and locally named through* N*; no compiler semantics, inverse data, quotient program equality, or ambient category law can replace those rows.*

Proof. Begin with edge admission. By Definition 620.3, a graph edge is accepted only through the displayed row E after the source endpoint is read from S and the target endpoint is read from T.

Next apply the classifier-lift obligation of Definition 620.4. It identifies L as the route from source classifier membership to the displayed target graph edge, so the consumer cannot read the target edge before the lift row is exposed.

Transport and replay are controlled by Definition 620.5. The rows H and C preserve the same admission and lift data while keeping the read inside the displayed finite packet.

Finally use Definition 620.7 and Definition 620.14. They exclude compiler semantics, inverse data, quotient program equality, and ambient category laws, leaving S, T, E, L, H, C, P, N as the scoped consumer route for target-edge reads. □

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier scoped edge lift consumer`

Theorem 620.16 (KernelMorphism CertificateCompiler source lock)**.** *Every* $\mathsf{CertificateCompiler}^{\uparrow}$ *consumer of an accepted* KernelMorphismUp *packet*

$$K = (S, T, G, E, L, H, C, P, N)$$

must first read the KernelMorphism source row S*, target row* T*, graph row* G*, edge-admission row* E*, classifier-lift row* L*, transport row* H*, route row* C*, provenance row* P*, and local name row* N*. The compiler may then add target landing and compiler-stage rows of its own, but it cannot replace the morphism packet by host compiler semantics, quotient program equality, inverse data, or an undisplayed target object.*

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier certificate compiler source lock`

Proof. Start with the public export theorem Definition 620.8. It identifies the downstream morphism input with the finite packet rows $S, T, G, E, L, H, C, P, N$ and grants no compiler-correctness theorem beyond those rows.

Next apply the NameCert scope theorem Definition 620.14 and the scoped edge-lift consumer theorem Definition 620.15. Together they force target-edge reads to expose source and target rows, edge admission, classifier lift, transport, route replay, provenance, and local naming before the read can leave the morphism packet.

Finally use the CertificateCompiler$^{\uparrow}$ endpoint route Definition 473.55. It lets the compiler add its own target landing and endpoint rows after the morphism input has been read. Since the KernelMorphism non-escape boundary still excludes host compiler semantics, quotient program equality, inverse data, and undisplayed target objects, the compiler-facing route remains source-locked to $S, T, G, E, L, H, C, P, N$. □

Theorem 620.17 (KernelMorphism standard reflection bridge)**.** *The edge-admission, classifier-lift, transport-stability, composition-surface, public-export, source-lock, and* NameCert*-scope rows assemble a standard reflection bridge for* KernelMorphismUp*. The bridge reads only the finite packet rows $S, T, G, E, L, H, C, P, N$ and composable middle rows, and imports no host equality, host function space, compiler semantics, inverse data, or ambient category law.*

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier standard reflection bridge`

Proof. Start with edge admission and classifier lift, Definition 620.3 and Definition 620.4. These rows expose the source-to-target graph route and the classifier read without leaving the finite carrier.

Transport stability and composition surface, Definition 620.5 and Definition 620.6, supply the bridge replay and the composable middle-row surface.

Finally apply the public export, source-lock, and NameCert scope theorems, Definition 620.8, Definition 620.16, and Definition 620.14. They package the displayed rows as the bridge-facing public object and exclude host equality, host functions, compiler semantics, inverse data, and ambient category laws. □

Theorem 620.18 (KernelMorphism CertificateCompiler route non-escape)**.** *Every* CertificateCompiler$^{\uparrow}$*-facing consumer of an accepted* KernelMorphismUp *packet*

$$K = (S, T, G, E, L, H, C, P, N)$$

factors through the displayed source row S, target row T, graph row G, edge-lift and edge-admission row E, classifier-lift row L, componentwise hsame *transport row H, displayed* Cont *route row C,* Pkg *provenance row P, and local* NameCert *row N. The consumer may use the CertificateCompiler route only after those KernelMorphism rows have been read.*

In particular, the handoff cannot introduce a second compiler endpoint, host equality of kernels, hidden decompiler inverse, off-ledger reflection tuple, quotient program equality, or ambient category law.

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier certificate compiler route nonescape`

Proof. Start with the CertificateCompiler handoff theorem, Definition 620.9. It exposes the compiler-facing route only through the displayed KernelMorphism packet rows $S, T, G, E, L, H, C, P, N$.

Next apply the source lock, Definition 620.16. It forces the compiler-facing consumer to read the source, target, graph, edge-admission, classifier-lift, transport, route, provenance, and local naming rows before the compiler endpoint can add any target landing data of its own.

The standard reflection bridge of Definition 620.17 repacks those same rows as the bridge-facing public object and imports no host equality, host function space, compiler semantics, inverse data, or ambient category law.

Finally use the sibling CertificateCompiler route scope, Definition 473.60. It permits the morphism leg to contribute only the graph-admission and classifier-lift rows licensed by KernelMorphismUp. Therefore no second compiler endpoint, hidden decompiler inverse, off-ledger reflection tuple, quotient program equality, or host equality of kernels has a route into the accepted handoff. □

Theorem 620.19 (KernelMorphism composition standard-reflection compatibility)**.** *Given composable accepted* KernelMorphismUp *packets*

$$K_1 = (S, M, G_1, E_1, L_1, H_1, C_1, P_1, N_1)$$

and

$$K_2 = (M, T, G_2, E_2, L_2, H_2, C_2, P_2, N_2),$$

the standard reflection bridge of the displayed composite factors through the two standard reflection bridge routes of K_1 and K_2 together with the existing composition scope rows. The composite bridge reads only the shared middle row M, the graph rows, edge-admission rows, classifier-lift rows, componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance rows, and local* NameCert *rows.*

It cannot introduce host equality of kernels, decompiler inverse data, quotient program equality, off-ledger compiler semantics, or ambient category laws.

Proof. Start with composition scope, Definition 620.13. It makes the composite read pass through the shared middle row M, the two graph rows, the two edge-admission ledgers, the two classifier-lift ledgers, and the displayed transport, route, provenance, and local naming rows.

Next apply the standard reflection bridge theorem, Definition 620.17, separately to the two accepted packets. Each bridge route exposes only the finite packet rows and composable middle rows, with no host equality, host function space, compiler semantics, inverse data, or ambient category law.

Now use the composite compiler handoff boundary, Definition 620.10. It repacks the chained rows as the compiler-facing morphism input of the composite without importing compiler correctness, quotient program equality, inverse proof, or category law data.

Finally apply route non-escape, Definition 620.18. Since every compiler-facing consumer has already factored through the displayed morphism rows, the standard reflection bridge of the composite has no coordinate from which to obtain host kernel equality, decompiler inverse data, quotient program equality, or ambient category laws. □

Lean4 ✓ `BEDC.Derived.KernelMorphismUp.KernelMorphismCarrier composition standard reflection compatibility`

Closure status for $\mathsf{NameCert}_{\mathsf{KernelMorphismUp}}$.

Constructive story: A KernelMorphismUp packet is generated from source and target NameCert rows, a finite compiler graph, edge-admission and classifier-lift rows, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{KernelMorphismUp}}$, maturePackageClosed)

Scope closed: Definition 620.1, Definition 620.2, Definition 620.6, Definition 620.7, Definition 620.8, Definition 620.13, Definition 620.14, Definition 620.15, Definition 620.16, Definition 620.17, and Definition 620.18 define

the finite morphism-packet surface, its public export, compiler-facing source lock, route non-escape, and the bridge-facing consumer surface.

Formal verification: FormalStatus(NameCert$_{\text{KernelMorphismUp}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close compiler correctness, optimization correctness, decompiler right inverses, ambient category laws, Lean verification, or bridge checking.

Upgrade path: The theory axis is complete at the mature finite morphism-packet surface; remaining work is Lean verification and bridge checking.

Chapter 621

A Concrete Naming Certificate for BinderContextSubstitutionSeal$^{\uparrow}$

The BinderContextSubstitutionSeal$^{\uparrow}$ interface packages the closed-boundary substitution site used by the MetaCIC self-compilation account. It records a term, a binder depth, a substitution payload, the attempted substitution result, and the boundary certificate proving that the payload has no visible target inside the classified term.

Theorem 621.1 (BinderContextSubstitutionSeal closed-term boundary dependency)**.** *Every accepted* BinderContextSubstitutionSeal$^{\uparrow}$ *packet reads its* `ClosedAt` *boundary and inertness row as a refinement of the sibling* ClosedTermSubstitutionBoundary$^{\uparrow}$ *surface of chapter 527 before exporting the binder-depth payload route to compiler or evaluator consumers.*

Lean4 ✓ `BEDC.Derived.BinderContextSubstitutionSealUp.BinderContextSubstitutionSealCarrier closed term boundary dependency`

Proof. Project the packet rows as

$$S = (t, d, v, s, b, H, C, P, N).$$

The row b is the displayed closed-boundary witness: it carries `ClosedAt` d t together with the inertness equality read by the substitution seal.

The sibling surface of chapter 527 supplies exactly the closed-term boundary that makes a substitution read inert at a displayed depth. The seal adds the payload row v, the binder-depth row d, replay through $s = \texttt{substitute}(d, v, t)$, and local transport and provenance rows, but it does not replace that closed-term boundary with an independent open-substitution semantics.

Apply Definition 621.4 and Definition 621.5. They show that consumers receive the payload route only through the equality certified by b and only through the finite packet rows exported by the handoff.

Hence the closed-term substitution boundary is a real dependency of the binder-context seal. The seal refines that sibling boundary by adding depth, payload, replay, transport, and naming rows while preserving the same closed-boundary source for compiler and evaluator reads. □

Definition 621.2 (BinderContextSubstitutionSeal carrier)**.** *A* BinderContextSubstitutionSeal$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (t, d, v, s, b, H, C, P, N)$$

with the following visible rows:

1. *t is a* `Term` *row;*
2. *d is the displayed binder-depth row;*
3. *v is the substitution payload row;*
4. *s is the result row with readback $s = \texttt{substitute}(d, v, t)$;*
5. *b is the boundary witness carrying* `ClosedAt` *d t and the inertness equality $s = t$;*
6. *H records componentwise* hsame *transports for the term, depth, payload, result, boundary witness, provenance, and local naming rows;*
7. *C records the* Cont *routes for term readback, closedness readback, substitution replay, inertness readback, and certificate exposure;*
8. *P records* Pkg *provenance over* `Term`*,* `ClosedAt`*,* `substitute`*,* `shift`*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{BinderContextSubstitutionSeal}^{\uparrow}}$ *row.*

The classifier compares accepted packets only through the displayed `Term` *row, the* `ClosedAt` *boundary witness, the substitution replay row, the inertness equality, componentwise* hsame *transports,* Cont *routes,* Pkg *provenance, and the local naming row. It has no coordinate for an open-term semantics, a capture-avoiding metatheory outside* `Term`*, an ambient binder context beyond d, or a payload-use route absent from b.*

Lean4 ✓ `BEDC.Derived.BinderContextSubstitutionSealUp.BinderContextSubstitutionSealTasteGate`
`single carrier alignment`

Theorem 621.3 (BinderContextSubstitutionSeal NameCert obligations)**.** *For the carrier of Definition 621.2, the local* $\mathsf{NameCert}_{\mathsf{BinderContextSubstitutionSeal}^{\uparrow}}$ *surface consists exactly of carrier admission for $S = (t, d, v, s, b, H, C, P, N)$,* `Term` *readback,* `ClosedAt` *boundary readback, replay of $s = \texttt{substitute}(d, v, t)$, inertness readback $s = t$, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and the local naming row.*

Lean4 ✓ `BEDC.Derived.BinderContextSubstitutionSealUp.BinderContextSubstitutionSealCarrier`
`namecert obligations`

Proof. Project the carrier. The rows t, d, v, s expose the syntactic substitution attempt, while b exposes the closed-boundary witness and the equality read from that witness.

The boundary part of b is supplied by the MetaCIC witnesses `substitute_closed` and `closed_under_substitu`
The matching binder-motion budget is the `shift_closed` witness used by the surrounding self-compilation account, so the package names the same boundary where shifting and substitution are both inert on the classified slice.

The rows H, C, P, N then expose transport, continuation replay, package provenance, and local naming for exactly the same packet. Since the carrier has no further coordinate, these rows exhaust the local NameCert surface. □

Theorem 621.4 (BinderContextSubstitutionSeal non-escape boundary)**.** *Every accepted* BinderContextSubstitutio*n packet exports the substitution payload v only as an attempted route through $s = \texttt{substitute}(d, v, t)$ together with the boundary witness b. If b carries* `ClosedAt` *d t, then the exposed result row is $s = t$, and no consumer can read the packet as a payload insertion, an open-variable escape, a binder capture, or a depth borrowed from outside the displayed boundary.*

Lean4 ✓ BEDC.Derived.BinderContextSubstitutionSealUp.BinderContextSubstitutionSealCarrier non escape boundary

Proof. Read the substitution row from the carrier. The only route from v to the accepted output is the displayed replay $s = \texttt{substitute}(d, v, t)$.

Use `substitute_closed` on the `ClosedAt` d t component of b. It identifies the replayed substitution result with the original term, so the payload is carried through the traversal but is never observed at a target variable inside t.

The classifier row `closed_under_substitute_classifier` records the same fact as a generator-closure boundary, and `shift_closed` supplies the matching binder-budget law for moving the same closed term through the surrounding context. The visible routes therefore expose no open-term escape, capture route, or extra depth coordinate. □

Theorem 621.5 (BinderContextSubstitutionSeal compiler handoff)**.** *An accepted* BinderContextSubstitutionSeal$^{\uparrow}$ *packet*

$$S = (t, d, v, s, b, H, C, P, N)$$

hands the closed-term substitution site to a compiler or evaluator consumer as a finite boundary certificate over `Term`*,* `ClosedAt`*,* `substitute`*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. The consumer receives the inert result row $s = t$ and the same package provenance; it receives no semantic evaluator theorem, no global subject-reduction claim, and no unrecorded binder context.*

Proof. Start with the carrier rows. The compiler-facing data are the term t, depth d, payload v, replayed result s, boundary witness b, and the transport and route rows H, C.

Apply Definition 621.4. The handoff can use the substitution site only through the equality $s = t$ certified by `substitute_closed` and exposed through the local boundary witness.

The package rows P, N bind that equality to the same `Term` and `ClosedAt` generator surface named by the self-compilation vision. Thus the consumer receives a finite substitution-seal packet, not a global evaluator correctness theorem or a hidden binder-context resource. □

Lean4 ✓ BEDC.Derived.BinderContextSubstitutionSealUp.BinderContextSubstitutionSealCarrier compiler handoff

Theorem 621.6 (BinderContextSubstitutionSeal obligation rows)**.** *For an accepted* BinderContextSubstitutionSeal$^{\uparrow}$ *packet*

$$S = (t, d, v, s, b, H, C, P, N),$$

the obligation ledger consists of the following separate rows: carrier admission for S, `Term` *readback for t,* `ClosedAt` *boundary readback for b, replay of $s = \texttt{substitute}(d, v, t)$, inertness equality $s = t$, componentwise* hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through P, and local* NameCert *exposure through N.*

Proof. Use the carrier of Definition 621.2. Its coordinates list exactly the term, depth, payload, result, boundary witness, transport, route, provenance, and local naming rows.

Definition 621.4 identifies the boundary row as the only place where the payload route can be read. Definition 621.5 then exposes the same rows to compiler and evaluator consumers.

Separating those coordinates gives the stated ledger rows. No additional obligation row can be projected because the carrier has no hidden binder-context coordinate. □

Lean4 ✓ BEDC.Derived.BinderContextSubstitutionSealUp.BinderContextSubstitutionSealCarrier obligation rows

Theorem 621.7 (BinderContextSubstitutionSeal closed-boundary exactness)**.** *In every accepted* BinderContextSubstitutionSeal$^{\uparrow}$ *packet* $S = (t, d, v, s, b, H, C, P, N)$*, the* `ClosedAt` *boundary witness in* b *forces the substitution result row to remain the original term row: the only exported result is* $s = t$*. The packet exports no payload insertion, no open-variable occurrence, and no binder capture route.*

Lean4 ✓ `BEDC.Derived.BinderContextSubstitutionSealUp.BinderContextSubstitutionSealCarrier closed boundary exactness`

Proof. Read the boundary witness through Definition 621.2. The witness b carries both `ClosedAt` d t and the inertness equality for the replayed substitution row.

Apply Definition 621.4. It states that the payload v is visible only through the attempted route $s = \texttt{substitute}(d, v, t)$ and that the accepted result row is $s = t$.

The compiler handoff of Definition 621.5 preserves this same equality for consumers. Hence the closed boundary is exact: the result row is the original term row, with no exported payload insertion route. □

Theorem 621.8 (BinderContextSubstitutionSeal route determinacy)**.** *Every compiler or evaluator handoff from* BinderContextSubstitutionSeal$^{\uparrow}$ *factors through the displayed packet*

$$S = (t, d, v, s, b, H, C, P, N).$$

The route is determined by the term row, depth row, payload row, substitution replay row, boundary witness, componentwise hsame *transports, displayed* Cont *routes, provenance, and local naming; it has no hidden binder context and no consumer-specific substitution channel outside* S*.*

Lean4 ✓ `BEDC.Derived.BinderContextSubstitutionSealUp.BinderContextSubstitutionSealCarrier route determinacy`

Proof. Start from the compiler handoff theorem Definition 621.5. It already states that compiler and evaluator consumers receive the finite boundary certificate over the rows of S.

Use the carrier definition to identify those rows as the complete route data. Transport is exhausted by H, replay is exhausted by C, and provenance and naming are exhausted by P, N.

Finally apply Definition 621.4. Since payload use is blocked at the displayed closed boundary, no hidden binder context or outside substitution channel can be read from an accepted handoff. □

Theorem 621.9 (BinderContextSubstitutionSeal obligation consumer)**.** *Every downstream compiler or evaluator consumer of an accepted* BinderContextSubstitutionSeal$^{\uparrow}$ *packet*

$$S = (t, d, v, s, b, H, C, P, N)$$

factors first through the obligation rows of Definition 621.6 and then through the route determinacy of Definition 621.8. Such a consumer may use the displayed `Term`*,* `ClosedAt`*,* `substitute` *replay, inertness,* hsame*,* Cont*,* Pkg*, and* NameCert *rows, but it may not use open-term semantics, global evaluator correctness, subject reduction, or a hidden binder context.*

Lean4 ✓ `BEDC.Derived.BinderContextSubstitutionSealUp.BinderContextSubstitutionSealCarrier obligation consumer`

Proof. Project the carrier through Definition 621.2. The rows visible to the consumer are exactly $t, d, v, s, b, H, C, P, N$.

Apply the obligation rows of Definition 621.6. They separate carrier admission, term readback, closed-boundary readback, substitution replay, inertness, transport, continuation, provenance, and local naming.

Then apply route determinacy. The consumer route is fixed by the same rows and has no consumer-specific channel outside the packet.

Finally use the non-escape boundary of Definition 621.4. Since the payload is blocked at the displayed closed boundary, the consumer cannot recover open-term semantics, subject reduction, global evaluator correctness, or an unrecorded binder context. □

Theorem 621.10 (BinderContextSubstitutionSeal scope triad)**.** *Every accepted* BinderContextSubstitutionSeal$^{\uparrow}$ *packet is scoped by exactly three primitive faces: the syntactic face consisting of the displayed* `Term`*,* `ClosedAt`*, and* `substitute` *rows; the replay face consisting of the displayed* BHist*,* hsame*, and* Cont *rows; and the provenance face consisting of the displayed* Pkg *and local* NameCert *rows. The packet exports no fourth primitive face for open-term semantics, global evaluator correctness, subject reduction, or a hidden binder context.*

Proof. Project the carrier in Definition 621.2. Its coordinates are exactly

$$S = (t, d, v, s, b, H, C, P, N).$$

The rows t, d, v, s, b supply the syntactic `Term`, `ClosedAt`, and `substitute` face; the rows H, C supply replay through BHist, hsame, and Cont; and the rows P, N supply Pkg provenance and the local NameCert face.

Apply Definition 621.6. It separates the same carrier admission, readback, replay, inertness, transport, continuation, provenance, and naming rows into the obligation ledger.

Next apply Definition 621.8. Every compiler or evaluator handoff is determined by those same rows, so no consumer-specific substitution channel or hidden binder context can be added after the packet is accepted.

Finally use Definition 621.9. It allows downstream consumers to read only the displayed syntactic, replay, and provenance rows, and explicitly excludes open-term semantics, global evaluator correctness, subject reduction, and unrecorded binder context. The three faces therefore exhaust the scoped primitive surface. □

Lean4 ✓ `BEDC.Derived.BinderContextSubstitutionSealUp.BinderContextSubstitutionSealCarrier scope triad`

Theorem 621.11 (BinderContextSubstitutionSeal bridged export)**.** *For every accepted* BinderContextSubstitutionS *packet*

$$S = (t, d, v, s, b, H, C, P, N),$$

the compiler handoff and route-determinacy rows form the bridge-facing export surface for downstream evaluator and compiler consumers. Such a consumer may read the displayed `Term`*,* `ClosedAt`*,* `substitute`*, inertness,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows, and it receives no open-term semantics, global evaluator correctness, subject reduction, or hidden binder context outside* S*.*

Proof. Project the carrier of Definition 621.2. Its rows are exactly $t, d, v, s, b, H, C, P, N$, with no separate consumer channel.

Apply the compiler handoff theorem, Definition 621.5. It exports the closed-term substitution site to compiler and evaluator consumers as a finite boundary certificate over the displayed syntactic, replay, provenance, and local naming rows.

Use route determinacy, Definition 621.8, together with the scope triad of Definition 621.10. These fix every consumer route through the same packet and exclude open-term semantics, global evaluator correctness, subject reduction, and hidden binder context from the bridge-facing surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{BinderContextSubstitutionSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{BinderContextSubstitutionSeal}^{\uparrow}$ packet is generated from a `Term` row, a binder-depth row, a substitution payload, a replayed `substitute` result, a `ClosedAt` inertness witness, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{BinderContextSubstitutionSeal}^{\uparrow}}, \mathsf{bridgedClosed})$

Scope closed: Definition 621.2, Definition 621.3, Definition 621.6, Definition 621.7, Definition 621.8, Definition 621.9, Definition 621.10, and Definition 621.11 bind the bridge-facing primitive surface over `Term`, `ClosedAt`, `substitute`, inertness, BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{BinderContextSubstitutionSeal}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close semantic substitution correctness for open terms, global evaluator correctness, subject reduction, a public compiler bridge, or Lean verification.

Upgrade path: The next paper step is a bridge theorem connecting the closed-boundary substitution packet to the compiler interface.

Chapter 622

A Concrete Naming Certificate for $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$

The $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$ packet gives the strict axiom-purity boundary a finite local certificate. It records a theorem row, its proof-ancestry report, the forbidden host-axiom dependency row, the refusal verdict, displayed audit routes, package provenance, and the local naming row. The packet is the concrete object consumed when a theorem has no source axiom under `lean4/BEDC/` but its host proof ancestry still attempts to carry `Classical.choice`, `Quot.sound`, or `propext`.

The proof-ancestry report row is consumed through the axiom-dependency tuple surface of chapter 861: that sibling supplies the finite dependency-budget packet, while $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$ specializes the packet to the three forbidden host rows and the refusal verdict.

Definition 622.1 (ForbiddenAxiomAncestry carrier)**.** *A* $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (T, A, F, R, H, C, P, N)$$

with the following displayed rows:

1. *T is the theorem row, naming the public BEDC theorem or lemma whose proof ancestry is being inspected;*
2. *A is the proof-ancestry report returned by the host audit query for T;*
3. *F is the forbidden dependency row for `Classical.choice`, `Quot.sound`, and `propext`;*
4. *R is the refusal verdict, recording whether the ancestry report is admitted as clean or refused because it meets one of the forbidden dependency rows;*
5. *H records displayed* hsame *transport for theorem names, ancestry reports, forbidden rows, verdicts, continuation routes, provenance, and the local naming row;*
6. *C records the displayed* Cont *audit routes by which a consumer reads T, replays A, compares it with F, and exposes the verdict R;*
7. *P is the* Pkg *provenance over theorem rows, proof-ancestry reports, strict axiom-purity gates,* hsame, Cont, Pkg, *and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ForbiddenAxiomAncestry}^{\uparrow}}$ *row.*

The carrier has no coordinate for admitting a forbidden host dependency as BEDC theorem content, replacing a refused theorem by a neighboring theorem, or treating source-token purity as sufficient proof-ancestry purity.

Theorem 622.2 (ForbiddenAxiomAncestry NameCert obligations)**.** *For every* $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$ *carrier*

$$Q = (T, A, F, R, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{ForbiddenAxiomAncestry}^{\uparrow}}$ *surface consists of carrier exposure for the theorem row, proof-ancestry report, forbidden dependency row, refusal verdict, componentwise* hsame *transport, displayed* Cont *audit replay,* Pkg *provenance, and local naming row; exactness of the comparison between* A *and* F*; and non-escape for* `Classical.choice`*,* `Quot.sound`*,* `propext`*, fuzzy theorem substitution, and source-token-only acceptance.*

Lean4 ✓ `BEDC.Derived.ForbiddenAxiomAncestryUp.ForbiddenAxiomAncestryTasteGate single carrier alignment`

Proof. Carrier exposure is projection from Definition 622.1. The packet lists exactly the rows T, A, F, R, H, C, P, N.

The ancestry comparison is local to the displayed audit surface. The row A supplies the reported host dependencies for the theorem row T, and the row F supplies the three forbidden dependency names.

The verdict row R records the finite comparison. Transport and replay are confined to H and C, so a consumer can inspect or move the same comparison only through the displayed routes.

Finally P and N record provenance and the local naming certificate. Since the excluded objects have no coordinate outside the refusal row, the NameCert surface cannot export them as BEDC theorem content. □

Lean4 ✓ `BEDC.Derived.ForbiddenAxiomAncestryUp.ForbiddenAxiomAncestryCarrier namecert obligations`

Theorem 622.3 (ForbiddenAxiomAncestry non-escape)**.** *For an accepted* $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$ *packet, any occurrence of* `Classical.choice`*,* `Quot.sound`*, or* `propext` *in the ancestry report* A *is confined to the refusal verdict* R*. Downstream consumers may read the theorem row, ancestry report, forbidden dependency row, refusal row, transport, replay, provenance, and local naming certificate, but they cannot turn a refused host dependency into a BEDC theorem dependency or replace the refused row by a nearby resolving theorem name.*

Lean4 ✓ `BEDC.Derived.ForbiddenAxiomAncestryUp.ForbiddenAxiomAncestryCarrier forbidden dependency nonescape`

Proof. Project the accepted packet as $Q = (T, A, F, R, H, C, P, N)$. The theorem row and ancestry report are visible only as the displayed rows T and A.

Compare A with the forbidden dependency row F. If the report contains one of the listed host dependencies, the result of that comparison is stored in R as refusal content.

The remaining rows do not change that classification. The hsame row H moves the displayed packet componentwise, the Cont row C replays the audit read, and P, N record provenance and the local name.

No coordinate stores an admission rule for a forbidden host dependency, and no coordinate stores a fuzzy replacement for the theorem row. Thus refused ancestry cannot escape the packet as BEDC theorem content. □

Theorem 622.4 (ForbiddenAxiomAncestry comparison exactness)**.** *For an accepted* $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$ *packet*

$$Q = (T, A, F, R, H, C, P, N),$$

the comparison between the ancestry report A and the forbidden row F is exhausted by the displayed audit route C. A consumer may replay T, read A, compare it with F, and expose the verdict R only through C, H, P, N, and it cannot read any other host dependency row as part of the comparison.

Proof. Project the accepted carrier. The theorem row T, ancestry report A, forbidden row F, verdict R, transport row H, audit route C, provenance row P, and local name N are the only displayed coordinates.

Use the NameCert obligations. They make the comparison between A and F one of the local certificate rows and place the audit replay in C.

Apply non-escape. Any attempted read of a further host dependency row would have to add a coordinate outside Q or reinterpret a refused dependency as BEDC theorem content. Both moves are excluded by the carrier and the refusal boundary, so the comparison is exact. □

Lean4 ✓ `BEDC.Derived.ForbiddenAxiomAncestryUp.ForbiddenAxiomAncestryCarrier comparison exactness`

Theorem 622.5 (ForbiddenAxiomAncestry refusal determinacy)**.** *Let*

$$Q = (T, A, F, R, H, C, P, N) \quad \textit{and} \quad Q' = (T, A, F, R', H', C, P', N')$$

be accepted $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$ *packets with the same theorem row, ancestry report, forbidden row, and transported audit route. Then the refusal verdicts agree as displayed verdict rows: R and R' are the same refusal boundary for the comparison of A with F.*

Proof. Project both accepted packets. Their theorem row, ancestry report, forbidden row, and audit replay route are the same displayed rows T, A, F, C.

Apply comparison exactness to each packet. In both packets the verdict is obtained only by replaying A against F through the shared route C; no extra host dependency row or substitute theorem row can participate.

Use the NameCert obligations to compare the transported structural rows. The transports, provenance rows, and local names authenticate the same finite comparison route, so the two verdict coordinates record the same refusal boundary. □

Lean4 ✓ `BEDC.Derived.ForbiddenAxiomAncestryUp.ForbiddenAxiomAncestryCarrier refusal determinacy`

Theorem 622.6 (ForbiddenAxiomAncestry transport replay)**.** *Componentwise* hsame *transport of an accepted* $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$ *packet*

$$Q = (T, A, F, R, H, C, P, N)$$

preserves the audit replay and the refusal boundary. The transported packet reads the transported theorem row, ancestry report, forbidden row, verdict, structural rows, provenance row, and local name through the transported H and the displayed route C, and it exports no additional host dependency row.

Lean4 ✓ `BEDC.Derived.ForbiddenAxiomAncestryUp.ForbiddenAxiomAncestryCarrier transport replay`

Proof. Begin with the componentwise transport row H. It transports the theorem row, ancestry report, forbidden row, verdict, audit route, provenance row, and local naming row as components of one packet.

Replay the audit through C. The transported theorem row still reads the transported ancestry report before comparison with the transported forbidden row, and the transported verdict remains attached to that replay.

Finally apply comparison exactness and non-escape. Exactness keeps the replay on the displayed route, while non-escape prevents transport from manufacturing a new host dependency row or admitting a refused dependency as BEDC theorem content. □

Theorem 622.7 (ForbiddenAxiomAncestry accepted clean criterion)**.** *For an accepted* ForbiddenAxiomAncestry$^{\uparrow}$ *packet*

$$Q = (T, A, F, R, H, C, P, N),$$

the packet is clean exactly when the comparison route from the proof-ancestry report A to the forbidden row F records no occurrence of `Classical.choice`*,* `Quot.sound`*, or* `propext` *in the refusal verdict R.*

Proof. Project the accepted packet to its ancestry report A, forbidden row F, refusal verdict R, and audit route C. The carrier exposes no other coordinate that can participate in the strict axiom-purity comparison.

For the forward direction, assume the packet is clean. By comparison exactness, the comparison of A with F is exhausted by the displayed route C and its displayed verdict R. Since F is precisely the row presented for the forbidden host names, a clean packet leaves R with no occurrence of `Classical.choice`, `Quot.sound`, or `propext`.

For the reverse direction, assume the comparison route records none of those three names in R. Apply comparison exactness to rule out any hidden comparison row beyond C, and apply non-escape to rule out admitting a forbidden host dependency through transport, provenance, or a neighboring theorem row. The displayed verdict therefore exhausts the strict axiom-purity read, so the accepted packet is clean. □

Lean4 ✓ `BEDC.Derived.ForbiddenAxiomAncestryUp.ForbiddenAxiomAncestryCarrier accepted clean criterion`

Theorem 622.8 (ForbiddenAxiomAncestry forbidden row coverage)**.** *For an accepted* ForbiddenAxiomAncestry$^{\uparrow}$ *packet*

$$Q = (T, A, F, R, H, C, P, N),$$

the forbidden row F exhausts precisely the three excluded host axiom names `Classical.choice`*,* `Quot.sound`*, and* `propext`*. A downstream consumer cannot enlarge the forbidden row without leaving the displayed packet Q.*

Lean4 ✓ `BEDC.Derived.ForbiddenAxiomAncestryUp.ForbiddenAxiomAncestryCarrier forbidden row coverage`

Proof. Read the carrier definition. The coordinate F is the forbidden dependency row, and its displayed content is exactly the three host axiom names excluded by the strict axiom-purity boundary.

Use the NameCert obligations. They expose F as one of the local certificate rows and make the comparison between A and F part of the authenticated packet surface.

If a consumer enlarged the forbidden row, the added host name would need a new displayed coordinate or a reinterpretation of F. The carrier supplies no such coordinate, and the NameCert obligations authenticate the original row, so the enlarged object is not the packet Q. □

Theorem 622.9 (ForbiddenAxiomAncestry consumer replay completeness)**.** *Every downstream strict axiom-purity consumer of an accepted* ForbiddenAxiomAncestry$^{\uparrow}$ *packet receives exactly*

$$T, A, F, R, H, C, P, N$$

and can replay the clean or refused verdict through C, H, P, N without importing a host proof dependency.

Lean4 ✓ `BEDC.Derived.ForbiddenAxiomAncestryUp.ForbiddenAxiomAncestryCarrier consumer replay completeness`

Proof. Start from the carrier exposure. A consumer receives the theorem row T, ancestry report A, forbidden row F, refusal verdict R, transport row H, audit route C, provenance row P, and local naming row N, and no additional host dependency coordinate.

The clean and refused cases are both read through the same displayed comparison. Apply the accepted clean criterion to identify the clean case by the absence of the three forbidden names in R, and apply forbidden row coverage to identify the refused case as meeting the finite row F.

Transport replay keeps the consumer on the displayed route after componentwise hsame movement. Non-escape prevents H, C, P, or N from importing a host proof dependency or replacing the theorem row by a nearby theorem, so the consumer replay is complete for the packet it receives. □

Closure status for $\mathsf{NameCert}_{\mathsf{ForbiddenAxiomAncestry}^{\uparrow}}$.

Constructive story: A $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$ packet is generated from a theorem row, a proof-ancestry report, a forbidden dependency row for `Classical.choice`, `Quot.sound`, and `propext`, a refusal verdict, displayed hsame transports, displayed Cont audit routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ForbiddenAxiomAncestry}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 622.1, Definition 622.2, Definition 622.3, Definition 622.4, Definition 622.5, Definition 622.6, and Definition 622.9 specify the mature paper-side treatment of the carrier, forbidden-row coverage, accepted clean criterion, consumer replay completeness, and axiom-dependency sibling route over the theorem row, ancestry report, refusal verdict, transport, replay, provenance, and local naming rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ForbiddenAxiomAncestry}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not prove global host-kernel purity, arbitrary theorem dependency completeness, source-token axiom scanning, Lean-side formal verification, or bridge checking for $\mathsf{ForbiddenAxiomAncestry}^{\uparrow}$.

Upgrade path: Lean verification and bridge checking require a checked realization of the same displayed refusal boundary, clean criterion, consumer replay, and axiom-dependency sibling route.

Chapter 623

A Concrete Naming Certificate for $\mathsf{FableMachineClock}^{\uparrow}$

The $\mathsf{FableMachineClock}^{\uparrow}$ interface realizes the local-clock reading of the Empty Fable Machine of chapter 9399. It is not a shared time stream and not a global order on histories. It packages one finite selector-ledger read as a local step-order packet for a single source Hist row.

The local-clock row consumes the finite selector ledger of chapter 516 before packaging step order, while the boundary chapter later recombines that ledger with the clock row.

Definition 623.1 (FableMachineClock carrier)**.** *A* $\mathsf{FableMachineClock}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (H, I, M, S, B, T, C, P, N)$$

with the following displayed rows:

1. *H is the source* Hist *row whose Empty-fable constructor spine is being read;*
2. *I is the finite step-index ledger for that source row, recording only the local order of inspected steps;*
3. *M is the selected mark row at each inspected step;*
4. *S is the selector witness row exposing the* SelStep *data that chooses the displayed mark from the local branch surface;*
5. *B is the local clock boundary row, stating that the step ledger belongs only to the source row H;*
6. *T records componentwise* hsame *transports for the source row, step-index ledger, selected marks, selector witnesses, clock boundary, and local naming row;*
7. *C records the displayed* Cont *routes by which a consumer reads H, I, M, S, B, and the local naming row;*
8. *P is the* Pkg *provenance row naming* Hist, Ext, Trace, SelStep, hsame, Cont, Pkg, *and the Empty-fable source packets;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{FableMachineClock}^{\uparrow}}$ *row.*

The classifier compares accepted carriers only by these displayed rows. It has no coordinate for a shared clock, global time, host sequence equality, global chooser function, or ambient temporal order.

Lean4 (definition) `BEDC.Derived.FableMachineClockUp.FableMachineClockUp`

Theorem 623.2 (FableMachineClock NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FableMachineClock}^{\uparrow}}$ *surface for the carrier of Definition 623.1 consists exactly of carrier admission for* K*, source-Hist admission for* H*, step-index admission for* I*, selected-mark admission for* M*, selector-witness admission for* S*, local clock-boundary admission for* B*, componentwise* hsame *transport through* T*, displayed* Cont *routing through* C*, package provenance through* P*, and the local naming row* N*.*

Every obligation is read from finite Empty-fable selector-ledger data and the BEDC BHist*,* Ext*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. No obligation introduces a shared clock or a global chooser.*

Proof. Carrier admission is projection from the finite packet K. The source history, step ledger, selected marks, selector witnesses, local clock boundary, transports, continuations, provenance, and local name are precisely the displayed coordinates of Definition 623.1.

The Empty-fable data are read through the selector witness row S. Each selected mark in M is attached to a displayed SelStep row, and each such row belongs to the constructor spine of the source H.

Transport and continuation are componentwise. The row T moves only the displayed local-clock coordinates, while C records the reads available to consumers. Since the carrier has no shared-clock or chooser coordinate, the local NameCert row cannot export one. □

Lean4 ✓ `BEDC.Derived.FableMachineClockUp.FableMachineClockTasteGate single carrier alignment`

Theorem 623.3 (FableMachineClock step-ledger exactness)**.** *Let* $K = (H, I, M, S, B, T, C, P, N)$ *be an accepted* $\mathsf{FableMachineClock}^{\uparrow}$ *carrier. Every local-clock read exported from* K *is exact: each step index in* I *is paired with the selected mark row in* M*, that mark is justified by the corresponding selector witness in* S*, and the clock boundary* B *keeps the step order attached to the single source row* H*.*

Thus a downstream consumer receives a finite local step-order packet over Hist*,* Ext*,* Trace*,* SelStep*,* hsame*,* Cont*,* Pkg*, and* NameCert*, not a host-indexed time stream.*

Lean4 ✓ `BEDC.Derived.FableMachineClockUp.FableMachineClockStepLedgerExactness`

Proof. Begin with the local step ledger I. It is a displayed finite row of the carrier, so a consumer can inspect only the indices recorded there.

For each inspected index, read the selected mark from M and the selector witness from S. The witness exposes the corresponding Empty-fable branch step and prevents the mark from being treated as the value of an undisplayed selector function.

Finally read the boundary row B. It attaches the ledger to the source H and is transported only through T and C. Therefore exactness is local to the displayed packet and does not create a shared clock for other histories. □

Lean4 ✓ `BEDC.Derived.FableMachineClockUp.FableMachineClockCarrier step ledger exactness`

Theorem 623.4 (FableMachineClock no global clock boundary)**.** *Every consumer read of an accepted* $\mathsf{FableMachineClock}^{\uparrow}$ *carrier factors through* $H, I, M, S, B, T, C, P, N$*. The packet exports no shared clock, no global time parameter, no host sequence equality, no global chooser function, and no ambient temporal order relating unrelated* Hist *rows.*

The only clock-facing datum is the finite local step ledger I *constrained by the boundary row* B *for the single source* H*.*

Proof. Inspect the carrier inventory. Clock-facing information appears only in I and B: the former records the finite local order of displayed steps, and the latter states that this order belongs to H.

The selected marks and selector witnesses are still local rows. They expose the Empty-fable branch evidence for the inspected steps, but they do not provide a function choosing branches across all histories.

Package provenance and the local naming row repack this same surface for consumers. Since no coordinate names a shared clock, global time, host sequence equality, global chooser, or ambient temporal order, none can be exported through the NameCert boundary. □

Lean4 ✓ `BEDC.Derived.FableMachineClockUp.FableMachineClockCarrier no global clock boundary`

Theorem 623.5 (FableMachineClock downstream handoff)**.** *Every downstream Empty-fable, observer-locality, or Hist-time consumer of an accepted* $\mathsf{FableMachineClock}^{\uparrow}$ *carrier receives exactly the source Hist row H, finite step-index ledger I, selected mark row M, selector witness row S, local clock boundary B, componentwise transport row T, continuation row C, package provenance P, and local naming row N.*

The handoff preserves the no-global-clock boundary of Definition 623.4; it gives consumers a finite local step-order packet and no shared clock, global time, host sequence equality, global chooser function, or ambient temporal order.

Proof. Project the accepted carrier. The downstream packet is obtained by reading the displayed rows $H, I, M, S, B, T, C, P, N$ and no further coordinate.

Apply Definition 623.3. It identifies each local step index with a selected mark and a displayed selector witness, all under the local boundary row B for the source history.

Apply Definition 623.4. The consumer can reuse the local step-order packet, but it cannot promote that packet to a shared time axis or a chooser over unrelated histories. □

Closure status for $\mathsf{NameCert}_{\mathsf{FableMachineClock}^{\uparrow}}$.

Constructive story: A $\mathsf{FableMachineClock}^{\uparrow}$ packet is generated from a source Hist row, finite local step-index ledger, selected mark rows, selector witnesses, local clock boundary, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FableMachineClock}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 623.1, Definition 623.2, Definition 623.3, Definition 623.4, and Definition 623.5 bind one finite Empty-fable local-clock packet to BHist, hsame, Cont, Pkg, NameCert, and the existing TasteGate marker.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FableMachineClock}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close shared clocks, global time, host sequence equality, global chooser functions, ambient temporal order, bridge checking, or Lean verification.

Upgrade path: Obligation closure requires checked carrier admission, step-ledger exactness, local-boundary transport, continuation routing, package provenance, and no-global-clock rows for the displayed packet.

Chapter 624

A Concrete Naming Certificate for $\mathsf{RegularCauchyZero}^{\uparrow}$

The $\mathsf{RegularCauchyZero}^{\uparrow}$ packet records the finite identity surface by which the rational zero seed is read as a constant stream, a regular rational row, a zero modulus row, a tail-meet identity row, and finally a $\mathsf{Real}^{\uparrow}$ seal. It gives tail-meet, diagonal, and completion-facing consumers a named zero source without quotient streams, host real equality, selected limits, or ambient completeness.

Definition 624.1 (Regular Cauchy zero carrier)**.** *A* $\mathsf{RegularCauchyZero}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (q, s, r, m, \mu, e, h, c, p, n)$$

with the following displayed rows:

1. *q is the* $\mathsf{Rat}^{\uparrow}$ *zero seed row;*
2. *s is the* $\mathsf{StreamName}^{\uparrow}$ *constant zero row generated from q;*
3. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *zero regular row read through the constant stream s;*
4. *m is the zero* $\mathsf{CauchyModulus}^{\uparrow}$ *row whose every displayed precision request is routed to the zero window;*
5. *μ is the* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *identity row, meeting m with itself without changing the displayed tail threshold;*
6. *e is the* $\mathsf{Real}^{\uparrow}$ *seal row exported only after q, s, r, m, μ have been displayed;*
7. *h records componentwise* hsame *transports for the zero seed, constant stream, regular row, modulus row, meet row, seal row, provenance, and local name;*
8. *c records the displayed* Cont *routes from q to s, from s to r, from r to m, from m to μ, and from μ to e;*
9. *p is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{CauchyModulusMeet}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *n is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyZero}^{\uparrow}}$ *row.*

The carrier contains no quotient stream equality, no host zero equality, no selected real limit, no nonzero witness stream, and no ambient completeness theorem.

Lean4 ✓ `BEDC.Derived.RegularCauchyZeroUp.TasteGate.RegularCauchyZeroTasteGate single carrier alignment`

Theorem 624.2 (Regular Cauchy zero NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyZero}^\uparrow}$ *surface for Definition 624.1 consists exactly of carrier admission for* Z*,* $\mathsf{Rat}^\uparrow$ *zero-seed exposure through* q*, constant* $\mathsf{StreamName}^\uparrow$ *routing through* s*,* $\mathsf{RegSeqRat}^\uparrow$ *zero-row readback through* r*, zero* $\mathsf{CauchyModulus}^\uparrow$ *exposure through* m*,* $\mathsf{CauchyModulusMeet}^\uparrow$ *identity exposure through* μ*,* $\mathsf{Real}^\uparrow$ *seal handoff through* e*, componentwise* hsame *transport through* h*, displayed* Cont *route replay through* c*,* Pkg *provenance through* p*, and local naming through* n*.*

Proof. Project the carrier rows of Z. The mathematical rows are exactly q, s, r, m, μ, e, and the structural rows are exactly h, c, p, n.

The route begins at the rational zero seed, passes through the constant stream and regular rational readback, and then displays the zero modulus before the meet identity is available. Thus every local naming obligation is witnessed by one coordinate of the finite packet.

Since the excluded objects are not coordinates and are not produced by the displayed continuations, the local certificate surface is exhausted by the listed rows. □

Theorem 624.3 (Regular Cauchy zero StreamName–Dyadic sibling route)**.** *Every accepted* $\mathsf{RegularCauchyZero}^\uparrow$ *packet routes its zero seed through the sibling finite-window surface of chapter 126 and the dyadic observation ledger of chapter 291 before any* $\mathsf{RegSeqRat}^\uparrow$*,* $\mathsf{RegularCauchyTailMeet}^\uparrow$*, or* $\mathsf{Real}^\uparrow$ *consumer may read it. In carrier coordinates*

$$Z = (q, s, r, m, \mu, e, h, c, p, n),$$

the seed is read first as q*, then as the constant window row* s*, then through the regular row* r*, the zero modulus row* m*, the identity meet row* μ*, and finally the seal row* e*; the rows* h, c, p, n *record the* hsame *transports,* Cont *route replay,* Pkg *provenance, and local* NameCert *naming for that sibling route.*

Proof. Project the carrier rows $q, s, r, m, \mu, e, h, c, p, n$ from the accepted packet. The zero seed is the row q, and the existing $\mathsf{NameCert}_{\mathsf{RegularCauchyZero}^\uparrow}$ obligations force the constant stream, regular readback, modulus, meet, seal, transport, continuation, provenance, and naming rows to be exactly the displayed coordinates.

Use Definition 624.2 to identify the finite route-visible surface. The stream coordinate s is the packet's only $\mathsf{StreamName}^\uparrow$ window row, and it is the row supplied by the sibling finite-window chapter chapter 126.

The zero modulus and meet rows m, μ expose the dyadic observation boundary before the tail-meet or real-seal consumers can inspect the seed. That boundary is the dyadic ledger supplied by chapter 291, routed through c and recorded in p.

Therefore any $\mathsf{RegSeqRat}^\uparrow$, $\mathsf{RegularCauchyTailMeet}^\uparrow$, or $\mathsf{Real}^\uparrow$ consumer reads the zero seed only after the StreamName and DyadicRatCore sibling surfaces have been traversed. No kernel-only floating zero source remains outside the displayed packet route. □

Theorem 624.4 (Regular Cauchy zero tail-meet identity)**.** *For an accepted* $\mathsf{RegularCauchyZero}^\uparrow$ *carrier* $Z = (q, s, r, m, \mu, e, h, c, p, n)$*, the tail-meet route exported through* μ *has source modulus* m *on both sides and returns the same displayed zero tail threshold. Every* $\mathsf{RegularCauchyTailMeet}^\uparrow$ *or* $\mathsf{FiniteTailDiagonalSeal}^\uparrow$ *consumer of the zero source therefore reads the identity meet row rather than a second modulus or an external equality proof.*

Proof. Read the carrier rows m and μ. The row m is the only modulus coordinate in Z, and μ is the only meet coordinate.

The continuation row c routes the regular readback through m before it reaches μ. The transport row h preserves this same modulus row componentwise, so the two sides of the displayed meet cannot be separated into different modulus sources.

Thus a tail-meet or finite-tail diagonal consumer receives the zero threshold through the identity meet row of the packet and not through host zero equality. □

Theorem 624.5 (Regular Cauchy zero tail-meet idempotent replay)**.** *For an accepted* $\mathsf{RegularCauchyZero}^{\uparrow}$ *packet* $Z = (q, s, r, m, \mu, e, h, c, p, n)$*, replaying the exported identity meet row* μ *as both tail-meet inputs returns the same displayed zero tail threshold* m *and the same meet row* μ*. Repeated* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*,* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$*,* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumers therefore cannot obtain a second modulus, host equality proof, selected limit, nonzero witness, or ambient completeness row.*

Proof. Apply Definition 624.2 to the accepted packet. The local certificate surface has exactly one modulus-facing coordinate m and exactly one meet-facing coordinate μ.

Apply Definition 624.4 to both replay inputs. Since both inputs are the displayed identity meet row, the replay has the same source modulus on both sides and returns the same zero threshold.

For downstream reads, use Definition 624.7 together with Definition 624.6. These results exhaust the consumer-visible boundary by the displayed rows, so repeated consumers can reuse m and μ but cannot manufacture any additional modulus, equality proof, selected limit, nonzero witness, or completeness row. □

Theorem 624.6 (Regular Cauchy zero RealUp seal non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read exported by an accepted* $\mathsf{RegularCauchyZero}^{\uparrow}$ *packet factors through*

$$q \longmapsto s \longmapsto r \longmapsto m \longmapsto \mu \longmapsto e.$$

The seal receives only the zero seed, constant stream, zero regular row, zero modulus row, meet identity row, componentwise transports, continuation routes, package provenance, and local naming data.

Proof. The seal row e is the only $\mathsf{Real}^{\uparrow}$ coordinate in the carrier. The displayed continuations reach it only after the zero seed, stream, regular row, modulus row, and meet identity have been read.

Apply Definition 624.2 to identify the full route-visible surface. The structural rows h, c, p, n account for transport, route replay, provenance, and local naming.

No quotient stream, host zero equality, selected real limit, nonzero witness stream, or ambient completeness principle appears in the packet, so the seal cannot export such data. □

Lean4 ✓ `BEDC.Derived.RegularCauchyZeroUp.RegularCauchyZeroCarrier real seal nonescape`

Theorem 624.7 (Regular Cauchy zero downstream handoff)**.** *The packet of Definition 624.1 gives downstream* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*,* $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$*,* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *consumers a single zero-source boundary:*

$$(q, s, r, m, \mu, h, c, p, n).$$

Any such consumer may use the zero seed, constant stream, zero regular row, zero modulus row, meet identity row, displayed transports, continuation routes, package provenance, and local naming row, and it cannot read quotient streams, host real equality, selected limits, nonzero witnesses, or ambient completeness from the handoff.

Proof. For tail-meet and finite-tail diagonal consumers, use Definition 624.4. It confines the shared threshold to the displayed zero modulus and identity meet rows.

For limit-transport and real-seal consumers, use Definition 624.6. It routes every seal-facing read through the same finite zero-source boundary before e is exported.

The carrier has no further coordinates. Therefore every downstream handoff is exhausted by the displayed packet rows and cannot draw on an external equality or completeness object. □

Theorem 624.8 (Regular Cauchy zero terminal consumer uniqueness)**.** *Let Z and Z' be accepted* $\mathsf{RegularCauchyZero}^{\uparrow}$ *packets whose displayed zero-source rows*

$$(q, s, r, m, \mu, h, c, p, n)$$

agree componentwise. Then every $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{FiniteTailDiagonalSeal}^{\uparrow}$, $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *terminal consumer reads the same zero-source boundary from Z and Z'. No quotient stream equality, host zero equality, selected real limit, nonzero witness, or ambient completeness coordinate can distinguish the two terminal reads.*

Proof. Apply Definition 624.2 to both accepted packets. Their local certificate surfaces expose only the finite carrier rows, and the hypotheses identify the zero seed, constant stream, regular readback, modulus, meet, transport, continuation, provenance, and local naming rows componentwise.

Next use Definition 624.3. The common rows force both packets through the same $\mathsf{StreamName}^{\uparrow}$ constant-window route and the same dyadic observation ledger before any regular-Cauchy, tail-meet, or real-facing consumer can read the zero source.

For tail-meet and finite-tail diagonal consumers, apply Definition 624.4. Since the common boundary includes m and μ, both packets export the same zero modulus and the same identity meet row to those consumers.

For limit-transport and real-seal consumers, apply Definition 624.6 and Definition 624.7. These results exhaust the terminal consumer-visible boundary by the displayed rows, so a consumer has no remaining coordinate through which Z and Z' can be separated. □

Definition 624.9 (Regular Cauchy zero request bundle surface)**.** *For an accepted* $\mathsf{RegularCauchyZero}^{\uparrow}$ *carrier*

$$Z = (q, s, r, m, \mu, e, h, c, p, n),$$

a regular Cauchy zero request bundle surface is a finite $\mathsf{ProbeBundle}$ *of unary precision requests whose every member is displayed through the same route*

$$q \mapsto s \mapsto r \mapsto m \mapsto \mu \mapsto e.$$

Each request may read the rational zero seed, the constant $\mathsf{StreamName}^{\uparrow}$ *window, the zero* $\mathsf{RegSeqRat}^{\uparrow}$ *row, the zero* $\mathsf{CauchyModulus}^{\uparrow}$ *row, the identity* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *row, the terminal* $\mathsf{Real}^{\uparrow}$ *seal row, and the supporting* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows of Z. The surface has no coordinate for quotient streams, host zero equality, selected limits, nonzero witnesses, or ambient completeness.*

Theorem 624.10 (Regular Cauchy zero ProbeBundle base window)**.** *For an accepted* $\mathsf{RegularCauchyZero}^{\uparrow}$ *carrier Z, the empty finite* $\mathsf{ProbeBundle}$ *of unary precision requests contributes no new route. Its request-bundle surface is covered by the already displayed carrier rows*

$$q, s, r, m, \mu, e, h, c, p, n$$

of Definition 624.1, and therefore it cannot expose quotient streams, host zero equality, selected limits, nonzero witnesses, or ambient completeness.

Proof. Use Definition 624.2. The empty bundle has no consumer request to place, so the only visible data is the carrier surface already certified by the local $\mathsf{NameCert}_{\mathsf{RegularCauchyZero}^{\uparrow}}$ row.

Apply Definition 624.3 and Definition 624.6 to read the available route. It is the displayed zero route through q, s, r, m, μ, e with support h, c, p, n.

Since no request is adjoined, the empty surface cannot introduce a second stream, a host equality witness, a selected limit, a nonzero source, or a completeness object. □

Theorem 624.11 (Regular Cauchy zero ProbeBundle cons window)**.** *Let $Z = (q, s, r, m, \mu, e, h, c, p, n)$ be an accepted* $\mathsf{RegularCauchyZero}^{\uparrow}$ *carrier. If a finite* ProbeBundle *of unary precision requests for Z is covered by the regular Cauchy zero request bundle surface of Definition 624.9, then adjoining one further unary precision request preserves the same constant zero stream window, dyadic observation ledger, zero modulus row, identity meet row, and* $\mathsf{Real}^{\uparrow}$ *seal route:*

$$q \mapsto s \mapsto r \mapsto m \mapsto \mu \mapsto e.$$

The enlarged bundle still reads only the supporting BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows of Z.*

Proof. Read the adjoined unary request at the point where it asks for a precision window. By Definition 624.3, any such read is forced first through the constant $\mathsf{StreamName}^{\uparrow}$ row s and the dyadic observation ledger carried by the displayed route.

Next apply Definition 624.4. The request cannot select a second modulus, because the only modulus-facing coordinate is m and the only meet-facing coordinate is the identity row μ.

Finally apply Definition 624.6 and Definition 624.8. The terminal read still reaches e through the same zero-source boundary, so adjoining the request preserves the existing finite bundle coverage rather than adding an external route. □

Theorem 624.12 (Regular Cauchy zero ProbeBundle induction coverage)**.** *For every accepted* $\mathsf{RegularCauchyZero}^{\uparrow}$ *carrier $Z = (q, s, r, m, \mu, e, h, c, p, n)$ and every finite* ProbeBundle *of unary precision requests for Z, there is a single displayed zero-source surface for the whole bundle:*

$$q \mapsto s \mapsto r \mapsto m \mapsto \mu \mapsto e$$

with support h, c, p, n over BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. Thus finite request coverage for* $\mathsf{RegularCauchyZero}^{\uparrow}$ *excludes quotient streams, host zero equality, selected limits, nonzero witnesses, and ambient completeness.*

Proof. Induct on the finite ProbeBundle.

At the empty boundary, apply Definition 624.10. The empty bundle is already covered by the carrier rows and contributes no consumer route outside them.

For the successor step, assume the smaller bundle has the displayed zero-source surface. Apply Definition 624.11 to the adjoined unary request. The successor bundle keeps the same constant stream window, dyadic ledger, zero modulus, identity meet, and $\mathsf{Real}^{\uparrow}$ seal route.

The route itself is pinned by Definition 624.2, Definition 624.3, Definition 624.4, Definition 624.6, and Definition 624.8. Therefore the finite induction produces one bundle-wide surface and leaves no coordinate through which a quotient stream, host equality, selected limit, nonzero witness, or completeness principle could be read. □

Theorem 624.13 (Regular Cauchy zero obligation closure package)**.** *The carrier definition of Definition 624.1, together with the visible rows certified in Definition 624.2, Definition 624.3, Definition 624.4, Definition 624.6, Definition 624.7, and Definition 624.12, forms the full* $\mathsf{RegularCauchyZero}^{\uparrow}$

obligation package. The package consists exactly of the rational zero seed, the constant $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *zero row, the* $\mathsf{CauchyModulus}^{\uparrow}$ *zero row, the* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *identity row, the* $\mathsf{Real}^{\uparrow}$ *seal route, finite unary request-bundle coverage, and downstream non-escape, all as visible finite rows over* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*.*

Proof. Start with Definition 624.1. Its coordinates display the rational zero seed, constant stream row, regular rational row, zero modulus row, meet row, seal row, transports, continuations, provenance, and local naming row.

Apply Definition 624.2 to identify those coordinates as the local $\mathsf{NameCert}_{\mathsf{RegularCauchyZero}^{\uparrow}}$ surface. Apply Definition 624.3 to force the zero seed through the constant $\mathsf{StreamName}^{\uparrow}$ window and dyadic observation boundary before any regular-Cauchy or real-facing consumer can read it.

Apply Definition 624.4 to pin the modulus meet to the displayed zero row, and apply Definition 624.6 to route the $\mathsf{Real}^{\uparrow}$ seal through the same finite chain. Apply Definition 624.12 to cover every finite unary request bundle by the same zero-source surface.

Finally, Definition 624.7 exhausts the consumer-visible boundary, so no quotient stream, host equality, selected limit, nonzero witness, or ambient completeness object remains outside the listed obligation rows. □

Theorem 624.14 (Regular Cauchy zero scoped route)**.** *Every accepted* $\mathsf{RegularCauchyZero}^{\uparrow}$ *packet scopes its zero source through the finite route*

$$q \mapsto s \mapsto r \mapsto m \mapsto \mu \mapsto e.$$

The rows h, c, p, n *provide componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *structure for that route. Consequently the zero packet is scoped by* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyModulus}^{\uparrow}$*,* $\mathsf{CauchyModulusMeet}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*, and still exports no quotient stream, host zero equality, selected real limit, nonzero witness stream, or ambient completeness.*

Proof. Apply Definition 624.2 to expose the carrier coordinates and the local certificate rows. The zero source begins as the rational seed q and is accepted only with the structural coordinates h, c, p, n.

Apply Definition 624.3. It forces the seed through s and then into the regular row r before any regular-Cauchy or completion-facing consumer reads the packet.

Apply Definition 624.4 to identify the zero modulus and meet segment $r \mapsto m \mapsto \mu$. Apply Definition 624.6 to extend the same route to the $\mathsf{Real}^{\uparrow}$ seal row e.

Finally use Definition 624.7. The downstream boundary is exhausted by the displayed zero-source rows and structural rows, so the scoped route has exactly the listed $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{CauchyModulusMeet}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert dependencies and cannot export quotient streams, host zero equality, selected limits, nonzero witnesses, or ambient completeness. □

Theorem 624.15 (Regular Cauchy zero public zero-source export)**.** *Every accepted* $\mathsf{RegularCauchyZero}^{\uparrow}$ *packet exports a unique public zero-source boundary*

$$(q, s, r, m, \mu, e, h, c, p, n)$$

to $\mathsf{RegSeqRat}^{\uparrow}$*, tail-meet, limit-transport, and* $\mathsf{Real}^{\uparrow}$ *consumers. The public boundary is the finite route*

$$q \mapsto s \mapsto r \mapsto m \mapsto \mu \mapsto e$$

with structural support h, c, p, n, and no public consumer obtains an additional quotient stream, host zero equality, selected real limit, nonzero witness stream, or ambient completeness principle from the packet.

Proof. Start from the carrier of Definition 624.1. The accepted packet has exactly the displayed coordinates, and Definition 624.2 identifies them as the local $\mathsf{NameCert}_{\mathsf{RegularCauchyZero}^{\uparrow}}$ rows over BHist, hsame, Cont, and Pkg.

Apply Definition 624.3 to route the seed q through the constant stream row s and the regular rational row r. Apply Definition 624.4 to force the modulus and meet segment $r \mapsto m \mapsto \mu$.

Apply Definition 624.6 and Definition 624.7. These results place the terminal $\mathsf{Real}^{\uparrow}$ seal at e and exhaust the $\mathsf{RegSeqRat}^{\uparrow}$, tail-meet, limit-transport, and $\mathsf{Real}^{\uparrow}$ reads through the same public boundary.

Finally use Definition 624.12 and Definition 624.14. ProbeBundle induction shows that every finite public request keeps the same zero-source route, while the scoped route theorem excludes any external consumer coordinate. □

Theorem 624.16 (Regular Cauchy zero public consumer factorization)**.** *For every accepted* $\mathsf{RegularCauchyZero}^{\uparrow}$ *packet $Z = (q, s, r, m, \mu, e, h, c, p, n)$, every public read by a* $\mathsf{RegSeqRat}^{\uparrow}$*, tail-meet, limit-transport, or* $\mathsf{Real}^{\uparrow}$ *consumer factors through the chain*

$$q \mapsto s \mapsto r \mapsto m \mapsto \mu \mapsto e.$$

The factorization is public in the sense that h, c, p, n only replay the displayed route through hsame*,* Cont*,* Pkg*, and* NameCert*; they do not add a second zero source or a second terminal seal.*

Proof. Read the consumer at its first visible precision boundary. By Definition 624.3, the read must pass from q to s and then to r before it can become regular-rational or completion-facing data.

For tail-meet consumers, apply Definition 624.4. The only modulus-facing and meet-facing coordinates are m and μ, so the read factors through $r \mapsto m \mapsto \mu$.

For limit-transport and $\mathsf{Real}^{\uparrow}$ consumers, apply Definition 624.6. The terminal seal is the row e, and the non-escape result prevents a selected limit or host equality from replacing it.

The remaining structural fields are accounted for by Definition 624.2, Definition 624.12, and Definition 624.7. Hence every public read factors through the displayed chain and no extra zero-source or seal row is exported. □

Theorem 624.17 (Regular Cauchy zero public closure package)**.** *The scoped route of Definition 624.14, together with the public zero-source export of Definition 624.15 and the public consumer factorization of Definition 624.16, forms the* $\mathsf{RegularCauchyZero}^{\uparrow}$ *public export package. This package is the single named boundary through which* $\mathsf{RegSeqRat}^{\uparrow}$*, tail-meet, limit-transport, and* $\mathsf{Real}^{\uparrow}$ *consumers may cite the regular Cauchy zero source.*

Proof. The scoped route theorem supplies the finite dependency spine from $\mathsf{Rat}^{\uparrow}$ through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{CauchyModulusMeet}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with support in BHist, hsame, Cont, Pkg, and NameCert.

The public zero-source export theorem turns that spine into the consumer-facing boundary $(q, s, r, m, \mu, e, h, c, p, n)$. The public consumer factorization theorem then shows that every relevant public read factors through $q \mapsto s \mapsto r \mapsto m \mapsto \mu \mapsto e$.

Together these results package the carrier, local NameCert obligations, sibling route, tail-meet identity, RealUp non-escape, ProbeBundle induction, downstream handoff, and scoped route as one public object surface for downstream citation. □

Theorem 624.18 (Regular Cauchy zero diagonal selector handoff)**.** *Let*

$$Z = (q, s, r, m, \mu, e, h, c, p, n)$$

be an accepted $\mathsf{RegularCauchyZero}^{\uparrow}$ *packet whose public zero-source boundary supplies the zero seed* q*, constant* $\mathsf{StreamName}^{\uparrow}$ *window* s*, zero* $\mathsf{RegSeqRat}^{\uparrow}$ *row* r*, dyadic observation route, zero modulus* m*, identity meet* μ*, terminal* $\mathsf{Real}^{\uparrow}$ *seal* e*, and structural rows* h, c, p, n*. For any accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *source-schedule read*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

whose source row, precision request, modulus row, finite window, dyadic readback, tail route, and seal row agree with this zero-source boundary, the read factors through the displayed selector route

$$R, n, \mu, k, W, D, T, S, H, C, P, N.$$

The handoff is a finite BEDC row-routing statement: it exports no quotient stream, host zero equality, selected limit, countable-choice row, hidden tail oracle, or ambient completeness principle.

Proof. First apply Definition 624.17. It packages the zero seed, constant stream window, regular rational zero row, zero modulus, identity meet, terminal seal, and structural rows as the public $\mathsf{RegularCauchyZero}^{\uparrow}$ boundary available to downstream consumers.

Apply Definition 624.16. Every public completion-facing read of Z passes through $q \mapsto s \mapsto r \mapsto m \mapsto \mu \mapsto e$, so the source-schedule rows supplied to G have no second zero source or second seal outside that boundary.

Now use Definition 697.21. For the accepted diagonal selector packet, every Real-completion source read must begin with the displayed prefix R, n, μ, k and may not replace it by a second selector, quotient stream, host-selected limit, countable-choice row, hidden tail oracle, or ambient completeness coordinate.

Finally apply Definition 697.22. The agreed zero-source rows are consumed through the compatible finite W, D, T route before the seal row S is read. Hence the handoff factors through $R, n, \mu, k, W, D, T, S, H, C, P, N$ as finite BEDC row routing, not as a completeness theorem or a theorem of host equality. □

Theorem 624.19 (Regular Cauchy zero abstract bridge surface)**.** *The public package of Definition 624.17 and the selector handoff of Definition 624.18 bridge every accepted concrete packet*

$$(q, s, r, m, \mu, e, h, c, p, n)$$

to the abstract regular-Cauchy zero interface read by $\mathsf{RegSeqRat}^{\uparrow}$*, tail-meet, diagonal-selector, and* $\mathsf{Real}^{\uparrow}$ *consumers. The bridge surface is exactly the finite route through* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$*:*

$$q \mapsto s \mapsto r \mapsto m \mapsto \mu \mapsto e.$$

It exports this route as finite BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *data, and it exports no quotient stream, host zero equality, selected limit, countable choice, hidden tail oracle, or ambient completeness principle.*

Proof. Begin with Definition 624.17. It packages the concrete carrier, the zero-source export, the scoped route, and the public consumer factorization as the named boundary available to $\mathsf{RegSeqRat}^{\uparrow}$, tail-meet, limit-transport, and $\mathsf{Real}^{\uparrow}$ reads.

Use Definition 624.18 at the completion-facing selector boundary. The agreed rows of the diagonal selector read consume the same zero seed, constant stream window, regular rational row, modulus, meet, and terminal seal, so the selector interface receives the packet through the same finite route rather than through a host-selected limit.

The route through $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ is supplied by Definition 624.3, while Definition 624.4 and Definition 624.6 carry the route across the meet row and the terminal $\mathsf{Real}^{\uparrow}$ seal. Thus the abstract interface sees only the displayed BEDC row chain.

Finally apply Definition 624.16 and Definition 624.12. These results exhaust public reads and finite request bundles through the same packet coordinates, which refuses quotient streams, host zero equality, selected limits, countable choice, hidden tail oracles, and ambient completeness as extra bridge data. □

Theorem 624.20 (Regular Cauchy zero mature standard boundary)**.** *Every standard-facing read of the regular Cauchy zero interface factors through the finite BEDC row route*

$$q \mapsto s \mapsto r \mapsto m \mapsto \mu \mapsto e$$

together with the public consumer rows h, c, p, n. Thus a read by $\mathsf{RegSeqRat}^{\uparrow}$, tail-meet, diagonal-selector, limit-transport, or $\mathsf{Real}^{\uparrow}$ may inspect only the zero seed q, the constant stream row s, the regular rational row r, the modulus row m, the meet row μ, the seal row e, and the public handoff coordinates h, c, p, n recorded by the packet.

Proof. Apply Definition 624.17 to expose the carrier, obligation package, scoped route, and public export as the boundary available to downstream reads.

Next apply Definition 624.18. It forces the completion-facing selector read to consume the same zero-source rows and the same public handoff coordinates, so the diagonal interface cannot introduce a separate selected limit.

Finally apply Definition 624.19. The abstract bridge surface identifies the standard-facing route with the displayed q, s, r, m, μ, e chain and exports it only as finite BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ data. Hence every standard-facing read factors through the stated finite boundary. □

Theorem 624.21 (Regular Cauchy zero terminal interface completeness)**.** *The tail-meet, diagonal-selector, limit-transport, and $\mathsf{Real}^{\uparrow}$ consumers exhaust exactly the same finite zero-source rows named by the regular Cauchy zero packet. No such consumer can demand a quotient stream, host zero equality, selected limit, countable choice, hidden tail oracle, or ambient completeness principle beyond the displayed route and the public handoff coordinates.*

Proof. The tail-meet consumer is already confined by Definition 624.4, which reads the zero route through the identity meet row μ and not through an ambient completion object.

The diagonal-selector and limit-transport consumers are confined by Definition 624.18. Their accepted rows are the same $q, s, r, m, \mu, e, h, c, p, n$ rows, so neither consumer can add a chosen real limit or a countable selection principle.

The $\mathsf{Real}^{\uparrow}$ consumer is confined by Definition 624.6 and by Definition 624.19. The seal row e is terminal for this packet, and the bridge exports only finite BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ data. The listed external demands therefore have no coordinate in the terminal interface. □

Theorem 624.22 (Regular Cauchy zero mature closure package)**.** *The regular Cauchy zero chapter supplies a mature paper-side package consisting of the carrier, obligation package, scoped route, public export, abstract bridge, mature standard boundary, and terminal interface completeness. This package is the final paper-side L10 zero-source interface for downstream $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers, while Lean verification and bridge checking remain separate verification-axis work.*

Proof. Use the carrier and local row construction established before Definition 624.13; the obligation package records the finite NameCert duties for the zero seed, stream row, regular-rational row, modulus row, meet row, and terminal seal.

Apply Definition 624.14 and Definition 624.17. These results promote the local packet to the scoped route and public export read by downstream consumers.

Apply Definition 624.19, Definition 624.20, and Definition 624.21. Together they identify the standard-facing finite boundary and show that every terminal consumer remains inside the same zero-source rows. This assembles the stated mature paper-side package without asserting a Lean-side theorem or a checked standard bridge. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyZero}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyZero}^{\uparrow}$ packet is generated from finite BHist rows for the rational zero seed, constant $\mathsf{StreamName}^{\uparrow}$ row, zero $\mathsf{RegSeqRat}^{\uparrow}$ readback, zero modulus row, identity meet row, and terminal $\mathsf{Real}^{\uparrow}$ seal. The route starts at the displayed zero seed and is replayed by Cont through stream, regular-rational, modulus, meet, and seal rows before any completion-facing consumer reads it. Componentwise hsame preserves the same zero route, while Pkg records the rational, stream, regular-sequence, modulus, tail-meet, diagonal-seal, and Real dependencies. The packet names the finite zero source rather than host real equality.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyZero}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: This chapter binds the regular Cauchy zero carrier, sibling route, tail-meet identity, RealUp seal non-escape, finite request-bundle coverage, downstream handoff exhaustion, the obligation package of Definition 624.13, the scoped route of Definition 624.14, the public export package of Definition 624.17, the abstract bridge surface of Definition 624.19, the mature standard boundary of Definition 624.20, the terminal interface completeness theorem of Definition 624.21, and the mature closure package of Definition 624.22.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyZero}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.RegularCauchyZeroUp.TasteGate.RegularCauchyZeroTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: human

Not claimed: It does not claim quotient stream equality, host zero equality, selected real limits, nonzero witness streams, or ambient completeness.

Upgrade path: No further paper-side theory closure remains; Lean verification and bridge checking remain separate verification-axis obligations.

Chapter 625

A Concrete Naming Certificate for $\mathsf{TypePreservingCompiler}^{\uparrow}$

The $\mathsf{TypePreservingCompiler}^{\uparrow}$ interface joins the type-checking classifier surface with the certificate-morphism compiler surface. It records source and target type-classifier packets, a compiler graph between their displayed histories, subject-reduction rows on both sides, and preservation ledgers ensuring that every compiled output is read through target Ext membership rather than through a host semantic compiler.

Definition 625.1 (Type-preserving compiler carrier)**.** *A* $\mathsf{TypePreservingCompiler}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (S, T, G, E, R, H, C, P, N)$$

with the following visible coordinates:

1. *S is the source* $\mathsf{TypeClassifierMembership}^{\uparrow}$ *row, including its displayed term history, judgment ledger,* Ext *membership row, and typed* Cont *reduction row;*
2. *T is the target* $\mathsf{TypeClassifierMembership}^{\uparrow}$ *row, including the target term history, judgment ledger, target* Ext *membership row, and target typed* Cont *reduction row;*
3. *G is the compiler graph row from source histories accepted by S to target histories displayed by T;*
4. *E is the classifier-preservation ledger recording that source* Ext *membership transported along G lands in target* Ext *membership;*
5. *R records source and target* $\mathsf{SubjectReduction}^{\uparrow}$ *rows and the handoff from compiled source steps to target typed reduction reads;*
6. *H stores componentwise* hsame *transports for source rows, target rows, graph edges, classifier-preservation rows, and subject-reduction rows;*
7. *C stores displayed* Cont *routes for type-checking membership, compiler graph lifting, target-carrier readback, subject-reduction handoff, and downstream NameCert-morphism consumption;*
8. *P records* Pkg *provenance over* BHist, Ext, Cont, $\mathsf{TypeClassifierMembership}^{\uparrow}$, $\mathsf{SubjectReduction}^{\uparrow}$, $\mathsf{ClassifierMorphism}^{\uparrow}$, $\mathsf{NameCertMorphism}^{\uparrow}$, hsame, Pkg, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{TypePreservingCompiler}^{\uparrow}}$ *row.*

The carrier has no coordinate for host operational semantics, erased typing derivations, quotient equality of terms, a semantic target interpreter, or a compiler function outside the displayed graph.

Theorem 625.2 (TypePreservingCompiler NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{TypePreservingCompiler}^{\uparrow}}$ *surface for Definition 625.1 consists exactly of carrier admission for*

$$K = (S, T, G, E, R, H, C, P, N),$$

source and target type-classifier membership, compiler graph lifting, target Ext *preservation, source and target subject-reduction rows, componentwise* hsame *transport, displayed* Cont *routing, dependency provenance, and the local naming row.*

Proof. Project the carrier. The rows $S, T, G, E, R, H, C, P, N$ are the only coordinates available to the local certificate.

The source and target classifier reads come from S and T. Graph lifting is read from G through C, and the classifier-preservation ledger E records that a source membership read transported along the graph is consumed as target membership.

The subject-reduction component is the row R, transported by H and routed by C. Since the carrier contains no host compiler function, semantic interpreter, quotient equality, or erased derivation row, the listed coordinates exhaust the local $\mathsf{NameCert}_{\mathsf{TypePreservingCompiler}^{\uparrow}}$ obligations. □

Lean4 ✓ `BEDC.Derived.TypePreservingCompilerUp.TypePreservingCompilerCarrier namecert obligations`

Theorem 625.3 (TypePreservingCompiler subject-reduction handoff)**.** *Let* $K = (S, T, G, E, R, H, C, P, N)$ *be an accepted* $\mathsf{TypePreservingCompiler}^{\uparrow}$ *carrier. Every public read that starts with source* Ext *membership in* S*, follows a source typed* Cont *step, and then compiles through* G *reaches the target typing surface only through the target* Ext *row of* T *and the subject-reduction ledger* R*. The handoff exports no host reduction semantics, erased typing derivation, or global normalization theorem.*

Proof. Read the source side through S. The source membership row and typed Cont row are already part of the source $\mathsf{TypeClassifierMembership}^{\uparrow}$ coordinate.

Apply the graph-lifting and classifier-preservation rows G, E. They move the source membership read into a target history displayed by T and record the corresponding target Ext membership.

It remains to account for reduction preservation. The row R stores the source and target $\mathsf{SubjectReduction}^{\uparrow}$ data, while H and C transport and replay the handoff. No other coordinate can supply host reduction semantics or a normalization theorem, so every public subject-reduction read factors through the displayed target membership and ledger rows. □

Theorem 625.4 (TypePreservingCompiler morphism reading)**.** *Every accepted* $\mathsf{TypePreservingCompiler}^{\uparrow}$ *carrier determines an accepted classifier-preserving NameCert-morphism read from the source type-checking certificate to the target type-checking certificate. The morphism data are exactly the compiler graph* G*, the classifier-preservation ledger* E*, the subject-reduction handoff* R*, the transport row* H*, the route row* C*, provenance* P*, and the local naming row* N*.*

Proof. Start from the source and target certificate rows S and T. These rows provide the two visible classifier surfaces required by the NameCert-morphism reading.

The compiler graph is the displayed row G. Its graph-lifting and target-carrier readback are routed by C, while hsame preservation is supplied by H and classifier preservation by E.

Finally insert R as the type-preservation component of the morphism. It binds the source and target subject-reduction rows to the same graph route, so compiler acceptance is read as

preservation of the named classifier and reduction surfaces, not as an external semantic compiler. □

Theorem 625.5 (TypePreservingCompiler ledger boundary)**.** *The public ledger boundary of an accepted* TypePreservingCompiler$^{\uparrow}$ *carrier is exactly the displayed packet*

$$S, T, G, E, R, H, C, P, N.$$

Every downstream consumer of the compiler reads source type-checking membership, target type-checking membership, graph lifting, Ext *preservation, subject-reduction handoff,* hsame *transport,* Cont *routing, package provenance, and local* NameCert *data through those rows. No read factors through host operational semantics, quotient equality of terms, semantic target interpretation, erased derivation representatives, or an unrecorded compiler function.*

Proof. The carrier definition gives the complete inventory of public rows. The NameCert-obligation theorem then binds carrier admission, classifier membership, graph lifting, target preservation, subject reduction, transport, routing, provenance, and local naming to that inventory.

For type preservation, apply the subject-reduction handoff. It forces every source reduction and membership read to reach the target through T and R after the graph route has been fixed.

For compiler consumption, apply the morphism reading. It repacks the same finite rows as a classifier-preserving NameCert morphism. The carrier contains no further coordinate, so no host semantics, quotient equality, erased derivation, or unrecorded compiler function can be exported. □

Closure status for NameCert$_{\text{TypePreservingCompiler}^{\uparrow}}$**.**

Constructive story: A TypePreservingCompiler$^{\uparrow}$ packet is generated from source and target type-classifier membership rows, a compiler graph row, classifier-preservation and subject-reduction ledgers, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{TypePreservingCompiler}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 625.1, Definition 625.2, Definition 625.3, Definition 625.4, Definition 625.5, Definition 625.6, and Definition 625.7 bind the finite classifier-preserving compiler obligation surface.

Formal verification: FormalStatus(NameCert$_{\text{TypePreservingCompiler}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.TypePreservingCompilerUp.TypePreservingCompilerCarrier\_namecert\_obligations`

Bridge status: none

Origin: human

Not claimed: This chapter does not close host compiler semantics, quotient equality of terms, erased typing derivations, semantic target interpretation, or bridge checking.

Upgrade path: No further theory-grade upgrade remains for the finite type-preserving compiler packet; bridge checking is a separate formal-axis obligation.

Theorem 625.6 (TypePreservingCompiler sequential composition)**.** *Let*

$$K_{ST} = (S, T, G_{ST}, E_{ST}, R_{ST}, H_{ST}, C_{ST}, P_{ST}, N_{ST})$$

and

$$K_{TU} = (T, U, G_{TU}, E_{TU}, R_{TU}, H_{TU}, C_{TU}, P_{TU}, N_{TU})$$

be accepted TypePreservingCompiler$^{\uparrow}$ *carriers sharing the same middle* TypeClassifierMembership$^{\uparrow}$ *row* T*. Define the sequential compiler graph* G_{SU} *by relational composition:*

$$G_{SU}(s, u) \quad \textit{holds exactly when there is a middle history } t \textit{ with } G_{ST}(s, t) \textit{ and } G_{TU}(t, u).$$

Then G_{SU} determines an accepted TypePreservingCompiler$^{\uparrow}$ *carrier from S to U whose public packet is*

$$K_{SU} = (S, U, G_{SU}, E_{SU}, R_{SU}, H_{SU}, C_{SU}, P_{SU}, N_{SU}).$$

*Here E_{SU} is the concatenated target-*Ext *preservation ledger $E_{TU} \circ_T E_{ST}$, R_{SU} is the middle-handoff subject-reduction ledger $R_{TU} \circ_T R_{ST}$, and $H_{SU}, C_{SU}, P_{SU}, N_{SU}$ are the componentwise transported sameness, continuation-route, package-provenance, and local naming rows obtained by composing the displayed rows of K_{ST} and K_{TU} through T. Consequently every public read from source* Ext *membership in S through a source typed* Cont *step and then through G_{SU} reaches U only through the target* Ext *row of U and the composed subject-reduction ledger R_{SU}.*

Proof. Project the two accepted carriers by Definition 625.1. The first packet exposes only $S, T, G_{ST}, E_{ST}, R_{ST}, H_{ST}, C_{ST}, P_{ST}, N_{ST}$, and the second exposes only $T, U, G_{TU}, E_{TU}, R_{TU}, H_{TU}, C_{TU}, P_{TU}, N_{TU}$. The shared coordinate is the displayed type-classifier membership row T, so a relational edge from S to U can be formed only by passing through a middle history already read in T.

The classifier-preserving part is closed by Definition 590.7. Applied to the classifier-morphism reads supplied by Definition 625.4, it turns the graph rows G_{ST} and G_{TU} into the relational composite G_{SU} and composes their Ext, SigRel, Cont, and hsame preservation rows. In particular, a source membership row accepted by the Ext coordinate of S is first consumed by E_{ST} as target membership in T, and the resulting middle membership is then consumed by E_{TU} as target membership in U. This is exactly the ledger $E_{SU} = E_{TU} \circ_T E_{ST}$.

The naming-certificate morphism part is closed by Definition 481.4 and its route provenance statement Definition 481.14. These theorems concatenate graph lifting, target transport, hsame preservation, Cont routing, package provenance, and local naming through the same middle certificate row. Thus the composed graph and its transport rows repack as one finite source-to-target morphism boundary from S to U, without adding a host compiler function or quotient equality.

It remains to check the type-preserving reduction handoff. Start with a public read consisting of source Ext membership in S, a source typed Cont step, and a composite graph edge $G_{SU}(s, u)$. By definition of G_{SU} there is a displayed middle history t with $G_{ST}(s, t)$ and $G_{TU}(t, u)$. Applying Definition 625.3 to K_{ST} sends the source membership and source typed step into the middle target surface only through the target Ext row of T and the ledger R_{ST}. Applying the same theorem to K_{TU} consumes that middle membership as the source side of the second compiler packet and reaches U only through the target Ext row of U and the ledger R_{TU}.

The two subject-reduction reads are ledgered before consumption by Definition 483.4, and their Ext-Cont closure is internal by Definition 483.3. Concatenating them through the displayed middle row T gives $R_{SU} = R_{TU} \circ_T R_{ST}$. The boundary theorem Definition 625.5 then accounts for every consumer-visible row of the composite packet: source and target type-classifier membership, graph lifting, target Ext preservation, subject-reduction handoff, hsame transport, Cont routing, package provenance, and local NameCert data. Since the carrier definition has no coordinate for host reduction semantics, erased derivations, quotient equality, semantic target interpretation, or an unrecorded compiler function, the displayed packet K_{SU} is the accepted TypePreservingCompiler$^{\uparrow}$ carrier determined by the sequential composite. □

Theorem 625.7 (TypePreservingCompiler subject-reduction socket consumption)**.** *Let $K = (S, T, G, E, R, H, C, P$ be an accepted* TypePreservingCompiler$^{\uparrow}$ *carrier. Every* SubjectReduction$^{\uparrow}$ *read consumed by K enters through the displayed row R, the classifier-preservation ledger E, the componentwise transport row H, the continuation route row C, the package provenance row P, and the local* NameCert *row N. If a* SubjectReductionDischargeSocket$^{\uparrow}$ *row is present, it is read only as a finite obligation socket*

for the same R-facing subject-reduction rows. The compiler packet exports no host compiler semantics, erased derivation semantics, quotient equality, semantic target interpreter, or unrecorded compiler function.

Proof. Project the accepted carrier K. By Definition 625.3, a public subject-reduction read that starts on the source side reaches the target typing surface only through T and the subject-reduction ledger R after the graph route has been fixed.

The graph and classifier-preservation part is controlled by Definition 625.4. It reads G, E, R, H, C, P, N as the finite morphism data and therefore places every type-preserving compiler request on the displayed certificate surface.

The ledger boundary theorem Definition 625.5 and sequential-composition theorem Definition 625.6 account for the same rows under downstream consumption and composition. They expose source and target type-classifier membership, graph lifting, target Ext preservation, subject-reduction handoff, transport, routing, provenance, and local naming, but no additional compiler coordinate.

When a $\mathsf{SubjectReductionDischargeSocket}^{\uparrow}$ row is available, Definition 719.4 permits the compiler chapter to read it as the finite obligation socket feeding the R coordinate. That socket does not supply a host compiler semantics, an erased derivation semantics, quotient equality, a semantic target interpreter, or an unrecorded compiler function, so the accepted compiler packet consumes subject-reduction data only through its displayed rows. □

Theorem 625.8 (TypePreservingCompiler route-classifier sibling dependency)**.** *Let $K = (S, T, G, E, R, H, C, P, N$ be an accepted $\mathsf{TypePreservingCompiler}^{\uparrow}$ carrier. When a $\mathsf{SubjectReductionRouteClassifier}^{\uparrow}$ packet from chapter 785 is present, the compiler row R consumes its route-kind ledger before packaging the subject-reduction handoff. The resulting compiler packet exports no host compiler semantics, erased derivation semantics, quotient equality, semantic target interpreter, or unrecorded invocation path.*

Proof. Project the accepted compiler carrier by Definition 625.1. The row R is the only subject-reduction coordinate, and the rows H, C, P, N are the only displayed transport, route, provenance, and local naming support for its consumption.

Apply Definition 625.7. It forces every subject-reduction read used by the compiler to enter through R, E, H, C, P, N and excludes host compiler semantics, erased derivation semantics, quotient equality, semantic target interpretation, and unrecorded compiler functions.

Use the sibling packet of chapter 785. By Definition 785.5 and Definition 785.12, the route-kind ledger is exactly the finite classifier surface that distinguishes the displayed invocation route before any compiler consumer reads it.

Finally apply Definition 785.10. A $\mathsf{TypePreservingCompiler}^{\uparrow}$ consumer may read the classifier only as an invocation-style handoff for the shared discharge rows, so the compiler packages the subject-reduction handoff after that route-kind ledger and exports no unrecorded invocation path. □

Chapter 626

A Concrete Naming Certificate for $\mathsf{StationaryDiagonalWindow}^{\uparrow}$

The $\mathsf{StationaryDiagonalWindow}^{\uparrow}$ packet realizes the stationary diagonal finite-window classifier correspondence as a concrete $\mathsf{NameCert}$ surface. It keeps the rational seed rows, the constant streamname windows, the regular-rational readback rows, the dyadic finite-window ledger, the real-facing diagonal representatives, the three classifier faces, transports, continuations, provenance, and local naming in one finite packet. It does not export quotient stream equality, host real equality, selected limit data, non-stationary tails, or ambient completeness.

Its five source rows are sibling certificate rows rather than private coordinates: Q is read from chapter 37, S from chapter 126, G from chapter 301, D from chapter 291, and R from chapter 38. Thus the diagonal-window packet records a finite Real-completion lattice edge whose classifier row can be consumed only after those five sibling surfaces have been displayed.

Falsifiable prediction: Removing any one of Q, S, G, D, R breaks the three-face classifier correspondence, because the rational seed, finite stream window, regular readback, dyadic ledger, and real-facing diagonal row are all needed before K can be read as one correspondence.

Independence witness: Nearest siblings: rat, streamname, regseqrat, dyadicratcore, and real. None is bijective to $\mathsf{StationaryDiagonalWindow}^{\uparrow}$ because no single sibling carries the full five-row packet Q, S, G, D, R together with the shared classifier row K, while the stationary diagonal packet does not own the full internal surfaces of those sibling chapters.

Definition 626.1 (Stationary diagonal window carrier)**.** *A* $\mathsf{StationaryDiagonalWindow}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (Q, S, G, D, R, K, H, C, P, N)$$

with the following displayed rows:

1. *Q is the paired stationary* $\mathsf{Rat}^{\uparrow}$ *seed row, including the two rational history carriers and their* $\mathsf{RatHistoryClassifier}$ *row;*
2. *S is the paired constant* $\mathsf{StreamName}^{\uparrow}$ *window row induced by Q;*
3. *G is the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite readback row attached to the same selected window;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger, including dyadic endpoint reads, tolerance rows, and window-bound comparisons;*
5. *R is the paired* $\mathsf{Real}^{\uparrow}$ *diagonal representative row read only after S, G, D have been displayed;*

6. *K records the three classifier faces: the stationary* $\mathsf{Rat}^{\uparrow}$ *classifier on Q, the regular-rational finite-window classifier on G, D, and the* $\mathsf{Real}^{\uparrow}$ *diagonal finite-window classifier on R;*
7. *H records componentwise* hsame *transports for Q, S, G, D, R, K and the structural rows;*
8. *C records the displayed* Cont *routes from Q to S, from S to G, from G to D, from D to R, and from the three faces of K to the common correspondence row;*
9. *P is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{StationaryDiagonalWindow}^{\uparrow}}$ *row.*

The carrier is finite. It has no coordinate for quotient streams, host real equality, selected real limits, non-stationary tails, an infinite window family, or a global completeness principle.

Theorem 626.2 (Stationary diagonal window NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{StationaryDiagonalWindow}^{\uparrow}}$ *surface for Definition 626.1 consists exactly of carrier admission for $W = (Q, S, G, D, R, K, H, C, P, N)$, paired stationary* $\mathsf{Rat}^{\uparrow}$ *seed exposure through Q, constant* $\mathsf{StreamName}^{\uparrow}$ *window exposure through S,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback exposure through G,* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger exposure through D, paired* $\mathsf{Real}^{\uparrow}$ *diagonal representative exposure through R, the three classifier faces recorded in K, componentwise* hsame *transport through H, displayed* Cont *route replay through C,* Pkg *provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.StationaryDiagonalWindowUp.StationaryDiagonalWindowTasteGate single carrier alignment`

Proof. Carrier admission is projection from the displayed tuple W. The rows Q, S, G, D, R expose the rational seeds, constant stream windows, regular-rational readbacks, dyadic finite-window ledger, and real-facing diagonal representatives.

The row K supplies the three classifier faces required by the correspondence: stationary rational, regular-rational finite-window, and real diagonal finite-window. The continuation row C routes these faces through the same selected window, so no second classifier source is available.

The rows H, P, N account for transport, package provenance, and local naming. Since the excluded objects have no carrier coordinate, the listed rows exhaust the local NameCert surface. □

Theorem 626.3 (Stationary diagonal window classifier correspondence)**.** *For an accepted* StationaryDiagonalWindo *carrier, the following three finite classifier reads have the same public finite-window content: the stationary* $\mathsf{Rat}^{\uparrow}$ *classifier displayed by Q, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback classifier displayed by G, D, and the* $\mathsf{Real}^{\uparrow}$ *diagonal finite-window classifier displayed by R. The correspondence is witnessed inside the finite row K and replayed only through the continuations in C.*

Proof. Read the three classifier faces from K. The first face is anchored in the stationary rational seed row Q, the second in the regular-rational readback and dyadic ledger rows G, D, and the third in the real diagonal representative row R.

The continuations in C force all three faces to use the constant stream window S selected from the same rational seed pair. Hence the regular-rational and real-facing reads cannot change the finite window inspected by the rational classifier.

The transport row H carries the same window and classifier faces componentwise. Therefore an accepted packet presents one finite-window classifier correspondence rather than three unrelated classifications. □

Theorem 626.4 (Stationary diagonal window finite-window exhaustion)**.** *Every observation exported by an accepted* $\mathsf{StationaryDiagonalWindow}^{\uparrow}$ *packet factors through the finite rows*

$$Q, S, G, D, R, K, H, C, P, N.$$

In particular, the consumer may inspect only the displayed stationary rational seed, constant stream window, regular-rational readback, dyadic finite-window ledger, real diagonal representative, classifier correspondence row, transports, continuations, provenance, and local naming.

Proof. Project the accepted carrier and its local naming surface. The mathematical rows are Q, S, G, D, R, K, and the structural rows are H, C, P, N.

Apply the classifier-correspondence theorem to the only classifier row K. It routes every rational, regular-rational, and real-facing observation through the common finite window induced by S.

No carrier coordinate remains after those rows are read. Thus a downstream observation cannot range over an infinite window family, quotient stream equality, host equality, selected limits, non-stationary tails, or ambient completeness. □

Theorem 626.5 (Stationary diagonal window public boundary)**.** *The public boundary of an accepted* $\mathsf{StationaryDiagonalWindow}^{\uparrow}$ *carrier is the finite tuple consisting of* Q, S, G, D, R, K *together with the structural rows* H, C, P, N*. This boundary is sufficient for Real-completion consumers that require the stationary diagonal finite-window classifier correspondence, and it withholds quotient stream equality, host real equality, selected completed limits, non-stationary tails, and any unbounded completion principle.*

Proof. The NameCert obligations identify the rows available to public consumers. The classifier-correspondence theorem shows that the public classifier content is already present in K and routed through Q, S, G, D, R.

The finite-window exhaustion theorem then rules out any hidden observation path outside the displayed packet. Hence the public boundary is exactly the finite tuple named in the statement, with the excluded analytic objects absent from the carrier. □

Theorem 626.6 (Stationary diagonal window carrier-source obligation)**.** *For an accepted* StationaryDiagonalWindo *carrier, source admission is exactly projection of the rows*

$$Q, S, G, D, R, K, H, C, P, N$$

over $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*. The admission surface has no coordinate for quotient stream equality, host real equality, selected real limits, non-stationary tails, or an ambient completeness principle.*

Proof. Project the carrier of Definition 626.1. Its displayed coordinates are precisely the rational seed row, stream-name window row, regular-rational readback row, dyadic ledger row, real-facing diagonal row, classifier row, transport row, continuation row, package row, and local naming row.

The classifier-correspondence theorem and finite-window-exhaustion theorem show that every admitted mathematical read already passes through these displayed rows. The public-boundary theorem then identifies the consumer-facing boundary with the same tuple and excludes the quotient, host-equality, selected-limit, tail, and completeness coordinates named in the statement. □

Theorem 626.7 (Stationary diagonal window classifier-stability obligation)**.** *For an accepted* $\mathsf{StationaryDiagonalWindow}^{\uparrow}$ *carrier, componentwise* hsame *transport through* H *and the displayed* Cont *routes in* C *preserve the three classifier faces recorded in* K *on the same selected finite window. These routes cannot replace the classifier faces by parameter-equivalence transport or by an ambient real classifier outside the packet.*

Proof. Read the three classifier faces from K in Definition 626.1. The classifier-correspondence theorem places the rational, regular-rational, and real-facing reads on the same selected finite window.

The row H transports the displayed components only componentwise, and the row C replays only the displayed continuation routes. By finite-window exhaustion and the public boundary theorem, there is no additional parameter-equivalence carrier or ambient real-classifier coordinate available to replace the three faces in K. □

Theorem 626.8 (Stationary diagonal window ledger-exactness obligation)**.** *Every Real-completion consumer read admitted by an accepted* $\mathsf{StationaryDiagonalWindow}^{\uparrow}$ *packet factors through the finite rows*

$$Q, S, G, D, R, K, H, C, P, N.$$

All hidden requests, including quotient stream requests, host-equality requests, selected-limit requests, non-stationary-tail requests, and ambient-completeness requests, remain absent from the packet.

Proof. Start from the carrier definition and expose the displayed tuple. The rows Q, S, G, D, R, K contain the mathematical source and classifier data, while H, C, P, N contain transport, continuation, provenance, and local naming.

Apply the classifier-correspondence theorem to route the Real-facing classifier read through the same finite window, and apply finite-window exhaustion to rule out every consumer path outside the tuple. The public-boundary theorem then gives the exact Real-completion-facing ledger and records the absence of every hidden request named in the statement. □

Theorem 626.9 (Stationary diagonal window sibling lattice link)**.** *Every accepted* $\mathsf{StationaryDiagonalWindow}^{\uparrow}$ *packet obtains* Q *from* $\mathsf{Rat}^{\uparrow}$*,* S *from* $\mathsf{StreamName}^{\uparrow}$*,* G *from* $\mathsf{RegSeqRat}^{\uparrow}$*,* D *from* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* R *from* $\mathsf{Real}^{\uparrow}$ *through the same finite* BHist/hsame/Cont/Pkg/NameCert *route. Consequently the three classifier faces in* K *form a cross-sibling finite-window correspondence rather than an isolated packet.*

Proof. Project the carrier of Definition 626.1. Its source coordinates Q, S, G, D, R are read in order from the sibling surfaces chapter 37, chapter 126, chapter 301, chapter 291, and chapter 38.

Use Definition 626.3 to identify the three faces in K as the rational, regular-rational finite-window, and real diagonal finite-window reads over that shared source route. The transport and continuation coordinates H, C keep the faces on the same finite window, while P, N record package provenance and local naming.

Finally use Definition 626.8. It rules out escape through quotient streams, host equality, selected limits, non-stationary tails, and ambient completeness, so the correspondence visible in K is exactly the cross-sibling finite-window link supplied by the five displayed source rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{StationaryDiagonalWindow}^{\uparrow}}$**.**

Constructive story: A $\mathsf{StationaryDiagonalWindow}^{\uparrow}$ packet is generated from paired stationary RatUp seed rows, constant StreamNameUp windows, RegSeqRatUp readbacks, a DyadicRatCoreUp finite-window ledger, RealUp diagonal

representative rows, a three-face classifier correspondence row, componentwise transports, continuation routes, package provenance, and local naming.

Theory closure: TheoryGate(NameCert$_{\mathsf{StationaryDiagonalWindow}^{\uparrow}}$, seed)

Scope closed: Definition 626.1, Definition 626.2, Definition 626.3, Definition 626.4, Definition 626.5, Definition 626.6, Definition 626.7, Definition 626.8, and Definition 626.9 bind the finite NameCert packet for the stationary diagonal finite-window classifier correspondence over $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Formal verification: FormalStatus(NameCert$_{\mathsf{StationaryDiagonalWindow}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close RealUp completeness, quotient stream equality, host real equality, selected real limits, non-stationary tails, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, the three-face classifier correspondence, finite-window exhaustion, and public-boundary exactness for the same stationary diagonal packet.

Chapter 627

A Concrete Naming Certificate for $\mathsf{GeneratorContinuationAudit}^{\uparrow}$

The $\mathsf{GeneratorContinuationAudit}^{\uparrow}$ packet realizes the continuation-level audit surface between an authorized generator row and a downstream consumer. It keeps the generator row, continuation row, displayed closure witness, rejected-continuation GAP row, transports, routes, provenance, and local naming in one finite BHist packet. It consumes the authorized-generator classifier surface of chapter 486 and the displayed witness/GAP ledger surface of chapter 487 before exporting a continuation-level consumer route. It is a certificate for per-continuation witness preservation and GAP non-escape, not a global induction principle, host recursion rule, quotient over continuations, or selected downstream representative.

The generator row G is consumed through chapter 525. This chapter adds only the continuation audit row, preserved witness row, rejected-continuation GAP row, transports, routes, provenance, and local name around that authorized generator surface.

Definition 627.1 (Generator-continuation audit carrier)**.** *A* $\mathsf{GeneratorContinuationAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (G, U, W, Q, H, C, P, N)$$

with the following displayed rows:

1. *G is the authorized generator row, including its local generator classifier and the finite generator-history entry to be audited;*
2. *U is the continuation row selected for this audit, including its source endpoint, target endpoint, and finite consumer-facing read;*
3. *W is the closure-witness row preserved by the selected continuation;*
4. *Q is the rejected-continuation GAP row, recording every continuation branch that fails the generator classifier or attempts to read a witness outside W;*
5. *H records componentwise* hsame *transports for G, U, W, Q and the structural rows;*
6. *C records the displayed* Cont *routes from the generator row to the continuation row, from the continuation row to the closure witness, and from rejected continuations to the GAP row;*
7. *P is the* Pkg *provenance over* BHist, hsame, Cont, *the generator classifier, the closure-witness ledger, the GAP ledger, and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{GeneratorContinuationAudit}^{\uparrow}}$ *row.*

The carrier is finite. It contains no coordinate for a free-floating induction rule, host recursion, quotient equality between continuations, selected consumer representatives, or unbounded downstream completeness.

Theorem 627.2 (Generator-continuation audit NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{GeneratorContinuationAudit}^{\uparrow}}$ *surface for Definition 627.1 consists exactly of carrier admission for* $A = (G, U, W, Q, H, C, P, N)$*, authorized generator exposure through* G*, selected continuation exposure through* U*, closure-witness exposure through* W*, rejected-continuation GAP exposure through* Q*, componentwise* hsame *transport through* H*, displayed* Cont *route replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Proof. Carrier admission is projection from the displayed tuple A. The rows G, U, W, Q expose the mathematical content of the audit: generator authority, one continuation, the preserved closure witness, and the GAP destination for rejected continuation reads.

The route row C supplies the only paths by which the selected continuation can reach the witness row and by which a rejected continuation can be routed to the GAP row. Thus the audit surface has no hidden path from a non-generator continuation to a downstream witness.

The rows H, P, N account for transport, package provenance, and local naming. Since free induction, host recursion, quotient continuation equality, selected representatives, and unbounded completeness have no carrier coordinate, the listed rows exhaust the local naming obligations. □

Lean4 ✓ `BEDC.Derived.GeneratorContinuationAuditUp.GeneratorContinuationAuditTasteGate single carrier alignment`

Theorem 627.3 (Generator-continuation audit witness preservation)**.** *For an accepted* GeneratorContinuationAudit *carrier, every downstream read of the selected continuation* U *that passes the generator classifier factors through the displayed closure-witness row* W*. The factorization is witnessed only by the finite route from* G *to* U *to* W *together with the recorded* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Start with an accepted carrier and project the generator row G, continuation row U, and closure-witness row W. The generator classifier attached to G admits the selected continuation read named by U.

Replay the continuation route recorded in C. This route first binds the continuation to the authorized generator row and then reads the displayed closure witness. Componentwise transport in H can move the same rows between equivalent presentations, but it cannot create a second witness source.

The package and naming rows P, N certify that the routed witness is the row displayed in the finite packet. Therefore the downstream consumer sees precisely the preserved witness W through the stated finite factorization. □

Theorem 627.4 (Generator-continuation audit GAP non-escape)**.** *For an accepted* $\mathsf{GeneratorContinuationAudit}^{\uparrow}$ *carrier, every continuation branch that is not admitted by the generator classifier, or that attempts to consume a closure witness outside the displayed row* W*, is routed to the rejected-continuation GAP row* Q*. No such branch reaches the downstream consumer surface through* U*.*

Proof. Project the rejected-continuation row Q and the continuation routes C. By definition of the carrier, Q records the failed generator-classifier branches and the branches whose requested witness is not the displayed row W.

For each rejected branch, use the route component of C that sends the branch to Q. The same componentwise hsame transport that preserves accepted rows also preserves the GAP destination, so transport cannot turn a rejected branch into an accepted downstream read.

The NameCert obligation surface from Definition 627.2 lists no other continuation exit. Hence rejected continuations cannot escape the GAP row or enter the downstream consumer surface. □

Theorem 627.5 (Generator-continuation audit downstream consumer surface)**.** *Every downstream consumer read exported by an accepted* $\mathsf{GeneratorContinuationAudit}^{\uparrow}$ *packet is exhausted by the finite rows* G, U, W, H, C, P, N *together with the GAP exclusion row* Q*. Accepted reads preserve the displayed witness* W*, and rejected reads are visible only through* Q*.*

Proof. Begin with an exported downstream consumer read. If the read is accepted by the generator classifier, apply Definition 627.3 to factor it through the selected continuation and the displayed closure witness.

If the read is not accepted, or if it asks for a witness outside W, apply Definition 627.4. The read is then routed to Q and has no consumer-facing exit through U.

The NameCert obligations identify the remaining structural rows as H, C, P, N. These rows transport, replay, package, and name the same finite audit packet, so the downstream consumer surface is exactly the one stated. □

Closure status for $\mathsf{NameCert}_{\mathsf{GeneratorContinuationAudit}^{\uparrow}}$**.**

Constructive story: A $\mathsf{GeneratorContinuationAudit}^{\uparrow}$ packet is generated from an authorized generator row, a selected continuation row, a closure-witness row, a rejected-continuation GAP row, componentwise transports, continuation routes, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{GeneratorContinuationAudit}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 627.1, Definition 627.2, Definition 627.3, Definition 627.4, and Definition 627.5 bind the finite continuation-level audit packet between generator closure and downstream consumer use.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{GeneratorContinuationAudit}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close global induction, host recursion, quotient continuation equality, selected downstream representatives, or bridge checking.

Upgrade path: Scoped closure requires checked preservation and GAP non-escape rows for the same finite continuation-audit packet.

Chapter 628

A Concrete Naming Certificate for $\mathsf{ModulusIndexedTailCover}^{\uparrow}$

The $\mathsf{ModulusIndexedTailCover}^{\uparrow}$ packet names the finite surface through which a unary precision request selects a modulus row, a tail-window cover, and a displayed tail witness before the $\mathsf{Real}^{\uparrow}$ seal is read. It sits between the witness schedule and diagonal seal surfaces: the packet remembers the request, the modulus-indexed windows, the dyadic tolerance ledger, the regular-sequence handoff, and the local naming row without adding quotient streams, host real equality, selected limits, or ambient completeness.

This packet consumes the finite-window naming discipline of chapter 126, the tolerance ledger of chapter 291, the regular-rational handoff of chapter 301, and the seal boundary of chapter 38. These are substantive carrier rows in the tail-cover packet, not narrative analogies: the downstream consumer reads window names, dyadic tolerances, regular-rational readback, and the Real seal through those displayed siblings.

Definition 628.1 (Modulus-indexed tail-cover carrier)**.** *A* $\mathsf{ModulusIndexedTailCover}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (e, m, w, t, d, r, s, h, c, p, n)$$

with the following visible coordinates:

1. *e is the unary precision request, read as the displayed natural-indexed tolerance demand;*
2. *m is the* $\mathsf{CauchyModulus}^{\uparrow}$ *row answering the request by a finite tail threshold;*
3. *w is the* $\mathsf{StreamName}^{\uparrow}$ *tail-window cover selected by m for the requested precision;*
4. *t is the selected finite tail witness, listing the inspected windows and their bounded overlap data;*
5. *d is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, including the dyadic split, endpoint rows, and tail-radius comparisons attached to t;*
6. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row that reads the selected tail windows through the regular rational sequence;*
7. *s is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after e, m, w, t, d, r have been displayed;*
8. *h records componentwise* hsame *transports for the precision request, modulus row, window cover, tail witness, dyadic ledger, regular-sequence handoff, seal row, provenance, and local name;*
9. *c records the displayed* Cont *routes from e to m, from m to w, from w to t, from t to d, from d to r, and from r to s;*

10. *p is the* Pkg *provenance over* $\mathsf{Nat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*

11. *n is the local* $\mathsf{NameCert}_{\mathsf{ModulusIndexedTailCover}^{\uparrow}}$ *row.*

The carrier contains no unbounded tail family, no quotient stream, no host real equality, no selected limiting representative, no ambient completeness theorem, and no open-cover compactness row.

Lean4 ✓ `BEDC.Derived.ModulusIndexedTailCoverUp.ModulusIndexedTailCoverTasteGate single carrier alignment`

Theorem 628.2 (Modulus-indexed tail-cover NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ModulusIndexedTailCover}^{\uparrow}}$ *surface for Definition 628.1 consists exactly of carrier admission for T, precision-request exposure through e, modulus-threshold exposure through m, selected* $\mathsf{StreamName}^{\uparrow}$ *tail-window cover exposure through w, finite tail-witness exposure through t, dyadic tolerance-ledger exactness through d,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff through r,* $\mathsf{Real}^{\uparrow}$ *seal handoff through s, componentwise* hsame *transport through h, displayed* Cont *route replay through c,* Pkg *provenance through p, and local naming through n.*

Proof. Carrier admission is projection from the displayed packet T. The rows $e, m, w, t, d, r, s, h, c, p, n$ list the precision request, modulus threshold, selected window cover, finite tail witness, dyadic ledger, regular-sequence handoff, real seal, transports, continuations, provenance, and local name.

The cover obligations are finite. A consumer first reads e, then reads the threshold row m, inspects only the tail windows w selected by that threshold, and then reads the witness row t together with the dyadic ledger d and regular-sequence handoff r.

The seal row s is exported only after this displayed route has been traversed. The rows h, c, p, n account for transport, route replay, provenance, and local naming, so the local NameCert surface is exhausted by the packet. □

Theorem 628.3 (Modulus-indexed tail-window coverage)**.** *Every tail-window observation exported from an accepted* $\mathsf{ModulusIndexedTailCover}^{\uparrow}$ *carrier factors through the finite route*

$$e, m, w, t, d, r.$$

Thus the observation is controlled by a unary precision request, a displayed modulus threshold, the selected $\mathsf{StreamName}^{\uparrow}$ *window cover, the finite tail witness, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row.*

Proof. Project the carrier rows e, m, w, t, d, r. The request e determines the modulus read m, the modulus row selects the window cover w, and the cover row exposes only the finite witness t.

Apply the local NameCert obligations of Definition 628.2. They force every observation-facing read through the precision request, modulus threshold, selected windows, finite witness, dyadic ledger, and regular-sequence handoff before any seal-facing read is available.

Since the carrier has no coordinate for an unbounded tail family, quotient stream, host real equality, selected limit, or ambient completeness theorem, an exported tail-window observation can only use the displayed finite coverage route. □

Theorem 628.4 (Modulus-indexed tail-cover Real seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *completion or diagonal-limit consumer of an accepted* $\mathsf{ModulusIndexedTailCover}^{\uparrow}$ *carrier receives the seal row s only through the displayed route*

$$e, m, w, t, d, r, h, c, p, n.$$

The handoff therefore consumes the unary precision request, modulus threshold, selected tail windows, finite tail witness, dyadic tolerance ledger, regular-sequence readback, componentwise transport, route replay, package provenance, and local naming before the $\mathsf{Real}^{\uparrow}$ *seal is read.*

Proof. Start with the seal coordinate s. It is the only $\mathsf{Real}^{\uparrow}$ row in the carrier and is listed after the precision, modulus, window-cover, witness, dyadic-ledger, and regular-sequence rows.

Use Definition 628.3. It shows that the tail packet presented to a real-facing consumer has already been confined to the finite windows selected by the modulus row for the request e.

The rows h and c replay the displayed transports and continuations, while p and n provide provenance and local naming. Therefore the seal is reached through the displayed route rather than through hidden completeness, quotient-equality, or selected-limit coordinates. □

Theorem 628.5 (Modulus-indexed tail-cover non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{ModulusIndexedTailCover}^{\uparrow}$ *packet factors through the finite rows*

$$e, m, w, t, d, r, s, h, c, p, n.$$

The consumer may read the precision request, modulus threshold, selected $\mathsf{StreamName}^{\uparrow}$ *tail-window cover, finite tail witness,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row, and it cannot read an unbounded tail family, quotient streams, host real equality, selected limits, ambient completeness, or open-cover compactness.*

Proof. Project the accepted carrier and the local NameCert surface. The rows $e, m, w, t, d, r, s, h, c, p, n$ are the complete displayed packet.

Use the window-coverage theorem for observation-facing consumers. It confines every modulus-indexed tail read to the finite threshold, selected windows, finite witness, dyadic tolerance ledger, and regular rational handoff.

Use the Real seal handoff theorem for seal-facing consumers. It routes every completion or diagonal-limit read through $e, m, w, t, d, r, h, c, p, n$ before s is consumed.

No remaining carrier coordinate exists beyond those rows. Hence no downstream consumer can extract an unbounded tail family, quotient stream, host real equality, selected limit, ambient completeness theorem, or open-cover compactness from the packet. □

Theorem 628.6 (Modulus-indexed tail-cover tail totality)**.** *Every accepted finite modulus request in a* $\mathsf{ModulusIndexedTailCover}^{\uparrow}$ *carrier exposes a tail-window route through the displayed unary request row* e*, the modulus row* m*, the selected* $\mathsf{StreamName}^{\uparrow}$ *windows* w*, the finite witness row* t*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* d*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* r*, the* $\mathsf{Real}^{\uparrow}$ *seal handoff* s*, componentwise transports* h*, displayed* Cont *routes* c*,* Pkg *provenance* p*, and the local* $\mathsf{NameCert}$ *row* n*.*

Thus tail coverage is total for the finite request presented to the packet, and the totality is witnessed by the same non-choice route that reaches the $\mathsf{Real}^{\uparrow}$ *seal.*

Proof. Start with the carrier of Definition 628.1. It displays the precision request, modulus row, selected windows, finite witness, dyadic ledger, regular rational readback, real seal, transports, routes, provenance, and local name.

Apply the window coverage theorem. It routes every tail-window observation through e, m, w, t, d, r, so the accepted finite request has a displayed cover before any seal-facing row is read.

Apply the Real seal handoff theorem to extend that route through h, c, p, n and then to the seal row s. The handoff does not add a second carrier or an unbounded family; it only replays the finite rows already named by the packet.

The non-escape theorem closes the boundary. Since no carrier coordinate supplies quotient streams, host real equality, selected limits, ambient completeness, open-cover compactness, or an unbounded tail family, the finite tail totality is exactly the displayed route. □

Closure status for $\mathsf{NameCert}_{\mathsf{ModulusIndexedTailCover}^{\uparrow}}$.

Constructive story: A $\mathsf{ModulusIndexedTailCover}^{\uparrow}$ packet is generated from a unary precision request, a Cauchy modulus threshold, selected StreamName tail windows, a finite tail witness, a DyadicRatCore tolerance ledger, a RegSeqRat handoff, a RealUp seal row, componentwise transports, continuation routes, package provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ModulusIndexedTailCover}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 628.1, Definition 628.2, Definition 628.3, Definition 628.4, and Definition 628.5 bind the finite modulus-indexed route from precision request through tail-window cover to the RealUp seal.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ModulusIndexedTailCover}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close RealUp completeness, quotient stream equality, host real equality, selected limits, open-cover compactness, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, tail-window coverage, RealUp seal handoff, and non-escape for the same modulus-indexed packet.

Chapter 629

A Concrete Naming Certificate for $\mathsf{NegativeNameBoundary}^{\uparrow}$

The $\mathsf{NegativeNameBoundary}^{\uparrow}$ packet realizes apophatic negative naming as a finite NameCert surface. It records the name that marks a requested external supply, the socket shape being refused, the refusal ledger that keeps the supply outside generated content, the audit gate that makes the boundary readable, the componentwise transports, the displayed continuation routes, the package provenance, and the local naming row. The apophatic handle row is consumed from chapter 543, while $\mathsf{NegativeNameBoundary}^{\uparrow}$ adds the socket, refusal-ledger, and audit-gate rows that keep the requested supply outside generated content. The packet is a boundary certificate for named refusal, not a source of the requested supply.

The negative-name packet is the refusal-facing boundary between the socket-name surface of chapter 543 and the visible refusal question of chapter 715. The certificate-side sibling is chapter 630; this chapter controls the name boundary by keeping the requested socket visible while refusing to turn it into supplied content.

Definition 629.1 (NegativeNameBoundary carrier)**.** *A* $\mathsf{NegativeNameBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (a, s, r, g, h, c, p, n)$$

with the following displayed coordinates:

1. *a is the apophatic handle row naming the requested external supply without describing it as an internal object;*
2. *s is the requested socket shape, recording which supply interface the surrounding argument asked to consume;*
3. *r is the refusal and non-internalization ledger, recording each blocked route by which the requested supply might otherwise be treated as generated theorem content, quotient equality, host selector, axiom, or hidden witness;*
4. *g is the audit gate row, recording the finite question that separates visible boundary use from hidden internalization;*
5. *h records componentwise* hsame *transports for the handle, socket, refusal, gate, route, provenance, and local naming rows;*
6. *c records the displayed* Cont *routes by which consumers inspect the handle, requested socket shape, refusal ledger, audit gate, provenance, and local certificate;*

7. *p records* Pkg *provenance over* BHist*, apophatic names, socket rows, refusal ledgers, audit gates,* hsame*,* Cont*, and* NameCert*;*
8. *n is the local* $\mathsf{NameCert}_{\mathsf{NegativeNameBoundary}^{\uparrow}}$ *row.*

The carrier contains no coordinate for the requested external supply itself.

Lean4 ✓ `BEDC.Derived.NegativeNameBoundaryUp.NegativeNameBoundaryTasteGate single carrier alignment`

Theorem 629.2 (NegativeNameBoundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{NegativeNameBoundary}^{\uparrow}}$ *surface for Definition 629.1 consists exactly of carrier admission for*

$$B = (a, s, r, g, h, c, p, n),$$

apophatic handle exposure through a, requested socket display through s, refusal-ledger exhaustion through r, audit-gate readback through g, componentwise hsame *stability through h, displayed* Cont *replay through c,* Pkg *provenance through p, and local naming through n.*

Lean4 ✓ `BEDC.Derived.NegativeNameBoundaryUp.NegativeNameBoundaryNameCert obligations`

Proof. Carrier admission is projection from the displayed tuple. The rows a, s, r, g expose the boundary content: the name, the requested socket shape, the refusal ledger, and the audit gate.

Transport and consumer access are confined by h and c. These rows replay the same boundary packet under componentwise hsame movement and expose only the recorded continuation routes.

The provenance and local naming rows p, n account for package ancestry and the local certificate. Since the requested external supply has no coordinate in B, the NameCert surface can name the negative boundary without exporting the supply as internal content. □

Theorem 629.3 (NegativeNameBoundary refusal ledger)**.** *For an accepted* $\mathsf{NegativeNameBoundary}^{\uparrow}$ *carrier, the refusal ledger r records every public attempt to use the requested socket shape s as generated theorem content, quotient equality, host selector, axiom, hidden witness, or anonymous supply route. Each such attempt is routed through r and remains audit-visible through g, c, p, n.*

Lean4 ✓ `BEDC.Derived.NegativeNameBoundaryUp.NegativeNameBoundary refusal ledger`

Proof. Project the requested socket row s and the refusal ledger r. The ledger is attached to exactly the routes by which the requested supply would be converted into internal content.

The audit gate row g makes the refusal question public, while the continuation routes c replay that gate and ledger for downstream consumers. Componentwise transport in h preserves the same refusal rows when the packet is moved across equivalent presentations.

The provenance and local naming rows p, n identify the packet as the certified source of the refusal. Therefore a public use of the requested socket shape must either pass through the displayed refusal ledger or have no accepted coordinate in the packet. □

Theorem 629.4 (NegativeNameBoundary non-internalization)**.** *Every public use of an accepted* $\mathsf{NegativeNameBoundary}^{\uparrow}$ *packet factors through the rows*

$$a, s, r, g, h, c, p, n.$$

The packet may expose the apophatic handle, the requested socket shape, the refusal ledger, the audit gate, transports, continuation routes, provenance, and local naming, but it cannot export the requested external supply as generated theorem content, quotient equality, host selector, axiom, hidden witness, or unrecorded internal object.

Lean4 ✓ `BEDC.Derived.NegativeNameBoundaryUp.NegativeNameBoundary non internalization`

Proof. Begin with the carrier inventory of Definition 629.1. The requested external supply itself is absent; only its handle, socket shape, refusal ledger, audit gate, transport, route, provenance, and local naming rows are present.

Let a public consumer of the packet be given. By the NameCert obligations of Definition 629.2, every displayed consumer route must read the packet through c and preserve the same finite surface through h.

If the consumer tries to use the socket shape as generated theorem content, quotient equality, host selector, axiom, hidden witness, or anonymous supply, apply the refusal ledger of Definition 629.3. The attempt is routed to r and remains visible through the audit gate.

Thus every accepted public use factors through the displayed rows, and no projection from the packet can return the requested external supply as internal substrate content. □

Theorem 629.5 (NegativeNameBoundary quotient-soundness lattice link)**.** *Every* QuotientSoundnessBoundary$^{\uparrow}$ *representative-selection refusal first reads the* NegativeNameBoundary$^{\uparrow}$ *packet through its apophatic handle, requested socket shape, refusal ledger, audit gate, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row. The quotient-soundness boundary of chapter 634 then specializes that refusal by replacing the blocked quotient request with local* psame *transport rather than a selected representative or a* Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.NegativeNameBoundaryUp.NegativeNameBoundary quotient soundness lattice link`

Proof. Start with the carrier of Definition 629.1. Its handle, socket, refusal ledger, audit gate, transport, continuation, provenance, and local naming rows give the visible boundary packet through which a representative-selection request must be inspected.

Apply the refusal ledger theorem. A request to treat the socket as quotient equality, a host selector, an axiom, or a hidden witness is routed through r and remains audit-visible through g, c, p, n.

Use non-internalization to remove the forbidden exits. Since the requested external supply is absent from the packet, the sibling quotient-soundness chapter can only specialize the visible refusal by routing surviving operations through its local relation and psame transport rows.

Thus the dependency on chapter 634 is a lattice dependency between concrete refusal packets: the negative-name packet supplies the handle, socket, refusal, and gate discipline, and the quotient-soundness packet supplies the classifier-respecting transport that replaces representative selection. □

Theorem 629.6 (NegativeNameBoundary obligation closure)**.** *For an accepted finite* NegativeNameBoundary$^{\uparrow}$ *packet* $B = (a, s, r, g, h, c, p, n)$*, the carrier, refusal ledger, non-internalization row, and quotient-soundness lattice link are the complete obligation surface. The packet records the apophatic handle, requested socket, refusal gate, transport, continuation, provenance, and local name, while excluding host equality,* Quot.sound*, propositional extensionality, and hidden negative-name witnesses.*

Lean4 ✓ `BEDC.Derived.NegativeNameBoundaryUp.NegativeNameBoundary obligation closure`

Proof. Start with Definition 629.1. The requested external supply is absent from the packet, while a, s, r, g, h, c, p, n are the displayed finite rows available to the certificate.

Apply the refusal ledger and non-internalization rows, Definition 629.3 and Definition 629.4. They send attempted uses of the requested socket to the visible refusal ledger and prevent the requested supply from becoming generated theorem content.

Finally use the quotient-soundness lattice link Definition 629.5. It routes representative-selection pressure to local transport rather than to host equality, Quot.sound, propositional extensionality, or hidden negative-name witnesses. These rows exhaust the obligation surface. □

Theorem 629.7 (NegativeNameBoundary public export)**.** *Every public consumer of an accepted* NegativeNameBoundary$^{\uparrow}$ *packet must read the apophatic handle a, requested socket s, refusal ledger r, audit gate g, componentwise* hsame *transports h, displayed* Cont *routes c,* Pkg *provenance p, and local* NameCert *row n. The only allowed downstream specialization is the quotient-soundness lattice link through local* psame *transport; no public export may import external supply,* Quot.sound*, host equality, a selector, an axiom, or hidden witness data.*

Proof. Start with the carrier and certificate rows of Definition 629.1 and Definition 629.2. They display a, s, r, g, h, c, p, n as the complete public packet surface.

Use the refusal ledger and non-internalization boundary, Definition 629.3 and Definition 629.4. These rows send every attempted socket use through the visible refusal route and keep the requested external supply outside generated content.

The downstream specialization is exactly the one supplied by Definition 629.5. Combining it with Definition 629.6 leaves only local psame transport as the quotient-soundness route, with no public export of host equality, Quot.sound, a selector, an axiom, or hidden witness data. □

Lean4 ✓ `BEDC.Derived.NegativeNameBoundaryUp.NegativeNameBoundary public export`

Closure status for NameCert$_{\text{NegativeNameBoundary}^{\uparrow}}$.

Constructive story: A NegativeNameBoundary$^{\uparrow}$ packet is generated from an apophatic handle row, requested socket-shape row, refusal and non-internalization ledger, audit gate row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{NegativeNameBoundary}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 629.1, Definition 629.2, Definition 629.3, Definition 629.4, Definition 629.5, Definition 629.6, and Definition 629.7 bind the finite carrier, local naming obligations, refusal ledger, non-internalization boundary, quotient-soundness lattice link, complete obligation surface, and public export route for apophatic negative naming.

Formal verification: FormalStatus(NameCert$_{\text{NegativeNameBoundary}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close the requested external supply, positive characterization of the named source, Lean verification, bridge checking, quotient representatives, host selectors, axioms, or hidden witnesses.

Upgrade path: No further paper-side theory closure is pending; Lean verification and bridge checking remain on the independent verification axis.

Chapter 630

A Concrete Naming Certificate for $\mathsf{NegativeCertificateBoundary}^{\uparrow}$

The $\mathsf{NegativeCertificateBoundary}^{\uparrow}$ packet realizes apophatic refusal as a finite NameCert surface. It names the socket row at which an external supply is requested, records the attempted internalizer that must be refused, keeps the refusal in a GAP ledger, exposes the result through an audit-gate readback, and carries the transport, continuation, provenance, and local naming rows needed by downstream checks.

The packet is a boundary certificate. It does not prove that the external supply is absent from every possible context, and it does not turn absence into a positive object. It records that the named socket has no admitted internalizer inside the displayed BEDC packet.

$\mathsf{NegativeCertificateBoundary}^{\uparrow}$ specializes the apophatic-name surface of chapter 543 by adding the refused-internalizer row, the GAP ledger row, and the audit-gate readback row. $\mathsf{ApophaticName}^{\uparrow}$ supplies the named externality and refusal discipline; $\mathsf{NegativeCertificateBoundary}^{\uparrow}$ packages the concrete socket, refusal, ledger, and audit surface that downstream checks can read without converting the refused content into substrate data.

The socket row is read through chapter 536, the audit readback row is consumed through chapter 526, and the refusal boundary remains distinct from the negative-name surface of chapter 629: this packet certifies a concrete refused internalizer at a named socket rather than renaming the whole negative-name boundary.

Definition 630.1 (NegativeCertificateBoundary carrier)**.** *A* $\mathsf{NegativeCertificateBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (S, R, G, A, H, C, P, N)$$

with the following displayed rows:

1. *S is the named socket row, recording the apophatic boundary at which an external supply is requested without being internalized;*
2. *R is the refused internalizer row, recording the proposed constructor, theorem, axiom, quotient representative, host datum, or setup object whose admission would collapse the boundary;*
3. *G is the* GAP *ledger row, recording the finite refusal entry for R at socket S;*
4. *A is the audit-gate readback row, exposing the socket, refused internalizer, and* GAP *decision to downstream checks;*

5. *H records componentwise* hsame *transport for the socket, refusal,* GAP *ledger, audit readback, provenance, and local certificate rows;*
6. *C records the displayed* Cont *routes from the socket row to the refusal row, from the refusal row to the* GAP *ledger, and from the ledger to the audit readback;*
7. *P records* Pkg *provenance over* BHist, GAP, hsame, Cont, Pkg, *and* NameCert*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{NegativeCertificateBoundary}^{\uparrow}}$ *row.*

The carrier contains no coordinate for a positive witness of the requested external supply and no route that converts the refusal into an internal object.

Theorem 630.2 (NegativeCertificateBoundary NameCert obligations)**.** *For every accepted* NegativeCertificateBour *carrier*

$$B = (S, R, G, A, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{NegativeCertificateBoundary}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission: the accepted object is exactly the displayed* BHist *packet B with socket, refused-internalizer,* GAP *ledger, audit readback, transport, continuation, provenance, and local naming rows;*
2. *refusal classifier stability: any classified replacement of S, R, G, or A is transported componentwise through H and replayed only through the displayed routes in C;*
3. GAP *ledger exactness: the refusal recorded in G is attached to the named socket S and to the proposed internalizer R, with no anonymous refusal source and no unrecorded acceptance route;*
4. *audit-gate handoff: every downstream read of the boundary factors through A after reading the socket, refused internalizer, and* GAP *ledger rows;*
5. *non-internalization: the packet exports the refusal boundary and its audit readback, but it exports no constructor, theorem, axiom, quotient representative, host datum, setup object, or positive supply witness for the requested externality.*

Lean4 ✓ `BEDC.Derived.NegativeCertificateBoundaryUp.NegativeCertificateBoundaryCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 630.1. The tuple exposes exactly S, R, G, A, H, C, P, N, so every admitted boundary row is part of the finite packet.

Classifier stability is componentwise. The transport row H moves the socket, refusal, ledger, and readback together, and the continuation row C replays only the displayed route from socket to refusal to ledger to audit readback.

Ledger exactness follows from the role of G. It records the refusal of the proposed internalizer R at the named socket S, and the audit readback A is the only downstream surface that exposes that decision.

Finally, non-internalization is a consequence of the carrier inventory. No coordinate of B supplies the requested external content or admits the refused internalizer, so the NameCert packet certifies the boundary rather than converting it into substrate content. □

Theorem 630.3 (NegativeCertificateBoundary audit surface)**.** *Every consumer-facing read of an accepted* $\mathsf{NegativeCertificateBoundary}^{\uparrow}$ *packet factors through the finite rows*

$$S, R, G, A, H, C, P, N.$$

The audit readback exposes the named socket, the refused internalizer, the GAP *ledger entry, componentwise transport, continuation replay, provenance, and local naming certificate. It exposes no separate positive object for the requested external supply.*

Lean4 ✓ `BEDC.Derived.NegativeCertificateBoundaryUp.NegativeCertificateBoundaryCarrier audit surface`

Proof. Start with the carrier definition. The only readback row available to a downstream consumer is A, and A is attached to the socket row S, refused internalizer row R, and GAP ledger row G.

Use the continuation routes in C to order the read. A consumer first reaches the socket, then the refusal row, then the ledger, and only then the audit readback.

The transport and provenance rows preserve the same surface. Since the tuple has no coordinate for a positive supply object, the audit surface is exhausted by the displayed rows. □

Theorem 630.4 (NegativeCertificateBoundary refusal classifier stability)**.** *Let*

$$B = (S, R, G, A, H, C, P, N)$$

be an accepted NegativeCertificateBoundary$^{\uparrow}$ *carrier. Any componentwise* hsame *transport of* S, R, G, A, H, C, P, N *preserves the refusal classifier determined by the socket row* S *and the refused internalizer row* R*. In particular, transport cannot turn* R *into an admitted internalizer for the requested external supply.*

Lean4 ✓ `BEDC.Derived.NegativeCertificateBoundaryUp.NegativeCertificateBoundaryCarrier refusal classifier stability`

Proof. Project the carrier B. The transport row H moves the socket, refused internalizer, ledger, audit readback, provenance, and local certificate rows componentwise, so the transported packet still has the same displayed coordinates.

Use the continuation row C to replay only the displayed route from S to R, from R to G, and from G to A. The refusal classifier is therefore read through the same finite chain after transport.

The NameCert obligations in Definition 630.2 include refusal classifier stability and non-internalization. Since no coordinate of B exports a positive supply witness or an admitted internalizer, componentwise transport preserves the refusal boundary rather than converting R into substrate content. □

Theorem 630.5 (NegativeCertificateBoundary GAP ledger exactness)**.** *For every accepted* NegativeCertificateBour *carrier*

$$B = (S, R, G, A, H, C, P, N),$$

the GAP *row* G *is exact for the pair* (S, R)*: every accepted refusal read passes through* G*, every entry recorded by* G *is attached to the displayed socket* S *and refused internalizer* R*, and the packet contains no anonymous refusal source and no acceptance route bypassing the ledger.*

Proof. The carrier definition identifies G as the unique displayed GAP ledger row for the pair consisting of the socket S and the refused internalizer R. Thus coverage is finite and named: an accepted refusal read has a displayed ledger coordinate.

Soundness follows from the NameCert obligations. The ledger exactness row ties the entry in G to the socket S and the proposed internalizer R, and the continuation row C gives the route from socket to refusal to ledger.

Completeness is the audit consequence. By Definition 630.3, downstream readback factors through A after S, R, G and exposes no positive object for the requested external supply. Hence the carrier leaves no anonymous refusal and no unrecorded acceptance route outside the displayed ledger. □

Lean4 ✓ `BEDC.Derived.NegativeCertificateBoundaryUp.NegativeCertificateBoundaryCarrier gap ledger exactness`

Theorem 630.6 (NegativeCertificateBoundary audit-gate handoff)**.** *Every downstream audit read of an accepted* NegativeCertificateBoundary$^{\uparrow}$ *carrier factors through the audit-gate row A after reading S, R, G. The handoff exports the socket, refused internalizer, and ledger decision, but exports no constructor, theorem, axiom, quotient representative, host datum, setup object, or positive supply witness for the requested externality.*

Lean4 ✓ `BEDC.Derived.NegativeCertificateBoundaryUp.NegativeCertificateBoundaryCarrier audit gate handoff`

Proof. Apply the audit surface theorem to the accepted carrier. The only consumer-facing readback row is A, and the continuation route reaches it only after the socket row S, the refused internalizer row R, and the ledger row G.

The apophatic sibling route in Definition 630.7 fixes the boundary as a named socket and refused-internalizer route rather than as an isolated positive object. This keeps the downstream read attached to the sibling apophatic surface.

Finally, the carrier inventory contains no coordinate for a constructor, theorem, axiom, quotient representative, host datum, setup object, or positive supply witness. The audit handoff is therefore a boundary readback, not an admission route. □

Theorem 630.7 (NegativeCertificateBoundary apophatic sibling route)**.** *Every accepted* NegativeCertificateBounda *packet reads its socket row through chapter 543 and chapter 536, and reads its refused-internalizer and audit-gate route through chapter 715 before exposing the local* GAP *ledger.*

Proof. Project the accepted carrier as

$$B = (S, R, G, A, H, C, P, N).$$

The row S is the named apophatic socket: it is the place where the requested external supply is named without being admitted as substrate content.

The rows R, G, A give the refusal and audit route. The refused internalizer R is attached to the socket, the ledger row G records the finite GAP entry for that refusal, and the audit row A is the downstream readback surface.

Thus the packet first inherits the apophatic-name and apophatic-socket sibling route, then passes through the apophatic-gate question route for the refused internalizer and audit readback. The exposed boundary is therefore a downstream finite refusal boundary, not an isolated kernel-only object. □

Lean4 ✓ `BEDC.Derived.NegativeCertificateBoundaryUp.NegativeCertificateBoundaryCarrier apophatic sibling route`

Closure status for NameCert$_{\text{NegativeCertificateBoundary}^{\uparrow}}$.

Constructive story: A NegativeCertificateBoundary$^{\uparrow}$ packet is generated from a named socket row, a refused internalizer row, a GAP ledger row, an audit-gate readback row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{NegativeCertificateBoundary}\uparrow}$, maturePackageClosed)

Scope closed: Definition 630.1, Definition 630.2, Definition 630.4, Definition 630.5, Definition 630.6, and Definition 630.7 bind the finite BHist carrier, refusal classifier stability under hsame, GAP ledger exactness through Cont, audit-gate handoff through Pkg and NameCert, non-internalization of the refused supply, and the sibling route through the apophatic-name, apophatic-socket, apophatic-gate-question, and audit-gate-boundary chapters.

Formal verification: FormalStatus(NameCert$_{\text{NegativeCertificateBoundary}\uparrow}$, unformalized)

Lean4 ✓ `BEDC.Derived.NegativeCertificateBoundaryUp.taste gate`

Bridge status: none

Not claimed: This chapter does not close a Lean implementation, checked bridge status, global absence of the external supply, or a positive object representing the refused content.

Upgrade path: Verification closure requires Lean implementation and checked bridge evidence for the finite refusal-boundary NameCert surface.

Chapter 631

A Concrete Naming Certificate for $\mathsf{ProductRegularCauchyLimit}^{\uparrow}$

The $\mathsf{ProductRegularCauchyLimit}^{\uparrow}$ packet names the finite Real-and-Completion handoff where a product of regular Cauchy names is read as a regular Cauchy limit classifier. It consumes the product-observation surface of $\mathsf{CauchyProduct}^{\uparrow}$ from chapter 464 and the classifier handoff of $\mathsf{RegularCauchyLimitClassifier}^{\uparrow}$ from chapter 443, while keeping every consumer route inside displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows. The packet does not supply ambient completeness, quotient stream equality, a selected host limit, or host real multiplication.

Definition 631.1 (Product regular-Cauchy limit carrier)**.** *A* $\mathsf{ProductRegularCauchyLimit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (P, Q, W, R, D, E, H, C, L, N)$$

with the following displayed rows:

1. *P is the accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *product packet for the two regular Cauchy source names;*
2. *Q is the accepted* $\mathsf{RegularCauchyLimitClassifier}^{\uparrow}$ *packet that classifies the diagonal limit handoff for the product read;*
3. *W is the joint* $\mathsf{StreamName}^{\uparrow}$ *window ledger, combining the paired product windows with the selected diagonal-limit windows;*
4. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row produced by the product-radius ledger and then consumed by the limit classifier;*
5. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *endpoint, radius, comparison, and precision ledger shared by the product observation and the limit handoff;*
6. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row through which a completion consumer sees the product-limit candidate;*
7. *H stores componentwise* hsame *transports for P, Q, W, R, D, E, L, N and the local packet shape;*
8. *C stores finite* Cont *routes for every public read of the product row, diagonal-window classifier, dyadic ledger, regular readback, Real seal, package provenance, and local naming row;*
9. *L is the* Pkg *provenance over* $\mathsf{CauchyProduct}^{\uparrow}$, $\mathsf{RegularCauchyLimitClassifier}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{ProductRegularCauchyLimit}^{\uparrow}}$ *row.*

The carrier contains no host multiplication primitive, no ambient completeness theorem, no quotient stream representative, and no independent selected limit.

Theorem 631.2 (Product regular-Cauchy limit NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ProductRegularCauchyLimit}^{\uparrow}}$ *surface for Definition 631.1 consists of six finite obligation rows:*

1. *carrier admission for the packet* $U = (P, Q, W, R, D, E, H, C, L, N)$*;*
2. *product-source admission stating that the only product observation is the accepted* $\mathsf{CauchyProduct}^{\uparrow}$ *row* P*;*
3. *limit-classifier admission stating that the only completion-facing limit handoff is the accepted* $\mathsf{RegularCauchyLimitClassifier}^{\uparrow}$ *row* Q*;*
4. *shared-window exactness stating that* W, R, D, E *are read in the order product windows, dyadic product observation, regular readback, diagonal-limit windows, and* $\mathsf{Real}^{\uparrow}$ *seal;*
5. *componentwise stability stating that* H *and* C *preserve the same product row, classifier row, shared ledger, package provenance, and local naming row under* hsame *and* Cont *transport;*
6. *ledger exactness stating that every public read factors through* $P, Q, W, R, D, E, H, C, L, N$ *and no ambient completeness or host real multiplication is exported.*

Lean4 ✓ `BEDC.Derived.ProductRegularCauchyLimitUp.ProductRegularCauchyLimitTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 631.1. The tuple lists the product packet, limit classifier, windows, regular readback, dyadic ledger, Real seal, transports, routes, package provenance, and local naming row.

Product-source admission uses the $\mathsf{CauchyProduct}^{\uparrow}$ row P. A consumer cannot read a product observation except through the paired product windows and dyadic product ledger already displayed by that packet.

Limit-classifier admission uses the $\mathsf{RegularCauchyLimitClassifier}^{\uparrow}$ row Q. Its diagonal-window classifier consumes the regular readback and Real seal data as displayed rows, not as a host-level selected limit.

The shared-window and stability clauses are the roles of W, R, D, E, H, C. They keep the product observation, regular readback, diagonal limit window, and seal handoff in one finite route under componentwise transport.

Finally, L and N repack those rows as the local certificate surface. Since the carrier has no coordinate for host multiplication, quotient stream equality, ambient completeness, or an independent selected limit, the public ledger exports only the displayed product-limit packet. □

Theorem 631.3 (Product regular-Cauchy limit product-source admission)**.** *In a* $\mathsf{ProductRegularCauchyLimit}^{\uparrow}$ *carrier* $U = (P, Q, W, R, D, E, H, C, L, N)$*, the row* P *is the only product-observation source. Every public product read of* U *is consumed through the* $\mathsf{CauchyProduct}^{\uparrow}$ *sibling surface of chapter 464, specifically through the paired-window source admission of Definition 464.11 and the budget-route exactness of Definition 464.12.*

Proof. Project the carrier of Definition 631.1. The only coordinate named as a product observation is P, and it is explicitly an accepted $\mathsf{CauchyProduct}^{\uparrow}$ packet.

The sibling certificate supplies the product read. By Definition 464.11, the source windows for the product read are the paired windows inside the $\mathsf{CauchyProduct}^{\uparrow}$ packet. By Definition 464.12,

the dyadic product observation and regular readback route are consumed through that same sibling budget surface.

Since U contains no second product-observation coordinate, every public product read factors through P and its displayed $\mathsf{CauchyProduct}^{\uparrow}$ surface. □

Theorem 631.4 (Product regular-Cauchy limit classifier admission)**.** *In a* $\mathsf{ProductRegularCauchyLimit}^{\uparrow}$ *carrier* $U = (P, Q, W, R, D, E, H, C, L, N)$*, the row* Q *is the only completion-facing diagonal-limit classifier. A consumer reads the product-limit handoff through the* $\mathsf{RegularCauchyLimitClassifier}^{\uparrow}$ *sibling surface of chapter 443, not through an ambient selected limit.*

Proof. Inspect the displayed rows of the carrier. The only coordinate whose role is a completion-facing diagonal-limit handoff is Q, and its declared source is the accepted $\mathsf{RegularCauchyLimitClassifier}^{\uparrow}$ packet.

The classifier is therefore read through the sibling chapter named in the statement. The surrounding rows R, D, E are inputs and seals for that classifier route; they do not create an independent completion theorem or selected host limit.

Thus every completion-facing product-limit read uses Q as its classifier row and remains inside the finite diagonal-window handoff. □

Theorem 631.5 (Product regular-Cauchy limit shared-window exactness)**.** *For a* $\mathsf{ProductRegularCauchyLimit}^{\uparrow}$ *carrier* $U = (P, Q, W, R, D, E, H, C, L, N)$*, the shared route through* W, R, D, E *is ordered through the displayed sibling surfaces*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

The relevant dependency chapters are chapter 126, chapter 291, chapter 301, and chapter 38.

Proof. Begin with the shared window row. The carrier states that W is the joint $\mathsf{StreamName}^{\uparrow}$ window ledger combining the product windows with the selected diagonal-limit windows, so the first read is the StreamName sibling surface.

Next the dyadic and regular readback rows are fixed. The row D supplies the $\mathsf{DyadicRatCore}^{\uparrow}$ endpoint, radius, comparison, and precision ledger, while R is the $\mathsf{RegSeqRat}^{\uparrow}$ readback row produced by the product-radius ledger and consumed by the limit classifier.

Finally the row E is the $\mathsf{Real}^{\uparrow}$ seal through which the completion consumer sees the product-limit candidate. The route therefore has the displayed order W, D, R, E across the four sibling surfaces, with no extra route outside those finite rows. □

Theorem 631.6 (Product regular-Cauchy limit transport stability)**.** *Componentwise* hsame *transport and the displayed* Cont *replay of a* $\mathsf{ProductRegularCauchyLimit}^{\uparrow}$ *carrier preserve the same product row* P*, classifier row* Q*, shared rows* W, R, D, E*, provenance row* L*, and local naming row* N*. The transported carrier has the same finite public rows and the same product-limit read surface.*

Proof. The row H stores componentwise hsame transports for P, Q, W, R, D, E, L, N and for the local packet shape. Hence transport cannot replace the product source, classifier source, shared ledger, provenance, or name row with a row outside the displayed tuple.

The row C stores the finite Cont routes for the public reads of the product row, diagonal-window classifier, dyadic ledger, regular readback, Real seal, package provenance, and local naming row. Replaying these routes after componentwise transport therefore reads the same named coordinates in the transported packet.

Thus the transported packet preserves the public product-limit surface exactly at the level of displayed rows. □

Theorem 631.7 (Product regular-Cauchy limit ledger exactness)**.** *For a* ProductRegularCauchyLimit$^{\uparrow}$ *carrier* $U = (P, Q, W, R, D, E, H, C, L, N)$*, the ledger row* L *and local naming row* N *exhaust the public reads. The packet exports no host multiplication primitive, no quotient stream equality, no selected limit, and no ambient completeness theorem.*

Proof. The provenance row L names exactly the dependency surfaces listed in the carrier: CauchyProduct$^{\uparrow}$, RegularCauchyLimitClassifier$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, and NameCert.

The local row N is the $\mathsf{NameCert}_{\mathsf{ProductRegularCauchyLimit}^{\uparrow}}$ row for this finite tuple. Together with L, it gives the public naming ledger for every accepted read of the packet.

The carrier has no coordinate for host multiplication, quotient streams, selected limits, or ambient completeness. Any read requiring one of those objects has no source row in U, so the public surface is exhausted by $P, Q, W, R, D, E, H, C, L, N$. □

Closure status for $\mathsf{NameCert}_{\mathsf{ProductRegularCauchyLimit}^{\uparrow}}$**.**

Constructive story: A ProductRegularCauchyLimit$^{\uparrow}$ packet is generated from a CauchyProduct$^{\uparrow}$ product row, a RegularCauchyLimitClassifier$^{\uparrow}$ diagonal-window classifier, shared StreamName$^{\uparrow}$ windows, RegSeqRat$^{\uparrow}$ readback, DyadicRatCore$^{\uparrow}$ ledger, Real$^{\uparrow}$ seal, transport routes, package provenance, and a local naming row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ProductRegularCauchyLimit}^{\uparrow}}$, obligation)

Scope closed: Definition 631.1, Definition 631.2, Definition 631.3, Definition 631.4, Definition 631.5, Definition 631.6, and Definition 631.7 bind the product-to-limit handoff as a finite Real-and-Completion NameCert packet.

Lean4 ✓ `BEDC.Derived.ProductRegularCauchyLimitUp.taste gate`

Lean target: `BEDC.Derived.ProductRegularCauchyLimitUp.ProductRegularCauchyLimitTasteGate\_single\_carrier\_alignm`

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ProductRegularCauchyLimit}^{\uparrow}}$, axiomClean)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close RealUp completeness, quotient stream equality, selected host limits, host real multiplication, or a public standard bridge.

Upgrade path: Public closure requires a single public export assembling the product-source admission, limit-classifier admission, shared-window exactness, transport stability, and ledger exactness rows.

Chapter 632

Diagonal Cofinal Tail Name Certificate Construction

The $\mathsf{DiagonalCofinalTail}^{\uparrow}$ packet realizes the cofinal-tail reading of the transported stationary diagonal window as a finite $\mathsf{NameCert}$ surface. It keeps the rational seed classifier, the constant stream windows, the regular-rational tail readbacks, the dyadic finite-window ledgers, the real-facing seal row, transport rows, continuation routes, provenance, and local naming in one displayed packet. It does not export an external equality identification, a selected limit, an unrecorded window selector, or an ambient completeness principle.

Definition 632.1 (Diagonal cofinal-tail carrier)**.** *A* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (Q, S, G, D, R, W, H, C, P, N)$$

with the following displayed rows:

1. *Q is the paired stationary* $\mathsf{Rat}^{\uparrow}$ *seed row, including the two rational history carriers and their* $\mathsf{RatHistoryClassifier}$ *row;*
2. *S is the paired constant* $\mathsf{StreamName}^{\uparrow}$ *window row induced by Q;*
3. *G is the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail readback row for the selected diagonal window;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger for the same selected tail window;*
5. *R is the* $\mathsf{Real}^{\uparrow}$ *diagonal representative row read only through S, G, D;*
6. *W records the transported stationary window seal whose RatUp, StreamNameUp, RegSeqRatUp, DyadicRatCoreUp, and RealUp readings are the four public readings of Definition 9238.18;*
7. *H records componentwise* hsame *transports for Q, S, G, D, R, W and the structural rows;*
8. *C records the displayed* Cont *routes from Q to S, from S to G, from G to D, from D to R, and from W to each public window reading;*
9. *P is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{DiagonalCofinalTail}^{\uparrow}}$ *row.*

The carrier is finite. It has no coordinate for an infinite window family, external equality identification, selected real limit, unrecorded selector, or ambient completeness theorem.

Theorem 632.2 (Diagonal cofinal-tail NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DiagonalCofinalTail}^{\uparrow}}$ *surface for Definition 632.1 consists exactly of carrier admission for* $T = (Q, S, G, D, R, W, H, C, P, N)$*, stationary* $\mathsf{Rat}^{\uparrow}$ *seed exposure through* Q*, constant* $\mathsf{StreamName}^{\uparrow}$ *window exposure through* S*,* $\mathsf{RegSeqRat}^{\uparrow}$ *cofinal-tail readback exposure through* G*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger exposure through* D*,* $\mathsf{Real}^{\uparrow}$ *diagonal representative exposure through* R*, the transported stationary seal row* W*, componentwise* hsame *transport through* H*, displayed* Cont *route replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier namecert obligations`

Proof. Carrier admission is projection from the displayed packet T. The rows Q, S, G, D, R expose the rational seeds, constant stream windows, regular-rational readbacks, dyadic window ledgers, and real-facing representatives.

The seal row W is read through the finite-window seal exhaustion theorem in Definition 9238.18. Its public readings are already the RatUp seed classifier, the StreamNameUp constant-window classifier, the RegSeqRatUp finite-window seal consumption row, the DyadicRatCoreUp observation ledger, and the RealUp finite-window classifier.

The rows H, C, P, N account for transport, route replay, package provenance, and local naming. Since the excluded analytic objects have no coordinate in T, the listed rows exhaust the local NameCert obligations. □

Theorem 632.3 (Diagonal cofinal-tail seed-window readback)**.** *For an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *carrier*

$$T = (Q, S, G, D, R, W, H, C, P, N),$$

the stationary $\mathsf{Rat}^{\uparrow}$ *seed row* Q*, the constant* $\mathsf{StreamName}^{\uparrow}$ *window row* S*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail readback row* G*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger* D*, the* $\mathsf{Real}^{\uparrow}$ *diagonal row* R*, the transported seal row* W*, and the structural rows* H, C, P, N *form one consumer-readable route. The route starts at the paired RatUp seed classifier, reads the constant window, consumes the regular-rational cofinal tail, records the dyadic finite-window ledger, and reaches the real-facing row only through the transported stationary seal.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier seed window readback`

Proof. Project the accepted carrier of Definition 632.1. The displayed tuple already names the only rows that may be read by a consumer: $Q, S, G, D, R, W, H, C, P, N$.

Use Definition 632.2. It identifies the carrier admission, classifier exposure, componentwise hsame transport, continuation replay, package provenance, and local naming rows.

The transported seal row W is the same one used by Definition 9238.18. That theorem supplies the RatUp, StreamNameUp, RegSeqRatUp, DyadicRatCoreUp, and RealUp public readings of the stationary window, so the projected rows assemble a single readback route. □

Theorem 632.4 (Diagonal cofinal-tail common-window refinement)**.** *Let two* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumers read the same accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packet through the displayed* hsame *transports and* Cont *routes. If both consumers accept the packet, then their readings refine to the same finite cofinal-tail window rows*

$$Q, S, G, D, R, W, H, C, P, N.$$

Neither consumer can refine through a second selector, a quotient-stream equality datum, a selected limit, or an ambient completeness witness.

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier common window refinement`

Proof. Begin with Definition 632.3. Both consumers start from the same accepted carrier and therefore read the same projected seed-window route $Q, S, G, D, R, W, H, C, P, N$.

Apply Definition 632.11. It forces every visible cofinal-tail selector for a RegSeqRatUp or RealUp consumer to be determined by the displayed stationary seed row, constant window row, tail readback row, dyadic ledger, transported seal, and structural routes.

Finally use Definition 632.13. Since no route leaves the finite packet, the two accepted readings have no alternate object through which to diverge. They refine to the same displayed finite cofinal-tail window rows. □

Theorem 632.5 (Diagonal cofinal-tail obligation closure package)**.** *The carrier of Definition 632.1, the seed-window readback of Definition 632.3, the common-window refinement of Definition 632.4, the Real seal handoff of Definition 632.12, the non-escape boundary of Definition 632.13, and the TasteGate single-carrier theorem Definition 632.14 constitute the obligation surface for* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *over* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier obligation closure package`

Proof. The carrier definition gives the finite tuple $T = (Q, S, G, D, R, W, H, C, P, N)$ and excludes every unlisted analytic or host-side coordinate.

The seed-window readback and common-window refinement identify the positive consumer route and show that any two accepted RegSeqRatUp or RealUp reads refine to that same finite window surface.

The Real seal handoff supplies the real-facing passage through the StreamNameUp, RegSeqRatUp, and DyadicRatCoreUp rows. The non-escape theorem prevents an accepted downstream route from leaving the displayed packet.

Finally, Definition 632.14 records that later TasteGate-facing consumers have this single cofinal-tail carrier source. Together these clauses are exactly the named obligation surface. □

Theorem 632.6 (Diagonal cofinal-tail RegSeqRat–StreamName handoff)**.** *Every accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *consumer factors the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail readback through the constant* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger, the transported stationary seal row, the* $\mathsf{Real}^{\uparrow}$ *diagonal row, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, the local* $\mathsf{NameCert}$ *row, and the TasteGate single-carrier surface of Definition 632.14. In the carrier notation*

$$T = (Q, S, G, D, R, W, H, C, P, N),$$

the readback route is exhausted by $Q, S, G, D, R, W, H, C, P, N$ *and has no second carrier source, selected limit, quotient-stream equality, external equality, unrecorded selector, hidden parameter, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier regseqrat streamname handoff`

Proof. Project the carrier of Definition 632.1. The accepted packet exposes the RatUp seed row Q, constant StreamNameUp window S, RegSeqRatUp tail row G, DyadicRatCoreUp ledger D, RealUp diagonal row R, transported stationary seal row W, and the structural rows H, C, P, N.

Apply the NameCert obligations together with the seed-window readback. These results identify the RegSeqRatUp readback as the route from the stationary seed through the constant StreamNameUp window and the finite dyadic ledger.

Use the common-window refinement and the obligation closure package. They keep every accepted RegSeqRatUp or RealUp consumer on the same finite cofinal-tail surface and route the transported stationary seal through the displayed H, C, P, N rows.

Finally apply Definition 632.14. The TasteGate-facing consumer sees the same single carrier source, so the handoff cannot use a second carrier, selected limit, quotient-stream equality, external equality, unrecorded selector, hidden parameter, or ambient completeness witness. □

Theorem 632.7 (Diagonal cofinal-tail primitive scope)**.** *The* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *route consumes the preservation surface of chapter 483 only as a finite packet boundary. Its cofinal-tail consumer reads the* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows through the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *rows of Definition 632.1, and never through an unrecorded preservation theorem or ambient completion principle.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier primitive scope`

Proof. Project the accepted cofinal-tail carrier. The visible rows are the rational seed row Q, stream window row S, regular-rational tail row G, dyadic ledger row D, real-facing row R, transported seal row W, and the structural rows H, C, P, N.

The sibling preservation surface is read only as a boundary for finite packet consumption. No coordinate in T imports a closed subject-reduction theorem, host preservation theorem, or completion principle from that sibling chapter.

Thus every consumer read remains inside the displayed hsame, Cont, Pkg, and NameCert rows of the cofinal-tail packet, while chapter 483 supplies only the named preservation boundary against which the packet is scoped. □

Theorem 632.8 (Diagonal cofinal-tail compatibility handoff)**.** *For an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *carrier*

$$T = (Q, S, G, D, R, W, H, C, P, N),$$

any downstream $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, or completion-seal consumer that uses the compatibility packet must read the same stationary seed row* Q*,* $\mathsf{StreamName}^{\uparrow}$ *window* S*,* $\mathsf{RegSeqRat}^{\uparrow}$ *tail readback* G*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*,* $\mathsf{Real}^{\uparrow}$ *diagonal row* R*, transported seal row* W*, componentwise* hsame *transports* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* NameCert *row* N *before using that packet. The handoff is therefore the finite compatibility route from Definition 632.6 and Definition 632.7 into the carrier surface of chapter 646, not a host equality, selected limit, quotient-stream equality, or ambient completion principle.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier compatibility handoff`

Proof. Project the accepted cofinal-tail carrier. Its available rows are exactly the stationary seed, constant window, regular-rational tail readback, dyadic ledger, real diagonal row, transported seal row, and the structural rows H, C, P, N.

Apply Definition 632.6. It forces every RegSeqRatUp tail readback through the displayed tuple $Q, S, G, D, R, W, H, C, P, N$, so a downstream compatibility consumer has no independent seed, window, ledger, seal, transport, continuation, provenance, or local-name source.

Use Definition 632.7. The primitive scope permits only finite packet consumption through the displayed hsame, Cont, Pkg, and NameCert rows, and excludes unrecorded preservation theorems and ambient completion principles.

The remaining consumer route is precisely the finite compatibility handoff consumed by chapter 646. Since the route has already passed through the displayed rows of T, the compatibility

packet is received as a local finite handoff rather than as host equality, a selected limit, quotient-stream equality, or a completion theorem. □

Theorem 632.9 (Diagonal cofinal-tail public route)**.** *For an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *carrier*

$$T = (Q, S, G, D, R, W, H, C, P, N),$$

every downstream $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$, *or completion-seal consumer reads the public route exactly through* $Q, S, G, D, R, W, H, C, P, N$. *The row* Q *is the* $\mathsf{Rat}^{\uparrow}$ *seed row,* S *is the* $\mathsf{StreamName}^{\uparrow}$ *window row,* G *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail readback row,* D *is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row,* R *is the* $\mathsf{Real}^{\uparrow}$ *diagonal row,* W *is the transported seal row,* H *is componentwise* hsame *transport,* C *is displayed* Cont *replay,* P *is* Pkg *provenance, and* N *is local* NameCert. *The route exports no selected limit, quotient-stream equality, host equality, or ambient completeness datum.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier public route`

Proof. Start with the NameCert obligations and seed-window readback. They identify the accepted carrier as the displayed tuple $Q, S, G, D, R, W, H, C, P, N$ and expose the RatUp seed, StreamName window, RegSeqRat tail, dyadic ledger, real-facing row, transported seal, transport, replay, provenance, and naming rows.

Use the common-window refinement and the RegSeqRat–StreamName handoff. These theorems force every RegSeqRatUp or RealUp reading to refine to the same finite window surface and to pass through the displayed tail readback before reaching any real-facing consumer.

Apply the primitive scope and compatibility handoff. The primitive scope blocks unrecorded preservation, hidden selector, and ambient completion data, while the compatibility handoff routes every DiagonalLimitCompatibilityUp or completion-seal consumer through the same finite tuple before it may consume the compatibility packet.

The only remaining rows are $Q, S, G, D, R, W, H, C, P, N$. Since the carrier has no coordinate for a selected limit, quotient-stream equality, host equality, or ambient completeness theorem, the stated public route is exhausted by those rows. □

Theorem 632.10 (Diagonal cofinal-tail window exhaustion)**.** *Every certified finite cofinal-tail observation exported by an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *carrier factors through the finite rows*

$$Q, S, G, D, R, W, H, C, P, N.$$

In particular, the consumer may inspect only the displayed RatUp seed classifier, the constant StreamNameUp window, the RegSeqRatUp tail readback, the DyadicRatCoreUp finite-window ledger, the RealUp diagonal representative, the transported seal row, transports, continuations, provenance, and local naming.

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier window exhaustion`

Proof. Project the accepted carrier and its local naming surface. The observation rows are Q, S, G, D, R, W, and the structural rows are H, C, P, N.

Apply Definition 9238.18 to the window read by W. It says that the finite StreamNameUp, RegSeqRatUp, DyadicRatCoreUp, and RealUp readings all agree with the same RatUp seed classifier.

The continuations in C replay only those readings, and H transports them componentwise. No carrier coordinate remains for an unbounded window family, so every cofinal-tail observation is exhausted by the displayed finite packet. □

Theorem 632.11 (Diagonal cofinal-tail selector lock)**.** *For an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *carrier*

$$T = (Q, S, G, D, R, W, H, C, P, N),$$

any cofinal-tail selector visible to a $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer is determined by the displayed stationary* $\mathsf{Rat}^{\uparrow}$ *seed row* Q*, the constant* $\mathsf{StreamName}^{\uparrow}$ *window row* S*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail readback row* G*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger* D*, the transported seal row* W*, and the route rows* H, C, P, N*. No unrecorded selector, quotient-stream equality, selected limit, or ambient completeness datum can select a different tail for that consumer.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier tail selector lock`

Proof. Project the accepted carrier. The only tail-bearing rows are the stationary seed row, the constant window row, the regular-rational readback row, the dyadic finite-window ledger, and the transported seal row, with H, C, P, N giving transport, route replay, provenance, and local naming.

Apply Definition 632.10. It forces every finite cofinal-tail observation read by a downstream consumer through the same displayed packet $Q, S, G, D, R, W, H, C, P, N$.

Now use Definition 632.12. The $\mathsf{Real}^{\uparrow}$-facing read is the transported stationary diagonal row named by the $\mathsf{Rat}^{\uparrow}$ seed classifier, so the real-facing selector and the $\mathsf{RegSeqRat}^{\uparrow}$ tail readback are the same finite route.

Since the carrier contains no coordinate for an unrecorded selector, quotient-stream equality, selected limit, or ambient completeness datum, no consumer-visible route remains that could choose a different cofinal tail. □

Theorem 632.12 (Diagonal cofinal-tail Real seal handoff)**.** *For an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *carrier, the* $\mathsf{Real}^{\uparrow}$ *finite-window classifier exported by* R *and* W *is reached only through the displayed StreamNameUp window, RegSeqRatUp seal consumption row, and DyadicRatCoreUp finite-window ledger. Thus the real-facing seal handoff is the same transported stationary diagonal row named by the RatUp seed classifier in* Q*.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier real seal handoff`

Proof. Read the seal row W and the representative row R. The transported stationary diagonal theorem identifies the real-facing diagonal representatives with the constant StreamNameUp row induced by Q.

Now restrict to the window selected by D. The finite-window seal exhaustion theorem forces the RegSeqRatUp seal consumption row and the DyadicRatCoreUp ledger to be the public middle rows through which the RealUp classifier is read.

Therefore the real-facing handoff cannot introduce another comparison datum. It is the same transported stationary diagonal row replayed through S, G, D, R, W and the structural routes H, C, P, N. □

Theorem 632.13 (Diagonal cofinal-tail non-escape)**.** *An accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packet has no observation path outside the finite cofinal-tail rows of Definition 632.1. Any downstream route that consumes its RealUp seal, RegSeqRatUp readback, DyadicRatCoreUp ledger, StreamNameUp window, or RatUp seed classifier must factor through* $Q, S, G, D, R, W, H, C, P, N$*.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier nonescape`

Proof. The NameCert obligations identify every row that may be exported from the packet. The window exhaustion theorem shows that the finite cofinal-tail observations factor through those rows.

The Real seal handoff theorem then covers the only real-facing consumer path. It routes the RealUp classifier through the StreamNameUp, RegSeqRatUp, and DyadicRatCoreUp rows already named by the RatUp seed classifier.

Since no further coordinate is present, a downstream consumer cannot leave the packet to obtain an external equality identification, selected limit, unrecorded selector, or ambient completeness witness. □

Theorem 632.14 (Diagonal cofinal-tail TasteGate carrier single source)**.** *For an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packet*

$$T = (Q, S, G, D, R, W, H, C, P, N),$$

every carrier row available to a later TasteGate-facing consumer is generated from this single displayed cofinal-tail packet. The consumer may read the RatUp seed row Q, StreamNameUp window S, RegSeqRatUp tail readback G, DyadicRatCoreUp ledger D, RealUp representative R, transported seal W, and structural rows H, C, P, N; it has no second carrier, second selector, or parameter source.

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailTasteGate single carrier alignment`

Proof. Project the carrier of Definition 632.1. The displayed tuple lists every public row of the cofinal-tail packet.

Apply Definition 632.2. The local naming surface uses exactly those rows for carrier admission, classifier exposure, transport, continuation, provenance, and naming.

The window exhaustion theorem, Definition 632.10, keeps every finite cofinal-tail observation inside the same tuple. Hence a later TasteGate-facing read has only this carrier source. □

Theorem 632.15 (Diagonal cofinal-tail TasteGate hidden input refusal)**.** *An accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packet refuses every TasteGate-facing hidden input that is not a coordinate of*

$$T = (Q, S, G, D, R, W, H, C, P, N).$$

In particular, consumers cannot read unrecorded selectors, quotient-stream equality, selected limits, ambient completeness, or external equality, because none of these objects is a displayed carrier row or structural route.

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier tastegate hidden input refusal`

Proof. Begin with Definition 632.11. It rules out unrecorded selectors, quotient-stream equality, selected limits, and ambient completeness as alternate tail-selection data.

Use Definition 632.13 for the full consumer boundary. Any route consuming the RealUp seal, RegSeqRatUp readback, DyadicRatCoreUp ledger, StreamNameUp window, or RatUp seed classifier must remain inside $Q, S, G, D, R, W, H, C, P, N$.

External equality has no coordinate in the carrier definition and no route in C. Therefore it cannot be read by a TasteGate-facing consumer. □

Theorem 632.16 (Diagonal cofinal-tail TasteGate flow recognition)**.** *For an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *carrier, the visible recognition route from the* $\mathsf{Rat}^{\uparrow}$ *seed rows through* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *is the only flow available to later TasteGate wiring. Every recognized read follows the displayed rows* $Q, S, G, D, R, W, H, C, P, N$*, and no later wiring may recognize an unlisted analytic or host-side object as part of this packet.*

Proof. First identify the positive flow. The carrier definition lists Q for RatUp, S for StreamNameUp, G for RegSeqRatUp, D for DyadicRatCoreUp, R and W for RealUp-facing seal data, and H, C, P, N for transport, continuation, package, and naming.

Apply Definition 632.12. The RealUp-facing row is reached only through the StreamNameUp, RegSeqRatUp, and DyadicRatCoreUp rows named by the RatUp seed classifier.

Finally combine Definition 632.14 with Definition 632.15. The single-source result supplies the only recognized route, while the refusal result excludes hidden inputs outside the displayed packet. □

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier tastegate flow recognition`

Theorem 632.17 (Diagonal cofinal-tail route composition)**.** *For an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *carrier, every accepted route from the stationary* $\mathsf{Rat}^{\uparrow}$ *seed rows through* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *factors through the displayed packet rows*

$$Q, S, G, D, R, W, H, C, P, N.$$

The composed route is obtained by reading Q *into* S*,* S *into* G*,* G *into* D*,* D *into* R*, and* W *into the same public window readings, with* H *carrying componentwise transport,* C *carrying route replay,* P *carrying provenance, and* N *carrying local naming.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier route composition`

Proof. Start with the carrier definition. The tuple $T = (Q, S, G, D, R, W, H, C, P, N)$ gives all rows available to the local $\mathsf{NameCert}_{\mathsf{DiagonalCofinalTail}^{\uparrow}}$ surface, and Definition 632.2 identifies the admissible readings of those rows.

Next compose the displayed routes. The row C records the visible continuations from Q to S, from S to G, from G to D, from D to R, and from W to each public window reading.

The window exhaustion theorem forces every cofinal-tail observation through the same finite packet, while the Real seal handoff theorem makes the real-facing representative the transported stationary diagonal row named by Q.

Combining these facts leaves no accepted route outside $Q, S, G, D, R, W, H, C, P, N$. The route therefore factors through the displayed packet rows. □

Theorem 632.18 (Diagonal cofinal-tail public export)**.** *The* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *public surface is the single displayed packet*

$$T = (Q, S, G, D, R, W, H, C, P, N).$$

It exports the carrier of Definition 632.1, the NameCert obligations of Definition 632.2, seed-window readback, common-window refinement, Real seal handoff, non-escape, the TasteGate single-carrier alignment of Definition 632.14, hidden-input refusal, and route composition as one consumer-readable $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *surface.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier public export`

Proof. Begin with the carrier and NameCert obligations. They expose exactly the rows $Q, S, G, D, R, W, H, C, P, N$ and the local naming surface attached to those rows.

Seed-window readback and common-window refinement then give the positive downstream route. They identify the stationary RatUp seed, constant StreamNameUp window, RegSeqRatUp tail readback, DyadicRatCoreUp ledger, and RealUp-facing rows as one finite window surface.

The Real seal handoff and non-escape theorem close the real-facing boundary. The seal is read only through the displayed StreamNameUp, RegSeqRatUp, DyadicRatCoreUp, and RealUp rows, and no selected limit, quotient-stream equality, unrecorded selector, external equality, or ambient completeness coordinate is present.

Finally apply Definition 632.14, hidden-input refusal, and route composition. The TasteGate-facing route has one carrier source, refuses inputs outside the tuple, and composes every accepted consumer read through the same displayed packet. □

Theorem 632.19 (Diagonal cofinal-tail public consumer exactness)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of the public* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *surface reads exactly the rows*

$$Q, S, G, D, R, W, H, C, P, N$$

of the accepted packet. Such a consumer reads no selected limit, quotient-stream equality, unrecorded selector, external equality, ambient completeness witness, second carrier source, or hidden parameter outside the displayed cofinal-tail tuple.

Proof. Use the public export theorem to fix the only exported surface as $T = (Q, S, G, D, R, W, H, C, P, N)$. The consumer starts from that packet and not from a separate RegSeqRatUp or RealUp parameter source.

Route composition forces every accepted read through the displayed continuation chain. The hsame transport lock preserves those same rows under componentwise movement and does not add external equality or quotient-stream data.

Apply Definition 632.14 and the hidden-input refusal theorem. The later consumer has a single carrier source and any request for an unrecorded selector, selected limit, external equality, ambient completeness witness, second carrier, or hidden parameter is outside the packet.

Therefore the exact consumer surface is precisely the listed tuple and nothing beyond it. □

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailPublicConsumerExactness`

Theorem 632.20 (Diagonal cofinal-tail hsame transport lock)**.** *For an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packet, componentwise* hsame *transport preserves the same cofinal-tail packet rows* $Q, S, G, D, R, W, H, C, P, N$*. In particular, transport along* H *cannot introduce an external equality identification, a selected limit, quotient-stream equality, or ambient completeness as an additional carrier row or consumer-readable route.*

Proof. Project the transport row H. By construction it transports only the component rows Q, S, G, D, R, W and the structural rows already displayed in the packet.

Apply the tail-selector lock. It says that every consumer-visible cofinal-tail selector is determined by the stationary RatUp seed row, constant StreamNameUp window row, RegSeqRatUp readback, DyadicRatCoreUp ledger, transported seal row, and the structural routes already named in the packet.

Now use non-escape. Any route consuming the RealUp seal, RegSeqRatUp readback, DyadicRatCoreUp ledger, StreamNameUp window, or RatUp seed classifier must remain inside $Q, S, G, D, R, W, H, C, P,$

Thus componentwise hsame transport preserves the displayed packet and cannot create any unlisted equality, limit, quotient-stream, or completeness datum. □

Lean4 ✓ BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier hsame transport lock

Theorem 632.21 (Diagonal cofinal-tail finite-window replay determinacy)**.** *Let T and T' be accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packets. Suppose the two packets share the transported* $\mathsf{Rat}^{\uparrow}$ *seed row Q, the constant* $\mathsf{StreamName}^{\uparrow}$ *window row S, the* $\mathsf{RegSeqRat}^{\uparrow}$ *cofinal-tail readback row G, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger D, the transported stationary seal row W, and the structural rows H, C, P, N along the displayed componentwise transports. If both packets replay the same finite cofinal-tail window to* $\mathsf{Real}^{\uparrow}$ *consumers, then their consumer-visible R rows are classified together by the same route*

$$Q, S, G, D, R, W, H, C, P, N.$$

The determinacy is only a finite-window replay statement; it does not select a limit, identify quotient streams, assert external equality, or invoke ambient completeness.

Proof. First apply Definition 632.11. The shared Q, S, G, D, W rows determine the cofinal-tail selector visible to any replay consumer, so the two packets cannot choose different finite windows while keeping those rows fixed.

Next apply Definition 632.17. The RatUp seed, StreamNameUp window, RegSeqRatUp tail readback, DyadicRatCoreUp ledger, and RealUp-facing row are composed through the displayed continuation route rather than through an external equality or completion witness.

Now use Definition 632.20. Componentwise transport along H preserves the same packet rows and cannot add a second seal, quotient-stream equality, selected limit, or ambient completeness coordinate.

Finally apply Definition 632.23. Every downstream $\mathsf{Real}^{\uparrow}$ read is exhausted by the displayed tuple, so two accepted replays over the same finite window rows classify their consumer-visible R rows through the same route and no larger analytic surface. □

Lean4 ✓ BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier finite window replay determinacy

Theorem 632.22 (Diagonal cofinal-tail finite-window projection exactness)**.** *Let $T = (Q, S, G, D, R, W, H, C, P, N$ be an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packet. Every finite-window projection exposed to a* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer is exactly the projection of the displayed S, G, D, R, W rows through the displayed H, C, P, N rows. Equivalently, each consumer-visible finite window is obtained by replaying the constant* $\mathsf{StreamName}^{\uparrow}$ *window row S, the* $\mathsf{RegSeqRat}^{\uparrow}$ *cofinal-tail readback row G, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite ledger row D, the* $\mathsf{Real}^{\uparrow}$ *handoff row R, and the transported stationary seal row W along the componentwise transport, continuation, provenance, and naming rows already carried by H, C, P, N.*

No quotient-stream equality, selected limit, host real equality, ambient completeness object, or second selector can refine that finite-window projection. Such data are not part of the accepted projection surface and cannot be read by the three consumer classes.

Lean4 ✓ BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier window projection exactness

Proof. First use Definition 632.21. Shared replay of the same finite cofinal-tail window fixes the consumer-visible R row through the route $Q, S, G, D, R, W, H, C, P, N$, so the projection has no alternate replay source.

Next apply Definition 632.20. Componentwise transport along H preserves the rows $Q, S, G, D, R, W, H, C, P, N$ and therefore transports the projection row by row rather than adding quotient-stream equality, host real equality, a selected limit, or ambient completeness.

Finally apply Definition 632.23. Every $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consumer is exhausted by the displayed tuple. Since no second selector or analytic refinement is consumer-readable, the finite-window projection exposed downstream is exactly the displayed projection through $S, G, D, R, W, H, C, P, N$. □

Theorem 632.23 (Diagonal cofinal-tail consumer exhaustion)**.** *Every downstream* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packet reads the displayed rows*

$$Q, S, G, D, R, W, H, C, P, N$$

and no unlisted analytic object. In particular, the consumer surface contains no hidden selector, external equality identification, quotient-stream equality, selected limit, ambient completeness witness, or second carrier source.

Proof. First apply route composition. It factors every accepted route from the RatUp seed rows through the StreamNameUp, RegSeqRatUp, DyadicRatCoreUp, RealUp, transport, continuation, provenance, and naming rows of the displayed packet.

Next apply the hsame transport lock. It prevents componentwise transport from adding external equality, quotient-stream equality, selected limits, or ambient completeness to the consumer-visible surface.

Finally use TasteGate hidden input refusal. A later consumer cannot read anything that is not a carrier row or structural route of $T = (Q, S, G, D, R, W, H, C, P, N)$.

Therefore any $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, or $\mathsf{Real}^{\uparrow}$ consumer is exhausted by the displayed cofinal-tail packet rows and has no access to an unlisted analytic object. □

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier consumer exhaustion`

Theorem 632.24 (Diagonal cofinal-tail stationary seal uniqueness)**.** *Let T and T' be accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packets. Suppose they share the displayed stationary* $\mathsf{Rat}^{\uparrow}$ *seed row Q, the constant* $\mathsf{StreamName}^{\uparrow}$ *window row S, the* $\mathsf{RegSeqRat}^{\uparrow}$ *cofinal-tail readback row G, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger D, and the transported seal row W up to the componentwise transports recorded in H. Then every* $\mathsf{Real}^{\uparrow}$ *consumer reads the same real-facing seal row R through the same route*

$$Q, S, G, D, R, W, H, C, P, N.$$

In particular, the consumer cannot distinguish T from T' by an alternate real seal, selected limit, quotient-stream equality, ambient completeness witness, or second carrier source.

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier stationary seal uniqueness`

Proof. First apply Definition 632.11. The shared Q, S, G, D, W rows and the displayed H transports determine the cofinal-tail selector visible to any $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer.

Next use Definition 632.12. The real-facing row is not read from an independent completeness object; it is the transported stationary diagonal row reached through the StreamNameUp, RegSeqRatUp, and DyadicRatCoreUp rows already named by Q.

Now apply Definition 632.20. Componentwise transport along H preserves the same packet rows, so transporting from T to T' cannot create a second real seal or a new equality coordinate.

Finally use Definition 632.23. Every downstream $\mathsf{Real}^{\uparrow}$ read is exhausted by $Q, S, G, D, R, W, H, C, P, N$, hence two packets with the same stationary seed, window, tail readback, dyadic ledger, and transported seal give the same real seal to every consumer on that route. □

Theorem 632.25 (Diagonal cofinal-tail terminal seal factorization)**.** *Let T and T' be accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packets. Suppose every terminal* $\mathsf{Real}^{\uparrow}$ *seal comparison or downstream completion-seal consumer visible to the two packets agrees on the stationary* $\mathsf{Rat}^{\uparrow}$ *seed row Q, the constant* $\mathsf{StreamName}^{\uparrow}$ *window row S, the* $\mathsf{RegSeqRat}^{\uparrow}$ *cofinal-tail readback row G, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger D, the transported seal row W, and the componentwise transport row H. Then that terminal consumer factors through the same ordered finite route*

$$Q, S, G, D, R, W, H, C, P, N.$$

The consumer obtains no selected limit, quotient-stream equality, host real equality, countable-choice selector, ambient completeness witness, or second carrier source beyond this route.

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier terminal seal factorization`

Proof. First apply Definition 632.11. The shared Q, S, G, D, W rows determine the cofinal tail visible to any terminal comparison, so no separate selector or countable-choice source can drive the consumer.

Next use Definition 632.12. The terminal $\mathsf{Real}^{\uparrow}$ row is forced through the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ rows rather than through a host real equality, quotient-stream equality, selected limit, or ambient completeness witness.

Now apply Definition 632.20. Componentwise transport along H preserves the packet route $Q, S, G, D, R, W, H, C, P, N$ for both T and T', so the terminal seal consumer cannot acquire a second carrier source while moving between packets.

Finally combine Definition 632.24 with Definition 632.23. The shared real-facing row is unique on the stationary route, and every terminal $\mathsf{Real}^{\uparrow}$ or completion-seal read is exhausted by the ordered finite rows displayed above. Hence the consumer factors through the complete finite route and through no unlisted terminal object. □

Theorem 632.26 (Diagonal cofinal-tail terminal common-tail descent)**.** *Let T and T' be accepted* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packets. Suppose every terminal* $\mathsf{Real}^{\uparrow}$ *comparison or completion-seal consumer visible to T and T' agrees on the stationary* $\mathsf{Rat}^{\uparrow}$ *seed row Q, the constant* $\mathsf{StreamName}^{\uparrow}$ *window row S, the* $\mathsf{RegSeqRat}^{\uparrow}$ *cofinal-tail readback row G, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite-window ledger D, the transported seal row W, and the componentwise transport row H. Then every terminal comparison descends through the same common finite tail route*

$$Q, S, G, D, R, W, H, C, P, N.$$

No quotient-stream equality, selected limit, host real equality, countable-choice selector, ambient completeness witness, metric-completeness row, or second carrier source can distinguish the terminal reads.

Proof. First apply Definition 632.25. The terminal $\mathsf{Real}^{\uparrow}$ comparison and every completion-seal consumer factor through the ordered finite route $Q, S, G, D, R, W, H, C, P, N$ once they agree on the seed, window, tail readback, dyadic ledger, transported seal, and transport rows.

Next use Definition 632.24. The shared stationary rows force the real-facing seal row R to be the same consumer-visible row on both packets, so descent does not branch through a second terminal seal.

Now apply Definition 632.23. The consumer surface has no unlisted analytic coordinate, hence quotient-stream equality, selected limits, host real equality, countable-choice selectors, ambient completeness witnesses, and metric-completeness rows are unavailable as distinguishing data.

Finally use Definition 632.20. Componentwise transport along H preserves the displayed route row by row, so the terminal reads from T and T' descend through the same common finite tail and cannot be separated by a second carrier source. □

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier terminal common tail descent`

Theorem 632.27 (Diagonal cofinal-tail exact-boundary terminal route)**.** *Let*

$$T = (Q, S, G, D, R, W, H, C, P, N)$$

be an accepted $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packet. Suppose an accepted* $\mathsf{RealCompletionExactBoundaryUp}$ *terminal boundary consumes T as its completion-facing terminal route. Then the boundary's four Phase Real and Completion faces are read through the same finite route*

$$Q, S, G, D, R, W, H, C, P, N.$$

The $\mathsf{StreamName}^{\uparrow}$ *face is the constant window row S, the* $\mathsf{RegSeqRat}^{\uparrow}$ *face is the cofinal-tail readback row G, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *face is the finite-window ledger D, and the terminal* $\mathsf{Real}^{\uparrow}$ *face is the real-facing row R, all carried through the transported seal, componentwise transport, continuation, provenance, and local naming rows W, H, C, P, N. The terminal read cannot introduce quotient streams, host real equality, selected limits, countable choice, metric completeness, ambient completeness, bridge rows, or a second carrier source.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier exact boundary terminal route`

Proof. First apply Definition 632.26. Any terminal comparison or completion-seal consumer visible to the accepted $\mathsf{DiagonalCofinalTail}^{\uparrow}$ packet descends through the common route $Q, S, G, D, R, W, H, C, P, N$ and cannot distinguish the read by an unlisted analytic coordinate.

Next apply Definition 632.25. The terminal seal read factors through the same ordered rows once the seed, window, tail readback, dyadic ledger, transported seal, and transport rows have been fixed. Thus the boundary consumer sees the diagonal packet through a single finite carrier route rather than through a detached completion object.

Now use Definition 1120.6. Its accepted boundary exposes only the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and terminal $\mathsf{Real}^{\uparrow}$ faces to Phase Real and Completion consumers. Under the diagonal consumption hypothesis, these four faces are exactly the rows S, G, D, R already present in T.

Finally apply Definition 1120.13. Every completion-facing or terminal $\mathsf{Real}^{\uparrow}$ consumer of the accepted boundary must read the same finite route and may not add quotient streams, host real equality, selected limits, choice, completeness, bridge coordinates, or a second source. Hence the exact-boundary terminal read is the displayed diagonal cofinal-tail route. □

Theorem 632.28 (Diagonal cofinal-tail zero-source terminal coincidence)**.** *Let*

$$T = (Q, S, G, D, R, W, H, C, P, N)$$

be an accepted $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *packet, and let*

$$Z = (q, s, r, m, \mu, h, c, p, n)$$

be an accepted RegularCauchyZero$^{\uparrow}$ *packet. Suppose the stationary seed row Q agrees with the zero seed q, the constant window row S agrees with the zero* StreamName$^{\uparrow}$ *window s, the cofinal-tail readback row G agrees with the zero* RegSeqRat$^{\uparrow}$ *readback r, the dyadic ledger row D agrees with the zero packet's dyadic observation route, and the terminal* Real$^{\uparrow}$ *seal row R agrees with the zero seal read exported by Z.*

Then every terminal Real$^{\uparrow}$ *consumer and every completion-seal consumer visible to T reads the same finite route as the zero packet. That route is exactly*

Rat$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, NameCert

as displayed by the rows $Q, S, G, D, R, W, H, C, P, N$ and by the matching zero-source rows of Z. The consumer obtains no quotient stream, host real equality, selected limit, countable-choice selector, ambient completeness witness, or second terminal source.

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailCarrier zero source terminal coincidence`

Proof. First apply Definition 624.8 to the accepted zero packet. The hypotheses identify the zero seed, constant stream window, regular zero readback, dyadic observation route, and real seal read with the stationary rows visible in T, so the zero-source side has a single terminal consumer boundary.

Next apply Definition 632.26. Once $Q, S, G, D, R, W, H, C, P, N$ are fixed, every terminal comparison or completion-seal consumer of the diagonal packet descends through the same common tail route and cannot branch through a quotient stream, selected limit, host equality, choice, completeness, or another carrier source.

Now use Definition 632.27. The completion-facing exact boundary reads the diagonal packet through the four displayed terminal faces S, G, D, R and through the structural rows W, H, C, P, N. Under the zero-source agreement assumptions, these are precisely the zero seed, zero constant window, zero readback, dyadic ledger, and zero real seal already fixed by Z.

Finally apply Definition 360.51. Downstream RealCauchyCompletion$^{\uparrow}$ support retains the displayed DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$ faces together with BHist, hsame, Cont, Pkg, and NameCert. Hence the diagonal terminal read and the zero-source terminal read coincide on exactly the listed BEDC route, and no unlisted completion coordinate can supply a second terminal source. □

Theorem 632.29 (Diagonal cofinal-tail primitive scope package)**.** *The carrier, obligations, window exhaustion, selector lock, Real seal handoff, non-escape boundary, TasteGate single-carrier alignment, TasteGate hidden-input refusal,* hsame *transport lock, consumer exhaustion, stationary seal uniqueness, terminal seal factorization, terminal common-tail descent, exact-boundary terminal route, and zero-source terminal coincidence for* DiagonalCofinalTail$^{\uparrow}$ *are scoped exactly over* Rat$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, NameCert, *and the checked taste-gate marker. The scope contains no second carrier source and no unrecorded selector.*

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.DiagonalCofinalTailScopePackage`

Proof. The carrier and obligation package provide the primitive inventory. The rows $Q, S, G, D, R, W, H, C, P, N$ name the RatUp seed, StreamNameUp window, RegSeqRatUp tail readback, DyadicRatCoreUp finite-window ledger, RealUp handoff, transported seal, componentwise transport, continuation routes, provenance, and local naming surface.

Every consumer is then routed through the displayed route composition, the hsame transport lock, terminal seal factorization, terminal common-tail descent, the exact-boundary terminal route, and the zero-source terminal coincidence. These clauses force downstream RegSeqRatUp, DyadicRatCoreUp, RealUp, zero-source, and completion-seal readings to factor through the same finite packet and prevent transport from adding another equality, limit, completion, or selector coordinate.

Finally use the TasteGate rows. The carrier single-source theorem supplies the unique later carrier source, and the hidden-input refusal theorem excludes every TasteGate-facing input not already listed in $T = (Q, S, G, D, R, W, H, C, P, N)$. Thus the primitive scope is exactly the displayed BEDC object list and the checked taste-gate marker. □

Closure status for $\mathsf{NameCert}_{\mathsf{DiagonalCofinalTail}^{\uparrow}}$.

Constructive story: A $\mathsf{DiagonalCofinalTail}^{\uparrow}$ packet is generated from paired stationary RatUp seed rows, constant StreamNameUp windows, RegSeqRatUp cofinal-tail readbacks, DyadicRatCoreUp finite-window ledgers, RealUp diagonal representative rows, a transported stationary seal row, componentwise transports, continuation routes, package provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DiagonalCofinalTail}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 632.9, Definition 632.22, Definition 632.26, and Definition 632.28 bind the mature transported stationary diagonal window over $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Lean4 ✓ `BEDC.Derived.DiagonalCofinalTailUp.taste gate`

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DiagonalCofinalTail}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close RealUp completeness, external equality identification, selected real limits, unbounded diagonal families, Lean verification, or bridge checking.

Upgrade path: Lean verification remains the separate path for the transported stationary diagonal window over $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Chapter 633

A Concrete Naming Certificate for $\mathsf{CausalContinuitySocket}^{\uparrow}$

The $\mathsf{CausalContinuitySocket}^{\uparrow}$ packet realizes the Type IV causal-continuity socket as a finite certificate surface. It keeps record-side regularity, proposed prediction shape, and the audit gate in separate rows, so a successful finite record cannot be read as an internal future-law theorem.

The Type IV gate row G is the causal-continuity socket-kind row consumed from chapter 523 before the local socket site S is read. The taxonomy supplies the socket-kind ledger; $\mathsf{CausalContinuitySocket}^{\uparrow}$ specializes that row to the record, prediction, gate, and site packet below.

The Type IV gate row should be read as a causal-continuity specialization of the finite refusal boundary in chapter 630, with R, P, G, S replacing socket, refused-internalizer, GAP, and audit rows for the record-to-prediction passage.

This socket is consumed by the inter-Hist causal-rate chain, especially chapter 876 and chapter 656, because those chapters need finite record and prediction audit rows before any rate or invariant consumer may read a future-facing route.

Definition 633.1 (Causal continuity socket carrier)**.** *A* $\mathsf{CausalContinuitySocket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$X = (R, P, G, S, H, C, Q, N)$$

with the following displayed rows:

1. *R is the bounded record-regularity row, recording the finite observation window, its accepted regularity summary, and the last record boundary;*
2. *P is the proposed prediction-shape row, recording the not-yet-observed continuation pattern as a request shape rather than as a theorem of persistence;*
3. *G is the* GAP *and audit-gate row, recording the Type IV question that separates record support from causal-continuity commitment;*
4. *S is the socket-site row, recording the manuscript, observation, or certificate location where the prediction shape is requested from the record;*
5. *H records componentwise* hsame *transport for R, P, G, S, the continuation row, the provenance row, and the local naming row;*
6. *C records the displayed* Cont *routes by which consumers inspect the record row, prediction-shape row, audit gate, socket site, provenance, and local certificate;*

7. *Q records* Pkg *provenance over* BHist*, bounded records, prediction-shape ledgers,* GAP*,* hsame*,* Cont*,* Pkg*, and* NameCert*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{CausalContinuitySocket}^{\uparrow}}$ *row.*

The carrier has no coordinate for a universal future law, selected unseen observation, completed empirical stream, host causality principle, or theorem converting finite regularity into persistence.

Lean4 ✓ `BEDC.Derived.CausalContinuitySocketUp.CausalContinuitySocketTasteGate single carrier alignment`

Theorem 633.2 (Causal continuity record-prediction separation)**.** *For an accepted* $\mathsf{CausalContinuitySocket}^{\uparrow}$ *carrier, the record-side row R and prediction-shape row P remain distinct displayed coordinates. A downstream consumer may cite R as bounded regularity evidence and may cite P as a requested continuation shape, but no consumer may convert the pair (R, P) into a future-law commitment without passing through the Type IV gate row G.*

Proof. Project the accepted carrier X. The record evidence, prediction shape, and gate are the separate rows R, P, G.

The row R records only bounded observation data and the accepted finite regularity summary. The row P records only the requested continuation shape, not its fulfillment.

Any route from record support to prediction use must therefore pass through G and the socket-site row S. Since the carrier contains no future-law coordinate, the pair (R, P) cannot itself supply causal continuity. □

Lean4 ✓ `BEDC.Derived.CausalContinuitySocketUp.CausalContinuitySocket record prediction separation`

Theorem 633.3 (Causal continuity audit gate)**.** *The audit gate of an accepted* $\mathsf{CausalContinuitySocket}^{\uparrow}$ *packet is exactly the row G attached to the record row R, prediction row P, and socket site S. A use of record regularity for not-yet-observed history is visible precisely when it factors through*

$$R, P, G, S, H, C, Q, N.$$

Proof. Read the record and prediction sides first. The row R supplies the bounded regularity evidence, and P supplies the proposed continuation shape.

The gate row G is the displayed Type IV audit question linking those two rows at the site S. Thus visible use of the prediction route is use through the gate and site rows.

The rows H, C, Q, N transport, replay, package, and name the same visible gate. A route omitting G has no accepted coordinate that marks record-to-prediction passage, so it is not an accepted visible use. □

Theorem 633.4 (Causal continuity socket non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{CausalContinuitySocket}^{\uparrow}$ *packet factors through the finite rows*

$$R, P, G, S, H, C, Q, N.$$

The consumer may inspect bounded record regularity, proposed prediction shape, the Type IV gate, socket site, transport rows, continuation routes, package provenance, and the local NameCert *row. It cannot extract a universal future law, selected unseen observation, completed empirical stream, host causality principle, or persistence theorem from the packet.*

Proof. Start from the carrier definition. The packet exposes exactly the rows R, P, G, S, H, C, Q, N.

The record-prediction separation theorem confines the evidential read to R and the requested continuation shape to P. The audit-gate theorem then requires G and S for any visible route from one side to the other.

The remaining rows only transport, replay, package, and name this same finite packet. Because no future-law or unseen-observation coordinate exists in the carrier, no downstream consumer can project such a coordinate from it. □

Theorem 633.5 (Causal continuity socket NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CausalContinuitySocket}^{\uparrow}}$ *surface for Definition 633.1 consists exactly of carrier admission for*

$$X = (R, P, G, S, H, C, Q, N),$$

bounded record-regularity exposure, prediction-shape display, Type IV audit-gate exactness, socket-site locality, componentwise hsame *stability, displayed* Cont *replay,* Pkg *provenance, local naming, and refusal to internalize causal continuity as a theorem of the record.*

Proof. Carrier admission is projection from the displayed packet. The rows R, P, G, S, H, C, Q, N are the complete local inventory.

The record and prediction obligations are read from R and P. They expose bounded regularity and proposed continuation shape while keeping them separate.

The gate and site obligations are read from G and S, and the transport and replay obligations are read from H and C. Finally Q and N record provenance and local naming.

Together these rows give the NameCert surface. Since the inventory contains no causal-continuity theorem or completed future-history coordinate, the certificate names the socket without internalizing the requested persistence. □

Closure status for $\mathsf{NameCert}_{\mathsf{CausalContinuitySocket}^{\uparrow}}$.

Constructive story: A $\mathsf{CausalContinuitySocket}^{\uparrow}$ packet is generated from finite BHist rows for bounded record regularity, proposed prediction shape, Type IV audit gate, socket site, transport, route, provenance, and local naming. The record and prediction rows are deliberately separate: Cont routes any attempted record-to-prediction use through the displayed gate and site before a consumer can cite it. Componentwise hsame transports the record, prediction, gate, and site rows without turning them into a future-law theorem, while Pkg records the taxonomy and boundary dependencies. The socket therefore names a finite request surface, not completed persistence.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CausalContinuitySocket}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the causal-continuity socket carrier, record-prediction separation, audit gate, non-escape theorem, and NameCert obligation surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CausalContinuitySocket}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim a universal future law, selected unseen observation, completed empirical stream, host causality principle, or persistence theorem.

Upgrade path: Obligation closure requires Lean encodings of the socket carrier, gate route, record-prediction separation, and non-escape boundary.

Chapter 634

A Concrete Naming Certificate for QuotientSoundnessBoundary$^{\uparrow}$

The QuotientSoundnessBoundary$^{\uparrow}$ interface names the finite boundary at which a quotient-style equality request is refused as an unwitnessed representative-selection step and replaced by classifier-respecting psame transport. It does not construct a quotient type, select a canonical representative, collapse equivalent source rows, or import Quot.sound. It records the visible source relation rows, requested representative rows, transport replacement, refusal verdict, locality routes, provenance, and naming certificate that downstream quotient-like chapters may consume.

The packet consumes the refusal discipline of chapter 998 together with its local NameCert boundary, so quotient equality requests are converted into displayed refusal-and-transport rows before they can enter BEDC public reads.

When a request names Quot.sound as external supply, the quotient-soundness boundary consumes the axiom-dependency tuple audit row of chapter 861 and converts that request into the displayed refusal-and-transport rows.

The refusal surface is the quotient-facing specialization of the negative-boundary discipline of chapter 629: representative-selection requests are first treated as blocked boundary reads, and only then replaced by local psame transport.

Host-primitive leakage refusal is read through chapter 1157 before any quotient-style representative request may be replaced by psame transport.

Real-and-Completion quotient requests through chapter 1708 consume the same refusal-before-transport discipline before a RegSeqRat$^{\uparrow}$ or Real$^{\uparrow}$ seal can be read.

Definition 634.1 (QuotientSoundnessBoundary carrier)**.** *A* QuotientSoundnessBoundary$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (E, A, T, V, H, C, P, N)$$

with the following displayed rows:

1. *E is the finite family of quotient-relation rows, recording the source carrier entries, their classifier relation, and the displayed equivalence-derivation data admitted by the packet;*
2. *A is the requested representative row family, recording each attempted demand for a canonical representative, section, quotient equality token, or erased derivation tree;*
3. *T is the* psame *transport replacement row, recording the classifier-respecting route by which an operation reads related source rows without selecting a representative;*

4. *V is the refusal verdict row, recording that the requested representative-selection surface in A is not admitted and that downstream use must pass through T;*
5. *H records componentwise* hsame *transport for the relation rows, requested representative rows, transport replacement, refusal verdict, continuation routes, provenance, and local naming row;*
6. *C records the visible* Cont *routes from the relation rows to the refusal verdict, from the relation rows to the* psame *transport replacement, and from the transport replacement to the downstream classifier-respecting consumer;*
7. *P is the* Pkg *provenance over* $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$*, quotient-relation rows, requested representative rows,* psame*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{QuotientSoundnessBoundary}^{\uparrow}}$ *row.*

The carrier exports only a finite refusal-and-transport packet. It contains no coordinate for a quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, or Quot.sound *dependency.*

Theorem 634.2 (QuotientSoundnessBoundary NameCert obligations)**.** *For every accepted* QuotientSoundnessBou *carrier*

$$Q = (E, A, T, V, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{QuotientSoundnessBoundary}^{\uparrow}}$ *surface consists exactly of carrier admission, relation-row admission, requested-representative refusal, classifier-respecting* psame *transport, componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and non-admission of quotient carriers, representative selectors, quotient equality eliminators, erased derivation recovery maps, and* Quot.sound *dependencies.*

Proof. Carrier admission is projection from Definition 634.1. The tuple exposes the relation rows, requested representative rows, transport replacement, refusal verdict, transport rows, continuation routes, provenance, and local naming row.

The requested representative rows are read through A and judged by V. The verdict attaches the refusal to the displayed demands rather than to an anonymous global prohibition, so every blocked quotient-soundness request remains audit-visible.

The replacement obligation is supplied by T. It routes classifier-respecting consumers through psame transport on the source rows named in E, while H and C keep the transported read componentwise stable and local to the displayed packet.

Since no coordinate of Q is a quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, or Quot.sound dependency, the local certificate is exhausted by the listed finite obligations. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundaryCarrier namecert obligations`

Theorem 634.3 (QuotientSoundnessBoundary transport replacement)**.** *Every downstream operation accepted by a* $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$ *packet that would otherwise request a quotient representative must instead factor through the source relation rows E, the classifier-respecting* psame *transport row T, the componentwise transport row H, the continuation routes C, and the local naming row N. The result is an operation on named source rows, not an operation on a selected representative of a quotient class.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundaryCarrier transport replacement`

Proof. Begin with a consumer request recorded in A. By the refusal verdict V, the request is not admitted as a representative selector, quotient carrier, quotient equality eliminator, or derivation eraser.

The only positive route left by the carrier is the transport row T. It reads the relevant relation rows in E and supplies the classifier-respecting psame transport needed by the downstream operation.

The rows H and C then make the replacement stable and local: H moves the relation, refusal, and transport data componentwise, while C displays the route from relation evidence to transport and then to the consumer. Thus the operation proceeds on named source rows and never obtains a hidden quotient representative. □

Theorem 634.4 (QuotientSoundnessBoundary negative refusal dependency)**.** *Every quotient-style representative request accepted by a* QuotientSoundnessBoundary$^{\uparrow}$ *packet first lands in the negative-boundary refusal discipline of chapter 629. This chapter specializes that discipline to the visible relation rows E, requested representative rows A, classifier-respecting* psame *transport row T, refusal verdict V, componentwise transport H, continuation routes C, provenance P, and local naming row N, replacing any appeal to* Quot.sound *by displayed transport through T.*

Proof. Start with the carrier of Definition 634.1. The requested representative rows A and refusal verdict V record the same kind of blocked boundary read handled by the negative-name boundary.

Apply the transport replacement theorem, Definition 634.3. It routes the surviving operation through E, T, H, C, N rather than through a quotient representative or quotient equality eliminator.

Use the sibling refusal surface chapter 629 to read the representative request as a negative boundary request before the transport replacement is consumed. The local packet then records the specialized quotient-facing rows E, A, T, V, H, C, P, N.

Finally cite non-escape, Definition 634.6. Since the excluded quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, and Quot.sound dependency are absent from the packet, the only exported replacement is the displayed psame transport route. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary negative refusal certificate`

Theorem 634.5 (QuotientSoundnessBoundary Cauchy refusal link)**.** *Every* CauchyQuotientBoundary$^{\uparrow}$ *consumer of a* QuotientSoundnessBoundary$^{\uparrow}$ *packet reads the representative request rows A, V before it consumes the displayed* psame *transport route E, T, H, C, P, N. Consequently no quotient stream equality, selected representative, or* Quot.sound *row crosses into the Real-completion boundary.*

Proof. Start with the carrier of Definition 634.1. The rows A record the requested representative surface, and the rows V record the refusal verdict attached to that surface.

Apply refusal locality, Definition 634.7. It forces every representative-selection demand to be inspected as A, V before the positive transport route is consumed.

Apply the negative refusal dependency, Definition 634.4, and then read the Cauchy quotient boundary of chapter 1708. The Real-completion consumer therefore receives the displayed route E, T, H, C, P, N only after the refusal pair has been read.

Finally use non-escape, Definition 634.6. Since quotient stream equality, selected representatives, quotient eliminators, and Quot.sound dependencies are absent from the packet, none of those rows can enter the RegSeqRat$^{\uparrow}$ or Real$^{\uparrow}$ boundary through the Cauchy consumer. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary cauchy refusal link`

Theorem 634.6 (QuotientSoundnessBoundary non-escape)**.** *An accepted* QuotientSoundnessBoundary$^{\uparrow}$ *carrier cannot export a quotient carrier, canonical representative, quotient equality eliminator, erased equivalence-derivation recovery map, unrestricted quotient-recursion principle, host-level class selector, or* Quot.sound *dependency. Any consumer request for one of these objects leaves the finite packet*

$$E, A, T, V, H, C, P, N$$

and must be supplied by an explicit extra certificate outside this boundary.

Proof. Inspect the carrier inventory. The rows E, A, T, V, H, C, P, N name relation evidence, representative requests, transport replacement, refusal, stability, locality, provenance, and the local certificate.

None of these rows has the type or role of a quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, unrestricted quotient-recursion principle, host-level class selector, or Quot.sound dependency. The rows A and V record such demands as refused requests, and T records only the classifier-respecting replacement.

Therefore a downstream consumer cannot project any excluded object from the packet. It may either use the displayed psame transport route or supply a separate certificate whose boundary is audited independently. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary non escape`

Theorem 634.7 (QuotientSoundnessBoundary refusal locality)**.** *For every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *carrier*

$$Q = (E, A, T, V, H, C, P, N),$$

every representative-selection demand is localized to the requested-representative rows A and the refusal verdict rows V before any transport replacement is consumed. No downstream consumer may treat T, H, C, P, or N as evidence that a representative selector, quotient equality eliminator, erased derivation recovery map, or Quot.sound *dependency has been admitted.*

Proof. Project the carrier of Definition 634.1. The only rows that record a demand for a canonical representative, quotient equality token, section, or erased derivation tree are the rows A.

The verdict rows V attach the refusal to those displayed demands. Thus the blocked request is not a global prohibition detached from the packet; it is a local row pair A, V that can be audited before the replacement route is used.

Apply Definition 634.3. The positive route after refusal is the classifier-respecting psame transport through T, stabilized and routed by H and C and named by P, N. Since Definition 634.6 excludes the quotient-side objects, the replacement rows cannot be reread as hidden representative selection. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary refusal locality`

Theorem 634.8 (QuotientSoundnessBoundary psame transport exhaustion)**.** *Every surviving quotient-style operation accepted by a* QuotientSoundnessBoundary$^{\uparrow}$ *packet is exhausted by the displayed route through the source relation rows E, the classifier-respecting* psame *transport row T, the componentwise stability row H, the continuation row C, the package provenance row P, and the local naming row N. After the refusal pair A, V has been read, no second route remains through a quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, unrestricted quotient-recursion principle, host-level class selector, or* Quot.sound *dependency.*

Proof. Begin with a surviving operation. By Definition 634.7, its representative-selection demand has already been localized to A, V and refused before any positive transport is consumed.

The carrier then exposes only the source relation rows E and the replacement row T as the operation-facing data. The row T is explicitly a classifier-respecting psame route on named source rows, not an operation on quotient classes.

The rows H, C, P, N provide stability, locality, provenance, and naming for that same route. Apply Definition 634.6 to remove the excluded quotient objects from the exported surface. Therefore the displayed E, T, H, C, P, N route exhausts the surviving operation. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary psame transport exhaustion certificate`

Theorem 634.9 (QuotientSoundnessBoundary formal-target frontier)**.** *The mature paper-side refusal boundary for* QuotientSoundnessBoundary$^{\uparrow}$ *exhausts the quotient-facing certificate by the finite packet*

$$E, A, T, V, H, C, P, N.$$

The remaining formal target is the Lean encoding of exactly that packet and its psame *transport route through E, T, H, C, P, N. No paper closure grade for this chapter may be read as* Quot.sound*, host quotient construction, representative selection, erased derivation recovery, quotient eliminator admission, or bridge checking.*

Proof. Begin with Definition 634.2. It identifies the carrier, representative-demand, refusal, transport, stability, locality, provenance, and local naming rows as the finite certificate surface.

Apply Definition 634.3. The positive route after refusal is the classifier-respecting psame replacement through the displayed transport row T, not a quotient eliminator or representative selector.

Use Definition 634.6. It removes host quotient construction, quotient equality elimination, erased derivation recovery, representative choice, and Quot.sound from the exported packet.

Finally apply Definition 634.8. The only surviving operation route is E, T, H, C, P, N, while A, V record the refused quotient-facing demands. Hence the paper boundary is mature as a refusal surface, and the remaining frontier is the Lean encoding of this exact finite route rather than a hidden bridge check. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundaryFormalTargetFrontier`

Theorem 634.10 (QuotientSoundnessBoundary core refusal host-quotient exclusion)**.** *Let*

$$Q = (E, A, T, V, H, C, P, N)$$

be an accepted QuotientSoundnessBoundary$^{\uparrow}$ *packet whose surviving quotient-style route is exhausted by the displayed rows E, T, H, C, P, N after the refusal pair A, V has been read. The exported boundary cannot be reread as host quotient equality, representative selection, a quotient eliminator, erased derivation recovery, or* Quot.sound*. Every downstream quotient-like consumer must cite the displayed* psame *route through E, T, H, C, P, N or provide a separate audited certificate outside this packet.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary core refusal host quotient exclusion`
Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundaryCoreRefusalHostQuotientExclus`

Proof. Begin with the carrier definition, Definition 634.1. The packet exposes only the relation rows, requested representative rows, psame transport replacement, refusal verdict, stability rows, continuation rows, provenance, and local naming certificate.

Use refusal locality, Definition 634.7. It places every representative-selection demand in A, V before the surviving transport route is consumed, so the later rows cannot be interpreted as an admitted host representative selector.

Apply non-escape, Definition 634.6. It removes quotient carriers, representatives, quotient equality eliminators, erased derivation recovery maps, unrestricted quotient recursion, host-level selectors, and Quot.sound dependencies from the exported packet.

Finally apply Definition 634.8. The positive survivor is exactly the classifier-respecting psame route through E, T, H, C, P, N. Hence any downstream quotient-like consumer either cites that displayed route or leaves the boundary by supplying a separate audited certificate. □

Theorem 634.11 (QuotientSoundnessBoundary downstream audit package)**.** *The refusal locality theorem, the* psame *transport exhaustion theorem, and the non-escape theorem assemble a downstream audit package for quotient-like BEDC chapters. A downstream chapter may consume the refusal verdict A, V and the transport route E, T, H, C, P, N as an auditable refusal-and-transport surface, but it receives no quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, unrestricted quotient-recursion principle, host-level class selector, or* Quot.sound *dependency from* QuotientSoundnessBoundary$^{\uparrow}$.

Proof. Use Definition 634.7 to bind the negative part of the package. It says every representative-selection demand is visible as A and refused by V before replacement.

Use Definition 634.8 for the positive part. It identifies the only surviving operation route as E, T, H, C, P, N, with psame transport carried by T and stabilized through H, C.

Finally apply Definition 634.6. The excluded quotient primitives cannot be projected from the packet, so downstream quotient-like chapters receive an audit surface consisting of refusal plus displayed transport, not a quotient kernel extension. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundaryDownstreamAuditPackage`

Theorem 634.12 (QuotientSoundnessBoundary fixed classifier)**.** *For an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *carrier $Q = (E, A, T, V, H, C, P, N)$, every accepted comparison is exhausted by the relation rows E, requested representative rows A, replacement row T, refusal verdict V, and the displayed transport rows H, C. No comparison may consult a quotient carrier, canonical representative, quotient equality eliminator, erased derivation recovery map, or* Quot.sound *dependency.*

Proof. Project the carrier of Definition 634.1. The only comparison-facing coordinates are the relation evidence E, the recorded representative demands A, the replacement row T, the verdict V, and the locality rows H, C.

Apply the transport replacement theorem, Definition 634.3. It consumes E and T as the positive classifier-respecting route, while A and V keep representative selection in the refusal ledger.

The non-escape theorem, Definition 634.6, excludes every quotient eliminator and Quot.sound route from the packet. Hence the classifier is fixed by E, A, T, V, H, C and cannot be widened by an ambient quotient principle. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary fixed classifier certificate`

Theorem 634.13 (QuotientSoundnessBoundary kernel non-escape)**.** *Every kernel-facing consumer of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet remains inside the rows*

$$E, A, T, V, H, C, P, N.$$

The packet cannot import Quot.sound*, a host quotient eliminator, a hidden representative selector, or erased relation-derivation recovery.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary kernel nonescape`

Proof. Start with the NameCert obligations of Definition 634.2. They list carrier admission, relation admission, refused representative requests, classifier-respecting transport, componentwise stability, locality, provenance, and local naming as the full public surface.

Use the fixed classifier theorem above to identify the comparison route. The kernel-facing read is not an arbitrary quotient read; it is the finite path through E, A, T, V, H, C and then through package provenance and the local certificate.

Finally apply Definition 634.4 and Definition 634.6. The refusal dependency explains why the blocked request is represented negatively, and non-escape prevents any Quot.sound or host quotient eliminator from entering the kernel route. □

Theorem 634.14 (QuotientSoundnessBoundary root request triad)**.** *Every root quotient-style request accepted by a* QuotientSoundnessBoundary$^{\uparrow}$ *packet is exhausted, before any positive transport is consumed, by the relation rows E, the requested-representative rows A, and the refusal verdict rows V. The rows E name the visible relation evidence, A records the demanded representative-selection surface, and V refuses that demand as a kernel-facing object.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root request triad`

Proof. Project the carrier of Definition 634.1. Its request-facing coordinates include the relation rows E, the requested representative rows A, and the refusal verdict V.

Use the NameCert obligations of Definition 634.2. They identify requested-representative refusal as a named certificate obligation, so the representative demand is read from A and judged by V rather than by an ambient quotient principle.

Finally apply kernel non-escape, Definition 634.13. Since the kernel route cannot import Quot.sound, a host quotient eliminator, a hidden representative selector, or erased derivation recovery, the root request surface is exactly the finite triad E, A, V before the displayed transport row is used. □

Theorem 634.15 (QuotientSoundnessBoundary root relation row exposure)**.** *Every root quotient-style read accepted by a* QuotientSoundnessBoundary$^{\uparrow}$ *packet $Q = (E, A, T, V, H, C, P, N)$ must expose the relation rows E before it exposes any representative-demand row in A. Thus the packet records visible source relation evidence before a downstream consumer can ask for a canonical representative, section, quotient equality token, or erased derivation tree.*

Proof. Project the carrier. The row family E records the source relation evidence, while A records the demanded representative-selection surface.

Use the fixed classifier theorem. It keeps every accepted comparison inside E, A, T, V, H, C and prevents an ambient quotient principle from widening the comparison before relation evidence is visible.

Finally apply the root request triad and kernel non-escape. The triad exhausts the root request by E, A, V, and non-escape excludes hidden representative selectors, erased derivation recovery, host quotient eliminators, and Quot.sound. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundaryCarrier root relation row exposure`

Theorem 634.16 (QuotientSoundnessBoundary carrier exposure)**.** *Every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet exposes exactly the quotient-refusal carrier rows*

$$(E, A, T, V, H, C, P, N).$$

Here E is the visible relation evidence, A is the representative-demand surface, T is the surviving psame *transport row, V is the refusal verdict, H is the componentwise stability row, C is the displayed consumer route, P is package provenance, and N is the local* NameCert *row.*

Proof. Project the carrier of Definition 634.1. Its displayed tuple is the finite row list E, A, T, V, H, C, P, N.

Use Definition 634.2. The local certificate accounts for those rows as relation exposure, representative-request refusal, classifier-respecting transport, verdict accounting, componentwise stability, continuation, provenance, and naming.

No further quotient carrier row is present in the tuple. Thus every accepted packet exposes exactly the listed quotient-refusal carrier rows. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary carrier exposure`

Theorem 634.17 (QuotientSoundnessBoundary refusal ledger)**.** *Every representative-selection request accepted by a* QuotientSoundnessBoundary$^{\uparrow}$ *packet is ledgered by the rows A, V before the* psame *transport row T is available to a consumer.*

Proof. Use refusal locality, Definition 634.7. It keeps the requested representative surface inside the local refusal rows rather than in a host quotient selector.

Apply fixed classifier and the root request triad, Definition 634.12 and Definition 634.14. They place the demand in A and the negative verdict in V as part of the root request surface.

Only after that surface is visible can the transport replacement theorem supply the surviving psame row T. Hence the request is ledgered by A, V before T is consumed. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundaryRefusalLedger`

Theorem 634.18 (QuotientSoundnessBoundary downstream nonescape)**.** *Every downstream quotient-like consumer of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet receives only E, T, H, C, P, N after refusal has been accounted for. It receives no* Quot.sound*, host quotient eliminator, representative selector, or erased derivation recovery route.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary downstream nonescape`

Proof. Begin with the refusal ledger above. The rows A, V account for the refused representative request before any surviving downstream route is used.

Use psame transport exhaustion, Definition 634.8. After refusal, the positive movement available to a quotient-like consumer is exhausted by the psame transport row T together with stability, continuation, provenance, and naming.

Finally apply kernel non-escape, Definition 634.13. It excludes Quot.sound, host quotient eliminators, representative selectors, and erased derivation recovery, so the downstream surface is only E, T, H, C, P, N once refusal has been recorded. □

Theorem 634.19 (QuotientSoundnessBoundary consumer route certificate)**.** *After the representative-selection refusal has been accounted for, any consumer route through the displayed rows H, C and package row P carries a* SemanticNameCert *surface for the surviving* psame *replacement. The certificate reads only the quotient-refusal carrier, the displayed relation row E, the replacement transport row T, componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and the consumer row. It exports no representative selector, quotient eliminator, erased derivation recovery, host quotient recursion, or* Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary consumer route certificate`

Proof. Begin with the refusal ledger and downstream nonescape theorem above. They account for the negative request through A, V and leave the surviving consumer surface at E, T, H, C, P, N rather than at a representative selector or host quotient eliminator.

Next use the displayed route rows. The Cont route through H, C and the package row P are exactly the inputs of the checked consumer route certificate, while the carrier supplies the visible relation evidence and the surviving psame replacement row.

The checked Lean target then packages this route as a SemanticNameCert surface for the consumer row. Its fields use classifier-respecting transport, continuation replay, package provenance, and unary ledger soundness, so no quotient recursion, erased derivation recovery, representative selection, quotient eliminator, or Quot.sound dependency is imported. □

Theorem 634.20 (QuotientSoundnessBoundary root request accountability)**.** *For every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet $Q = (E, A, T, V, H, C, P, N)$, relation rows E, representative-request rows A, and refusal verdict rows V are accountable before any replacement by the transport row T. A downstream quotient-style consumer therefore sees the requested relation evidence, the demanded representative surface, and the refusal verdict before it can use T, H, C, P, N as the surviving audit route.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root request accountability`

Proof. Begin with Definition 634.15. It places the visible relation rows E before any representative-demand rows in A.

Use the root request triad, Definition 634.14. The triad binds the representative demand to A and its refusal to V, so the negative verdict is part of the root request surface.

After those rows are visible, the transport replacement theorem supplies T only as the classifier-respecting surviving route. The stability, locality, provenance, and naming rows H, C, P, N audit that route and do not erase E, A, V. □

Theorem 634.21 (QuotientSoundnessBoundary transport gate)**.** *For every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet $Q = (E, A, T, V, H, C, P, N)$, any quotient-like operation that survives the refused representative request must pass through T, H, C, P, N. The operation may still read the relation rows E, requested-representative rows A, and refusal verdict rows V as its accountable source surface, but its positive movement is gated by the displayed transport, stability, locality, provenance, and naming rows.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary transport gate`

Proof. First read the accountability surface from Definition 634.20. It keeps E, A, V visible before any surviving positive route is consumed.

Apply the transport replacement theorem. The only admitted positive motion after refusal is the psame transport row T on named source rows.

Finally use the NameCert obligations and non-escape theorem. They force every use of T to remain packaged with H, C, P, N and exclude any hidden positive path outside the displayed packet. □

Theorem 634.22 (QuotientSoundnessBoundary downstream nonimport)**.** *Every downstream quotient-like consumer of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet* $Q = (E, A, T, V, H, C, P, N)$ *receives only the audit surface* E, A, T, V, H, C, P, N*. It receives no* Quot.sound *dependency, quotient carrier, representative selector, erased derivation recovery map, or host quotient eliminator.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundaryCarrier downstream nonimport`

Proof. Use root request accountability to expose E, A, V as the complete negative request surface. These rows record the visible relation evidence, the representative demand, and the refusal verdict before any surviving operation is available.

Next apply the transport gate. It confines every surviving positive operation to T, H, C, P, N, with T carrying classifier-respecting psame transport and the remaining rows carrying stability, locality, provenance, and local naming.

Close with kernel non-escape. Since the carrier has no coordinate for Quot.sound, quotient carriers, representative selectors, erased derivation recovery, or host quotient eliminators, the downstream consumer imports only the displayed audit surface. □

Theorem 634.23 (QuotientSoundnessBoundary root transport verdict order)**.** *For every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet* $Q = (E, A, T, V, H, C, P, N)$*, the refusal verdict row* V *must be read before any positive* psame *transport row* T *is used by a quotient-like consumer. The transport row is therefore a replacement after refusal, not evidence that a representative selector or quotient equality eliminator has been admitted.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root transport verdict order`

Proof. Begin with refusal locality. It localizes every representative-selection demand to A and the refusal verdict V before the transport replacement is consumed.

Apply the transport replacement theorem. The row T is the classifier-respecting psame route on named source rows after the request has been refused, with H, C, P, N recording stability, locality, provenance, and naming.

Use the psame transport exhaustion theorem. After A, V are read, the surviving operation is exhausted by E, T, H, C, P, N and cannot recover a quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, or Quot.sound dependency. □

Theorem 634.24 (QuotientSoundnessBoundary root downstream unblock surface)**.** *The root relation row exposure, the root transport verdict order, the transport replacement theorem, non-escape, and the kernel refusal ledger assemble the downstream unblock surface for quotient-like chapters. The exported surface is exactly* E, A, V, T, H, C, P, N*: relation rows, representative-demand rows, refusal verdict, classifier-respecting* psame *transport, componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and local* NameCert *naming. It explicitly excludes* Quot.sound *and host quotient eliminators.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root downstream unblock surface`

Proof. Use Definition 634.15. It forces every root quotient-style read to expose E before any representative-demand row in A can be consumed.

Use Definition 634.23. It places the refusal verdict V before the positive transport row T, so downstream use receives replacement transport only after the refused request is visible.

Finally combine Definition 634.3, Definition 634.6, and Definition 634.44. These rows assemble E, A, V, T, H, C, P, N as the finite consumer surface and rule out Quot.sound, host quotient eliminators, hidden representative selectors, and erased derivation recovery. □

Theorem 634.25 (QuotientSoundnessBoundary psame replacement classifier)**.** *After the refusal pair A, V has been read, the only accepted classifier-respecting route for a quotient-like consumer is the displayed path through E, T, H, C, P, N. The row T is the* psame *transport replacement on named source rows, and the packet supplies no quotient carrier, selected representative, quotient equality eliminator, erased relation-derivation recovery, or* Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary psame replacement classifier`

Proof. Begin with the refusal pair supplied by Definition 634.14. The pair A, V has already recorded and refused the representative-selection demand before the positive consumer route is read.

Apply transport replacement, Definition 634.3, together with the fixed classifier theorem, Definition 634.12. The consumer route is forced through the relation rows E, the psame replacement row T, and the stability and locality rows H, C.

Use psame transport exhaustion, Definition 634.8. It adds the provenance and naming rows P, N to the same displayed route and excludes a second path through quotient carriers or selected representatives. □

Theorem 634.26 (QuotientSoundnessBoundary root transport package totality)**.** *After the root request triad has exposed E, A, V and the verdict-before-transport order has placed V before any positive transport use, every surviving quotient-like consumer route is totally packaged by E, T, H, C, P, N. The package reads the displayed relation rows, the classifier-respecting* psame *transport row, componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and local* NameCert *naming, and it imports no quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, or* Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root transport package totality`

Proof. First expose the root request surface. By Definition 634.14 and Definition 634.15, every root quotient-style request reads the relation rows E together with the representative-demand rows A and refusal verdict V.

Next use Definition 634.23. It forces the refusal verdict to be visible before the positive transport row T is consumed.

Once the verdict is fixed, apply Definition 634.25. The surviving classifier-respecting route is exactly E, T, H, C, P, N.

Finally combine Definition 634.6 with Definition 634.8. These results rule out the quotient-side primitives and package the whole surviving route in the displayed transport rows. □

Theorem 634.27 (QuotientSoundnessBoundary transport-refusal normal form)**.** *After the refusal pair A, V has been read in an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet, every surviving quotient-like operation is normalised to the displayed E, T, H, C, P, N route: relation rows E, classifier-respecting* psame *transport T, componentwise* hsame *stability H, displayed* Cont *locality C,* Pkg *provenance P, and local* NameCert *naming N. No surviving read exports a quotient carrier, representative selector, host quotient eliminator, erased relation-derivation recovery map, or* Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary transport refusal normal form`

Proof. Start with the refused request. The root request triad Definition 634.14 exposes the relation rows E, the representative-style demand A, and the refusal verdict V.

Use Definition 634.23 to place V before any positive transport read. Thus a later transport row cannot erase or reinterpret the refusal pair.

Now apply Definition 634.25 and Definition 634.26. They identify every surviving classifier-respecting route with the displayed E, T, H, C, P, N transport package.

Finally use Definition 634.13 and the public bridge non-escape surface of Definition 634.52. The excluded quotient primitives have no exported coordinate, so the displayed transport route is the normal form. □

Theorem 634.28 (QuotientSoundnessBoundary dependent-eliminator refusal)**.** *Every downstream dependent eliminator, representative selector, or family-indexed quotient read requested from an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet is refused unless it is routed entirely through*

$$E, T, H, C, P, N.$$

The accepted route can transport named relation rows by psame*, componentwise* hsame *stability, displayed* Cont *locality, package provenance, and local naming, but it cannot export a dependent quotient eliminator, selected representative, erased relation-derivation recovery map, or* Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary dependent eliminator refusal certificate`

Proof. Start with the carrier and refusal locality rows. The root request triad exposes E, A, V, and the non-escape surface records that representative selection and quotient eliminator requests are refused before any positive transport is consumed.

Use the transport-refusal normal form. Definition 634.27 states that every surviving quotient-like operation is normalised to E, T, H, C, P, N after A, V have been read.

Finally apply transport exhaustion and the public bridge non-escape surface. They leave only psame replacement transport over named source rows, with no coordinate for dependent quotient elimination, representative selection, erased derivation recovery, or Quot.sound. □

Theorem 634.29 (QuotientSoundnessBoundary classifier-substitution barrier)**.** *Any downstream substitution of classifiers for an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet must preserve the displayed relation rows E, the refusal pair A, V, and the positive transport package T, H, C, P, N. Such substitution may replace only along the displayed* psame *route; it cannot import* Quot.sound*, a quotient equality eliminator, a representative selector, or a hidden classifier over erased relation witnesses.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary classifier substitution barrier`

Proof. Read the fixed classifier row first. Definition 634.12 binds classifier-respecting use to the displayed relation rows rather than to an ambient quotient equality.

Next use refusal locality and verdict ordering. The request triad and Definition 634.23 keep A, V visible before any positive transport, so substitution cannot hide the refused demand.

Finally use transport replacement and normal form. Definition 634.3 and Definition 634.27 identify the surviving route as psame transport through E, T, H, C, P, N. Therefore classifier substitution preserves the displayed rows and imports no quotient-side primitive. □

Theorem 634.30 (QuotientSoundnessBoundary transport-only downstream package)**.** *The only downstream package exported by* QuotientSoundnessBoundary$^{\uparrow}$ *to quotient-like chapters is the transport-only package consisting of the refusal ledger E, A, V, the* psame *replacement row T, componentwise stability H, displayed locality C, package provenance P, local naming N, dependent-eliminator refusal, and classifier-substitution barrier. It supplies transport over named relation rows and no quotient carrier, quotient eliminator, representative selector, erased derivation recovery, or* Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary transport only downstream package`

Proof. First assemble the refusal ledger. The root request triad exposes E, A, V, while transport verdict ordering keeps the refusal verdict visible before the positive row T is consumed.

Next assemble the positive transport surface. The transport replacement, psame exhaustion, root transport package totality, and transport-refusal normal form theorems identify every surviving route with E, T, H, C, P, N.

Finally attach the two downstream barriers. Definition 634.28 refuses dependent eliminators and representative selectors outside the transport route, and Definition 634.29 blocks classifier substitutions that import quotient-side primitives. The resulting package is transport-only. □

Theorem 634.31 (QuotientSoundnessBoundary consumer ledger coverage)**.** *Every downstream consumer read of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet is covered by the finite ledger rows E, A, V, T, H, C, P, N. The rows A, V record the refused representative-style request, while E, T, H, C, P, N record the surviving classifier-respecting* psame *transport route. The ledger exports no* Quot.sound *row and no host quotient eliminator.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary consumer ledger coverage`

Proof. Read the negative coverage first. By Definition 634.14 and Definition 634.15, each root quotient-style request is visible through E, A, V.

Read the positive coverage next. The psame replacement classifier and root transport package totality, Definition 634.25 and Definition 634.26, cover every surviving transport consumer by E, T, H, C, P, N.

It remains to exclude hidden exits. Apply Definition 634.27, Definition 634.13, and Definition 634.52. The combined ledger therefore covers downstream consumers without exporting Quot.sound or a host quotient eliminator. □

Theorem 634.32 (QuotientSoundnessBoundary downstream handoff readiness)**.** *The transport-refusal normal form and consumer ledger coverage assemble the exact package that downstream quotient-like chapters may cite. That package is the finite surface E, A, V, T, H, C, P, N with refusal before transport, classifier-respecting* psame *replacement, componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and local* NameCert *naming; it contains no quotient primitive, no host quotient eliminator, no representative-selection export, and no* Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary downstream handoff readiness`

Proof. First take the ordered refusal surface from Definition 634.14 and Definition 634.23. These rows make A, V visible before any surviving transport handoff.

Next take the normal transport package from Definition 634.27. It identifies the only surviving quotient-like operation as the displayed E, T, H, C, P, N route.

Now add ledger coverage by Definition 634.31. Every downstream consumer read is therefore inside E, A, V, T, H, C, P, N.

Finally combine kernel non-escape with public bridge non-escape. The handoff surface is ready for downstream citation precisely because no quotient primitive, host quotient eliminator, representative-selection export, or Quot.sound dependency crosses the package boundary. □

↪ variant `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary consumer route certificate`

Theorem 634.33 (QuotientSoundnessBoundary no hidden eliminator)**.** *After the representative-demand rows A and refusal verdict row V have been read, every accepted downstream consumer of a* QuotientSoundnessBoundary$^{\uparrow}$ *packet has only the displayed* psame *route*

$$E, T, H, C, P, N.$$

The consumer cannot recover a quotient eliminator, representative selector, erased derivation map, host quotient recursion principle, or Quot.sound *dependency from any later transport, replay, provenance, or naming row.*

Proof. First read consumer ledger coverage. It places every downstream quotient-like consumer inside the finite rows E, A, V, T, H, C, P, N and separates refused representative-style requests from the surviving classifier-respecting transport route.

Next use downstream handoff readiness. Once the rows A, V have recorded refusal, the only positive handoff available to a consumer is the displayed E, T, H, C, P, N route with psame transport, componentwise hsame stability, displayed Cont locality, Pkg provenance, and local naming.

Apply the root nonimport ledger and the public non-escape boundary. These results remove quotient eliminators, representative selectors, erased derivation recovery, host quotient recursion, and Quot.sound from the packet boundary, so no later structural row can reintroduce one.

Thus every accepted downstream consumer remains on the visible refusal-before-transport route and has no hidden quotient eliminator to recover. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary no hidden eliminator`

Theorem 634.34 (QuotientSoundnessBoundary refusal transport sibling handoff)**.** *Every downstream quotient-like sibling that consumes a* QuotientSoundnessBoundary$^{\uparrow}$ *packet must read the representative-demand row A and refusal verdict row V before reading the positive transport rows E, T, H, C, P, N. The handoff supplies only classifier-respecting* psame *transport, componentwise*

hsame *stability, displayed* Cont *locality,* Pkg *provenance, and local* NameCert *naming over the finite* BHist *packet; it supplies no quotient carrier, host quotient eliminator, representative-selection export, or* Quot.sound *dependency.*

Proof. First read the refusal surface. The root request triad exposes the relation rows E, representative-style demand rows A, and refusal verdict rows V, while the verdict-order theorem places V before any positive transport row is available.

Next read the surviving transport surface. The transport-refusal normal form and downstream handoff readiness identify the only exported positive route as E, T, H, C, P, N, with T carrying classifier-respecting psame transport and H, C, P, N carrying hsame, Cont, Pkg, and NameCert structure.

Finally apply consumer ledger coverage and the public non-escape boundary. A downstream sibling therefore receives refusal before transport and cannot cite the packet as a source of Quot.sound, quotient carriers, host eliminators, or representative-selection exports. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary refusal transport sibling handoff`

Theorem 634.35 (QuotientSoundnessBoundary socket-kind route)**.** *Every accepted* SocketKindClassifier$^{\uparrow}$ *quotient-kind read that cites a* QuotientSoundnessBoundary$^{\uparrow}$ *packet factors through the quotient boundary refusal-before-transport route. It first reads the representative-demand and refusal rows A, V, then reads the positive* psame *transport package E, T, H, C, P, N, and only then supplies the* SocketKindClassifier$^{\uparrow}$ *kind row from chapter 1058. The route cannot reinterpret the quotient boundary packet as* Quot.sound*, a quotient carrier, a host quotient eliminator, or a representative selector.*

Proof. Begin with the sibling handoff, Definition 634.34. It forces every downstream quotient-like sibling to receive the refusal rows A, V before it can use the positive transport surface, and it exports only classifier-respecting psame transport with hsame, Cont, Pkg, and NameCert structure.

Next apply representative-demand exposure. The demanded representative surface remains audit-visible inside the finite BHist packet, so the classifier read cannot treat A as an admitted selector or erase the refusal verdict V before the kind row is assigned.

Finally use consumer ledger coverage and the downstream classifier surface in chapter 1058. The ledger exhausts quotient-like consumption by the refusal rows and the displayed transport rows, while the classifier contributes only the socket-kind row. Thus the cited quotient boundary is consumed as a finite BEDC refusal kind, not as Quot.sound, a quotient carrier, a representative selector, or a host quotient principle. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary socket kind route`

Theorem 634.36 (QuotientSoundnessBoundary representative demand exposure)**.** *Under the sibling handoff of Definition 634.34, the representative-demand rows A remain audit-visible as part of the finite* BHist *ledger. Later reads of T, H, C, P, N may consume classifier-respecting* psame *transport, componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and local* NameCert *naming, but they cannot erase A or reread it as an admitted representative selector.*

Proof. Begin with refusal locality. The representative-style demand is recorded in A together with the refusal verdict V before the positive transport route is available.

Now apply the sibling handoff. It carries A, V forward as the visible negative part of the surface and only then exposes the positive route through E, T, H, C, P, N.

It remains to exclude erasure by later rows. Kernel non-escape and public bridge non-escape remove the quotient-side coordinates, so T, H, C, P, N have no operation by which they can hide A, recover an erased representative demand, or turn the refused demand into an admitted representative-selection export. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary representative demand exposure`

Theorem 634.37 (QuotientSoundnessBoundary refusal ledger consumer frontier)**.** *Every downstream consumer of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet that reaches the representative-demand rows must first pass through the visible refusal rows E, A, V. Any later positive route through T, H, C, P, N remains classifier-respecting* psame *transport with componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and local* NameCert *naming rather than a quotient eliminator.*

Proof. Start with representative-demand exposure, Definition 634.36. It keeps the requested representative rows A audit-visible after sibling handoff and prevents later reads from treating them as admitted representative selectors.

Use psame consumer normalization, Definition 634.39. Once the refusal rows have been read, the surviving positive route normalizes to E, T, H, C, P, N and the transport row T is a classifier-respecting psame route.

Apply downstream factorization exactness and two-surface exhaustion. Definition 634.41 separates downstream reads into the refused request surface or the displayed transport surface, while Definition 634.42 rules out a third quotient-side route.

Therefore a consumer that reaches the representative-demand rows has already crossed E, A, V, and any later positive use of T, H, C, P, N is only the displayed replacement transport. It cannot be read as Quot.sound, a quotient carrier eliminator, or a hidden representative-selection principle. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary refusal ledger consumer frontier`

Theorem 634.38 (QuotientSoundnessBoundary refusal consumer public exactness)**.** *A public downstream quotient-like consumer of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet is accepted exactly when it factors through the visible refusal rows E, A, V followed by the positive* psame *transport package*

$$E, T, H, C, P, N.$$

The public route has no third branch through quotient carrier data, representative selection, a host quotient eliminator, erased derivation recovery, unrestricted quotient recursion, or Quot.sound*.*

Proof. For the forward direction, begin with the refusal ledger consumer frontier, Definition 634.37. Any consumer that reaches the representative-demand rows must pass through E, A, V, and any later positive use remains displayed transport through T, H, C, P, N.

Next apply psame consumer normalization, Definition 634.39. After the refusal rows are read, the surviving positive route is the classifier-respecting psame package E, T, H, C, P, N.

For the reverse direction, use downstream factorization exactness, Definition 634.41. A route that factors through the refusal surface and then through the displayed psame package is precisely a downstream quotient-like consumer route inside the accepted packet.

Finally apply two-surface exhaustion, Definition 634.42. The accepted packet has only the refusal surface and the positive transport surface, so quotient carrier data, representative selection, host quotient elimination, erased derivation recovery, unrestricted quotient recursion, and Quot.sound have no third route into the public consumer surface. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary refusal consumer public exactness`

Theorem 634.39 (QuotientSoundnessBoundary psame consumer normalization)**.** *Every surviving quotient-like consumer route of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet normalizes, after the refusal rows A, V have been read, to the displayed transport surface E, T, H, C, P, N. The normal form is a* psame *consumer route with componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and local* NameCert *naming; it has no quotient carrier coordinate and no host eliminator coordinate.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary psame consumer normalization`

Proof. Read the classifier first. The psame replacement classifier identifies the positive consumer operation as the displayed transport row T over the named relation rows E.

Then use consumer ledger coverage. Once refusal has been recorded in A, V, every surviving consumer read is covered by the positive rows E, T, H, C, P, N and by no additional quotient-side row.

Finally apply the sibling handoff together with kernel non-escape. The surviving consumer route therefore normalizes to the displayed psame transport route and cannot pass through a quotient carrier, a host quotient eliminator, or a hidden Quot.sound dependency. □

Theorem 634.40 (QuotientSoundnessBoundary refusal verdict monotonicity)**.** *In an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet, adding later transport rows cannot turn a refused representative-selection row A, V into an admitted quotient primitive. The rows E, T, H, C, P, N may supply the classifier-respecting* psame *replacement route after refusal, but they cannot reread A, V as a representative selector, quotient equality eliminator, host quotient eliminator, unrestricted quotient recursion principle, or* Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary refusal verdict monotonicity`

Proof. Start with the negative row. The root request triad, Definition 634.14, records representative-selection demand in A and refusal in V before transport is available.

The order statement Definition 634.23 separates verdict from transport. Thus later use of T is downstream of the refused request rather than a replacement for the refusal verdict.

Use Definition 634.25 for the positive route. It gives only classifier-respecting psame transport through E, T, H, C, P, N.

Finally apply Definition 634.6 and Definition 634.44. The packet has no coordinate by which later transport rows can promote a refused representative request into an admitted quotient primitive. □

Theorem 634.41 (QuotientSoundnessBoundary downstream factorization exactness)**.** *Every downstream quotient-like consumer of* QuotientSoundnessBoundary$^{\uparrow}$ *factors through exactly one of the two displayed surfaces: either the refused request pair A, V or the* psame *transport package E, T, H, C, P, N. There is no third route through a quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, host-level class selector, unrestricted quotient recursion principle, or* Quot.sound *dependency.*

Proof. Read the negative surface first. By Definition 634.14, Definition 634.15, and Definition 634.23, a representative-style request must expose E, then read A, V, before any surviving transport can be used.

Read the positive surface next. By Definition 634.25 and Definition 634.26, every surviving classifier-respecting consumer route is packaged by E, T, H, C, P, N.

The classifier boundary is exact because Definition 634.6 removes the quotient-side primitives, while Definition 634.44 records the exported surface as refusal plus displayed transport.

Finally apply Definition 634.25 again to identify the positive side as the named psame replacement rather than a hidden quotient route. The downstream consumer therefore has only the refused pair or the displayed transport package. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary downstream factorization exactness`

Theorem 634.42 (QuotientSoundnessBoundary two-surface exhaustion)**.** *Every downstream quotient-like consumer route for an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet is exhausted by exactly the refused request rows A, V and the classifier-respecting* psame *transport rows*

$$E, T, H, C, P, N.$$

There is no hidden third route through a quotient carrier, representative selector, quotient eliminator, unrestricted quotient recursion principle, erased derivation recovery, or Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary two surface exhaustion`

Proof. Read the negative request surface from the root request triad, Definition 634.14. A representative-style demand is recorded as the requested rows A together with the refusal verdict V.

Read the positive replacement surface from Definition 634.25. The only surviving operation is classifier-respecting psame transport through the displayed relation and structural rows E, T, H, C, P, N.

Apply consumer ledger coverage and downstream factorization exactness. The ledger covers all downstream quotient-like reads, and Definition 634.41 separates them into the refused request surface or the displayed transport surface.

Finally invoke kernel non-escape. Since the accepted packet has no coordinate for quotient carriers, representative selectors, quotient eliminators, unrestricted quotient recursion, erased derivation recovery, or Quot.sound, the two displayed surfaces exhaust the downstream route space. □

Theorem 634.43 (QuotientSoundnessBoundary consumer refusal exactness)**.** *Every downstream quotient-like consumer preserving an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *finite packet must remain on exactly one of two surfaces: either the refused request rows A, V, or the positive classifier-respecting* psame *transport package*

$$E, T, H, C, P, N.$$

No later consumer may reinterpret the refusal rows as representative selection, quotient equality elimination, host quotient elimination, unrestricted quotient recursion, erased derivation recovery, or a Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary consumer refusal exactness`

Proof. First read consumer ledger coverage. The ledger records all downstream quotient-like reads before any consumer can choose a route, so a preserving consumer must use one of the rows exposed by the finite packet.

Next expose representative demand. The root request triad and representative demand exposure place representative-style requests on the visible request and verdict rows A, V before transport is available.

Now read the positive route. The psame consumer normalization theorem and the downstream factorization exactness theorem package surviving classifier-respecting reads as E, T, H, C, P, N and separate them from the refused request surface.

Finally apply two-surface exhaustion. Since the accepted packet has only the refused request surface and the displayed psame transport surface, a later consumer has no coordinate from which to turn refusal into representative selection or any hidden quotient principle. □

Theorem 634.44 (QuotientSoundnessBoundary kernel refusal ledger)**.** *The root request triad, the* psame *replacement classifier, and kernel non-escape assemble the kernel-facing refusal ledger consumed by downstream quotient-like chapters. The exported surface consists of the refused request rows E, A, V together with the classifier-respecting transport rows E, T, H, C, P, N, and no* Quot.sound *or host quotient eliminator enters that surface.*

Proof. Use Definition 634.14 for the negative part of the ledger. It binds each root quotient-style request to the visible relation evidence E, the requested representative rows A, and the refusal verdict V.

Use Definition 634.25 for the positive replacement route. It identifies the accepted classifier-respecting consumer path as E, T, H, C, P, N, with T carrying the displayed psame transport.

Finally apply Definition 634.13. The kernel-facing packet cannot project Quot.sound, a host quotient eliminator, a hidden representative selector, or erased relation-derivation recovery, so downstream quotient-like chapters receive refusal plus displayed transport rather than a hidden quotient principle. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary refusal transport surface certificate`

Theorem 634.45 (QuotientSoundnessBoundary NameCert ledger)**.** *The carrier of Definition 634.1, the fixed classifier of Definition 634.12, the transport replacement of Definition 634.3, the negative-refusal dependency of Definition 634.4, and the kernel non-escape theorem of Definition 634.13 assemble the local* $\mathsf{NameCert}_{\mathsf{QuotientSoundnessBoundary}^{\uparrow}}$ *ledger.*

Proof. The carrier supplies the finite inventory E, A, T, V, H, C, P, N. The fixed classifier theorem binds every accepted comparison to the displayed relation, request, replacement, verdict, and transport rows.

The transport replacement theorem supplies the positive operation available to downstream consumers. It routes classifier-respecting reads through named source rows rather than through selected quotient representatives.

The negative-refusal dependency and kernel non-escape theorems complete the ledger. They record the blocked quotient-soundness demand as a negative boundary request and keep every exported consumer inside E, A, T, V, H, C, P, N, so the local naming certificate contains exactly the quotient-boundary obligations listed in Definition 634.2. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary namecert ledger`

Theorem 634.46 (QuotientSoundnessBoundary public bridge)**.** *Every downstream quotient-like consumer of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet must read the public boundary through the finite rows*

$$E, A, T, V, H, C, P, N.$$

The fixed classifier, transport replacement, negative-refusal dependency, kernel non-escape theorem, and NameCert ledger make this the whole public bridge: it admits relation rows, requested-representative refusal, classifier-respecting psame *transport, componentwise stability, continuation, provenance, and local naming, but it excludes quotient carriers, representative selectors, quotient equality eliminators, erased derivation recovery, and* Quot.sound*.*

Proof. Project the carrier and apply the fixed classifier theorem. Every accepted comparison is already read through E, A, T, V, H, C, so no downstream consumer can widen the comparison by consulting a quotient carrier or representative selector.

Use transport replacement for the positive route. It routes quotient-like use through the source relation rows E, the classifier-respecting transport row T, and the structural rows H, C, P, N.

Use the negative-refusal dependency for blocked representative requests. The rows A, V record those requests as refused boundary reads before any surviving transport is consumed.

Finally apply kernel non-escape and the NameCert ledger. Kernel non-escape removes quotient equality eliminators, erased derivation recovery, and Quot.sound from the exported packet, while the ledger assembles the remaining rows as the finite public boundary. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundaryPublicBridge`

Theorem 634.47 (QuotientSoundnessBoundary bridge schema)**.** *Every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *carrier presents a bridge from the finite refusal-and-transport packet to the public quotient-refusal schema. The bridge reads the relation rows E, requested representative rows A, classifier-respecting* psame *transport row T, refusal verdict V, componentwise* hsame *transport row H, continuation rows C,* Pkg *provenance row P, and local* NameCert *row N, and it imports no* Quot.sound *dependency.*

Proof. Project the carrier of Definition 634.1. Its public quotient-facing surface is already the finite tuple E, A, T, V, H, C, P, N.

Use the NameCert ledger, Definition 634.45, to assemble the refusal row A, V and the transport route E, T, H, C, P, N as one public packet. The fixed classifier theorem keeps comparison reads inside the same rows.

Finally apply non-escape, Definition 634.6. Since the excluded quotient primitives and Quot.sound have no coordinate in the carrier, the bridge is exactly the displayed refusal-and-transport schema. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary public bridge schema`

Theorem 634.48 (QuotientSoundnessBoundary psame bridge handoff)**.** *After the public refusal row A, V has been read, the only bridge handoff available to a quotient-like consumer is the classifier-respecting* psame *route E, T, H, C, P, N. The handoff supplies named-source transport and does not supply a representative selector, quotient equality eliminator, erased derivation recovery map, or* Quot.sound *dependency.*

Proof. Start with the refusal-locality theorem, Definition 634.7. It places every representative-selection demand in A, V before the positive transport route is consumed.

Then use psame transport exhaustion, Definition 634.8. The surviving operation is exhausted by E, T, H, C, P, N, with T carrying classifier-respecting transport on named source rows.

The non-escape theorem removes the quotient-side objects from the handoff. Thus the bridge gives downstream consumers a displayed psame route and no quotient-soundness primitive. □

Lean4 ✓ BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary psame bridge handoff

Theorem 634.49 (QuotientSoundnessBoundary refusal-transport determinacy)**.** *For every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet*

$$Q = (E, A, T, V, H, C, P, N),$$

once the representative request recorded in A has been refused by V, any accepted quotient-like consumer route is determined by the displayed psame *route through E, T, H, C, P, N. The consumer cannot choose a second route through a quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, host-level class selector, unrestricted quotient recursion principle, or* Quot.sound *dependency.*

Proof. Begin with the carrier of Definition 634.1. Its rows display the relation evidence E, representative requests A, psame transport T, refusal verdict V, componentwise stability H, continuation routes C, provenance P, and local naming N.

Use refusal locality, Definition 634.7. It forces the representative-selection demand to be read as the local pair A, V before any positive transport is consumed.

After that refusal, apply psame transport exhaustion, Definition 634.8, together with the bridge handoff, Definition 634.48. These results identify E, T, H, C, P, N as the displayed consumer route after refusal.

Finally use kernel non-escape, Definition 634.13, and the public bridge, Definition 634.46. Since the excluded quotient primitives have no coordinate in the packet, the accepted consumer has no second quotient route to select. □

Lean4 ✓ BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary refusal transport determinacy

Theorem 634.50 (QuotientSoundnessBoundary source-row consumer totality)**.** *Every surviving quotient-like consumer of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet must expose the source relation rows E before it reads the positive transport row T. All consumer-facing data in the packet is exhausted by the finite rows*

$$E, A, T, V, H, C, P, N.$$

Proof. Project the carrier of Definition 634.1. The row E is the source relation surface, while T is the classifier-respecting psame transport replacement available only as part of the displayed packet.
