Apply root relation row exposure, Definition 634.15, and root transport verdict order, Definition 634.23. These force relation exposure and refusal to be visible before the positive transport row can be consumed.

Then use psame transport exhaustion and the bridge handoff. The surviving consumer route is the single path through E, T, H, C, P, N after the refusal pair A, V has been read.

Kernel non-escape and the public bridge complete the totality claim. They keep every consumer-facing read inside E, A, T, V, H, C, P, N and exclude quotient carriers, hidden representative selectors, erased derivation recovery, host quotient eliminators, and Quot.sound. □

Lean4 ✓ BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary source row consumer totality

Theorem 634.51 (QuotientSoundnessBoundary verdict-transport separation)**.** *In every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet* $Q = (E, A, T, V, H, C, P, N)$*, the row* V *is a negative refusal row for the representative request in* A*, while* T *is a positive classifier-respecting* psame *transport row on the source relation surface* E*. Neither row can be reread as the other, and neither row can be reread as* Quot.sound*.*

Proof. The carrier separates the roles at the level of rows. The row V records the refusal verdict for the requested representative surface in A, while T records the positive psame transport replacement over the relation rows E.

Use refusal locality to read A, V as the negative part of the packet before transport. Use psame transport exhaustion and the bridge handoff to read E, T, H, C, P, N as the positive route made available after that refusal.

The two readings therefore have different positions and different consumer roles inside the finite packet. The verdict row blocks representative selection; the transport row carries classifier-respecting named-source transport.

Finally apply kernel non-escape and the public bridge non-escape, Definition 634.52. Since Quot.sound and the host quotient primitives are outside the public bridge, neither V nor T can be reinterpreted as a quotient-soundness primitive. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary verdict transport separation`

Theorem 634.52 (QuotientSoundnessBoundary public bridge non-escape)**.** *The public bridge supplied by* QuotientSoundnessBoundary$^{\uparrow}$ *is non-escaping: every consumer read remains inside* E, A, T, V, H, C, P, N*, and any request for quotient carriers, representative selectors, quotient equality eliminators, erased derivation recovery maps, host-level class selectors, unrestricted quotient recursion, or* Quot.sound *lies outside the bridge.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary public bridge nonescape`

Proof. Apply the bridge schema theorem above to identify the public bridge with the refusal-and-transport tuple E, A, T, V, H, C, P, N.

Apply the psame bridge handoff theorem above for the positive route after refusal. It leaves only named-source transport through E, T, H, C, P, N.

Finally apply Definition 634.13. The kernel-facing route has no quotient primitive coordinate, so any request for such an object must be supplied by a separate certificate outside this chapter. □

Theorem 634.53 (QuotientSoundnessBoundary erased derivation refusal)**.** *For every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet*

$$Q = (E, A, T, V, H, C, P, N),$$

any request to recover an erased quotient derivation is first routed to the representative-request row A *and the refusal-verdict row* V*. The request is refused before the positive transport row* T *is readable by a downstream consumer.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary erased derivation refusal certificate`

Proof. The carrier in Definition 634.1 separates representative requests, refusal verdicts, and positive transport into the rows A, V, T. A recovery demand for an erased derivation is therefore not a transport demand; it is a representative-side demand.

Apply refusal locality, Definition 634.7. It forces the demand through A, V before any consumer can use the positive transport route.

Then use verdict-transport separation, Definition 634.51. The refusal row V cannot be reread as the transport row T, and T cannot be used to reconstruct a denied representative witness.

Finally apply public bridge non-escape, Definition 634.52. Erased derivation recovery has no bridge coordinate, so the only public response is the local refusal recorded by A, V. □

Theorem 634.54 (QuotientSoundnessBoundary psame-only descent)**.** *After the refusal of representative recovery in an accepted* $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$ *packet* $Q = (E, A, T, V, H, C, P, N)$*, every accepted descent route factors only through* E, T, H, C, P, N *using classifier-respecting* psame *transport. No accepted descent route uses representative selection, quotient equality elimination, erased derivation recovery, host quotient recursion, or* Quot.sound*.*

Proof. Begin after the refusal supplied by Definition 634.53. At that point the consumer may read the positive route only as a route downstream of A, V.

Apply psame transport exhaustion, Definition 634.8. It identifies the surviving positive descent as classifier-respecting psame transport through E, T, H, C, P, N.

Use the psame bridge handoff, Definition 634.48, to pass this displayed route to the public bridge. Then apply source-row consumer totality, Definition 634.50, which exhausts the downstream read by the finite rows E, A, T, V, H, C, P, N.

The excluded quotient primitives have no coordinate in those rows. Hence an accepted descent route is psame-only and cannot pass through representative selection, quotient equality elimination, erased derivation recovery, host quotient recursion, or Quot.sound. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary psame only descent`

Theorem 634.55 (QuotientSoundnessBoundary consumer non-escape)**.** *Every downstream quotient-like consumer of an accepted* $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$ *packet is exhausted by the finite rows*

$$E, A, T, V, H, C, P, N.$$

It cannot reinterpret the refusal verdict V *or the positive transport row* T *as quotient equality elimination, erased derivation recovery, host quotient recursion, or* Quot.sound*.*

Proof. First apply erased derivation refusal, Definition 634.53. Any recovery demand is already localized to A, V and refused before T is available.

Next apply psame-only descent, Definition 634.54. The surviving positive route factors through E, T, H, C, P, N as classifier-respecting psame transport.

Finally use public bridge non-escape, Definition 634.52. Since every consumer read stays inside E, A, T, V, H, C, P, N, neither V nor T can be reinterpreted as a quotient-side eliminator, recovery map, recursion principle, or Quot.sound witness. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary consumer nonescape`

Theorem 634.56 (QuotientSoundnessBoundary representative request frontier)**.** *For every accepted* $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$ *packet* $Q = (E, A, T, V, H, C, P, N)$*, any request for a representative, representative selector, erased derivation, or host quotient witness is exhausted by the*

source row E, representative-request row A, and refusal-verdict row V before the positive transport row T is readable. The request therefore reaches a visible refusal frontier before any downstream psame *transport is exposed.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary representative request frontier`

Proof. Start with erased derivation refusal, Definition 634.53. It routes recovery demands to A, V before the positive transport row is available.

Apply refusal locality and verdict-transport separation, Definition 634.7 and Definition 634.51. These rows prevent a representative request from being reread as transport and prevent T from reconstructing a denied witness.

Finally use consumer non-escape, Definition 634.55. The public consumer remains inside E, A, T, V, H, C, P, N, so the representative-side request is exhausted at E, A, V before transport can be used. □

Theorem 634.57 (QuotientSoundnessBoundary psame consumer closure)**.** *After the representative frontier refuses the representative-side request, every surviving downstream consumer closes through E, T, H, C, P, N by classifier-respecting* psame *transport. The surviving route has no representative selector, quotient equality eliminator, erased derivation recovery map, host quotient recursion, or* Quot.sound *coordinate.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary psame consumer closure`

Proof. First apply the representative request frontier above. It leaves the positive route available only after E, A, V have already recorded the refusal boundary.

Use psame-only descent, Definition 634.54. The surviving route factors through E, T, H, C, P, N as classifier-respecting psame transport.

Then apply the public bridge non-escape theorem, Definition 634.52. The bridge has no coordinate for the excluded quotient primitives, so the psame-only consumer route is closed by the displayed finite rows. □

Theorem 634.58 (QuotientSoundnessBoundary Quot.sound refusal exactness)**.** *In an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet, a request for* Quot.sound *is refused exactly at the visible boundary rows E, A, V and cannot be served by the positive transport row T or by the consumer rows H, C, P, N. Conversely, the admitted positive route through E, T, H, C, P, N is precisely the* psame-*only route that remains after that refusal.*

Proof. For the refusal direction, apply the representative request frontier above. A Quot.sound demand is a representative-side quotient primitive request, so it is routed to E, A, V before T is readable.

Apply kernel non-escape and public bridge non-escape, Definition 634.13 and Definition 634.52. Neither the kernel-facing route nor the bridge exposes a Quot.sound coordinate.

For the surviving route, use psame consumer closure above. Once the refusal is recorded, every admitted consumer is exactly the classifier-respecting psame route through E, T, H, C, P, N, so the refusal boundary and the positive route are exact complements inside the finite packet. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary quot sound refusal exactness`

Theorem 634.59 (QuotientSoundnessBoundary refusal stability row)**.** *In every accepted* QuotientSoundnessBound *packet $Q = (E, A, T, V, H, C, P, N)$, componentwise* hsame *transport through the history row H preserves the visible refusal pair A, V and the surviving transport row T. The stable row remains a refusal-and-*psame *ledger entry and does not admit representative selection, erased derivation recovery, host quotient recursion, or* Quot.sound*.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary refusal stability row`

Proof. The carrier definition, Definition 634.1, makes H a row of the finite packet rather than a quotient eliminator. Hence componentwise hsame transport can only move along the displayed history coordinate of Q.

Apply the representative request frontier, Definition 634.56. It fixes the visible refusal boundary at E, A, V before the positive transport row T is available.

Then apply psame consumer closure, Definition 634.57. After the refusal boundary is recorded, the surviving consumer route is exactly the classifier-respecting psame route through E, T, H, C, P, N.

Finally use Quot.sound refusal exactness, Definition 634.58. Since Quot.sound is refused at E, A, V and the admitted route is the displayed psame route, hsame transport through H cannot create a hidden representative selector or quotient-soundness witness. □

Theorem 634.60 (QuotientSoundnessBoundary Cont route locality)**.** *Every consumer route through the continuation row C of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet reads the relation rows E, then the refusal rows A, V, and then the positive* psame *transport row T in the displayed order. There is no hidden route through a quotient eliminator, representative selector, erased derivation recovery map, host quotient recursion, or* Quot.sound*.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary cont route locality`

Proof. The carrier definition places C after the source, refusal, transport, and history rows in the finite packet $Q = (E, A, T, V, H, C, P, N)$. A continuation consumer therefore receives only the rows already exposed by the packet.

Use the representative request frontier, Definition 634.56, to locate every representative-side demand at E, A, V before any positive transport is readable.

Next apply psame consumer closure, Definition 634.57. It identifies the route available to C as the classifier-respecting psame route through E, T, H, C, P, N after the refusal frontier has been crossed.

Quot.sound refusal exactness, Definition 634.58, rules out the hidden branch. The continuation row has no coordinate that can bypass A, V or reinterpret T as Quot.sound. □

Theorem 634.61 (QuotientSoundnessBoundary Pkg NameCert ledger totality)**.** *In every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet, the package row P and NameCert row N account for the whole finite ledger E, A, T, V, H, C. The exported object is exactly this ledger package and exports no quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery primitive, host quotient recursion principle, or* Quot.sound *primitive.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary pkg namecert ledger totality`

Proof. By the carrier definition, the public packet has exactly the displayed rows $Q = (E, A, T, V, H, C, P, N)$. The rows P, N package and certify the preceding ledger rows; they are not extra quotient primitives.

Apply the representative request frontier to account for the refusal ledger E, A, V. It records every representative-side request before positive transport is exposed.

Apply psame consumer closure to account for the positive ledger E, T, H, C, P, N. The downstream route that survives the refusal is the classifier-respecting psame route over the displayed packet.

Finally use Quot.sound refusal exactness. Since Quot.sound is refused exactly at the visible boundary and the surviving route is already exhausted by the packet rows, P, N are total for the finite ledger and cannot export any additional quotient primitive. □

Theorem 634.62 (QuotientSoundnessBoundary psame request determinacy)**.** *For every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet* $Q = (E, A, T, V, H, C, P, N)$*, a representative-side request is deterministically routed to the visible refusal rows* E, A, V *before the admitted* psame *route through* E, T, H, C, P, N *is readable. Thus a downstream consumer can read either the recorded refusal frontier or the surviving classifier-respecting* psame *transport, but it receives no ambiguous branch between representative access and positive transport.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary psame request determinacy`

Proof. Apply the representative request frontier, Definition 634.56. It sends every representative, selector, erased-derivation, host-quotient, and Quot.sound demand to E, A, V before T is exposed.

Next use psame consumer closure, Definition 634.57. After the refusal frontier is recorded, the only surviving positive consumer is the classifier-respecting psame route through E, T, H, C, P, N.

The two surfaces are separated by Quot.sound refusal exactness, Definition 634.58. Hence the packet presents a determined refusal surface first and a determined psame surface second, with no hidden branch that can choose a representative route. □

Theorem 634.63 (QuotientSoundnessBoundary NameCert refusal totality)**.** *For every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet, the package row* P *and NameCert row* N *are total for the refusal-plus-transport ledger consisting of the visible refusal rows* E, A, V *and the admitted transport rows* E, T, H, C, P, N*. The certified export exposes no* Quot.sound *primitive, representative selector, erased-derivation recovery coordinate, or host quotient recursion coordinate.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary namecert refusal totality`

Proof. First apply psame request determinacy above. It fixes the order in which E, A, V are readable as refusal rows and E, T, H, C, P, N are readable as the positive psame route.

Use Cont route locality, Definition 634.60, to keep continuation consumers inside that displayed route. The continuation row cannot bypass A, V or reinterpret T as a quotient eliminator.

Finally apply Pkg NameCert ledger totality, Definition 634.61. Since P, N already certify the entire finite ledger and expose no excluded quotient primitive, the NameCert surface is total for exactly the refusal-plus-transport ledger stated here. □

Theorem 634.64 (QuotientSoundnessBoundary downstream representative non-escape)**.** *Every downstream consumer of the* QuotientSoundnessBoundary$^{\uparrow}$ *chapter factors through the deterministic refusal surface of Definition 634.62 and the total NameCert surface of Definition 634.63. Consequently the surviving* psame *route through* E, T, H, C, P, N *cannot be reinterpreted as a quotient eliminator, representative selector, erased-derivation recovery map, host quotient recursion principle, or* Quot.sound *witness.*

Lean4 ✓ BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary downstream representative nonescape certificate

Proof. Apply psame request determinacy to determine the public request boundary. A downstream consumer first sees the visible refusal rows E, A, V and only then the classifier-respecting psame route through E, T, H, C, P, N.

Apply NameCert refusal totality above. The certified export is the finite refusal-plus-transport ledger, so its public rows expose no representative selector, recovery coordinate, host quotient recursion coordinate, or Quot.sound primitive.

Use Cont route locality and Pkg NameCert ledger totality, Definition 634.60 and Definition 634.61. They force every continuation and package read to stay inside the same finite ledger, so the surviving psame route is a consumer closure route rather than a quotient eliminator. □

Theorem 634.65 (QuotientSoundnessBoundary refusal exact complement)**.** *In an accepted* QuotientSoundnessBou *packet*

$$Q = (E, A, T, V, H, C, P, N),$$

every downstream consumer request is either the visible representative-side refusal through E, A, V or the admitted psame*-only route through E, T, H, C, P, N. These two surfaces are exact complements inside the finite packet: a request that asks for a representative, selector, erased-derivation recovery, host quotient recursion, quotient equality eliminator, or* Quot.sound *witness is refused at E, A, V, while a request that survives the refusal boundary factors through the classifier-respecting* psame *route and no third route remains.*

Proof. Apply the representative request frontier, Definition 634.56. It places every representative-side demand at the visible refusal surface E, A, V before a positive transport row can be consumed.

Use psame consumer closure, Definition 634.57. Once the representative-side request has been refused, the surviving consumer route is the classifier-respecting psame route through E, T, H, C, P, N.

Invoke Quot.sound refusal exactness, Definition 634.58. It separates the forbidden representative primitive from the admitted psame transport, so the refusal surface cannot be reinterpreted as a hidden quotient witness.

Finally apply NameCert refusal totality, Definition 634.63. The package and naming rows certify only the refusal-plus-transport ledger, hence the two surfaces exhaust the finite packet and form exact complements for downstream consumers. □

Lean4 ✓ BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary refusal exact complement certificate

Theorem 634.66 (QuotientSoundnessBoundary consumer scope triad)**.** *Every downstream quotient-like consumer of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet must first read the refusal surface E, A, V: the visible relation rows E, the representative-demand rows A, and the refusal verdict rows V. Only after that triad is visible may the consumer read any positive motion through the classifier-respecting* psame *route E, T, H, C, P, N. The handoff receives no quotient carrier, representative selector, erased derivation recovery map, host quotient recursion principle, or* Quot.sound *witness.*

Lean4 ✓ BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary consumer scope triad certificate

Proof. Use psame request determinacy, Definition 634.62. It routes every representative-side request to E, A, V before the positive psame route is readable.

Apply NameCert refusal totality, Definition 634.63. The certified export is the finite refusal-plus-transport ledger, so a downstream consumer reads the refusal triad before it receives the transport rows.

Finally use downstream representative non-escape above. It keeps the surviving route inside E, T, H, C, P, N and excludes quotient carriers, representative selectors, erased derivation recovery, host quotient recursion, and Quot.sound from the handoff. □

Theorem 634.67 (QuotientSoundnessBoundary psame consumer factorization)**.** *After the refusal surface E, A, V has been read, every surviving positive motion of a downstream quotient-like consumer factors only through the classifier-respecting* psame *package E, T, H, C, P, N. The factorization uses the displayed relation rows, transport replacement, componentwise* hsame *stability,* Cont *locality,* Pkg *provenance, and local* NameCert *naming, and it has no coordinate for a quotient carrier, representative selector, erased derivation recovery map, host quotient recursion principle, or* Quot.sound *witness.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary psame consumer factorization`

Proof. Begin with the consumer scope triad above. It places the downstream read at E, A, V before any positive transport row can be consumed.

Use psame consumer closure, Definition 634.57. Once the representative-side request is refused, every accepted consumer closes through the classifier-respecting route E, T, H, C, P, N.

Use Pkg NameCert ledger totality, Definition 634.61, to account for the package and naming rows in the same factorization.

Finally apply public bridge non-escape, Definition 634.52. The bridge exports no quotient carrier, representative selector, recovery coordinate, host quotient recursion, or Quot.sound witness, so the displayed psame package is the only surviving route. □

Theorem 634.68 (QuotientSoundnessBoundary downstream boundary readiness)**.** *The consumer scope triad and psame consumer factorization assemble the downstream boundary package for* QuotientSoundnessBoundary$^{\uparrow}$*. A downstream quotient-like chapter receives the refusal surface E, A, V first and then, for any surviving positive motion, the classifier-respecting* psame *route E, T, H, C, P, N; it receives no quotient carrier, representative selector, erased derivation recovery map, host quotient recursion principle, or* Quot.sound *witness.*

Proof. First apply the consumer scope triad. It fixes the downstream entry surface as E, A, V, with visible relation rows, requested representative rows, and refusal verdict rows read before positive transport.

Next apply psame consumer factorization above. It identifies every surviving positive motion with the displayed classifier-respecting route E, T, H, C, P, N.

Finally use downstream representative non-escape together with public bridge non-escape. These results prevent the boundary package from exporting quotient carriers, representative selectors, erased derivation recovery maps, host quotient recursion, or Quot.sound witnesses, so the chapter is ready as a downstream nonimport boundary. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary downstream boundary readiness`

Theorem 634.69 (QuotientSoundnessBoundary downstream nonimport totality)**.** *Every downstream consumer of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet factors through the refused*

representative surface E, A, V and the admitted psame *transport surface E, T, H, C, P, N. This factorization is total for the downstream nonimport boundary: no downstream consumer imports quotient carriers, representative selectors, quotient equality eliminators, erased derivation recovery, host quotient recursion, or* Quot.sound.

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary downstream nonimport totality`

Proof. First apply public bridge non-escape, Definition 634.52. It keeps every consumer read inside E, A, T, V, H, C, P, N and gives no bridge coordinate for the excluded quotient primitives.

Next use erased derivation refusal and psame-only descent, Definition 634.53 and Definition 634.54. The representative-side demand is routed to E, A, V and refused before the admitted positive motion is read as classifier-respecting psame transport through E, T, H, C, P, N.

Finally cite the root nonimport ledger, Definition 634.79. The root ledger already packages the same refusal surface and positive transport surface without quotient carriers, representative selectors, quotient equality eliminators, erased derivation recovery, host quotient recursion, or Quot.sound, so the downstream consumer has no additional import route. □

Theorem 634.70 (QuotientSoundnessBoundary kernel dependency route)**.** *The downstream nonimport scope of* QuotientSoundnessBoundary$^{\uparrow}$ *is read first through chapter 629 for representative-refusal discipline and then through chapter 1157 for host-primitive leakage refusal. Only after those sibling boundaries are visible does the local quotient-soundness packet replace quotient elimination with displayed* psame *transport through E, T, H, C, P, N.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundaryKernelDependencyRoute`

Proof. Start with the downstream nonimport totality theorem above. It keeps downstream consumers inside the refused representative surface E, A, V and the admitted psame transport surface E, T, H, C, P, N.

Read the negative-name sibling first. The refusal discipline of chapter 629 classifies representative recovery as a boundary request rather than as supplied quotient content.

Read the host-primitive sibling next. The leakage refusal of chapter 1157 prevents the same request from being reintroduced as a host primitive, host quotient recursion, or Quot.sound witness.

Finally apply public bridge non-escape and psame consumer factorization. The surviving route is displayed psame transport inside the local rows, so the dependency route has no escape into quotient elimination or host-side primitive supply. □

Theorem 634.71 (QuotientSoundnessBoundary root psame route totality)**.** *For every accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet, every surviving root operation after representative refusal factors through the displayed* psame *route E, T, H, C, P, N. The packet exports no root operation through a representative selector, quotient equality eliminator, erased derivation recovery map, host quotient recursion, or* Quot.sound *witness.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root psame route totality`

Proof. Begin with the NameCert obligations and fixed classifier, Definition 634.2 and Definition 634.12. They identify the relation source and classifier rows read by any accepted packet.

Next use kernel non-escape and psame transport exhaustion, Definition 634.13 and Definition 634.8. These results leave only the classifier-respecting psame transport row and the structural rows H, C, P, N for a surviving root operation.

Finally apply Definition 634.58. Once Quot.sound is refused at the visible boundary, the positive consumer route is exactly E, T, H, C, P, N. □

Theorem 634.72 (QuotientSoundnessBoundary root psame source admission)**.** *Every root quotient-style operation accepted by a* QuotientSoundnessBoundary$^{\uparrow}$ *packet exposes the source relation rows E before the* psame *transport row T is readable. Thus the positive route E, T, H, C, P, N is admitted only after the relation source has been displayed, and no representative, erased derivation, host quotient witness, or* Quot.sound *token can stand in for that source admission.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root psame source admission`

Proof. Begin with the root request triad and root relation row exposure, Definition 634.14 and Definition 634.15. They make the source relation rows E visible at the root boundary before any consumer reads a surviving transport.

Next apply root transport verdict order, Definition 634.23. The refusal verdict is fixed before the positive route is consumed, so the later psame transport cannot create its own source relation.

Finally use psame transport exhaustion and non-escape, Definition 634.8 and Definition 634.13. The only surviving transport route is the displayed E, T, H, C, P, N route, and the excluded quotient primitives have no source-admission coordinate. □

Theorem 634.73 (QuotientSoundnessBoundary root representative refusal totality)**.** *Every root request for a representative, section, equality token, erased derivation, host quotient witness, or* Quot.sound *dependency is exhausted by the representative-request row A and refusal-verdict row V before any positive transport route is consumed. After A, V are read, the only admitted consumer route is the classifier-respecting* psame *route through E, T, H, C, P, N.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root representative refusal totality`

Proof. Use the root request triad, Definition 634.14. It sends representative-style demands to the visible request and refusal rows A, V while keeping the relation source row E explicit.

Apply root transport verdict order and the representative request frontier, Definition 634.23 and Definition 634.56. Together they place the refusal verdict before the transport row is available to a downstream consumer.

Then use psame transport exhaustion and non-escape, Definition 634.8 and Definition 634.13. They leave only the classifier-respecting route E, T, H, C, P, N after the refused request has been exhausted by A, V. □

Theorem 634.74 (QuotientSoundnessBoundary root Quot.sound exclusion)**.** *The combined root packet*

$$E, A, T, V, H, C, P, N$$

has no coordinate for Quot.sound*, quotient eliminators, host class selectors, representative recovery, erased derivation recovery, or hidden section choices. Relation exposure is recorded by E, representative-style refusal is recorded by A, V, and the only positive transport route is the displayed* psame *route E, T, H, C, P, N.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root quotsound nonimport certificate`

Proof. First combine the root source and refusal boundaries. By Definition 634.72 and Definition 634.73, the packet exposes E before transport and exhausts representative-style requests by A, V.

Next apply the root psame route totality, Definition 634.71. Every surviving root operation after refusal factors through the displayed E, T, H, C, P, N route.

Finally use psame transport exhaustion and kernel non-escape, Definition 634.8 and Definition 634.13. The packet contains only the displayed source, refusal, transport, stability, continuation, provenance, and naming rows, so Quot.sound and the other quotient primitives are excluded from the public surface. □

Theorem 634.75 (QuotientSoundnessBoundary refusal before transport)**.** *In every accepted* QuotientSoundnessBo *packet, the representative-request row A and refusal-verdict row V are read before the positive* psame *transport row T. Thus no surviving use of T can retroactively supply a representative selector, erased derivation, quotient equality eliminator, host quotient recursion, or* Quot.sound *witness.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary refusal before transport`

Proof. Apply the root transport verdict order and representative request frontier, Definition 634.23 and Definition 634.56. Together they place A, V at the visible refusal boundary before T is available to a downstream consumer.

Use verdict-transport separation, Definition 634.51. The positive transport row cannot reread the refusal verdict as a quotient eliminator or as evidence for a representative witness.

Finally invoke Definition 634.58. The exact complement between refusal and the surviving psame route gives the required order: refusal first, transport only after that refusal has been displayed. □

Theorem 634.76 (QuotientSoundnessBoundary kernel consumer audit triad)**.** *The kernel-facing audit surface of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet consists exactly of the relation exposure row, the refusal verdict for representative-side quotient primitives, and the surviving* psame *replacement route. Equivalently, every kernel consumer reads the triad*

$$E, A, V \quad \textit{and} \quad E, T, H, C, P, N$$

with the refusal side preceding transport, and no further quotient-soundness coordinate is exported.

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary kernel consumer audit triad`

Proof. First apply relation row exposure and the fixed classifier, Definition 634.15 and Definition 634.12. They expose the source relation and classifier rows without admitting a host quotient witness.

Next use refusal before transport above. The representative-request row and refusal-verdict row are read before the positive transport row, so the audit records the negative verdict before any surviving consumer can proceed.

Finally combine root psame route totality with quotient-sound refusal exactness. The surviving side is exactly the psame replacement route through E, T, H, C, P, N, while the refused side stays at E, A, V; kernel non-escape then rules out any additional quotient-soundness coordinate. □

Theorem 634.77 (QuotientSoundnessBoundary root representative refusal)**.** *Every root representative-side quotient request accepted by a* QuotientSoundnessBoundary$^{\uparrow}$ *packet is read through the relation row E, the requested-representative row A, and the refusal-verdict row V before the transport row T becomes available. Thus the root request reaches the visible representative refusal frontier before any surviving* psame *replacement route can be consumed.*

Proof. Start with the representative request frontier, Definition 634.56. It exhausts representative, representative-selector, erased-derivation, and host quotient requests by E, A, V before the transport row T is readable.

Apply refusal before transport, Definition 634.75. The refusal verdict is consumed before any positive transport use, so a downstream root consumer cannot reverse the order and treat T as representative evidence.

Finally use the kernel consumer audit triad, Definition 634.76. The kernel-facing surface keeps the refusal side E, A, V distinct from the surviving transport side E, T, H, C, P, N, giving the stated root order. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root representative refusal certificate`

Theorem 634.78 (QuotientSoundnessBoundary root psame transport admission)**.** *Every surviving root operation of an accepted* QuotientSoundnessBoundary$^{\uparrow}$ *packet is admitted only through the classifier-respecting* psame *transport route E, T, H, C, P, N. The operation may read the refused representative-side rows E, A, V as its accountability surface, but its positive movement is exactly the displayed transport, stability, locality, provenance, and naming route.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root psame transport admission`

Proof. Begin after the refusal surface has been read. By Definition 634.77, every root representative-side request has already passed through E, A, V before the positive route is available.

Use psame-only descent, Definition 634.54. It states that accepted descent after refusal factors only through E, T, H, C, P, N by classifier-respecting psame transport.

Now apply root psame route totality, Definition 634.71. This makes the same E, T, H, C, P, N route total for surviving root operations and excludes representative selection, quotient equality elimination, erased derivation recovery, host quotient recursion, and Quot.sound. □

Theorem 634.79 (QuotientSoundnessBoundary root nonimport ledger)**.** *The root kernel ledger exported by a* QuotientSoundnessBoundary$^{\uparrow}$ *packet is exactly the refused representative surface E, A, V together with the admitted* psame *transport surface E, T, H, C, P, N. It imports no quotient carrier, representative selector, quotient equality eliminator, erased derivation recovery map, host quotient recursion principle, or* Quot.sound *dependency.*

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary root nonimport ledger`

Proof. First combine root representative refusal with root psame transport admission, Definition 634.77 and Definition 634.78. These two rows identify the negative ledger side E, A, V and the surviving positive side E, T, H, C, P, N.

Apply the kernel consumer audit triad, Definition 634.76. It packages those two sides as the kernel-facing audit surface and records that no further quotient-soundness coordinate is exported.

Finally cite public bridge non-escape and psame-only descent, Definition 634.52 and Definition 634.54. The bridge and descent rows exclude quotient carriers, representative selectors, erased derivation recovery, host quotient recursion, and Quot.sound, so the ledger is a nonimport ledger rather than a quotient extension. □

Closure status for $\mathsf{NameCert}_{\mathsf{QuotientSoundnessBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$ packet is generated from relation rows, requested representative rows, classifier-respecting psame transport, refusal verdicts, componentwise transports, displayed continuations, package provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{QuotientSoundnessBoundary}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 634.1, Definition 634.2, Definition 634.3, Definition 634.4, Definition 634.12, Definition 634.13, Definition 634.14, Definition 634.15, Definition 634.23, Definition 634.24, Definition 634.25, Definition 634.44, Definition 634.45, Definition 634.47, Definition 634.48, Definition 634.49, Definition 634.50, Definition 634.51, Definition 634.52, Definition 634.53, Definition 634.54, and Definition 634.55 bind the relation rows, representative-refusal rows, refusal-to-transport determinacy, source-row consumer totality, verdict-transport separation, erased derivation refusal, psame-only descent, root relation exposure, verdict-before-transport order, psame transport row, locality rows, provenance, public bridge, and non-escape boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{QuotientSoundnessBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not construct quotient carriers, representative selectors, quotient equality eliminators, erased derivation recovery maps, or any dependency on Quot.sound.

Upgrade path: No paper theory-axis grade remains; Lean verification and bridge checking remain independent obligations for the same finite refusal-and-transport packet.

Theorem 634.80 (QuotientSoundnessBoundary negative-boundary route)**.** *Every quotient-style representative request exposed to an accepted* $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$ *packet is first read as a negative-name boundary request through chapter 629. Only after that boundary has displayed the blocked request may the quotient-soundness packet replace the attempted representative read by the local* psame *transport row over its visible relation data.*

Proof. Read the requested representative rows and refusal verdict from the carrier in Definition 634.1. These rows place the demand for a representative, quotient equality token, section, erased derivation tree, or Quot.sound dependency on the public refusal surface before any positive transport row is consumed.

The negative-name boundary of chapter 629 supplies the sibling route for that refusal. It treats the representative request as a blocked boundary read rather than as generated content.

After this refusal route is visible, apply Definition 634.3. The surviving operation is the classifier-respecting psame route through the displayed relation rows, componentwise hsame transport, visible Cont replay, Pkg provenance, and local NameCert row. No quotient representative, quotient eliminator, erased derivation recovery map, or Quot.sound dependency is exported. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary negative boundary route`

Theorem 634.81 (QuotientSoundnessBoundary negative-route visibility)**.** *Any quotient-style representative request exposed to an accepted* $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$ *packet must display the negative-name boundary row and its refusal verdict before the local* psame *transport replacement can be read. The request may not consume quotient representatives, quotient eliminators, erased derivation recovery, or* Quot.sound *as hidden data behind the transport row.*

Proof. Apply the negative-boundary route of Definition 634.80. It places every representative request on the visible refusal surface before the packet admits any replacement transport.

Then use the transport replacement theorem, Definition 634.3. The replacement is the local psame route over displayed relation data, componentwise hsame transport, continuation replay, package provenance, and local naming.

Since the refusal verdict precedes the transport read, no consumer can reinterpret the replacement as a quotient representative, quotient eliminator, erased derivation recovery map, or Quot.sound dependency. Those requests remain visible as refused boundary rows. □

Lean4 ✓ `BEDC.Derived.QuotientSoundnessBoundaryUp.QuotientSoundnessBoundary negative route visibility`

The quotient-soundness boundary also records a sibling refusal route through chapter 998. That sibling supplies the quotient-facing refusal discipline consumed by the local QuotientSoundnessBoundary$^{\uparrow}$ rows before classifier-respecting psame transport replaces any representative-selection request.

Chapter 635

A Concrete Naming Certificate for $\mathsf{RealInverse}^{\uparrow}$

The $\mathsf{RealInverse}^{\uparrow}$ interface names the finite reciprocal packet for a real source whose nonzero domain is witnessed by apartness. It follows the Bishop–Bridges discipline: the reciprocal route is available only after an $\mathsf{ApartnessReal}^{\uparrow}$ witness supplies the constructive guard, and the resulting packet hands a product-seal route to $\mathsf{Real}^{\uparrow}$ without importing trichotomy, host division, quotient real equality, a selected limit, or completeness.

The reciprocal packet records its sibling route explicitly. It consumes the nonzero-domain witness from chapter 304, the product verification route from chapter 464, the finite-window route from chapter 126, the regular rational readback from chapter 301, and the seal surface from chapter 38. This is the dependency route for the displayed rows $x, a, p, w, r, s, h, c, l, n$; it is not another theorem and not a host division principle.

Definition 635.1 (Real inverse carrier)**.** *A* $\mathsf{RealInverse}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$I = (x, a, p, w, r, s, h, c, l, n)$$

with the following displayed coordinates:

1. *x is the source* $\mathsf{Real}^{\uparrow}$ *row whose reciprocal is being named;*
2. *a is an* $\mathsf{ApartnessReal}^{\uparrow}$ *nonzero-domain witness licensing the reciprocal route for x;*
3. *p is the* $\mathsf{CauchyProduct}^{\uparrow}$ *product route that checks the candidate inverse against the source;*
4. *w is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row used to read the guarded source and candidate reciprocal;*
5. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular rational window row exposed through w;*
6. *s is the* $\mathsf{Real}^{\uparrow}$ *seal row receiving the guarded reciprocal packet;*
7. *h stores componentwise* hsame *transports for the source, apartness witness, product route, windows, regular rational row, seal, provenance, and local name;*
8. *c stores the displayed* Cont *routes from the apartness witness to the reciprocal window, from the window to the regular rational row, from the product route to the seal, and from the finite packet to the local name;*
9. *l records* Pkg *provenance over* $\mathsf{Real}^{\uparrow}$, $\mathsf{ApartnessReal}^{\uparrow}$, $\mathsf{CauchyProduct}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*

10. n is the local $\mathsf{NameCert}_{\mathsf{RealInverse}^\uparrow}$ *row.*

The carrier has no coordinate for trichotomy, host division, quotient real equality, selected real values, infinite tails, or $\mathsf{Real}^\uparrow$ *completeness.*

Lean4 ✓ `BEDC.Derived.RealInverseUp.RealInverseTasteGate single carrier alignment`
Lean4 (definition) `BEDC.Derived.RealInverseUp.RealInverseCarrier`

Theorem 635.2 (Real inverse NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RealInverse}^\uparrow}$ *surface for Definition 635.1 consists exactly of source* $\mathsf{Real}^\uparrow$ *admission,* $\mathsf{ApartnessReal}^\uparrow$ *nonzero-domain admission,* $\mathsf{CauchyProduct}^\uparrow$ *product-route exposure,* $\mathsf{StreamName}^\uparrow$ *finite-window readback,* $\mathsf{RegSeqRat}^\uparrow$ *regular rational exposure,* $\mathsf{Real}^\uparrow$ *seal handoff, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local naming row.*

Lean4 ✓ `BEDC.Derived.RealInverseUp.RealInverseNameCertObligations`

Proof. Carrier admission is projection from the displayed packet I. Its rows list the real source, apartness guard, product route, finite window, regular rational readback, seal, transport, continuation, provenance, and local certificate.

The reciprocal obligation is guarded by the apartness row. The certificate first reads a, then uses the continuation rows to expose the finite window w and the regular rational row r that describe the candidate reciprocal.

The product route p supplies the only multiplication-facing check before the seal s is exposed. The remaining rows h, c, l, n transport and name this finite route, so the certificate contains no trichotomy, host division, quotient real equality, selected limit, infinite tail, or completeness coordinate. □

Theorem 635.3 (Real inverse apartness domain)**.** *Every accepted* $\mathsf{RealInverse}^\uparrow$ *packet licenses reciprocal use only through its displayed* $\mathsf{ApartnessReal}^\uparrow$ *witness a. A consumer that cannot read a receives no reciprocal window, no regular rational candidate row, and no product-seal route.*

Proof. Project the carrier $I = (x, a, p, w, r, s, h, c, l, n)$. The only coordinate naming a nonzero domain is the apartness row a.

Read the continuation routes in c. They place the reciprocal window w and the regular rational row r downstream of the apartness witness, and the product route p is exposed only along the same guarded path.

Thus the reciprocal is not a total host operation on $\mathsf{Real}^\uparrow$. Without the constructive apartness witness, the packet has no route to a reciprocal candidate, product check, or seal handoff. □

Lean4 ✓ `BEDC.Derived.RealInverseUp.RealInverseApartnessDomain`

Theorem 635.4 (Real inverse apartness denominator handoff)**.** *For an accepted* $\mathsf{RealInverse}^\uparrow$ *carrier $I = (x, a, p, w, r, s, h, c, l, n)$, every denominator or reciprocal-candidate read must pass through the displayed* $\mathsf{ApartnessReal}^\uparrow$ *witness a, then the* $\mathsf{StreamName}^\uparrow$ *window w, then the* $\mathsf{RegSeqRat}^\uparrow$ *row r, before the* $\mathsf{CauchyProduct}^\uparrow$ *route p may certify the product seal. The handoff exposes no trichotomy, host division, quotient real equality, selected limit, infinite tail, or ambient* $\mathsf{Real}^\uparrow$ *completeness.*

Proof. Project the accepted carrier $I = (x, a, p, w, r, s, h, c, l, n)$. The only row licensing a denominator read is the displayed apartness witness a.

Apply Definition 635.3. It forces the nonzero guard before any reciprocal window, regular rational candidate row, or product-seal route can be consumed.

The denominator read is then ordered through w and r. The $\mathsf{StreamName}^{\uparrow}$ window supplies the bounded observation of the source and candidate reciprocal, and the $\mathsf{RegSeqRat}^{\uparrow}$ row supplies the regular rational readback attached to that window.

Only after those rows are visible may the $\mathsf{CauchyProduct}^{\uparrow}$ route p certify the product seal. The structural rows h, c, l, n replay and name this same guarded path, so the packet refuses trichotomy, host division, quotient real equality, selected limits, infinite tails, and ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Lean4 ✓ `BEDC.Derived.RealInverseUp.RealInverseApartnessDenominatorHandoff`

Theorem 635.5 (Real inverse product seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealInverse}^{\uparrow}$ *packet factors through the* $\mathsf{CauchyProduct}^{\uparrow}$ *product route* p*, the* $\mathsf{StreamName}^{\uparrow}$ *window* w*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *row* r*, the displayed transport and continuation rows, the provenance ledger, and the seal row* s*. The handoff exposes reciprocal information only as the apartness-guarded product certificate named by the packet.*

Proof. Begin with the apartness-domain theorem. It places every reciprocal read downstream of the nonzero-domain witness a.

The finite observation then runs through w and r. The $\mathsf{StreamName}^{\uparrow}$ row supplies the bounded read, and the $\mathsf{RegSeqRat}^{\uparrow}$ row is the regular rational surface passed to the product check.

Finally the $\mathsf{CauchyProduct}^{\uparrow}$ route p supplies the product certificate consumed by the seal row s. The transport, continuation, provenance, and local naming rows record this route, so the real-facing handoff receives only the guarded finite packet. □

Lean4 ✓ `BEDC.Derived.RealInverseUp.RealInverseProductSealHandoff`

Theorem 635.6 (Real inverse guarded product uniqueness)**.** *Let* $I = (x, a, p, w, r, s, h, c, l, n)$ *and* $I' = (x, a', p', w', r', s, h', c', l', n')$ *be accepted* $\mathsf{RealInverse}^{\uparrow}$ *packets for the same* $\mathsf{Real}^{\uparrow}$ *source row* x*. If the apartness witnesses* a, a' *name the same* $\mathsf{ApartnessReal}^{\uparrow}$ *guard, the product routes* p, p' *expose* hsame*-compatible* $\mathsf{CauchyProduct}^{\uparrow}$ *certificates, and both packets hand off to the same terminal* $\mathsf{Real}^{\uparrow}$ *seal row* s*, then* I *and* I' *are classifier-equal as* $\mathsf{RealInverse}^{\uparrow}$ *packets.*

Proof. Project the two carriers through Definition 635.1. The source row and seal row are shared by assumption, while the only reciprocal-domain coordinates are the apartness witnesses.

Apply the apartness-domain theorem, Definition 635.3. Since both witnesses name the same constructive guard, both reciprocal reads must pass through the same guarded route before any reciprocal window or product certificate is visible.

Next use the product-seal handoff of Definition 635.5. The hsame-compatible product routes align the $\mathsf{CauchyProduct}^{\uparrow}$ rows, the finite windows w, w', the $\mathsf{RegSeqRat}^{\uparrow}$ readbacks r, r', and the common seal s along the displayed continuation rows.

It remains only to compare the bookkeeping rows. Componentwise transport in h, h' carries the aligned analytic rows, c, c' replay the same guarded route, l, l' record the same provenance surface, and n, n' name the local certificate. The non-escape theorem then rules out any hidden trichotomy, host division, quotient real equality, selected limit, infinite tail, or completeness coordinate, so classifier equality is componentwise. □

Lean4 ✓ `BEDC.Derived.RealInverseUp.RealInverseGuardedProductUniqueness`

Theorem 635.7 (Real inverse non-escape)**.** *The carrier, NameCert obligations, apartness domain, and product seal handoff of Definition 635.1, Definition 635.2, Definition 635.3, and Definition 635.5 assemble one constructive reciprocal certificate over* $\mathsf{Real}^{\uparrow}$, $\mathsf{ApartnessReal}^{\uparrow}$, $\mathsf{CauchyProduct}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert.

The certificate exports exactly the rows

$$x, a, p, w, r, s, h, c, l, n.$$

It exports no trichotomy, host division, quotient real equality, selected limit, infinite tail, or completeness principle.

Lean4 ✓ `BEDC.Derived.RealInverseUp.RealInverseNonEscape`

Proof. The carrier definition lists every row in the reciprocal packet. The NameCert obligations bind source admission, apartness admission, product-route exposure, finite-window readback, regular rational exposure, seal handoff, transport, continuation, provenance, and naming to those rows.

The apartness-domain theorem makes the reciprocal route partial in the constructive sense: it is available only after the nonzero-domain witness has been read. The product seal handoff then routes every real-facing consumer through the finite window, regular rational row, product certificate, and seal.

No other coordinate remains from which to read trichotomy, host division, quotient real equality, a selected limit, an infinite tail, or completeness. The displayed rows therefore exhaust the $\mathsf{RealInverse}^{\uparrow}$ observation surface. □

Theorem 635.8 (Real inverse obligation closure package)**.** *The carrier of Definition 635.1, the NameCert obligations of Definition 635.2, the apartness-domain theorem Definition 635.3, the product-seal handoff Definition 635.5, guarded product uniqueness Definition 635.6, and non-escape Definition 635.7 assemble the obligation-closure surface for* $\mathsf{RealInverse}^{\uparrow}$ *over* $\mathsf{Real}^{\uparrow}$, $\mathsf{ApartnessReal}^{\uparrow}$, $\mathsf{CauchyProduct}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert. *The package remains apartness-guarded and refuses trichotomy, total reciprocal on all real rows, host division, quotient equality, selected limits, infinite tails, and* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Begin with the carrier and NameCert obligations. They display the source, apartness guard, product route, StreamName window, RegSeqRat readback, Real seal, transport, continuation, provenance, and local naming rows as the full reciprocal packet.

Apply the apartness-domain and product-seal handoff theorems. The reciprocal route is available only after the constructive nonzero witness is read, and the Real-facing seal is reached only through the finite product certificate, window, and regular rational rows.

Next use guarded product uniqueness to make the package stable under matching apartness witnesses, compatible product certificates, and the same terminal Real seal. The non-escape theorem then removes trichotomy, total reciprocal, host division, quotient equality, selected limits, infinite tails, and Real completeness from the available surface, so the named rows form the obligation-closure package. □

Lean4 ✓ `BEDC.Derived.RealInverseUp.RealInverseObligationClosurePackage`

Theorem 635.9 (Real inverse apartness-product scoped factorization)**.** *Every* $\mathsf{RealInverse}^{\uparrow}$ *consumer factors through the displayed* $\mathsf{ApartnessReal}^{\uparrow}$ *nonzero guard,* $\mathsf{CauchyProduct}^{\uparrow}$ *product route,* $\mathsf{StreamName}^{\uparrow}$ *finite windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *regular rational row,* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame

transport, displayed Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RealInverse}^\uparrow}$ *row before any reciprocal read is public.*

The factorization is guarded by the apartness row and product route. It does not produce a total reciprocal on all real rows, trichotomy, host division, quotient real equality, selected limits, infinite tails, or ambient $\mathsf{Real}^\uparrow$ *completeness.*

Proof. Project the carrier of Definition 635.1 and the NameCert obligations of Definition 635.2. They make the rows $x, a, p, w, r, s, h, c, l, n$ exhaustive for an accepted reciprocal packet.

Apply the apartness-domain theorem Definition 635.3. It places every reciprocal read downstream of the displayed $\mathsf{ApartnessReal}^\uparrow$ nonzero guard, so no consumer can reach a reciprocal window without first reading a.

Next apply the product-seal handoff of Definition 635.5. The handoff orders the consumer through the $\mathsf{CauchyProduct}^\uparrow$ route, finite $\mathsf{StreamName}^\uparrow$ windows, $\mathsf{RegSeqRat}^\uparrow$ readback, and the terminal $\mathsf{Real}^\uparrow$ seal, with transport and continuation preserving the same route.

Guarded product uniqueness in Definition 635.6 identifies compatible guarded product routes, and non-escape in Definition 635.7 removes trichotomy, total reciprocal, host division, quotient equality, selected limits, infinite tails, and completeness from the available surface. The obligation-closure package of Definition 635.8 then repacks exactly this route with Pkg provenance and the local NameCert row. □

Lean4 ✓ `BEDC.Derived.RealInverseUp.RealInverseApartnessProductScopedFactorization`

Theorem 635.10 (Real inverse public inverse domain)**.** *The public* $\mathsf{RealInverse}^\uparrow$ *interface is a partial reciprocal domain. A consumer may read a reciprocal only after the displayed* $\mathsf{ApartnessReal}^\uparrow$ *guard,* $\mathsf{CauchyProduct}^\uparrow$ *product route,* $\mathsf{StreamName}^\uparrow$ *finite window,* $\mathsf{RegSeqRat}^\uparrow$ *row,* $\mathsf{Real}^\uparrow$ *seal, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RealInverse}^\uparrow}$ *rows are visible.*

The public route is therefore

$$\mathsf{ApartnessReal}^\uparrow \longmapsto \mathsf{CauchyProduct}^\uparrow \longmapsto \mathsf{StreamName}^\uparrow \longmapsto \mathsf{RegSeqRat}^\uparrow \longmapsto \mathsf{Real}^\uparrow \longmapsto \mathsf{NameCert}_{\mathsf{RealInverse}^\uparrow},$$

with the structural rows carried by h, c, l, n*. It does not claim trichotomy, total inverse on all real rows, host division, quotient real equality, selected limits, infinite tails, or ambient* $\mathsf{Real}^\uparrow$ *completeness.*

Proof. Start with the apartness-domain theorem, Definition 635.3. It places every reciprocal read downstream of the constructive nonzero guard, so the public interface cannot be total on all $\mathsf{Real}^\uparrow$ rows.

Apply the denominator handoff and product-seal handoff, Definition 635.4 and Definition 635.5. Together they order the read through the $\mathsf{StreamName}^\uparrow$ window, $\mathsf{RegSeqRat}^\uparrow$ rational row, $\mathsf{CauchyProduct}^\uparrow$ certificate, and terminal $\mathsf{Real}^\uparrow$ seal.

Guarded product uniqueness, Definition 635.6, identifies compatible guarded product routes only after the same apartness guard, product certificate, and seal have been displayed. Non-escape, Definition 635.7, removes every coordinate for trichotomy, host division, quotient equality, selected limits, infinite tails, and completeness.

Finally use the scoped factorization theorem Definition 635.9. It repacks the public route with componentwise transport, continuation replay, provenance, and local naming, so the exported interface is exactly the apartness-guarded partial reciprocal domain. □

Theorem 635.11 (Real inverse public transport consumer factorization)**.** *Every public reciprocal consumer for an accepted* $\mathsf{RealInverse}^{\uparrow}$ *packet transports compatible apartness guards,* $\mathsf{CauchyProduct}^{\uparrow}$ *routes,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *rows, and* $\mathsf{Real}^{\uparrow}$ *seals through componentwise* hsame*, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{RealInverse}^{\uparrow}}$ *row before reading the reciprocal.*

The factorization is the public route

$$\mathsf{ApartnessReal}^{\uparrow} \longmapsto \mathsf{CauchyProduct}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow} \longmapsto \mathsf{NameCert}_{\mathsf{RealInverse}^{\uparrow}},$$

with the structural rows h, c, l, n *preserving the same guarded reciprocal packet. It does not export a total reciprocal, trichotomy, host division, quotient real equality, selected limits, infinite tails, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Begin with the public inverse-domain theorem, Definition 635.10. It makes the reciprocal read public only after the apartness guard, product route, finite window, regular rational row, Real seal, transport, replay, provenance, and local name are all visible.

Apply apartness-domain and denominator handoff, Definition 635.3 and Definition 635.4. They force every denominator and reciprocal-candidate read through the displayed $\mathsf{ApartnessReal}^{\uparrow}$ witness before the $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ rows can be inspected.

Next use product-seal handoff and guarded product uniqueness, Definition 635.5 and Definition 635.6. The $\mathsf{CauchyProduct}^{\uparrow}$ route supplies the product certificate consumed by the $\mathsf{Real}^{\uparrow}$ seal, and compatible guarded product routes identify the same public reciprocal surface.

Finally apply non-escape and scoped factorization, Definition 635.7 and Definition 635.9. These results repack the route through hsame, Cont, Pkg, and NameCert while excluding every coordinate for total reciprocals, trichotomy, host division, quotient equality, selected limits, infinite tails, or Real completeness. □

Lean4 ✓ `BEDC.Derived.RealInverseUp.RealInversePublicTransportConsumerFactorization`

Closure status for $\mathsf{NameCert}_{\mathsf{RealInverse}^{\uparrow}}$**.**

Constructive story: A $\mathsf{RealInverse}^{\uparrow}$ packet is generated from a $\mathsf{Real}^{\uparrow}$ source, an $\mathsf{ApartnessReal}^{\uparrow}$ nonzero-domain witness, a $\mathsf{CauchyProduct}^{\uparrow}$ product route, $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ finite readback rows, a $\mathsf{Real}^{\uparrow}$ seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RealInverse}^{\uparrow}}$, publicClosed)

Scope closed: Definition 635.1, Definition 635.2, Definition 635.3, Definition 635.5, Definition 635.6, Definition 635.7, Definition 635.8, the scoped factorization witness Definition 635.9, the public inverse-domain theorem Definition 635.10, and the public transport consumer factorization Definition 635.11 bind the apartness-guarded reciprocal carrier, product route, finite windows, regular rational row, seal handoff, uniqueness, refusal ledger, obligation package, and public consumer route.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RealInverse}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close trichotomy, total reciprocal on all real rows, host division, quotient real equality, selected limits, infinite tails, $\mathsf{Real}^{\uparrow}$ completeness, Lean verification, or bridge checking.

Upgrade path: Bridged closure requires Lean verification and a standard bridge for the public apartness guard, product route, finite windows, regular rational row, Real seal, transport, replay, provenance, and local NameCert primitives.

Chapter 636

A Concrete Naming Certificate for CauchyModulusComparison$^{\uparrow}$

The CauchyModulusComparison$^{\uparrow}$ packet names the finite comparison surface between two Cauchy-modulus schedules before a real-facing consumer reads a shared tail. It transports the stationary diagonal observation pattern into a concrete NameCert row: two CauchyModulus$^{\uparrow}$ schedules are compared through one RegularCauchyTailMeet$^{\uparrow}$ threshold, finite StreamName$^{\uparrow}$ windows, DyadicRatCore$^{\uparrow}$ tolerance rows, RegSeqRat$^{\uparrow}$ readbacks, and a Real$^{\uparrow}$ seal handoff. The packet exports no quotient stream, no host real equality, no selected limiting representative, and no ambient completeness theorem.

The comparison packet consumes the shared-threshold source of chapter 560 before the StreamName$^{\uparrow}$ and Real$^{\uparrow}$ seal rows are read.

Definition 636.1 (Cauchy modulus comparison carrier)**.** *A* CauchyModulusComparison$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (M_0, M_1, T, W, Q, E, H, C, P, N)$$

with the following displayed coordinates:

1. M_0 *is the first accepted* CauchyModulus$^{\uparrow}$ *schedule row;*
2. M_1 *is the second accepted* CauchyModulus$^{\uparrow}$ *schedule row;*
3. T *is the shared* RegularCauchyTailMeet$^{\uparrow}$ *threshold packet reading both schedules through one tail-meet demand;*
4. W *is the finite* StreamName$^{\uparrow}$ *window ledger selected by the shared threshold for the two schedule presentations;*
5. Q *is the combined* DyadicRatCore$^{\uparrow}$ *tolerance ledger and* RegSeqRat$^{\uparrow}$ *readback row attached to the selected windows;*
6. E *is the* Real$^{\uparrow}$ *seal row reached only after the shared tail threshold, windows, tolerance ledger, and regular readback have been displayed;*
7. H *stores componentwise* hsame *transports for* $M_0, M_1, T, W, Q, E, P, N$ *and for the local packet shape;*
8. C *stores displayed* Cont *routes from each schedule to* T*, from* T *to* W*, from* W *to* Q*, from* Q *to* E*, and from the packet rows to the local naming row;*

9. *P is the* Pkg *provenance over* $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyModulusComparison}^{\uparrow}}$ *row.*

The carrier contains no external modulus ordering, no quotient equality of streams, no host real equality, no hidden tail oracle, no selected real value, and no ambient completeness coordinate.

Lean4 (definition) `BEDC.Derived.CauchyModulusComparisonUp.CauchyModulusComparisonUp`
Lean4 ✓ `BEDC.Derived.CauchyModulusComparisonUp.CauchyModulusComparisonTasteGate single carrier alignment`

Theorem 636.2 (Cauchy modulus comparison NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CauchyModulusComparison}^{\uparrow}}$ *surface for Definition 636.1 consists of six finite obligation rows:*

1. *carrier admission for $K = (M_0, M_1, T, W, Q, E, H, C, P, N)$;*
2. *paired schedule admission exposing exactly the two* $\mathsf{CauchyModulus}^{\uparrow}$ *rows M_0 and M_1;*
3. *shared-threshold admission exposing the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *row T as the only tail comparison datum;*
4. *finite-window and tolerance exactness forcing every compared read through W and Q;*
5. *componentwise stability under the displayed* hsame *rows and replay through the displayed* Cont *routes;*
6. *ledger exactness stating that every real-facing read factors through $M_0, M_1, T, W, Q, E, H, C, P, N$ and no host comparison or quotient stream is exported.*

Proof. Carrier admission is projection from the displayed packet. The tuple lists the two schedules, the shared tail-meet threshold, selected windows, tolerance and regular-readback ledger, Real seal, transports, continuations, provenance, and local name.

The paired schedule clause reads M_0 and M_1 before any comparison result is available. The packet therefore compares displayed schedule rows rather than an external ordering on functions.

The threshold clause uses the single row T. Since T is the only tail-meet coordinate, every downstream comparison has to pass through the same shared threshold before it can inspect W or Q.

Finally H, C, P, N repack the route as a local NameCert surface. With no carrier coordinate for quotient streams, host real equality, selected limits, hidden tail oracles, or ambient completeness, the six rows exhaust the public comparison packet. □

Theorem 636.3 (Cauchy modulus comparison paired schedule admission)**.** *Let $K = (M_0, M_1, T, W, Q, E, H, C, P,$ be an accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *carrier. Before any comparison route is read, the packet exposes exactly the two* $\mathsf{CauchyModulus}^{\uparrow}$ *schedule rows M_0 and M_1. No third schedule row, ambient order on modulus functions, quotient stream representative, or hidden tail oracle is available to the comparison consumer.*

Proof. Project the carrier tuple of Definition 636.1. The first two coordinates are precisely the displayed $\mathsf{CauchyModulus}^{\uparrow}$ rows M_0 and M_1.

Use the paired schedule row of Definition 636.2. It names those two rows before the threshold, window, tolerance, seal, transport, continuation, package, and local certificate coordinates are consumed.

The later directional route in Definition 636.6 starts from the same two rows and then passes through T, W, Q, H, C, P, N. Since the carrier contains no additional schedule coordinate or ambient ordering field, admission is exactly the displayed pair M_0, M_1. □

Theorem 636.4 (Cauchy modulus comparison finite-window tolerance exactness)**.** *Let $K = (M_0, M_1, T, W, Q, E, H, C, P, N)$ be an accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *carrier. Every comparison read passes through the shared threshold T, the finite window ledger W, and the tolerance-readback ledger Q. Hence the read is mediated by* $\mathsf{StreamName}^{\uparrow}$ *finite windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows, and* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks before any* $\mathsf{Real}^{\uparrow}$ *seal row can be consumed.*

Proof. Start with the carrier inventory and the finite-window row of Definition 636.2. The only comparison path after the two schedules proceeds through the threshold coordinate T and then the selected window coordinate W.

Apply Definition 636.6 for comparison-facing reads. Its route includes T, W, Q before any public comparison conclusion is available.

Use Definition 636.7 to identify T as the single shared tail threshold and W as the downstream finite window ledger. Then use Definition 636.8: the $\mathsf{Real}^{\uparrow}$ seal E is reached only after Q has supplied the dyadic tolerance and regular rational readback rows. This proves exactness of the displayed finite-window tolerance route. □

Theorem 636.5 (Cauchy modulus comparison transport route stability)**.** *For an accepted* CauchyModulusComparis *carrier $K = (M_0, M_1, T, W, Q, E, H, C, P, N)$, componentwise* hsame *rows in H and displayed* Cont *routes in C preserve the schedule, threshold, window, tolerance, seal, package, and local* NameCert *coordinates. A transported read therefore remains a read of the same displayed packet rows $M_0, M_1, T, W, Q, E, P, N$.*

Proof. Project the transport and continuation coordinates of the carrier. The row H is indexed componentwise over the schedule rows, threshold, windows, tolerance-readback ledger, seal row, package provenance, local name, and packet shape; C displays the replay routes between those coordinates.

Use the stability row of Definition 636.2. It requires transported comparison reads to move along these displayed hsame and Cont rows, so transport cannot replace any schedule, threshold, window, tolerance, seal, package, or local naming coordinate by an unlisted one.

The directional, shared-tail, and seal-facing conclusions of Definition 636.6, Definition 636.7, and Definition 636.8 all use the same route inventory. Thus stability preserves the displayed packet coordinates through every public comparison read. □

Theorem 636.6 (Cauchy modulus comparison directional monotonicity)**.** *Let $K = (M_0, M_1, T, W, Q, E, H, C, P, N$ be an accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *carrier. Any consumer read asserting that the first schedule is no harder than the second schedule factors through the displayed route*

$$M_0, M_1, T, W, Q, H, C, P, N.$$

The directional read is therefore a finite shared-tail NameCert comparison over the two schedule rows, not an ambient order on external modulus functions.

Proof. Project the accepted carrier and read the two schedule rows M_0 and M_1. These are the only coordinates that name Cauchy-modulus schedules.

Next read the shared threshold T and its selected windows W. The threshold packet supplies the common tail at which the two schedules are compared, and the window ledger records only the finite observations selected by that threshold.

The tolerance and readback ledger Q supplies the dyadic comparison rows and the regular rational readback rows attached to the same selected windows. Transport through H and replay through C preserve this route componentwise.

Thus a directional comparison can only be the displayed shared-tail comparison. The provenance P and local name N close the certificate without adding an external modulus order, quotient stream, host real equality, or hidden tail oracle. □

Theorem 636.7 (Cauchy modulus comparison shared-tail exactness)**.** *Every finite tail observation exported by an accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *carrier uses the same* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold row T for both schedules. The observation cannot replace one side by an unlisted threshold, an unbounded tail family, a quotient stream representative, or an external tail oracle.*

Proof. Begin with the threshold coordinate T in the carrier. It is the only row whose role is to meet the two Cauchy-modulus schedules at a shared tail.

The selected windows W are downstream of T, and the tolerance-readback ledger Q is downstream of those windows. Hence every tail observation has already passed through the same threshold row before either side of the comparison can be read.

Componentwise hsame transport in H and displayed continuation replay in C preserve the identity of the threshold row through consumer reads. The package and local NameCert rows record this same dependency, so no unlisted threshold or hidden tail family remains available. □

Theorem 636.8 (Cauchy modulus comparison Real seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *carrier receives the seal row E only after reading the two modulus schedules, the shared tail threshold, the selected stream windows, the dyadic tolerance and regular-readback ledger, the componentwise transports, the continuation routes, the provenance row, and the local NameCert row.*

Proof. Start with the seal coordinate E. It is listed after the schedule rows, shared threshold, selected windows, and tolerance-readback ledger, and no other $\mathsf{Real}^{\uparrow}$ seal coordinate appears in the carrier.

Use the directional monotonicity theorem for comparison-facing consumers. It confines the comparison route to $M_0, M_1, T, W, Q, H, C, P, N$ before any seal-facing conclusion is available.

Use the shared-tail exactness theorem for tail-facing consumers. It ensures that both sides of the seal route use the same threshold T and the same selected finite window ledger.

Consequently the Real seal handoff is the finite route through $M_0, M_1, T, W, Q, E, H, C, P, N$. The packet has no coordinate for quotient equality, host real equality, selected limits, hidden representatives, external modulus functions, or ambient completeness. □

Theorem 636.9 (Cauchy modulus comparison non-escape boundary)**.** *An accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *packet exposes only the rows*

$$M_0, M_1, T, W, Q, E, H, C, P, N.$$

It excludes quotient streams, selected limits, host real equality, ambient completeness, hidden modulus schedules, external tail oracles, and any comparison read that bypasses the shared threshold row T.

Proof. Inspect the carrier of Definition 636.1. Its coordinates are exactly the two schedule rows, one shared threshold, finite windows, dyadic tolerance and regular-readback ledger, Real seal, transports, routes, provenance, and local name.

The positive comparison route has already been constrained by Definition 636.6, Definition 636.7, and Definition 636.8. Each route passes through T, W, Q before any seal-facing read.

Since no coordinate stores a quotient stream, selected limiting representative, host real equality, ambient completeness theorem, hidden schedule, or external oracle, no accepted packet can export such data. □

Theorem 636.10 (Cauchy modulus comparison shared-threshold package)**.** *For every accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *carrier* $K = (M_0, M_1, T, W, Q, E, H, C, P, N)$*, the obligation package consists of the two modulus schedules* M_0, M_1*, the shared tail threshold* T*, the dyadic request and finite stream-window data stored in* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance data stored in* Q*, the* $\mathsf{Real}^{\uparrow}$ *seal* E*, the componentwise* hsame *rows* H*, the displayed* Cont *routes* C*, the* Pkg *provenance* P*, and the local* $\mathsf{NameCert}$ *row* N*.*

Proof. Project the tuple K. The first two rows are the only displayed Cauchy-modulus schedules, and T is the only shared threshold that can compare them.

Read W and Q as the finite observation package. The dyadic request and selected windows live in W, while regular rational readback and dyadic tolerance evidence live in Q.

The seal-facing and certification rows are E, H, C, P, N. They hand the package to $\mathsf{Real}^{\uparrow}$, preserve componentwise agreement, replay the route, record provenance, and name the packet without adding any further comparison datum. □

Theorem 636.11 (Cauchy modulus comparison threshold-window coherence)**.** *Let* $K = (M_0, M_1, T, W, Q, E, H, C$ *be an accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *carrier. Every accepted packet routes both schedules through the same threshold row* T *before any finite* $\mathsf{StreamName}^{\uparrow}$ *window* W *or* $\mathsf{DyadicRatCore}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *ledger* Q *is read. Thus the window and tolerance reads are downstream of one displayed shared-threshold route, not independent side reads of the two schedules.*

Proof. Project the carrier of Definition 636.1. Its third coordinate is the shared $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ row T, and the finite window and tolerance-readback coordinates W and Q are listed only after that threshold row.

Apply the directional routing of Definition 636.6. A comparison-facing consumer must read $M_0, M_1, T, W, Q, H, C, P, N$, so the schedules meet at T before any window or tolerance ledger is inspected.

Use Definition 636.7 and Definition 636.10. Both name the same threshold coordinate as the sole shared tail row and place W and Q downstream of it. Hence threshold-window coherence is exactly the displayed carrier route. □

Theorem 636.12 (Cauchy modulus comparison window-ledger source exhaustion)**.** *Let* $K = (M_0, M_1, T, W, Q, E, H, C, P, N)$ *be an accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *carrier. Every Real-facing comparison read whose seal row is* E *is sourced exactly by the two schedule rows* M_0, M_1*, the single shared threshold row* T*, the selected* $\mathsf{StreamName}^{\uparrow}$ *window ledger* W*, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *ledger* Q*. The route cannot substitute an independent window, an unlisted tolerance row, a quotient stream, host real equality, or ambient completeness for those displayed sources.*

Proof. Project the carrier of Definition 636.1. The rows available to a seal-facing comparison read are the two schedules M_0, M_1, the shared threshold T, the window ledger W, the tolerance and regular-readback ledger Q, the seal E, the transport row H, the route row C, provenance P, and the local naming row N.

Apply Definition 636.11. It forces the route through T before W and Q are read, so the selected window and tolerance ledgers are downstream of one displayed shared threshold rather than independent side data.

Apply Definition 636.13. The only schedule sources are M_0 and M_1, and every comparison read starts from that pair before moving through the displayed threshold, window, ledger, transport, and route rows.

Finally use Definition 636.14. The seal row E is a downstream Real-facing row of this finite route, and the carrier inventory contains no coordinate for an independent window, unlisted tolerance row, quotient stream, host real equality, or ambient completeness. Hence the listed rows exhaust the source surface for the seal-facing comparison read. □

Theorem 636.13 (Cauchy modulus comparison schedule-pair source lock)**.** *Let $K = (M_0, M_1, T, W, Q, E, H, C, P,$ be an accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *carrier. The pair (M_0, M_1) is the complete source surface for comparison reads. It cannot be replaced by a hidden third modulus schedule, an external ordering of host functions, or a comparison source not transported through the displayed* hsame *and* Cont *rows.*

Proof. Read the first two coordinates of the carrier in Definition 636.1. They are the only $\mathsf{CauchyModulus}^{\uparrow}$ schedule rows in the packet.

The paired schedule admission theorem and Definition 636.6 start every comparison route from those same two rows. The route then proceeds through T, W, Q, H, C, P, N rather than through a host-level order or an unlisted schedule.

Finally apply Definition 636.9 and Definition 636.10. The non-escape boundary excludes hidden schedules and external orders, while the package theorem lists no source coordinate beyond M_0 and M_1. □

Theorem 636.14 (Cauchy modulus comparison Real seal comparison non-escape)**.** *For an accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *carrier $K = (M_0, M_1, T, W, Q, E, H, C, P, N)$, the* $\mathsf{Real}^{\uparrow}$ *seal E is only a downstream seal of the displayed finite comparison route*

$$M_0, M_1, T, W, Q, E, H, C, P, N.$$

It does not assert $\mathsf{Real}^{\uparrow}$ *completeness, selected limits, quotient stream equality, or host real equality.*

Proof. Start from the seal coordinate in Definition 636.1. The carrier places E after the two schedules, the shared threshold, the finite window ledger, and the dyadic and regular rational readback ledger.

Apply Definition 636.8. It states that every Real-facing consumer receives E only after the displayed comparison route has been read.

Use Definition 636.9 for the excluded conclusions. Since the carrier has no coordinate for completeness, selected limiting representatives, quotient stream equality, or host real equality, the seal remains a downstream row of the finite comparison packet. The shared threshold package records the same finite route and supplies no additional Real-side claim. □

Theorem 636.15 (Cauchy modulus comparison obligation triad)**.** *Every accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *packet supplies exactly three consumer-facing obligation groups: paired schedule admission for M_0 and M_1; shared threshold, window, and tolerance routing through T, W, Q; and* $\mathsf{Real}^{\uparrow}$ *seal handoff through E with non-escape from quotient streams and host real equality.*

Proof. The first group is paired schedule admission. Apply Definition 636.3: the packet exposes exactly the two $\mathsf{CauchyModulus}^{\uparrow}$ rows M_0 and M_1 before any comparison route is read.

The second group is the shared threshold, window, and tolerance route. Apply Definition 636.11 to force both schedules through T before W and Q are inspected. Then apply Definition 636.12 to exhaust the selected window ledger, dyadic tolerance data, and regular rational readback rows.

The third group is the Real seal handoff. Apply Definition 636.14: the seal row E is downstream of the displayed finite route and does not assert quotient stream equality, host real equality, selected limits, or ambient completeness.

These three groups cover the carrier rows used by comparison consumers. The transport, continuation, provenance, and local naming rows preserve and expose the same route; they do not add a fourth consumer-facing obligation group. □

Theorem 636.16 (Cauchy modulus comparison obligation closure package)**.** *The finite obligation-closure surface for* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *is assembled by the carrier of Definition 636.1, the NameCert obligations of Definition 636.2, the directional monotonicity route of Definition 636.6, the shared-tail exactness of Definition 636.7, the Real seal handoff of Definition 636.8, and the non-escape boundary of Definition 636.9.*

Proof. The carrier supplies the rows of the package, and the NameCert theorem turns those rows into the local obligation surface.

Directional monotonicity constrains comparison-facing reads. Shared-tail exactness forces both schedules through the same threshold before window and tolerance data are inspected.

The Real seal handoff constrains seal-facing consumers, and the non-escape boundary records the excluded quotient, limit, host equality, completeness, hidden schedule, and oracle coordinates. Together these clauses give the finite obligation package without changing the chapter's closure grade. □

Theorem 636.17 (Cauchy modulus comparison scope package)**.** *Every obligation row of an accepted* $\mathsf{CauchyModulusComparison}^{\uparrow}$ *packet*

$$K = (M_0, M_1, T, W, Q, E, H, C, P, N)$$

is scoped by the displayed $\mathsf{CauchyModulus}^{\uparrow}$ *schedule rows* M_0, M_1*, the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold* T*, the* $\mathsf{StreamName}^{\uparrow}$ *finite windows* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows and* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks in* Q*, the* $\mathsf{Real}^{\uparrow}$ *seal* E*, the* hsame *transports* H*, the* Cont *routes* C*, the* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{CauchyModulusComparison}^{\uparrow}}$ *row* N*.*

Proof. Carrier scoping is projection from Definition 636.1. The tuple lists exactly the two schedule rows, shared threshold, windows, tolerance-readback ledger, seal, transport rows, route rows, provenance, and local name.

Paired-schedule admission and threshold-window coherence bind the source and tail rows. Apply Definition 636.3 for M_0, M_1, then apply Definition 636.11 for the route through T before W and Q are inspected.

Window-ledger source exhaustion accounts for the finite observation rows. Apply Definition 636.12: every selected window, dyadic tolerance row, and regular rational readback is already a component of W and Q.

The Real seal comparison non-escape theorem closes the consumer boundary. Apply Definition 636.14; it keeps E downstream of the displayed comparison route and excludes quotient streams, selected limits, host real equality, hidden schedules, and ambient completeness. Thus every obligation row is scoped by the listed packet coordinates. □

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyModulusComparison}^{\uparrow}}$.

Constructive story: A $\mathsf{CauchyModulusComparison}^{\uparrow}$ packet is generated from two $\mathsf{CauchyModulus}^{\uparrow}$ schedule rows, one $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ shared threshold, finite $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance rows, $\mathsf{RegSeqRat}^{\uparrow}$ readback, a $\mathsf{Real}^{\uparrow}$ seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyModulusComparison}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 636.1, Definition 636.2, Definition 636.6, Definition 636.7, Definition 636.8, and Definition 636.17 bind the finite comparison route from two Cauchy-modulus schedules through a shared tail threshold to the RealUp seal.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CauchyModulusComparison}^{\uparrow}}, \mathsf{axiomClean})$

Lean4 ✓ `BEDC.Derived.CauchyModulusComparisonUp.taste gate`

Lean target: `BEDC.Derived.CauchyModulusComparisonUp.CauchyModulusComparisonTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a public order on modulus functions, RealUp completeness, quotient stream equality, host real equality, selected limits, or bridge checking.

Upgrade path: The paper theory axis has no further closure-grade upgrade pending; bridge checking remains a separate verification-axis matter for the same displayed schedule, threshold, window, tolerance, readback, and seal rows.

Chapter 637

A Concrete Naming Certificate for $\mathsf{RealApproximationEnvelope}^{\uparrow}$

The $\mathsf{RealApproximationEnvelope}^{\uparrow}$ interface names the finite observation packet used by Real and Completion consumers before any completed real value is available. It packages a tolerance request, a finite stream window, a dyadic observation, a regular-sequence classifier row, and a $\mathsf{Real}^{\uparrow}$ seal handoff into one local $\mathsf{NameCert}$ surface. The packet is designed for diagonal representatives, stationary rational finite windows, Cauchy-modulus extraction, and RealUp classifier handoffs without importing host real equality, quotient stream equality, selected limits, or ambient completeness.

The envelope consumes the finite-window route of chapter 126, the dyadic observation ledger of chapter 291, the regular-rational classifier of chapter 301, and the seal surface of chapter 38. These sibling surfaces are the rows W, D, R, S of the carrier below, and the edge is a finite observation-envelope route rather than an independent completed real.

Definition 637.1 (Real approximation-envelope carrier)**.** *A* $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

with the following displayed rows:

1. *ε is the tolerance request row naming the precision scale to be answered by the envelope;*
2. *W is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row selected for that tolerance request;*
3. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation row read through W, including the displayed endpoint, radius, and finite arithmetic ledger;*
4. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row that reads the same window as a regular rational observation;*
5. *S is the* $\mathsf{Real}^{\uparrow}$ *seal handoff row receiving the observation packet for downstream real-name consumers;*
6. *H records componentwise* hsame *transports for the tolerance request, window, dyadic observation, classifier row, seal row, provenance, and local name;*
7. *C records the displayed* Cont *routes from tolerance request to window, from window to dyadic observation, from dyadic observation to classifier row, and from classifier row to seal handoff;*
8. *P is the* Pkg *provenance over* BHist, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, *and* $\mathsf{NameCert}$*;*

9. N is the local $\mathsf{NameCert}_{\mathsf{RealApproximationEnvelope}^{\uparrow}}$ *row.*
The carrier stores no host real equality, no quotient stream equality, no selected limit, no completed-real inverse law, and no ambient completeness premise.

Theorem 637.2 (Real approximation-envelope NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RealApproximationEnvelope}^{\uparrow}}$ *surface for Definition 637.1 consists exactly of tolerance-request admission, selected* $\mathsf{StreamName}^{\uparrow}$ *window admission,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation admission,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier readback,* $\mathsf{Real}^{\uparrow}$ *seal handoff, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and the local naming row.*

Proof. Carrier admission is projection from the displayed packet E. Its rows list the tolerance request, finite window, dyadic observation ledger, regular rational classifier row, RealUp seal handoff, transport witnesses, continuation routes, provenance, and local certificate.

The observation side first reads ε and then follows the continuation route to W. The selected window exposes only finite stream data, and D records the dyadic endpoint, radius, and arithmetic ledger obtained from that window.

The classifier side routes the same finite read through R and then to the seal row S. The stored hsame and Cont rows ensure that the classifier handoff is tied to the same tolerance request and window, while P and N record the package provenance and local name.

No remaining coordinate can supply host real equality, quotient stream equality, selected limits, completed-real inverse laws, or ambient completeness. The obligations therefore exhaust the finite Real-and-Completion observation envelope. □

Lean4 ✓ `BEDC.Derived.RealApproximationEnvelopeUp.RealApproximationEnvelopePacket namecert obligations`

Theorem 637.3 (Real approximation-envelope tolerance-window admission)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. Each accepted tolerance request in the row ε reaches the selected* $\mathsf{StreamName}^{\uparrow}$ *finite window W through the same finite support rows H, C, P, N, and the admission path uses no stream coordinate outside the window row displayed in E.*

Proof. Project the rows of E from Definition 637.1. The row ε stores the tolerance request, W stores the selected $\mathsf{StreamName}^{\uparrow}$ finite window, H stores the componentwise hsame transport, C stores the displayed Cont route, P stores the Pkg provenance, and N stores the local NameCert row.

Apply Definition 637.2. Its first two obligations admit the tolerance request and then the selected finite window for the same local packet, while the transport, route, provenance, and naming obligations keep the path inside H, C, P, N.

Since the carrier lists no second stream read and no ambient stream equality, the admitted tolerance request can reach a consumer-visible stream observation only through W. Thus every accepted tolerance request reaches the selected finite window through the displayed rows $\varepsilon, W, H, C, P, N$. □

Theorem 637.4 (Real approximation-envelope dyadic observation soundness)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The selected finite window* W *determines the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation row* D *and the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* R *along the displayed route*

$$W \longrightarrow D,$$
$$D \longrightarrow R.$$

The determination is internal to the support rows H, C, P, N *and does not use quotient stream equality, host real equality, or a selected limit.*

Lean4 ✓ `BEDC.Derived.RealApproximationEnvelopeUp.RealApproximationEnvelope dyadic observation soundness`

Proof. Start with the window admission theorem Definition 637.3. It places the accepted tolerance request at the selected $\mathsf{StreamName}^{\uparrow}$ row W through the local support rows of the envelope.

The NameCert obligations of Definition 637.2 then admit the $\mathsf{DyadicRatCore}^{\uparrow}$ observation row D and the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row R for the same packet. The continuation ledger C records the route from W to D and from D to R, while H, P, N keep the route attached to the same finite carrier.

No coordinate of Definition 637.1 records quotient stream equality, host real equality, or a selected limit. The dyadic observation and classifier row are therefore sound exactly as the displayed W to D to R observation route. □

Theorem 637.5 (Real approximation-envelope seal ledger exactness)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The* $\mathsf{Real}^{\uparrow}$ *seal row* S *is admissible exactly as the downstream ledger endpoint of the finite route*

$$\varepsilon \longrightarrow W \longrightarrow D \longrightarrow R \longrightarrow S$$

with support rows H, C, P, N*. It exports no host real equality, quotient stream equality, selected limit, completed-real inverse law, or ambient completeness principle.*

Proof. First apply Definition 637.3 and Definition 637.4. These identify the admitted route from the tolerance request ε through the selected window W, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation row D, and the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row R.

Apply Definition 637.2 to the downstream row. It admits the $\mathsf{Real}^{\uparrow}$ seal handoff and records, through C, that the seal is reached after the classifier row for the same carrier, with H, P, N preserving transport, provenance, and local naming.

The carrier definition lists the seal as a row of the finite packet rather than as a completed real value or an ambient equality principle. Since the negative boundary excludes host real equality, quotient stream equality, selected limits, completed-real inverse laws, and ambient completeness, the row S is exact only as the endpoint of the displayed finite ledger. □

Theorem 637.6 (Real approximation-envelope consumer boundary)**.** *Every diagonal-representative, stationary rational finite-window, Cauchy-modulus, or* $\mathsf{Real}^{\uparrow}$ *classifier consumer of an accepted* $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *packet must read the rows*

$$\varepsilon, W, D, R, S, H, C, P, N.$$

Such a consumer may inspect the selected $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row, and the* $\mathsf{Real}^{\uparrow}$ *seal handoff, but it cannot replace that route by host real equality, quotient stream equality, a selected limit, a completed-real inverse law, or ambient completeness.*

Proof. Begin with the NameCert obligations of Definition 637.2. They force every observation request to pass from ε through the selected window W before any dyadic or regular rational data is consumed.

Diagonal representatives and stationary rational finite-window consumers read the finite window side of the packet. The dyadic ledger D records the observed endpoint data, and the classifier row R records the regular rational readback for the same selected window.

Cauchy-modulus and $\mathsf{Real}^{\uparrow}$ classifier consumers then reach the real-facing boundary through S. The transport, continuation, provenance, and local naming rows keep the seal attached to the same finite observation route.

The carrier inventory is exhausted by the displayed rows. Since none of them is host real equality, quotient stream equality, a selected limit, a completed-real inverse law, or an ambient completeness theorem, no accepting consumer can export such data. □

Lean4 ✓ `BEDC.Derived.RealApproximationEnvelopeUp.RealApproximationEnvelope consumer boundary`

Theorem 637.7 (Real approximation-envelope window readback totality)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. Every accepted tolerance request in* E *reaches the selected* $\mathsf{StreamName}^{\uparrow}$ *finite window by the displayed route through* ε*,* W*,* H*,* C*,* P*, and* N*, and the readback uses no stream coordinate except those recorded in that finite window row.*

Lean4 ✓ `BEDC.Derived.RealApproximationEnvelopeUp.RealApproximationEnvelope window readback totality`

Proof. The carrier definition in Definition 637.1 displays ε as the tolerance request row, W as the selected $\mathsf{StreamName}^{\uparrow}$ finite-window row, H as the componentwise transport ledger, C as the continuation route ledger, P as provenance, and N as the local certificate.

Apply the NameCert obligation inventory of Definition 637.2. It requires tolerance-request admission, selected $\mathsf{StreamName}^{\uparrow}$ window admission, componentwise hsame transport, displayed Cont route replay, provenance, and local naming for the same packet E.

Finally apply the consumer boundary in Definition 637.6. A consumer may inspect the selected $\mathsf{StreamName}^{\uparrow}$ window but cannot replace that finite route by unrecorded stream access, so the readback is total exactly along the displayed envelope rows. □

Theorem 637.8 (Real approximation-envelope dyadic classifier handoff)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The selected* $\mathsf{StreamName}^{\uparrow}$ *finite window* W *determines the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation row* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* R*, and the* $\mathsf{Real}^{\uparrow}$ *seal row* S *along the displayed continuation route*

$$\begin{aligned} \varepsilon &\longrightarrow W, \\ W &\longrightarrow D, \\ D &\longrightarrow R, \\ R &\longrightarrow S. \end{aligned}$$

Lean4 ✓ BEDC.Derived.RealApproximationEnvelopeUp.RealApproximationEnvelopeDyadicClassifierHandoff

Proof. By Definition 637.1, the packet stores the $\mathsf{StreamName}^{\uparrow}$ row W, the $\mathsf{DyadicRatCore}^{\uparrow}$ row D, the $\mathsf{RegSeqRat}^{\uparrow}$ row R, the $\mathsf{Real}^{\uparrow}$ row S, and the continuation ledger C in one finite BHist carrier.

The NameCert obligations in Definition 637.2 bind these rows as a single route: tolerance request to selected window, selected window to dyadic observation, dyadic observation to classifier row, and classifier row to seal handoff.

The boundary theorem Definition 637.6 then fixes the consumer-visible handoff. Any diagonal-representative, stationary rational finite-window, Cauchy-modulus, or $\mathsf{Real}^{\uparrow}$ classifier consumer sees the same W, D, R, S chain, so the dyadic, classifier, and seal rows are the displayed continuation of the selected window. □

Theorem 637.9 (Real approximation-envelope transport non-escape)**.** *For an accepted* RealApproximationEnvelope *carrier*

$$E = (\varepsilon, W, D, R, S, H, C, P, N),$$

componentwise hsame *transport of E preserves the tolerance request ε, the selected* $\mathsf{StreamName}^{\uparrow}$ *finite window W, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation row D, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row R, and the* $\mathsf{Real}^{\uparrow}$ *seal handoff S. The transported packet exports no host real equality, quotient stream equality, selected limit, completed-real inverse law, or ambient completeness principle.*

Proof. The transport coordinates are part of the carrier itself by Definition 637.1: H records componentwise hsame transports for the tolerance request, window, dyadic observation, classifier row, seal row, provenance, and local name.

Use Definition 637.2 to replay those transport rows together with the displayed Cont routes and Pkg provenance. This keeps the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surfaces attached to the same finite envelope packet after transport.

The non-escape claim is exactly the negative boundary of Definition 637.6. Since every accepted consumer must read the displayed rows of E, and since those rows do not contain host real equality, quotient stream equality, selected limits, completed-real inverse laws, or ambient completeness, componentwise transport cannot export any such object. □

Theorem 637.10 (Real approximation-envelope classifier handoff)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The accepted packet routes the tolerance request ε and the selected* $\mathsf{StreamName}^{\uparrow}$ *finite window W through the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation row D into the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row R, using only the displayed rows $\varepsilon, W, D, R, H, C, P, N$ of the same finite packet.*

Proof. Project the carrier coordinates from Definition 637.1. The packet displays the tolerance request, selected window, dyadic observation, classifier row, componentwise transport ledger, continuation ledger, provenance, and local certificate in one finite BHist object.

Apply the NameCert obligations in Definition 637.2. They require admission of ε, W, D, and R together with replay of the displayed Cont routes for the same local certificate.

The route is therefore the finite chain ε to W, W to D, and D to R. No coordinate outside $\varepsilon, W, D, R, H, C, P, N$ is needed to hand the selected observation to the regular-rational classifier. □

Theorem 637.11 (Real approximation-envelope seal routing)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The* $\mathsf{Real}^{\uparrow}$ *seal row* S *is reachable only after the classifier row* R *for the same finite observation route, and this seal exports no selected limit, quotient stream equality, host real equality, completed-real inverse law, or ambient completeness premise.*

Proof. First apply Definition 637.10. It fixes the observation route from the tolerance request through the selected $\mathsf{StreamName}^{\uparrow}$ window and $\mathsf{DyadicRatCore}^{\uparrow}$ row into the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row R.

The carrier and NameCert obligations then place the seal row after the classifier row by the displayed continuation route R to S. Thus any accepted access to S is tied to the same finite observation chain already used by the classifier.

Finally apply the consumer boundary theorem Definition 637.6. Since accepted consumers may inspect the seal handoff but cannot replace the finite route by selected limits, quotient stream equality, host real equality, completed-real inverse laws, or ambient completeness, the seal row exports none of those objects. □

Theorem 637.12 (Real approximation-envelope seal-classifier compatibility)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier handoff row* R *and the* $\mathsf{Real}^{\uparrow}$ *seal row* S *are compatible exactly when both are read through the same displayed finite route*

$$\varepsilon \longrightarrow W \longrightarrow D \longrightarrow R \longrightarrow S$$

and through the same support rows H, C, P, N*. No second classifier, selected limit, quotient stream equality, host real equality, or ambient completeness coordinate may mediate the seal.*

Proof. Apply Definition 637.10. It identifies the unique classifier-facing route from the tolerance request ε through the selected $\mathsf{StreamName}^{\uparrow}$ window W and the $\mathsf{DyadicRatCore}^{\uparrow}$ observation row D into the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row R.

Apply Definition 637.11. The seal-facing route reaches the $\mathsf{Real}^{\uparrow}$ row S only after the already displayed classifier row R, so the classifier handoff and the seal handoff share the same finite boundary

$$\varepsilon \longrightarrow W \longrightarrow D \longrightarrow R \longrightarrow S.$$

Finally use Definition 637.9 and Definition 637.6. These exclude selected limits, quotient stream equality, host real equality, completed-real inverse laws, ambient completeness, and unrecorded consumer coordinates, leaving only the displayed route together with H, C, P, N as the finite packet boundary. □

Theorem 637.13 (Real approximation-envelope window-classifier exactness)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The finite window row* W *is the unique public route by which the dyadic observation row* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row* R*, and the* $\mathsf{Real}^{\uparrow}$ *seal row* S *are exported. Every accepted classifier or seal read factors through the displayed chain*

$$\varepsilon \longrightarrow W \longrightarrow D \longrightarrow R \longrightarrow S$$

together with the support rows H, C, P, N, and no selected limit, quotient stream equality, host real equality, completed-real inverse law, or ambient completeness premise can replace that route.

Lean4 ✓ `BEDC.Derived.RealApproximationEnvelopeUp.RealApproximationEnvelope window classifier exactness`

Proof. The carrier definition Definition 637.1 displays exactly the rows $\varepsilon, W, D, R, S, H, C, P, N$. Thus any public read of a dyadic observation, classifier row, or seal row must be a read of one of the named coordinates of the same finite BHist packet.

Apply Definition 637.7 to the first step. It makes W the total finite-window readback for the tolerance request ε and excludes unrecorded stream coordinates from that read.

Next apply Definition 637.8 and Definition 637.10. These identify the dyadic observation row D and the classifier row R as the displayed continuation of the same selected window, with only H, C, P, N available as support.

Apply Definition 637.11 for the real-facing end of the route. The seal row S is reached only after the classifier row R, so a seal read cannot bypass the window, dyadic observation, or classifier handoff.

Finally use Definition 637.6. It rules out selected limits, quotient stream equality, host real equality, completed-real inverse laws, and ambient completeness as replacement routes, leaving the displayed finite chain as the exact public export path. □

Theorem 637.14 (Real approximation-envelope regularity propagation)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier row R propagates regularity to the* $\mathsf{Real}^{\uparrow}$ *seal row S exactly along the finite envelope route*

$$\varepsilon \longrightarrow W \longrightarrow D \longrightarrow R \longrightarrow S$$

with support rows H, C, P, N. No selected limit, quotient stream equality, host real equality, completed-real inverse law, ambient completeness premise, or second classifier mediates this propagation.

Lean4 ✓ `BEDC.Derived.RealApproximationEnvelopeUp.RealApproximationEnvelope regularity propagation`

Proof. The carrier definition Definition 637.1 gives the only available rows of an accepted envelope. Thus a regularity read starting at R can only move through coordinates already present in E.

Apply Definition 637.4 and Definition 637.10. They place the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row after the tolerance request, finite window, and dyadic observation rows, so the regularity obligation attached to R is already tied to the route $\varepsilon \to W \to D \to R$.

Apply Definition 637.12 and Definition 637.13. These force the real seal row S to be read after the same classifier row and rule out every route that bypasses the finite window, dyadic observation, classifier handoff, and support rows H, C, P, N.

The sibling anchors `RegSeqRatStreamCarrier_regularit_obligation_surface` and `RegSeqRatStreamCarri` name the regularity and seal faces that this envelope exposes. The preceding exactness results show that those faces meet only through the displayed finite chain, not through a selected limit, stream quotient, host equality, completed-real inverse law, ambient completeness premise, or second classifier. □

Theorem 637.15 (Real approximation-envelope obligation coverage)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The carrier definition and the obligation theorems discharge exactly the seven obligation faces for the envelope package: carrier admission, finite-window readback, dyadic observation soundness,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier handoff,* $\mathsf{Real}^{\uparrow}$ *seal routing, componentwise* hsame *transport stability, and consumer non-escape. The discharged package is the finite route*

$$\varepsilon \longrightarrow W \longrightarrow D \longrightarrow R \longrightarrow S$$

with support rows H, C, P, N*, and it claims no selected limit, quotient stream equality, host real equality, completed-real inverse law, ambient completeness premise, Lean verification, or standard bridge.*

Proof. Carrier admission is the displayed inventory of Definition 637.1. It supplies exactly the tolerance request, finite window, dyadic observation row, classifier row, seal row, componentwise transport ledger, continuation ledger, provenance row, and local certificate row.

Finite-window readback is Definition 637.7. Dyadic observation soundness and the classifier-facing handoff are supplied by Definition 637.8 and Definition 637.10; together they force the selected $\mathsf{StreamName}^{\uparrow}$ row W to feed D and then R inside the same finite packet.

The real-facing endpoint is Definition 637.11. It places the $\mathsf{Real}^{\uparrow}$ seal row S after the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row R and prevents the seal from becoming an independent completed-real object.

Transport stability is exactly the componentwise hsame boundary of Definition 637.9. The final consumer boundary is Definition 637.13: every accepted classifier or seal read factors through the same finite window route, and no unrecorded equality, selected limit, inverse law, or completeness principle can replace it. □

Theorem 637.16 (Real approximation-envelope primitive scope closure)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The seven obligation faces of Definition 637.15 are scoped exactly by the primitive rows* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*, together with the four sibling surfaces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. Every tolerance-window read, dyadic observation, classifier handoff, seal route, componentwise transport, and consumer read factors through those rows. The package cannot use selected limits, quotient stream equality, host real equality, completed-real inverse laws, ambient completeness, Lean verification, or bridge checking.*

Proof. The carrier inventory is Definition 637.1. It exposes only the tolerance request ε, finite window W, dyadic observation D, classifier row R, seal row S, componentwise transport ledger H, continuation ledger C, provenance row P, and local certificate row N.

Admission is supplied by Definition 637.2. Thus the available primitive rows are exactly the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, with the sibling surfaces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ named by the coordinates of E.

The route from tolerance to seal is forced by Definition 637.7, Definition 637.8, Definition 637.11, and Definition 637.12. These results identify the finite chain $\varepsilon \to W \to D \to R \to S$ as the only route available for tolerance-window reads, dyadic observations, classifier handoffs, and seal reads.

Transport cannot leave that primitive scope by Definition 637.9. Finally, Definition 637.15 repacks the carrier, admission, route, transport, and consumer faces into the seven-face package, with selected limits, quotient stream equality, host real equality, completed-real inverse laws, ambient completeness, Lean verification, and bridge checking outside the claim. □

Theorem 637.17 (Real approximation-envelope four-face public export)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. Its public Real-and-Completion export is exactly the four-face packet*

$$\mathsf{StreamName}^{\uparrow}(W) \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}(D) \longrightarrow \mathsf{RegSeqRat}^{\uparrow}(R) \longrightarrow \mathsf{Real}^{\uparrow}(S)$$

over the tolerance request ε*, the componentwise* hsame *rows* H*, the displayed* Cont *routes* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{RealApproximationEnvelope}^{\uparrow}}$ *row* N*. Every downstream diagonal-representative, stationary-window, Cauchy-modulus, Real-name, or Completion consumer reaches the L10 phase boundary through those rows, and no quotient stream, host real equality, selected limit, ambient completeness, metric-completeness, arithmetic/order package, or standard bridge row is exported by the envelope.*

Proof. Project the accepted carrier by Definition 637.1. The only public face rows in the packet are the selected $\mathsf{StreamName}^{\uparrow}$ window W, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation D, the $\mathsf{RegSeqRat}^{\uparrow}$ classifier R, and the $\mathsf{Real}^{\uparrow}$ seal S, with ε, H, C, P, N supplying the tolerance, transport, route, provenance, and local certificate support.

Apply Definition 637.2. It admits precisely those face rows and the support rows for the same local $\mathsf{NameCert}$ surface, so the export cannot acquire a detached quotient stream, host equality, selected limit, completeness witness, arithmetic/order package, or bridge coordinate.

Next apply Definition 637.13 and Definition 637.15. These force every classifier or seal read to factor through the finite route from ε to W, then to D, then to R, and finally to S, while preserving the componentwise hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

The consumer boundary of Definition 637.6 and the primitive scope closure of Definition 637.16 place the same route at the public edge of the chapter. Downstream, Definition 1120.6 and Definition 1120.9 are the Real L10 four-face exactness and pullback boundary: they consume only the corresponding StreamName, DyadicRatCore, RegSeqRat, and Real faces through finite structural rows. Thus the envelope exports exactly the displayed four-face packet to that boundary and nothing outside it. □

Theorem 637.18 (Real approximation-envelope four-face transport stability)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

and

$$E' = (\varepsilon', W', D', R', S', H', C', P', N')$$

be accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carriers. Suppose the tolerance requests,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations,* $\mathsf{RegSeqRat}^{\uparrow}$ *classifier rows,* $\mathsf{Real}^{\uparrow}$ *seal rows, componentwise transport rows, continuation routes, provenance rows, and local* $\mathsf{NameCert}_{\mathsf{RealApproximationEnvelope}^{\uparrow}}$ *rows are matched by componentwise* hsame *through the displayed support rows* H, C, P, N *and* H', C', P', N'*. Then the public four-face export*

$$\mathsf{StreamName}^{\uparrow}(W) \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}(D) \longrightarrow \mathsf{RegSeqRat}^{\uparrow}(R) \longrightarrow \mathsf{Real}^{\uparrow}(S)$$

is transported to the same finite public packet

$$\mathsf{StreamName}^{\uparrow}(W') \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}(D') \longrightarrow \mathsf{RegSeqRat}^{\uparrow}(R') \longrightarrow \mathsf{Real}^{\uparrow}(S')$$

over the matched tolerance, transport, route, provenance, and local certificate rows. This preservation introduces no quotient stream equality, host real equality, selected limit, ambient completeness, metric-completeness, arithmetic/order package, or bridge row.

Proof. Start with Definition 637.9. The componentwise hsame rows keep the matched tolerance, window, dyadic observation, classifier, seal, provenance, and local name inside the two displayed finite carriers, so transport cannot leave the rows H, C, P, N and H', C', P', N'.

Apply Definition 637.13 to both accepted envelopes. It identifies the unique public route from the tolerance request through the selected $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation, and the $\mathsf{RegSeqRat}^{\uparrow}$ classifier row. The matched support rows therefore carry the same route shape on both sides.

Next use Definition 637.14. Regularity reaches the $\mathsf{Real}^{\uparrow}$ seal only through the already matched classifier row, so the transported classifier route and the transported seal route remain a single finite packet rather than two independent public objects.

Finally invoke Definition 637.17. Since that theorem makes the StreamName, DyadicRatCore, RegSeqRat, and Real rows the exact public boundary of the envelope, the componentwise transport preserves precisely the displayed four-face packet and adds none of the excluded quotient, host-equality, limit, completeness, arithmetic/order, or bridge data. □

Theorem 637.19 (Real approximation-envelope public export boundary)**.** *Let*

$$E = (\varepsilon, W, D, R, S, H, C, P, N)$$

be an accepted $\mathsf{RealApproximationEnvelope}^{\uparrow}$ *carrier. The public export of E is exactly the four-face route*

$$\mathsf{StreamName}^{\uparrow}(W) \longrightarrow \mathsf{DyadicRatCore}^{\uparrow}(D) \longrightarrow \mathsf{RegSeqRat}^{\uparrow}(R) \longrightarrow \mathsf{Real}^{\uparrow}(S)$$

supported by the displayed tolerance request ε, componentwise hsame *rows H, continuation rows C, provenance row P, and local* $\mathsf{NameCert}_{\mathsf{RealApproximationEnvelope}^{\uparrow}}$ *row N. This is the complete public Real-and-Completion boundary of the envelope: selected limits, quotient stream equality, host real equality, completed-real inverse laws, ambient completeness, arithmetic/order packages, and bridge data remain outside the export.*

Proof. The public four-face theorem Definition 637.17 identifies the visible packet as the StreamName, DyadicRatCore, RegSeqRat, and Real route over the support rows ε, H, C, P, N. The classifier exactness theorem Definition 637.13 forces every classifier or seal read through that same finite route.

Transport stability is supplied by Definition 637.18. It shows that componentwise hsame preserves the four-face packet without adding quotient, host-equality, limit, completeness, arithmetic/order, or bridge coordinates.

Finally, Definition 1120.6 and Definition 1120.9 give the Real completion boundary consumed by this envelope. They use only the matching StreamName, DyadicRatCore, RegSeqRat, and Real faces, so the accepted envelope exports exactly the displayed public route and nothing beyond it. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealApproximationEnvelope}^{\uparrow}}$.

Constructive story: A $\mathsf{RealApproximationEnvelope}^{\uparrow}$ packet is generated from a tolerance request, selected $\mathsf{StreamName}^{\uparrow}$ finite window, $\mathsf{DyadicRatCore}^{\uparrow}$ observation row, $\mathsf{RegSeqRat}^{\uparrow}$ classifier row, $\mathsf{Real}^{\uparrow}$ seal handoff, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RealApproximationEnvelope}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: Definition 637.1, Definition 637.2, Definition 637.15, Definition 637.16, Definition 637.17, Definition 637.18, and Definition 637.19 bind the primitive finite envelope from tolerance requests through StreamNameUp windows, DyadicRatCore observations, RegSeqRat classifier rows, RealUp seal handoffs, componentwise transport, and the public Real-and-Completion export boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RealApproximationEnvelope}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.RealApproximationEnvelopeUp.RealApproximationEnvelope\_window\_classifier\_exactness`

Bridge status: none

Origin: human

Not claimed: This chapter does not close RealUp completeness, uniqueness of completed limits, quotient stream equality, host real equality, completed-real inverse laws, arithmetic/order packages, or bridge checking.

Upgrade path: The remaining route to a higher closure grade is a bridge theorem for the public StreamNameUp, DyadicRatCoreUp, RegSeqRatUp, and RealUp four-face export.

Chapter 638

A Concrete Naming Certificate for $\mathsf{FiniteWitnessRoute}^{\uparrow}$

The $\mathsf{FiniteWitnessRoute}^{\uparrow}$ interface names the finite route packet that carries closed-observation witness records into Real-and-Completion consumers. It is a concrete $\mathsf{NameCert}$ surface for the passage from a selected observation request through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ readbacks to a $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ seal row, with every transport, continuation, and provenance step present in the finite history.

The route is downstream of chapter 126, chapter 301, chapter 291, chapter 386, and chapter 38. $\mathsf{StreamName}^{\uparrow}$ supplies the finite window, $\mathsf{RegSeqRat}^{\uparrow}$ supplies the readback, $\mathsf{DyadicRatCore}^{\uparrow}$ supplies the comparison ledger, $\mathsf{CauchyLimitSeal}^{\uparrow}$ supplies the sealed completion boundary, and $\mathsf{Real}^{\uparrow}$ supplies the terminal real-facing seal.

Definition 638.1 (Finite witness-route carrier)**.** *A* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (q, w, r, d, s, h, c, p, n)$$

with the following displayed rows:

1. *q is the closed-observation request row naming the finite witness demand, tolerance scale, and downstream Real-and-Completion consumer;*
2. *w is the selected* $\mathsf{StreamName}^{\uparrow}$ *window inspected for that request;*
3. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row exposed through the selected window;*
4. *d is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger containing the dyadic comparisons, radius splits, and finite arithmetic reads used by the route;*
5. *s is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal row that receives the completed finite witness route;*
6. *h records componentwise* hsame *transports for the request row, selected window, regular rational readback, dyadic ledger, seal row, provenance, and local name;*
7. *c records the displayed* Cont *routes from request to window, from window to regular rational readback, from readback to dyadic ledger, and from the dyadic ledger to the seal row;*
8. *p is the* Pkg *provenance over* BHist, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *n is the local* $\mathsf{NameCert}_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$ *row.*

The carrier contains no host-level infinite trace, no quotient stream equality, no selected real value, no unrecorded limit, and no consumer route outside the displayed finite packet.

Lean4 ✓ `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteTasteGate single carrier alignment`

Theorem 638.2 (Finite witness-route NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$ *surface for Definition 638.1 consists exactly of carrier admission, request exposure, selected* $\mathsf{StreamName}^{\uparrow}$ *window admission,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback admission,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger admission,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal handoff, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and the local naming row.*

Proof. Carrier admission is projection from the displayed packet R. The rows name the request, selected observation window, rational readback, dyadic ledger, seal, transports, continuations, provenance, and local certificate.

The request and window obligations are read through q and w. They ensure that a consumer sees a finite observation demand and exactly the selected $\mathsf{StreamName}^{\uparrow}$ window used to answer it.

The readback and ledger obligations are read through r and d. The regular rational row supplies the observed sequence data, and the dyadic row supplies the comparison and radius ledger used by the route.

The remaining rows s, h, c, p, n expose the seal handoff, componentwise transports, route replay, package provenance, and local naming. Since every coordinate of the packet is accounted for, these obligations exhaust the local certificate surface. □

Lean4 ✓ `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteNameCert obligations`

Theorem 638.3 (Finite witness-route non-escape)**.** *Every accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *carrier exports witness information only through the finite rows*

$$q, w, r, d, s, h, c, p, n.$$

It exports no host-level infinite trace, no quotient stream equality, no selected real value, no unrecorded limit, and no Real-and-Completion consumer route that bypasses the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Project the accepted carrier as $R = (q, w, r, d, s, h, c, p, n)$. The definition lists every exported row of the finite witness route.

The observation side is exhausted by q, w, r, d. These rows record the request, selected stream window, regular rational readback, and dyadic comparison ledger.

The consumer side is exhausted by s, h, c, p, n. These rows record the seal handoff, transport, continuation, provenance, and local name.

No coordinate remains from which to read an infinite trace, quotient stream equality, selected real value, unrecorded limit, or bypass route. The accepted packet therefore has the stated non-escape boundary. □

Lean4 ✓ `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteNonEscape boundary`

Theorem 638.4 (Finite witness-route transport stability)**.** *Let*

$$R = (q, w, r, d, s, h, c, p, n)$$

be an accepted $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *carrier. Any* hsame *transport recorded in* h *preserves the request row, selected* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, seal row, continuation routes, package provenance, and local name as one finite route packet for the same Real-and-Completion consumer.*

Proof. Read the transport row h. Its components are indexed by the coordinates of the carrier, so each displayed row has a matching transport witness.

Transporting q, w, r, d preserves the finite observation side of the route: the request, selected window, regular rational readback, and dyadic ledger stay attached to the same finite demand.

Transporting s, c, p, n preserves the consumer side of the route: the seal handoff, continuation replay, provenance, and local certificate stay attached to that demand. Thus the transported data is again one finite witness-route packet for the same consumer boundary. □

Lean4 ✓ `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteTransport stability`

Theorem 638.5 (Finite witness-route consumer factorization)**.** *Every* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer that accepts a* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet factors through the selected* $\mathsf{StreamName}^{\uparrow}$ *window* w*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* r*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* d*, the seal row* s*, the displayed transports* h*, the continuation routes* c*, the package provenance* p*, and the local* $\mathsf{NameCert}_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$ *row* n*. The consumer receives the finite witness route, not an independent route ledger.*

Lean4 ✓ `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteConsumer factorization`

Proof. Begin with an accepted packet $R = (q, w, r, d, s, h, c, p, n)$. The request row q names the finite demand and the downstream consumer boundary.

The only observation path in the carrier runs through w, r, d. The selected stream window exposes the inspected records, the regular rational row exposes their sequence readback, and the dyadic ledger exposes the comparison data.

The handoff to the consumer then runs through s, h, c, p, n. These rows seal, transport, replay, package, and name the same finite route. Hence any accepting consumer factors through the displayed packet rather than through an independent ledger. □

Theorem 638.6 (Finite witness-route request-window admission)**.** *Let*

$$R = (q, w, r, d, s, h, c, p, n)$$

be an accepted $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet. Every finite witness demand read by a Real-and-Completion consumer must pass through the request row* q *and the selected* $\mathsf{StreamName}^{\uparrow}$ *window row* w*. No consumer may read a route from* R *without first exposing those two rows.*

Proof. Project the carrier of Definition 638.1. The row q names the finite witness demand, tolerance scale, and downstream consumer, while w names the selected stream window inspected for that request.

Apply Definition 638.2. Its request exposure and selected-window admission clauses make q and w part of the local $\mathsf{NameCert}_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$ surface.

Thus any accepted consumer route that reads the finite witness demand must open q and then the selected window w. A route that omits either row is not a read of the displayed packet. □

Theorem 638.7 (Finite witness-route regular readback admission)**.** *For an accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet*

$$R = (q, w, r, d, s, h, c, p, n),$$

every accepted regular rational readback in the route is exposed through the same selected $\mathsf{StreamName}^{\uparrow}$ *window* w *and through the* $\mathsf{RegSeqRat}^{\uparrow}$ *row* r*. The dyadic comparison ledger* d *records the finite comparison data, and the route imports neither quotient stream equality nor a selected real.*

Proof. Read the observation rows w, r, d from Definition 638.1. The selected window w is the inspection boundary, r is the regular rational readback exposed through that window, and d is the dyadic ledger for the finite comparisons.

Use Definition 638.2 to attach those three rows to the local certificate surface. The readback admission row is therefore tied to the same selected window that answers the request.

Finally apply Definition 638.3. It excludes quotient stream equality, selected real values, unrecorded limits, and host-level infinite traces from the accepted packet, so the regular readback remains a finite row of the displayed route. □

Theorem 638.8 (Finite witness-route seal-budget exactness)**.** *For an accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet*

$$R = (q, w, r, d, s, h, c, p, n),$$

any $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal-budget consumer factors through the request row* q*, the selected* $\mathsf{StreamName}^{\uparrow}$ *window* w*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* r*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* d*, the seal row* s*, and the displayed* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$ *rows before receiving the route. The packet exports no hidden observation budget, quotient stream equality, host real equality, selected host limit, countable-choice row, ambient completeness coordinate, independent dyadic ledger, or standard bridge row.*

Proof. Project the carrier in Definition 638.1. Its displayed coordinates are exactly $q, w, r, d, s, h, c, p, n$, with q naming the request, w the selected stream window, r the regular rational readback, d the dyadic ledger, s the seal row, and h, c, p, n the transport, continuation, package, and naming rows.

The local certificate surface is fixed by Definition 638.2. Its clauses expose carrier admission, request exposure, selected-window admission, readback admission, dyadic ledger admission, seal handoff, hsame transport, Cont replay, Pkg provenance, and the local naming row for the same finite packet.

Now apply non-escape, Definition 638.3. The route has no coordinate for host infinite traces, quotient stream equality, host real equality, selected host limits, ambient completeness, metric completion, countable choice, independent dyadic ledgers, or standard bridge data.

Finally use request-window admission, Definition 638.6, and regular readback admission, Definition 638.7. Every seal-budget read enters through q, w, then reads only r, d below that selected window before reaching s, h, c, p, n. Thus every budget coordinate received by a $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer is already one of the displayed packet rows. □

Lean4 ✓ `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteSeal budget exactness`

Theorem 638.9 (Finite witness-route consumer route exactness)**.** *Every Real-and-Completion consumer route that accepts a* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet factors through the displayed rows*

$$q, w, r, d, s, h, c, p, n$$

in that dependency order. The seal row s *cannot be consumed unless the request, selected window, regular readback, and dyadic ledger rows* q, w, r, d *have already been exposed in the same finite packet.*

Proof. Begin with Definition 638.5. It sends every accepting $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer through the selected window, regular readback, dyadic ledger, seal, transport, continuation, provenance, and local naming rows of the packet.

Attach Definition 638.6. The consumer route cannot reach the observation side without the request row q and the selected window row w.

Next use Definition 638.8. The readback and dyadic comparison rows are the finite rows r and d, and the seal-budget consumer receives no hidden observation budget, quotient stream equality, selected real value, countable-choice row, ambient completeness coordinate, independent dyadic ledger, or standard bridge row.

The seal row s is therefore downstream of q, w, r, d, and the remaining rows h, c, p, n preserve, replay, package, and name the same route. Hence the accepting consumer factors through the displayed dependency order. □

Lean4 ✓ `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteConsumer route exactness`

Theorem 638.10 (Finite witness-route selected-window seal uniqueness)**.** *Let*

$$R = (q, w, r, d, s, h, c, p, n)$$

be an accepted $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet. Any Real-and-Completion consumer route that reads the seal row s must use the same request row q, selected* $\mathsf{StreamName}^{\uparrow}$ *window w,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback r, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger d. Inside the packet there is no second selected window, readback, dyadic ledger, or seal handoff available for that consumer route.*

Proof. The request-window admission theorem fixes the route entrance. By Definition 638.6, every accepted read of the finite witness demand opens the request row q and the selected window row w.

The regular readback admission theorem then fixes the observation rows below that window. By Definition 638.7, the readback and dyadic comparison data are exactly the displayed rows r and d, and the packet imports neither quotient stream equality nor a selected real value.

Finally apply Definition 638.9. The consumer route reaches the seal row s only after q, w, r, d have been exposed in that dependency order. The non-escape boundary of Definition 638.3 excludes an external equality, selected real, or route ledger that could furnish a second handoff, so the seal read is unique to the displayed packet rows. □

Lean4 ✓ `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteSelectedWindowSeal uniqueness`

Theorem 638.11 (Finite witness-route scoped export factorization)**.** *Every Real-and-Completion consumer that accepts a* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet factors through the displayed request row q, the selected* $\mathsf{StreamName}^{\uparrow}$ *window w, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback r, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger d, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal row s, and the* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$ *support rows recorded by*

$$R = (q, w, r, d, s, h, c, p, n).$$

Thus the consumer exports the finite witness route only along the open Real-and-Completion kernel and sibling surface named by those rows.

Proof. The route entrance is the request-window admission of Definition 638.6. It forces any accepting consumer read of the finite witness demand to expose the request row q and the selected window w.

The observation layer is then fixed by Definition 638.7. The readback row is r, the comparison ledger is d, and both are tied to the same selected $\mathsf{StreamName}^{\uparrow}$ window rather than to quotient stream equality or a selected real value.

The consumer handoff is supplied by Definition 638.9. It sends the accepting route through $q, w, r, d, s, h, c, p, n$ in the displayed dependency order.

Finally, Definition 638.10 rules out a second selected window, readback, dyadic ledger, or seal handoff inside the packet. The only remaining support rows are the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$ rows, so the consumer factors through exactly the stated scoped export surface. □

Theorem 638.12 (Finite witness-route kernel scope lock)**.** *The scoped route of Definition 638.11 exposes no host infinite trace, quotient stream equality, selected real value, unrecorded limit, countable-choice row, or independent dyadic ledger. Its Real-and-Completion exit surface is only the finite packet*

$$R = (q, w, r, d, s, h, c, p, n)$$

and the sibling rows named by w, r, d, s, h, c, p, n.

Proof. Apply Definition 638.3. It excludes host-level infinite traces, quotient stream equality, selected real values, unrecorded limits, and bypass consumer routes from every accepted $\mathsf{FiniteWitnessRoute}^{\uparrow}$ packet.

Now use Definition 638.11. Any accepting Real-and-Completion consumer must factor through the request, selected window, readback, dyadic ledger, seal, transport, continuation, provenance, and local certificate rows of the displayed packet.

Since the factorization already names the only dyadic ledger row and the non-escape theorem removes every bypass route, there is no remaining coordinate for a choice row or independent ledger. The kernel scope is therefore locked to the finite route and to the sibling rows carried by that route. □

Theorem 638.13 (Finite witness-route scoped support rows)**.** *For every accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet*

$$R = (q, w, r, d, s, h, c, p, n),$$

the support scope is exactly the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows together with the* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *faces read by* w, r, d, s*. The scope contains no host-level infinite trace, quotient stream equality, selected real value, ambient Real completeness, metric completeness, countable choice, or standard bridge row.*

Proof. Project the carrier through Definition 638.1. Its coordinates are the request row q, selected window w, regular rational readback r, dyadic ledger d, seal row s, transports h, routes c, provenance p, and local certificate n.

Apply Definition 638.2. The certificate surface accounts for carrier admission, request exposure, selected-window admission, readback admission, ledger admission, seal handoff, transport, route replay, package provenance, and the local naming row.

The sibling faces are the ones named by those coordinates: $\mathsf{StreamName}^{\uparrow}$ through w, $\mathsf{RegSeqRat}^{\uparrow}$ through r, $\mathsf{DyadicRatCore}^{\uparrow}$ through d, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ through s. Apply Definition 638.4 to keep those rows attached under the componentwise hsame transports.

Finally use Definition 638.3. It removes host infinite traces, quotient stream equality, selected real values, unrecorded limits, and bypass routes; the same packet has no coordinate for ambient Real completeness, metric completeness, countable choice, or a standard bridge row. The displayed rows therefore give the whole scoped support. □

Theorem 638.14 (Finite witness-route bridged standard surface)**.** *For every accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet*

$$R = (q, w, r, d, s, h, c, p, n),$$

every bridge-facing consumer must first read the finite request q, the selected $\mathsf{StreamName}^{\uparrow}$ *window w, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback r, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger d, the seal row s, and the support rows $q, w, r, d, s, h, c, p, n$. This is the standard-surface precondition for later bridge checking. It asserts no* $\mathsf{Real}^{\uparrow}$ *completeness theorem, no standard bridge theorem, and no bridgeChecked verification status.*

Proof. First use scoped export factorization. It orders every accepted Real-and-Completion consumer through $q, w, r, d, s, h, c, p, n$ before the route can expose any public exit surface.

Next apply kernel scope lock and scoped support rows. These theorems identify the bridge-facing support as the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows together with the named $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces, while excluding host traces, quotient equality, selected real values, countable choice, metric completeness, and standard bridge rows.

Finally compare with the Real-and-Completion scope and public NameCert export. They package the same finite route as the public surface of the certificate. Therefore a later bridge checker may require this surface as input, but the theorem itself does not supply Real completeness or a checked standard bridge. □

Theorem 638.15 (Finite witness-route Real and Completion scope)**.** *Every Phase Real or Completion consumer read that accepts a* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet factors through the finite route*

$$q, w, r, d, s, h, c, p, n.$$

The read may use the named $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *faces carried by those rows, but it receives no independent real value, limit object, completeness principle, metric completion row, quotient stream equality, countable-choice selector, or standard bridge route.*

Proof. Start with the consumer factorization theorem, Definition 638.5. It sends every accepting $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer through the selected window, readback, ledger, seal, transport, continuation, provenance, and local naming rows.

The request and observation side is fixed by Definition 638.6 and Definition 638.7. Thus the consumer first reads q, w and then the regular rational and dyadic rows r, d.

The seal side is fixed by Definition 638.9. The consumer reaches s only after q, w, r, d, and the remaining rows h, c, p, n preserve, replay, package, and name that same finite route.

Apply Definition 638.13 for the scope boundary. Since the accepted packet has only the displayed support rows and sibling faces, no Phase Real or Completion read can acquire an independent real value, limit object, completeness principle, metric completion row, quotient equality, countable-choice selector, or standard bridge route. □

Theorem 638.16 (Finite witness-route StreamName source lock)**.** *Every accepted Real-and-Completion consumer read of a* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet first exposes the request row q and the selected* $\mathsf{StreamName}^{\uparrow}$ *window w before any* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row or* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row is readable. The read has no route that starts from r or d, and it cannot bypass the selected window through a host trace, quotient stream equality, selected real value, countable-choice selector, or independent dyadic ledger.*

Proof. Begin with request-window admission, Definition 638.6. It makes the entrance to the finite witness packet the displayed request row q together with the selected window w.

Next apply regular readback admission, Definition 638.7. The regular rational readback r and dyadic ledger d are admitted only as rows below that selected window, so neither row can be the first readable Real-and-Completion coordinate.

Finally use non-escape, Definition 638.3. Since the carrier contains no host trace, quotient stream equality, selected real, choice selector, or separate dyadic ledger, every accepted consumer read is source-locked to q, w before it reaches r, d. □

Lean4 ✓ `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteStreamName source lock`

Theorem 638.17 (Finite witness-route RegSeq budget exhaustion)**.** *For every accepted Real-and-Completion read of*

$$R = (q, w, r, d, s, h, c, p, n),$$

the rows r and d exhaust the $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *budget segment after the selected window w. The consumer receives no quotient stream equality, selected real, countable choice, or independent dyadic ledger beyond the displayed readback and ledger rows.*

Proof. Use regular readback admission, Definition 638.7, to identify the observation segment below w. The regular rational row is exactly r, and the dyadic comparison ledger is exactly d.

Now apply consumer route exactness, Definition 638.9. A Real-and-Completion consumer reaches the seal side only after the displayed request, window, readback, and dyadic rows have been read in that order.

The kernel scope lock, Definition 638.12, removes every attempt to extend that segment by an ambient equality or selector. Thus the budget after w is exhausted by r, d, with no remaining coordinate for quotient stream equality, a selected real, countable choice, or a second dyadic ledger. □

Lean4 ✓ `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteRegSeq budget exhaustion`

Theorem 638.18 (Finite witness-route Real seal factorization)**.** *Every* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet factors through the ordered finite route*

$$q, w, r, d, s, h, c, p, n.$$

The consumer first reads the request and selected $\mathsf{StreamName}^{\uparrow}$ *window, then the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, then the seal row, transport, continuation, provenance, and local naming rows. Hence the consumer receives only the finite L10 route and no independent limit object, real value, completeness principle, quotient equality, countable-choice selector, host trace, metric-completion row, or standard bridge route.*

Proof. First apply the StreamName source lock, Definition 638.16. It forces every accepted seal or real consumer to enter through q, w before any regular or dyadic row is readable.

Next use RegSeq budget exhaustion, Definition 638.17. The rows r, d are the whole observation budget below w, so the route cannot add quotient equality, a selected real, countable choice, or a second dyadic ledger before reaching the seal.

Now apply Real and Completion scope, Definition 638.15, together with consumer route exactness, Definition 638.9. These theorems place s, h, c, p, n after q, w, r, d and keep the consumer on the displayed CauchyLimitSeal and Real faces.

Finally invoke scoped support rows and kernel scope lock, Definition 638.13 and Definition 638.12. The accepted packet has no coordinate for an external limit, real, completeness principle, host trace, metric-completion row, or standard bridge, so the ordered finite route is the entire consumer factorization. □

Theorem 638.19 (Finite witness-route seal boundary scope)**.** *For every accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet*

$$R = (q, w, r, d, s, h, c, p, n),$$

the seal row s *is downstream of the request row* q*, selected* $\mathsf{StreamName}^{\uparrow}$ *window* w*, regular* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* r*, dyadic* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* d*, componentwise transport row* h*, continuation row* c*, package provenance* p*, and local naming row* n*. No Real or Completion consumer may read* s *as a boundary supplied by host traces, quotient equality, selected real values, ambient completeness, metric completeness, countable choice, or a standard bridge row.*

Proof. The route entrance is determined by Definition 638.6. Any accepted finite witness demand read opens the request row q and the selected window row w.

The observation data below the window is determined by Definition 638.7. The readback row is r, the comparison ledger is d, and neither quotient stream equality nor a selected real value is imported into the packet.

The consumer dependency order is determined by Definition 638.9 together with Definition 638.10. The seal row s is read only after q, w, r, d, and there is no second selected window, readback, dyadic ledger, or seal handoff inside the carrier.

Finally apply Definition 638.15. The remaining rows h, c, p, n are the only transport, continuation, provenance, and naming rows available to the seal consumer, and the excluded host, quotient, completeness, choice, and bridge coordinates have no public entry point. □

Theorem 638.20 (Finite witness-route four-face exit exactness)**.** *Every current Phase Real and Completion consumer that reaches a* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal through an accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet factors through exactly the selected* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal row carried by that packet. Its support is only the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows of the same finite carrier.*

No such consumer imports host infinite traces, quotient stream equality, selected real values, ambient Real completeness, metric completeness, countable choice, independent dyadic ledgers, or standard bridge rows.

Proof. Apply Definition 638.11. It orders the route through the request row, selected window, regular readback, dyadic ledger, seal row, componentwise transport, continuation, package provenance, and local naming row.

Apply Definition 638.13. The only support rows available along that ordered route are the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows together with the named $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces.

Now use Definition 638.15. It restricts Phase Real and Completion consumers to the same finite route and excludes independent real values, limit objects, completeness principles, metric completion rows, quotient equality, countable-choice selectors, and standard bridge routes.

Finally apply Definition 638.19. The seal read is downstream of the selected window, readback, ledger, transport, continuation, provenance, and naming rows, so the entrance to the $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ seal is exactly the four-face route displayed in the statement. □

Theorem 638.21 (Finite witness-route public NameCert export)**.** *For every accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet*

$$R = (q, w, r, d, s, h, c, p, n),$$

the public certificate $\mathsf{NameCert}_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$ *exports exactly the finite packet* R *and the four L10 faces* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *displayed by*

w, r, d, s. Its support is only the displayed BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows of the same finite carrier.*

No public consumer of this certificate receives a host infinite trace, quotient stream equality, selected real value, ambient Real completeness, metric completeness, countable-choice selector, independent dyadic ledger, or standard bridge row.

Proof. First read the public certificate obligations. By Definition 638.2, the local naming row accounts for carrier admission, request exposure, selected-window admission, readback admission, dyadic ledger admission, seal handoff, componentwise transport, route replay, and package provenance for the same finite packet R.

Next restrict the support rows. Apply Definition 638.13; it identifies the available support as the displayed BHist, hsame, Cont, Pkg, and local NameCert rows together with the named $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces.

Now factor the seal side through the Real and Completion boundary. By Definition 638.18, every $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer follows the ordered finite route $q, w, r, d, s, h, c, p, n$ and gains no independent limit object, real value, completeness principle, quotient equality, countable-choice selector, host trace, metric-completion row, or standard bridge route.

Finally use Definition 638.20. The public exit surface is exactly the selected $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ seal row carried by the packet. Combining these four results repacks the same finite route as the public $\mathsf{NameCert}_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$ export, with no coordinate left for the excluded host, quotient, real-value, completeness, choice, ledger, or bridge data. □

Theorem 638.22 (Finite witness-route choice-refusal boundary)**.** *Every accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *Real-and-Completion consumer route remains on the displayed finite rows*

$$q, w, r, d, s, h, c, p, n.$$

No countable-choice selector, selected host limit, quotient stream equality, or independent real value can be inserted between the selected $\mathsf{StreamName}^{\uparrow}$ *window w and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal row s.*

Proof. Begin with request-window admission, Definition 638.6. It forces every accepted finite witness demand to expose q and the selected $\mathsf{StreamName}^{\uparrow}$ window w before any downstream read.

Use regular readback admission and consumer route exactness next. By Definition 638.7, the route reads r, d through the same selected window; by Definition 638.9, the seal row s is downstream of q, w, r, d in the same finite packet.

Now apply public NameCert export, Definition 638.21. The exported certificate is exactly the displayed packet and the four L10 faces carried by w, r, d, s.

Finally use non-escape, Definition 638.3. Since no countable-choice selector, selected host limit, quotient stream equality, or independent real value is a coordinate of the carrier, none can be inserted between the selected window and the seal. □

Theorem 638.23 (Finite witness-route L10 terminal four-object handoff)**.** *Every accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *consumer that reaches a Real-facing witness route reaches it through the displayed L10 handoff*

$$\mathsf{StreamName}^{\uparrow} \longrightarrow \mathsf{RegSeqRat}^{\uparrow} \longrightarrow \mathsf{DyadicRatCore}^{\uparrow} \longrightarrow \mathsf{CauchyLimitSeal}^{\uparrow} \text{ or } \mathsf{Real}^{\uparrow}.$$

Equivalently, for every accepted packet

$$R = (q, w, r, d, s, h, c, p, n),$$

the consumer first reads the selected $\mathsf{StreamName}^{\uparrow}$ *finite window* w*, then the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* r*, then the* $\mathsf{DyadicRatCore}^{\uparrow}$ *comparison ledger* d*, then the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *seal boundary or* $\mathsf{Real}^{\uparrow}$ *terminal seal row* s*. The remaining rows* h, c, p, n *transport, replay, package, and name that same finite route, and no Real-facing witness is exported outside this four-object path.*

Proof. First apply consumer factorization, Definition 638.5. It places every accepting $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer on the packet rows w, r, d, s, h, c, p, n rather than on an external witness source.

The entrance is fixed by request-window admission, Definition 638.6. The selected finite window is w, so the route cannot begin at a quotient stream, host trace, selected real, or hidden selector.

The observation segment is fixed by regular readback admission, Definition 638.7, and RegSeq budget exhaustion, Definition 638.17. These identify r as the regular readback and d as the dyadic comparison ledger below the same selected window.

Finally use seal-budget exactness, Definition 638.8, and public NameCert export, Definition 638.21. The seal row s is the downstream CauchyLimitSeal or Real terminal face, while h, c, p, n only transport, replay, package, and name the already displayed route. □

Theorem 638.24 (Finite witness-route no-choice Real completion boundary)**.** *The L10 handoff in Definition 638.23 exports no quotient stream, hidden selector, countable-choice row, host real equality, ambient completeness row, selected host limit, independent dyadic ledger, or standard bridge route. Its Real-facing witness is only the public route through* w, r, d, s, h, c, p, n*.*

Proof. Begin with the choice-refusal boundary, Definition 638.22. It keeps every accepted Real-and-Completion consumer on the displayed finite rows and blocks countable-choice selectors, selected host limits, quotient stream equality, and independent real values between w and s.

Next apply seal boundary scope, Definition 638.19. The seal row is downstream of q, w, r, d, h, c, p, n, so it cannot be replaced by an ambient completeness row, host real equality, metric completion row, or standard bridge.

Finally use scoped support rows, Definition 638.13, together with public NameCert export, Definition 638.21. The certificate exposes only the finite packet and the four L10 faces, leaving no coordinate for the excluded quotient, selector, choice, host-equality, completeness, ledger, or bridge data. □

Theorem 638.25 (Finite witness-route cofinal-window factorization)**.** *Every cofinal-window read admitted by an accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet factors through the same displayed L10 route*

$$q, w, r, d, s, h, c, p, n.$$

The read enters through the $\mathsf{StreamName}^{\uparrow}$ *finite window* w*, obtains its* $\mathsf{RegSeqRat}^{\uparrow}$ *readback through* r*, checks its* $\mathsf{DyadicRatCore}^{\uparrow}$ *comparisons through* d*, and reaches the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *terminal row through* s*. It cannot bypass the* $\mathsf{StreamName}^{\uparrow}$ *or* $\mathsf{DyadicRatCore}^{\uparrow}$ *rows through a quotient stream, ambient real, hidden selector, independent ledger, or host completeness principle.*

Proof. The source of a cofinal-window read is controlled by the StreamName source lock, Definition 638.16. Any accepted Real-and-Completion read must expose q, w before r or d is readable.

The regular and dyadic layers are then controlled by regular readback admission, Definition 638.7, and RegSeq budget exhaustion, Definition 638.17. They force the cofinal readback through r and the comparison ledger through d below the same selected window.

The seal side is controlled by Real seal factorization, Definition 638.18, and seal boundary scope, Definition 638.19. The route reaches only the CauchyLimitSeal or Real row s carried by the packet.

Apply the L10 terminal four-object handoff, Definition 638.23, to assemble the same ordered path. The preceding source, readback, ledger, and seal constraints leave no bypass around the $\mathsf{StreamName}^{\uparrow}$ or $\mathsf{DyadicRatCore}^{\uparrow}$ rows. □

Theorem 638.26 (Finite witness-route CofinalModulusSeal handoff)**.** *Every accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *Real-facing packet that consumes a cofinal modulus route reads* $\mathsf{CofinalModulusSeal}^{\uparrow}$ *through the same selected* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal row,* BHist *packet, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row already carried by*

$$R = (q, w, r, d, s, h, c, p, n).$$

No cofinal modulus handoff may insert a quotient stream, selected host limit, countable-choice selector, ambient completeness row, detached window service, or separate completion operator between the finite witness route and the seal boundary.

Proof. Start with cofinal-window factorization, Definition 638.25. It places every cofinal-window read admitted by R on the displayed rows $q, w, r, d, s, h, c, p, n$, with entrance through w, readback through r, dyadic comparison through d, and seal access through s.

Next apply the L10 terminal four-object handoff, Definition 638.23. The Real-facing consumer therefore reaches the terminal side only through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$, while h, c, p, n transport, replay, package, and name that same finite route.

Finally use the CofinalModulusSeal L10 exit boundary, Definition 1198.45. Its public exit is the finite cofinal modulus route and it excludes quotient streams, selected host limits, countable choice, ambient completeness, detached windows, and separate completion operators. Combining the two finite route descriptions gives the stated handoff through the same packet rows and support structures. □

Theorem 638.27 (Finite witness-route Stream-RegSeq budget factorization)**.** *For an accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet*

$$R = (q, w, r, d, s, h, c, p, n),$$

the selected $\mathsf{StreamName}^{\uparrow}$ *window* w *and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* r *are the only budget-bearing entrance into the* $\mathsf{CofinalModulusSeal}^{\uparrow}$ *consumer route. Any Real-facing or completion-facing cofinal modulus read admitted by* R *must pass first through* q, w*, then through* r, d*, and then through the seal and support rows* s, h, c, p, n*.*

Proof. Use request-window admission, Definition 638.6. It makes q, w mandatory before a Real-and-Completion consumer reads any finite witness demand.

Then apply regular readback admission, Definition 638.7. The regular rational readback is r, the dyadic comparison ledger is d, and both sit below the same selected $\mathsf{StreamName}^{\uparrow}$ window rather than below quotient stream equality or a selected real value.

It remains to connect this entrance with the cofinal modulus route. The handoff theorem Definition 638.26 consumes $\mathsf{CofinalModulusSeal}^{\uparrow}$ through the same w, r, d, s, h, c, p, n rows. Thus the StreamName window and RegSeqRat readback are the only budget-bearing entry coordinates available to that route. □

Theorem 638.28 (Finite witness-route Real Completion readiness)**.** *The combined* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *route through* $\mathsf{CofinalModulusSeal}^{\uparrow}$ *is ready as a Phase Real and Completion paper target over* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*: its consumer surface is the finite packet* $q, w, r, d, s, h, c, p, n$ *together with the same* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. This readiness does not claim quotient stream equality, selected host limits, countable choice, ambient completeness, or a* StandardBridge *route.*

Proof. First combine the CofinalModulusSeal handoff, Definition 638.26, with Stream-RegSeq budget factorization, Definition 638.27. These results identify the selected window and readback entrance and keep the cofinal modulus consumer on the finite packet rows.

Now apply the no-choice Real completion boundary, Definition 638.24. It states that the L10 handoff exports no quotient stream, hidden selector, countable-choice row, host real equality, ambient completeness row, selected host limit, independent dyadic ledger, or standard bridge route.

The two positive factorization results and the refusal boundary together give a precise paper target for later Real-and-Completion formalization: the route is exposed through the displayed finite rows and support structures, while the excluded quotient, choice, host-limit, completeness, and bridge claims remain outside the chapter. □

Theorem 638.29 (Finite witness-route Real completion exact-boundary handoff)**.** *Let an accepted* $\mathsf{FiniteWitnessRoute}^{\uparrow}$ *packet*

$$R = (q, w, r, d, s, h, c, p, n)$$

be consumed by an accepted RealCompletionExactBoundaryUp *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N).$$

After the governing seal, classifier, witness-ledger, and budget rows L, K, J, S *of* B *have been displayed, the handoff identifies the route faces* w, r, d, s *with the exact-boundary faces* W, R, D, E*. The consumer remains on the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows of the two packets. It receives no quotient stream, host real equality, selected limit, countable-choice row, ambient completeness row, metric-completeness row, independent dyadic ledger, or standard bridge row.*

Proof. First use the L10 terminal four-object handoff, Definition 638.23. It places the finite route on the four displayed faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ through w, r, d, s, with h, c, p, n carrying the transport, continuation, provenance, and local naming rows.

Next apply the Real Completion readiness theorem, Definition 638.28, together with the no-choice Real completion boundary, Definition 638.24. These results keep the route on the same finite packet rows and exclude quotient streams, hidden selectors, countable-choice rows, host real equality, ambient completeness, selected host limits, independent dyadic ledgers, and bridge routes.

Finally consume the route through the exact-boundary packet. The four-face exactness theorem Definition 1120.6 identifies the only boundary faces after L, K, J, S as W, R, D, E. The terminal-consumer exactness theorem Definition 1120.13 keeps the consumer on H, C, P, N, and the no-completeness-escape theorem Definition 1120.14 refuses quotient, host-equality, selected-limit, choice, completeness, and bridge rows. Composing these route descriptions gives the stated identification of w, r, d, s with W, R, D, E under the displayed structural rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$.

Constructive story: A FiniteWitnessRoute$^{\uparrow}$ packet is generated from a finite witness request, selected StreamName$^{\uparrow}$ window, RegSeqRat$^{\uparrow}$ readback, DyadicRatCore$^{\uparrow}$ observation ledger, CauchyLimitSeal$^{\uparrow}$ or Real$^{\uparrow}$ seal row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 638.1, Definition 638.17, Definition 638.28, and Definition 638.29 bind the mature FiniteWitnessRoute$^{\uparrow}$ scope: the existing finite carrier, RegSeq budget exhaustion, completion-facing consumer surface, downstream route integration, and the StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, and Real$^{\uparrow}$ route through the same BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus(NameCert$_{\mathsf{FiniteWitnessRoute}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.FiniteWitnessRouteUp.FiniteWitnessRouteRegSeq\_budget\_exhaustion`

Bridge status: none

Origin: human

Not claimed: This chapter does not close RealUp completeness, uniqueness of completed limits, quotient stream equality, infinite traces, independent route ledgers, Lean verification, or bridge checking.

Upgrade path: No further paper-side theory grade remains; later work is optional bridge synchronization or downstream consumption of the same finite route.

Chapter 639

A Concrete Naming Certificate for CompilerOptimizationEndomorphism$^{\uparrow}$

The CompilerOptimizationEndomorphism$^{\uparrow}$ interface packages source-to-source compiler optimisation as a finite accepted endomorphism over one local NameCert row. It realizes the Cook compile-frontier route of chapter 9417 as a before/after compiler trace whose accepted rows can be read by the certificate compiler of chapter 473, the composition trace of chapter 679, the closed-term substitution compiler of chapter 540, and the cellular audit surfaces of chapter 934 and chapter 937. It consumes the compiler-morphism, certificate-compiler, classifier-morphism, BHist, hsame, Cont, Pkg, and local naming rows already used by compiler and decompiler certificates, but it does not import host program equality or a semantic optimisation theorem.

Falsifiable prediction: If the semantic-preservation row is removed, a frontier-improving packet can no longer certify that the before and after compiler traces decode to the same substrate observation row.

Independence witness: certificatecompiler, compilercompositiontrace, closedtermsubstitution-compiler, cellularautomaton, and cellulartrustsubstrate: none carries the joint before/after optimization endomorphism plus frontier-coordinate effect. CertificateCompiler exposes one compiler edge surface, CompilerCompositionTrace exposes sequential composition, ClosedTermSubstitutionCompiler exposes the closed syntactic boundary, CellularAutomaton exposes the local orbit ledger, and CellularTrustSubstrate exposes substrate trust rows; the optimization endomorphism alone binds the before trace, after trace, semantic-preservation row, and frontier-coordinate improvement in one NameCert packet.

Definition 639.1 (CompilerOptimizationEndomorphism carrier)**.** *A* CompilerOptimizationEndomorphism$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (S, B, A, G, E, L, F, H, C, P, N)$$

with the following displayed rows:

1. *S is the source* NameCert *row that is also the target naming row of the optimisation;*
2. *B is the before compiler trace row, read through the same stage order as the Cook pipeline stages of section 9417.2;*
3. *A is the after compiler trace row, displaying the optimized trace over the same source and target naming row;*

4. *G is an accepted endomorphism graph on S, displaying source-to-source compiler edges from B to A rather than a host optimiser function;*
5. *E is the same-source landing row recording that every displayed graph edge starts in the carrier of S and lands back in the same carrier;*
6. *L is the classifier-preservation row recording that source classifier membership is transported along the displayed endomorphism graph;*
7. *F is the frontier-coordinate row recording that the after trace improves a displayed compile-frontier coordinate while still decoding to the same substrate observation row as the before trace;*
8. *H records componentwise* hsame *preservation for the source row, before and after trace rows, graph row, same-source landing row, classifier row, frontier row, continuation rows, package row, and local naming row;*
9. *C is the displayed* Cont *route replay row, pairing every source continuation read used by G with its routed post-optimisation continuation inside the same certificate S;*
10. *P names the dependency surface* $\mathsf{NameCertMorphism}^{\uparrow}$, $\mathsf{CertificateCompiler}^{\uparrow}$, $\mathsf{CompilerCompositionTrace}^{\uparrow}$, $\mathsf{ClosedTermSubstitutionCompiler}^{\uparrow}$, $\mathsf{ClassifierMorphism}^{\uparrow}$, $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{CellularTrustSubstrate}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{CompilerOptimizationEndomorphism}^{\uparrow}}$ *row.*

The carrier is an accepted NameCert endomorphism packet. It has no coordinate for host program equality, denotational semantics, hidden cost improvement, global category laws, or a semantic optimiser correctness theorem outside the displayed semantic-preservation row.

Lean4 ✓ `BEDC.Derived.CompilerOptimizationEndomorphismUp.CompilerOptimizationEndomorphismTasteGate`
`single carrier alignment`

Theorem 639.2 (CompilerOptimizationEndomorphism NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CompilerOptimizat}}$ *surface for Definition 639.1 consists exactly of carrier admission, before-trace exposure through B, after-trace exposure through A, accepted same-source graph edges on S, source-to-source landing through E, classifier preservation through L, semantic-preservation and frontier-coordinate exposure through F,* hsame *preservation through H, displayed continuation replay through C, dependency provenance through P, and the local naming row N.*

Proof. Project the finite packet O. The source row, before trace, after trace, graph, same-source landing row, classifier-preservation row, frontier row, transport row, continuation replay row, provenance row, and local name are all displayed coordinates.

The endomorphism condition is also a projection. Both the edge source and edge target are read from the same NameCert row S, so no additional target certificate can be introduced by the obligation surface.

Classifier, semantic-preservation, hsame, and continuation obligations are read from L, F, H, and C. The package row P records the compiler, composition, closed-substitution, cellular, and trust-substrate dependencies, and N names the local certificate. Since no other coordinate is present, these rows exhaust the local NameCert obligations. □

Theorem 639.3 (CompilerOptimizationEndomorphism composition)**.** *Let*

$$O_1 = (S, B_1, A_1, G_1, E_1, L_1, F_1, H_1, C_1, P_1, N_1)$$

and

$$O_2 = (S, B_2, A_2, G_2, E_2, L_2, F_2, H_2, C_2, P_2, N_2)$$

be accepted CompilerOptimizationEndomorphism$^{\uparrow}$ *packets over the same source* NameCert *row* S*. Their displayed composite is the finite packet whose before trace is* B_1*, whose middle trace is* $A_1 = B_2$ *as a displayed compiler-composition handoff, whose after trace is* A_2*, whose graph row is the relational composite of* G_1 *and* G_2*, whose same-source landing row chains* E_1 *with* E_2*, whose classifier-preservation row chains* L_1 *with* L_2*, whose semantic-preservation and frontier-coordinate row chains* F_1 *with* F_2*, and whose* hsame*,* Cont*,* Pkg*, and local naming rows are obtained by replaying the displayed rows of* O_1 *and* O_2 *in order.*

Proof. Project the two accepted packets. Both expose the same source and target naming row S, so the middle landing of the first graph is exactly the source row consumed by the second graph.

Compose the graph rows relationally. A displayed source row is related to a displayed final row when a middle row of S is named by an edge of G_1 followed by an edge of G_2.

The landing, classifier, and frontier rows compose along the same middle row. The E_i rows keep both edges inside S, the L_i rows transport classifier membership first across G_1 and then across G_2, and the F_i rows keep the before and after traces semantically pinned to the same substrate observation while recording the displayed frontier-coordinate effect.

Finally replay the hsame, Cont, Pkg, and local naming rows in the displayed order. The result is again a finite endomorphism packet over S, with no appeal to an ambient optimiser semantics. □

Theorem 639.4 (CompilerOptimizationEndomorphism non-escape)**.** *Every consumer read of an accepted* CompilerOptimizationEndomorphism$^{\uparrow}$ *packet factors through*

$$S,\ B,\ A,\ G,\ E,\ L,\ F,\ H,\ C,\ P,\ N.$$

A request for host optimisation semantics, host program equality, denotational equivalence beyond the displayed semantic-preservation row, hidden cost improvement, a global compiler category law, or an undisplayed target certificate is outside the carrier and is not exported as NameCert evidence.

Proof. Read the request through the displayed continuation route C. If it asks for the source certificate, before trace, after trace, graph, same-source landing row, classifier-preservation row, semantic-preservation and frontier-coordinate row, hsame transport, continuation replay, package provenance, or local name, the carrier supplies exactly the corresponding coordinate.

Any other request leaves the tuple O. The carrier contains no coordinate for a semantic optimiser theorem outside F, host equality of programs, denotational model, hidden cost comparison, ambient category law, or separate target certificate.

Thus the accepted packet exports only the finite NameCert endomorphism surface. Optimisation correctness available to downstream compiler or decompiler certificates is the displayed preservation route through $B, A, G, E, L, F, H, C, P, N$, not a host-level theorem. □

Closure status for NameCert$_{\text{CompilerOptimizationEndomorphism}^{\uparrow}}$**.**

Constructive story: A CompilerOptimizationEndomorphism$^{\uparrow}$ packet is generated from finite BHist rows for one source NameCert, before and after compiler traces, an accepted endomorphism graph, same-source landing, classifier preservation, frontier-coordinate preservation, and structural rows. The optimisation route is replayed by Cont from before trace to after trace inside the same certificate surface, while hsame transports source, trace, graph, landing, classifier, and frontier rows componentwise. Pkg records the compiler, composition, substitution, classifier, cellular, and trust-substrate dependencies. Thus optimization correctness is the displayed preservation row inside the packet, not host program equality or denotational semantics.

Theory closure: TheoryGate(NameCert$_{\text{CompilerOptimizationEndomorphism}^{\uparrow}}$, seed)

Scope closed: This chapter binds the endomorphism carrier, NameCert obligations, composition theorem, and non-escape boundary for $\mathsf{CompilerOptimizationEndomorphism}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CompilerOptimizationEndomorphism}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim host optimization semantics, program equality, hidden cost improvement, global compiler category laws, or an undisplayed target certificate.

Upgrade path: Obligation closure requires Lean encodings of the endomorphism carrier, same-source composition, preservation rows, and non-escape theorem.

Chapter 640

A Concrete Naming Certificate for $\mathsf{ObserverKernelTrace}^{\uparrow}$

The $\mathsf{ObserverKernelTrace}^{\uparrow}$ surface realizes observer identity as a finite trace packet rather than as a subject behind the trace. It packages history rows, history-sameness transport, continuation reads, licensed probe and signature observations, provenance, and a local naming row into one NameCert boundary. A consumer may compare observer traces through the displayed packet, but it receives no observer-substance coordinate and no host equality of subjects.

$\mathsf{ObserverKernelTrace}^{\uparrow}$ supplies the no-subject finite trace surface consumed by chapter 477 before pairwise observer-history comparison is licensed.

Definition 640.1 (ObserverKernelTrace carrier)**.** *An* $\mathsf{ObserverKernelTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (T, H, C, B, S, L, P, N)$$

with the following displayed rows:

1. *T is the finite observer-trace ledger, whose entries are* BHist *rows recording the histories available to an observer-facing consumer;*
2. *H records componentwise* hsame *transport for trace rows, observation rows, licensed readback rows, provenance rows, and the local naming row;*
3. *C records the displayed* Cont *routes by which a consumer reads trace rows, transports, probe bundles, signature events, provenance, and local naming;*
4. *B is the finite* ProbeBundle *observation row attached to the same trace ledger;*
5. *S is the* SigRel *observation row attached to the bundled probe reads;*
6. *L is the no-subject ledger recording that every exported observer read is one of the displayed trace, transport, route, probe, signature, provenance, or local naming rows;*
7. *P is the* Pkg *provenance over T, H, C, B, S, L;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverKernelTrace}^{\uparrow}}$ *row.*

The carrier has no coordinate for an observer-substance type, subject identity row, hidden owner of the observations, or host equality principle outside BHist*,* hsame*,* Cont*,* ProbeBundle*,* SigRel*,* Pkg*, and* NameCert*.*

Lean4 ✓ `BEDC.Derived.ObserverKernelTraceUp.ObserverKernelTraceTasteGate single carrier alignment`

Theorem 640.2 (ObserverKernelTrace NameCert obligations)**.** *For the carrier of Definition 640.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverKernelTrace}^{\uparrow}}$ *surface consists exactly of carrier admission for* O*, trace-ledger stability, componentwise* hsame *transport, displayed* Cont *route replay, licensed* ProbeBundle *and* SigRel *observation exactness, no-subject ledger exactness,* Pkg *provenance, and local naming exactness.*

Lean4 ✓ `BEDC.Derived.ObserverKernelTraceUp.ObserverKernelTraceNameCert obligations`

Proof. Carrier admission is projection from the finite packet O. The trace ledger T, transports H, routes C, probe row B, signature row S, no-subject ledger L, package row P, and local naming row N are the displayed coordinates of the carrier.

The stability and replay obligations are componentwise. Transport through H preserves the trace and observation rows, while the routes in C replay only the listed reads.

Probe and signature exactness come from B and S, and the no-subject ledger L records every exported observer read before it reaches the consumer. Since the carrier has no coordinate beyond T, H, C, B, S, L, P, N, the local naming certificate is exhausted by the stated finite obligations. □

Theorem 640.3 (ObserverKernelTrace no-subject non-escape)**.** *Every accepted* $\mathsf{ObserverKernelTrace}^{\uparrow}$ *packet exposes observer identity only through its finite* BHist *trace rows,* hsame *transport,* Cont *routes, licensed* ProbeBundle *readback, licensed* SigRel *readback, no-subject ledger,* Pkg *provenance, and local* NameCert *row. It exports no observer-substance carrier, subject identity coordinate, hidden owner of the trace, or host equality of subjects.*

Lean4 ✓ `BEDC.Derived.ObserverKernelTraceUp.ObserverKernelTrace non escape`
↪ variant `BEDC.Derived.ObserverKernelTraceUp.ObserverKernelTrace no subject non escape`

Proof. Project the accepted packet and inspect the coordinates of Definition 640.1. The only rows available to a consumer are T, H, C, B, S, L, P, N.

Apply the NameCert obligations from Definition 640.2. They identify transport, route replay, probe readback, signature readback, no-subject ledgering, package provenance, and local naming as the whole certificate surface.

A requested subject carrier would require a coordinate outside the displayed tuple. Because no such coordinate is part of the packet, the accepted boundary cannot export observer-substance, subject identity, hidden ownership, or host equality data. □

Theorem 640.4 (ObserverKernelTrace public export boundary)**.** *The public export of an accepted* $\mathsf{ObserverKernelTrace}^{\uparrow}$ *packet is exactly the finite route*

$$T, H, C, B, S, L, P, N.$$

It exports trace rows, componentwise transport, displayed continuation routes, probe bundles, signature observations, the no-subject ledger, package provenance, and local naming, and it exports no subject carrier, host equality of subjects, hidden owner, or global observation equivalence.

Lean4 ✓ `BEDC.Derived.ObserverKernelTraceUp.ObserverKernelTrace public export boundary`

Proof. Project the carrier of Definition 640.1. Its displayed rows are precisely T, H, C, B, S, L, P, N, so the public surface starts from this finite tuple.

Apply the NameCert obligations of Definition 640.2. They identify trace-ledger stability, componentwise hsame transport, displayed Cont replay, probe and signature exactness, no-subject ledgering, package provenance, and local naming as the whole certificate route.

Finally use Definition 640.3. A subject carrier, host equality of subjects, hidden owner, or global observation equivalence would require a coordinate absent from the carrier, so the public export is exactly the displayed route. □

Theorem 640.5 (ObserverKernelTrace public bridge route)**.** *For an accepted* $\mathsf{ObserverKernelTrace}^{\uparrow}$ *packet, the public bridge route from the packet to downstream observer-history consumers is exactly*

$$T, H, C, B, S, L, P, N.$$

The probe-bundle row B and signature row S are visible before any observer-history identity consumer reads the trace, and the route carries no subject carrier, host subject equality, hidden owner, or observer-substance coordinate outside the displayed packet.

Lean4 ✓ `BEDC.Derived.ObserverKernelTraceUp.ObserverKernelTrace public bridge route`

Proof. Project the accepted carrier of Definition 640.1. Its finite rows are T, H, C, B, S, L, P, N, and no additional subject coordinate is part of the carrier.

Use Definition 640.4 to identify the public export with the same finite tuple. The probe and signature rows B and S are listed in that export before the no-subject ledger, provenance, and local naming rows are consumed by downstream observers.

Finally apply Definition 640.3. Any subject carrier, host subject equality, hidden owner, or observer-substance coordinate would have to be a packet row outside T, H, C, B, S, L, P, N, which the carrier and public export do not contain. □

Theorem 640.6 (ObserverKernelTrace mature consumer coverage)**.** *Every ObserverHistoryIdentity consumer and every observer-history consumer of an accepted* $\mathsf{ObserverKernelTrace}^{\uparrow}$ *packet receives exactly the displayed trace ledger T, componentwise transport row H,* Cont *replay row C,* ProbeBundle *row B,* SigRel *row S, no-subject ledger L,* Pkg *provenance row P, and local* $\mathsf{NameCert}_{\mathsf{ObserverKernelTrace}^{\uparrow}}$ *row N. The consumer receives no subject-substance coordinate, host-subject equality row, hidden owner row, or global observation-equivalence row.*

Lean4 ✓ `BEDC.Derived.ObserverKernelTraceUp.ObserverKernelTrace mature consumer coverage`

Proof. Project the accepted carrier of Definition 640.1. The available rows are exactly T, H, C, B, S, L, P, N, and the definition lists no subject-substance or host-subject equality coordinate.

Apply Definition 640.2. It identifies trace-ledger stability, componentwise transport, displayed replay, licensed probe and signature observations, no-subject ledgering, provenance, and local naming as the complete certificate surface.

Use Definition 640.4 and Definition 640.5. The public export and bridge route both expose the same finite tuple before any ObserverHistoryIdentity or observer-history consumer reads the packet.

Finally invoke Definition 640.3. A subject-substance coordinate or host-subject equality row would have to be outside the displayed tuple, so mature consumer coverage is exactly the finite observer-kernel trace surface stated above. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverKernelTrace}^{\uparrow}}$**.**

Constructive story: An $\mathsf{ObserverKernelTrace}^{\uparrow}$ packet is generated from finite BHist trace rows, componentwise hsame transport, displayed Cont routes, licensed ProbeBundle and SigRel observations, a no-subject ledger, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverKernelTrace}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 640.1, Definition 640.2, Definition 640.3, Definition 640.4, Definition 640.5, and Definition 640.6 bind the carrier, NameCert obligation rows, no-subject non-escape surface, public export boundary, public bridge route, and downstream observer-history consumer coverage for observer-kernel traces.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverKernelTrace}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close a Lean theorem, a host observer model, subject identity, hidden ownership, global observation equivalence, or equality of subjects.

Upgrade path: Bridge checking requires a Lean bridge target for the same trace, probe, signature, transport, replay, provenance, and local NameCert packet.

Chapter 641

A Concrete Naming Certificate for $\mathsf{CauchyModulusExtraction}^{\uparrow}$

The $\mathsf{CauchyModulusExtraction}^{\uparrow}$ packet records the finite observation-budget surface that a Real-completeness consumer uses before applying the diagonal route of chapter 9238. It turns a regular Cauchy input over $\mathsf{RegSeqRat}^{\uparrow}$ into explicit witness schedules, selected stream windows, and dyadic tolerance rows, while keeping the resulting modulus read inside displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{NameCert}$ data.

It consumes the finite modulus-indexed schedule exposed by chapter 593: $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$ supplies the scheduled $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ family row, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{Real}^{\uparrow}$ seal handoff that this chapter repackages as an extracted modulus.

Definition 641.1 (Cauchy modulus-extraction carrier)**.** *A* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N)$$

with the following displayed rows:

1. *E is the positive tolerance request read through the* $\mathsf{Rat}^{\uparrow}$ *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *precision ledgers;*
2. *B is the finite observation budget selected for the requested tolerance and diagonal scale;*
3. *W is the* $\mathsf{StreamName}^{\uparrow}$ *window family inspected under that budget;*
4. *S is the* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule row naming the regular Cauchy witnesses consumed by the diagonal route;*
5. Mu *is the extracted modulus row, recording the natural threshold produced from E, B, W, S;*
6. *Q is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *comparison and half-radius ledger used to justify the threshold;*
7. *H records componentwise* hsame *transports for the tolerance request, budget, window family, schedule row, modulus row, dyadic ledger, package provenance, and local name;*
8. *C records the displayed* Cont *routes from tolerance to budget, from budget to windows, from windows to schedule reads, from schedule reads to* Mu*, and from* Mu *to the* $\mathsf{Real}^{\uparrow}$ *diagonal consumer;*
9. *P is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyModulusExtraction}^{\uparrow}}$ *row.*

The classifier compares accepted packets only after transporting the same tolerance request, finite budget, inspected windows, schedule row, extracted modulus, and dyadic ledger to a common Real-completion surface. The carrier contains no host-level limit, no quotient stream equality, no ambient completeness theorem, and no modulus chosen outside the displayed finite budget.

Theorem 641.2 (Cauchy modulus-extraction NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CauchyModulusExtraction}^{\uparrow}}$ *surface for Definition 641.1 consists exactly of five finite obligations:*

1. *carrier admission for the displayed packet* $M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N)$*;*
2. *budget exposure stating that* B *is the only finite observation budget available for the tolerance request* E*;*
3. *schedule extraction stating that* W *and* S *are read through* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *rows before the modulus row* Mu *is exported;*
4. *dyadic soundness stating that* Q *supplies the positive half-radius and comparison ledgers needed by the extracted threshold;*
5. *ledger exactness stating that all transport, continuation, package, and naming reads factor through* H, C, P, N *and no external modulus selector is present.*

Lean4 ✓ `BEDC.Derived.CauchyModulusExtractionUp.CauchyModulusExtractionCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 641.1. The tuple lists the tolerance request, finite budget, inspected windows, regular Cauchy schedule, extracted modulus, dyadic ledger, transports, continuations, provenance, and local name.

Budget exposure uses the row B. A consumer may inspect only the finite windows listed by that budget, so the modulus row is tied to displayed observation data rather than to an ambient convergence choice.

Schedule extraction uses W and S. The $\mathsf{StreamName}^{\uparrow}$ windows identify the inspected rational observations, while the $\mathsf{RegSeqRat}^{\uparrow}$ schedule row records the regular Cauchy witnesses consumed by the diagonal Real-completion route.

Dyadic soundness is the role of Q. It stores the half-radius split and comparison ledger that justify the threshold recorded in Mu for the requested tolerance.

Finally, H, C, P, N repack the same rows under componentwise transport, route replay, package provenance, and local naming. Since no remaining coordinate contains an external modulus selector, these five obligations exhaust the local certificate surface. □

Theorem 641.3 (Cauchy modulus-extraction budget-window coverage)**.** *For an accepted* CauchyModulusExtraction *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

every tolerance request E *that is accepted by the packet is routed through the finite budget row* B *before any* $\mathsf{StreamName}^{\uparrow}$ *window in* W *is inspected and before any* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule row* S *is used to export* Mu*. Thus the budget-window surface covers the whole route from requested tolerance to inspected stream data.*

Proof. Project the accepted carrier to the displayed tuple. The rows available between the tolerance request and the modulus export are exactly the finite budget B, the window family W, and the schedule row S, together with the dyadic and certificate rows used later in the packet.

Use the NameCert obligations of Definition 641.2. Budget exposure identifies B as the only finite observation budget available for E, and schedule extraction states that W and S are read before Mu is exported.

It follows that a consumer cannot inspect a StreamName window or use a RegSeqRat schedule directly from the tolerance request. The accepted route first passes through B, then through W and S, so the finite budget-window surface covers the route to the extracted modulus. □

Theorem 641.4 (Cauchy modulus-extraction window induction)**.** *For an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

suppose a finite budget row B^+ *extends* B *by one displayed* $\mathsf{StreamName}^{\uparrow}$ *window while preserving the tolerance request* E*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule row* S*, the dyadic ledger row* Q*, and the continuation route from* Mu *to the* $\mathsf{Real}^{\uparrow}$ *consumer. Then the extracted modulus route through*

$$E, B^+, W, S, \mathsf{Mu}, Q, H, C, P, N$$

remains accepted: the added window is consumed inside the finite budget-window surface, and the modulus export still passes through the same dyadic ledger, transport, replay, provenance, and local naming rows.

Proof. Use finite-window induction on the displayed extension from B to B^+. The base case is the budget-window coverage theorem, Definition 641.3, which places the accepted route through B, W, S before Mu is exported.

For the one-window step, read the added $\mathsf{StreamName}^{\uparrow}$ window as another row of the same finite observation budget. Because B^+ preserves E, S, Q and the continuation route to the $\mathsf{Real}^{\uparrow}$ consumer, schedule extraction still reads the window family through W and the regular Cauchy witnesses through S before the modulus row is exposed.

Apply dyadic ledger positivity from Definition 641.5. The threshold exported by Mu is justified by the same positive half-radius and comparison ledger Q, so the additional window supplies no second threshold selector.

Finally use the Real seal boundary of Definition 641.6. The completion-facing handoff remains downstream of $B^+, W, S, Q, \mathsf{Mu}, H, C, P, N$ and still has no coordinate for quotient stream equality, selected limits, host real equality, trichotomy, ambient completeness, or an external modulus choice. □

Theorem 641.5 (Cauchy modulus-extraction dyadic ledger positivity)**.** *For an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

the dyadic ledger row Q *supplies the positive half-radius and comparison rows used by the extracted modulus row* Mu*. No threshold can be exported from the packet unless that export is justified through the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* Q*.*

Lean4 ✓ `BEDC.Derived.CauchyModulusExtractionUp.CauchyModulusExtractionCarrier dyadic ledger positivity`

Proof. Project the carrier. The displayed row Q is the packet coordinate assigned to the $\mathsf{DyadicRatCore}^{\uparrow}$ comparison and half-radius ledger, and Mu is the only extracted modulus row.

Apply dyadic soundness from Definition 641.2. That obligation binds the positive half-radius split and comparison data needed by the threshold to Q.

Since the carrier contains no second dyadic ledger and no external threshold selector, any exported threshold must use the same Q row. Therefore the positivity and comparison data required by Mu are supplied by the displayed ledger and cannot be bypassed inside the packet. □

Theorem 641.6 (Cauchy modulus-extraction RealUp seal boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing consumer of an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N)$$

reaches the RealUp seal only after the finite budget B, StreamName windows W, RegSeqRat schedule S, dyadic ledger Q, and extracted modulus row Mu *have been displayed by the same packet. The seal-facing route imports no quotient stream equality, host real equality, trichotomy, selected limits, ambient completeness, or threshold chosen outside the displayed rows.*

Proof. Project the carrier and read the continuation row C. The displayed routes go from tolerance to budget, from budget to windows, from windows to schedule reads, from schedule reads to Mu, and from Mu to the $\mathsf{Real}^{\uparrow}$ diagonal consumer.

Use budget-window coverage to place B, W, S before the extracted modulus, and use dyadic ledger positivity to place Q before the threshold export. These rows account for the data consumed by the RealUp-facing route before the seal is reached.

Finally apply ledger exactness from Definition 641.2. The carrier has no coordinate for quotient stream equality, host real equality, trichotomy, selected limits, ambient completeness, or an outside threshold selector, so the RealUp seal boundary is exactly the displayed finite packet boundary. □

Theorem 641.7 (Cauchy modulus-extraction budget soundness)**.** *For an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

the extracted modulus row Mu *is sound for every diagonal Real-completion consumer that reads the same finite budget B,* $\mathsf{StreamName}^{\uparrow}$ *windows W,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness schedule S, and dyadic comparison ledger Q. The consumer receives a natural threshold justified by the displayed observation budget and receives no host-selected convergence modulus, quotient stream representative, or ambient completeness witness.*

Proof. Read the tolerance request E and the budget row B. The budget determines the finite observation family available to the extraction packet.

Read the window and schedule rows W, S. They identify the StreamName observations and RegSeqRat witnesses that the real-completeness diagonal route may consume for the requested scale.

Use the dyadic ledger Q to justify the half-radius comparisons attached to those reads. The extracted row Mu records the resulting natural threshold and is transported by H along the continuation routes in C.

The package and naming rows P, N expose exactly that finite packet. Because the carrier has no coordinate for an external modulus, a host-selected limit, or quotient equality, the handoff to the $\mathsf{Real}^{\uparrow}$ diagonal consumer is precisely the displayed budget-sound modulus row. □

Theorem 641.8 (Cauchy modulus-extraction budget threshold uniqueness)**.** *For an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

the displayed rows E, B, W, S, Q determine the exported threshold row Mu *for every consumer that reads the same finite budget. No second modulus row, host-selected convergence modulus, quotient stream representative, or ambient completeness witness can determine a different threshold inside the packet.*

Proof. Project the displayed packet. The only tolerance request is E, the only observation budget is B, the only window family is W, the only regular schedule is S, and the only dyadic comparison ledger is Q.

Use the NameCert obligations. Budget exposure fixes B as the source of the observations, schedule extraction fixes W, S before the modulus is exported, and dyadic soundness fixes Q as the ledger attached to the threshold.

Apply budget soundness from Definition 641.7. Since the consumer receives Mu only as the threshold justified by those finite rows and the carrier has no second selector coordinate, the threshold exported inside the packet is unique for that budget route. □

Theorem 641.9 (Cauchy modulus-extraction StreamName RegSeqRat factorization)**.** *Every consumer route from the tolerance request E to the extracted modulus row* Mu *factors through the finite* $\mathsf{StreamName}^{\uparrow}$ *window row W and the* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule row S of the same packet*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N).$$

The factorization reads the budget row B first, then the window and schedule rows, then the dyadic ledger Q, and only then exports Mu*.*

Proof. Begin with carrier admission. The tuple presents B, W, S, Q as the only finite observation, window, schedule, and dyadic comparison rows available before Mu.

Use budget exposure and schedule extraction from Definition 641.2. These clauses force the route from E to the modulus to pass through the finite budget and then through the StreamName and RegSeqRat rows.

Finally use budget soundness. The Real-completion consumer receives the modulus only after the dyadic ledger has justified the threshold for those rows, so the StreamName and RegSeqRat factorization is part of every accepted route to Mu. □

Theorem 641.10 (Cauchy modulus-extraction RealUp seal non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal-facing consumer of an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *packet reads the same finite budget, window, schedule, dyadic, and modulus rows*

$$B, W, S, Q, \mathsf{Mu}$$

before reaching the RealUp handoff. The packet exports no seal-facing route through quotient stream equality, selected limits, host real equality, trichotomy, ambient completeness, or an external modulus selector.

Proof. Project the carrier and the continuation row C. The displayed continuation routes include the path from tolerance to budget, from budget to windows, from windows to schedule reads, from schedule reads to Mu, and from Mu to the $\mathsf{Real}^{\uparrow}$ diagonal consumer.

Apply the StreamName-RegSeqRat factorization and budget-threshold uniqueness established above. They show that the consumer reaches the same exported modulus only through B, W, S, Q.

Finish with ledger exactness from the NameCert obligations and budget soundness from Definition 641.7. Since the finite packet has no coordinate for quotient equality, selected limits, host real equality, trichotomy, ambient completeness, or an outside selector, no RealUp seal-facing consumer can escape that route. □

Theorem 641.11 (Cauchy modulus-extraction budget monotonicity)**.** *For an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

let B^+ *be a displayed finite budget row containing the same tolerance request* E*, the same* $\mathsf{StreamName}^{\uparrow}$ *windows needed by* W*, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule row* S*, and the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *comparison ledger* Q*. Then the extracted modulus row* Mu *remains sound for every* $\mathsf{Real}^{\uparrow}$ *diagonal consumer that reads through* B^+*. The larger displayed budget may contain additional visible observations, but it cannot change the extracted threshold, introduce a second modulus selector, or supply quotient stream equality, a host limit, or ambient completeness.*

Proof. Project the accepted carrier to the tuple $E, B, W, S, \mathsf{Mu}, Q, H, C, P, N$. The local rows identify the tolerance request, the original finite budget, the inspected windows, the regular Cauchy schedule, the extracted threshold, and the dyadic comparison ledger.

Apply the NameCert obligations of Definition 641.2. Budget exposure fixes the displayed observation source for E, schedule extraction fixes W, S before Mu is exported, and dyadic soundness fixes Q as the comparison ledger attached to the threshold.

Now read the consumer through B^+. By assumption, the rows of B^+ contain exactly the tolerance request, window reads, schedule row, and dyadic ledger already used by B, W, S, Q for the extracted threshold.

Use budget soundness from Definition 641.7 on those common rows. The row Mu is therefore still the threshold justified by the displayed budget data, and the consumer receives it without any host-selected convergence modulus or quotient stream representative.

The extra rows of B^+ are exhausted by coordinate inspection. They are not read by Mu, have no selector coordinate in the carrier, and do not add a host limit or ambient completeness witness. Hence enlarging the finite observation budget preserves the same budget-sound modulus handoff. □

Theorem 641.12 (Cauchy modulus-extraction transport stability)**.** *For an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

any componentwise hsame *transport of* $E, B, W, S, \mathsf{Mu}, Q, H, C, P, N$ *preserves the extracted modulus row* Mu *and preserves the finite budget source* B *from which that row is read. The transported packet exports the same tolerance request, finite observation budget, StreamName windows, RegSeqRat schedule, dyadic comparison ledger, continuation routes, package provenance, and local naming row, and it exports no host-selected convergence modulus.*

Proof. Project the accepted carrier to its displayed tuple. The row H records componentwise transport for the tolerance request, budget, windows, schedule row, modulus row, dyadic ledger, provenance, and local name.

Apply the NameCert obligations of Definition 641.2. Carrier admission fixes the tuple, budget exposure fixes B as the finite source for the tolerance request, schedule extraction fixes W, S before Mu is exported, and ledger exactness routes all transport through H, C, P, N.

Finally use budget soundness from Definition 641.7. The Real-completion handoff receives Mu only as the threshold justified by the displayed budget and schedule rows, so componentwise transport preserves both the modulus row and its finite budget source. □

Theorem 641.13 (Cauchy modulus-extraction selector stability)**.** *For an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

componentwise hsame *transport of the tolerance request E, finite budget B,* $\mathsf{StreamName}^{\uparrow}$ *windows W,* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule S,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger Q, and modulus row* Mu *preserves the same selected modulus for any* $\mathsf{Real}^{\uparrow}$ *diagonal consumer. The transported consumer reads the same finite selector surface and receives no external modulus selector, quotient stream representative, selected limit, host real equality, or ambient completeness witness.*

Proof. Start with the carrier definition. The selector data visible before the $\mathsf{Real}^{\uparrow}$ handoff are exactly $E, B, W, S, Q, \mathsf{Mu}$, and the transport row H is componentwise over those coordinates.

Apply the NameCert obligations and budget soundness. Carrier admission fixes the tuple, budget exposure fixes the finite source B, schedule extraction fixes W, S, dyadic soundness fixes Q, and budget soundness identifies Mu as the threshold justified by those displayed rows.

Use transport stability from Definition 641.12. Since the transported packet preserves both the modulus row and the finite budget source, the selected modulus seen by a diagonal consumer is the same selected row Mu.

Finally apply the StreamName–RegSeqRat factorization and the $\mathsf{Real}^{\uparrow}$ seal non-escape theorem. The consumer reaches the handoff only through the finite budget, stream windows, regular schedule, dyadic ledger, and exported modulus, so no outside selector or completion object can alter the selected threshold. □

Theorem 641.14 (Cauchy modulus-extraction finite-budget handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *completion-facing handoff from an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *packet factors through the finite budget row B before reading the* $\mathsf{StreamName}^{\uparrow}$ *windows W, the* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule S, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *comparison ledger Q, and the exported modulus row* Mu*. Thus the completion-facing route is a finite-budget handoff rather than a direct appeal to host convergence, quotient stream equality, selected limits, trichotomy, or ambient completeness.*

Proof. Read the accepted packet through Definition 641.1. The continuation row C lists the route from tolerance to budget, from budget to windows, from windows to schedule reads, from schedule reads to Mu, and from Mu to the $\mathsf{Real}^{\uparrow}$ diagonal consumer.

Apply the NameCert obligations and budget soundness. Budget exposure makes B the only finite observation source for E, while budget soundness ties the exported modulus to the displayed budget, windows, schedule, and dyadic ledger.

Next use the StreamName–RegSeqRat factorization. It places W and S after the budget row and before the modulus export, and it places Q as the dyadic ledger required by the extracted threshold.

Finish with the $\mathsf{Real}^{\uparrow}$ seal non-escape theorem. Since every seal-facing route reads through B, W, S, Q, Mu and the carrier has no coordinate for host convergence or quotient stream equality, every completion-facing handoff factors through the finite budget before the remaining rows are consumed. □

Theorem 641.15 (Cauchy modulus-extraction real diagonal handoff)**.** *Any* $\mathsf{Real}^{\uparrow}$ *diagonal or completion consumer of an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N)$$

may read the extracted modulus row Mu *only after the* $\mathsf{StreamName}^{\uparrow}$ *windows W, the* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule S, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *comparison ledger Q, and the finite budget row B have been displayed through the same local packet.*

Proof. Project the accepted carrier. The rows available before the modulus handoff are the tolerance request E, finite budget B, window family W, schedule row S, and dyadic ledger Q.

Apply the NameCert obligations of Definition 641.2. Budget exposure places B before any window read, schedule extraction places W, S before the export of Mu, and dyadic soundness places Q as the comparison ledger attached to the threshold.

Use budget soundness from Definition 641.7. Since the handoff to the diagonal consumer is precisely the displayed budget-sound modulus row, any $\mathsf{Real}^{\uparrow}$ completion route reads Mu only after the windows, schedule, dyadic comparison ledger, and finite budget rows have appeared. □

Theorem 641.16 (Cauchy modulus-extraction ledger exactness)**.** *For an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

the ledger is exact for the route from tolerance request to finite budget, StreamName windows, RegSeqRat schedule, extracted modulus, dyadic comparison ledger, and local NameCert:

$$E, B, W, S, \mathsf{Mu}, Q, H, C, P, N.$$

It excludes quotient stream equality, host real equality, selected limits, trichotomy, ambient completeness, and any modulus selector not displayed by the finite packet.

Proof. Project the accepted carrier to the ten displayed rows. The route begins at the tolerance request E and reaches the finite budget B, windows W, schedule S, extracted modulus Mu, dyadic ledger Q, transports H, routes C, provenance P, and local name N.

Apply the NameCert obligations of Definition 641.2. They bind carrier admission, budget exposure, schedule extraction, dyadic soundness, and transport, continuation, package, and naming reads to the same finite tuple.

Finally use budget soundness from Definition 641.7. The exported modulus is justified by the displayed observation budget and carries no coordinate for quotient stream equality, host real equality, selected limits, trichotomy, ambient completeness, or an outside selector, so the ledger is exact. □

Theorem 641.17 (Cauchy modulus-extraction route exactness)**.** *For an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

every accepted consumer route from the tolerance request E to the extracted modulus row Mu *factors through exactly the displayed rows*

$$E, B, W, S, \mathsf{Mu}, Q, H, C, P, N.$$

Thus the route passes through the finite budget, StreamName window family, RegSeqRat schedule row, dyadic comparison ledger, componentwise transports, continuation routes, package provenance, and local naming row, and it has no additional Real-completion coordinate.

Proof. Project the accepted carrier to its displayed tuple. The carrier presentation supplies the tolerance request, budget row, inspected windows, schedule row, extracted modulus, dyadic ledger, transports, continuations, provenance, and local name.

Apply the local NameCert obligations of Definition 641.2. Carrier admission identifies the tuple, budget exposure fixes B, schedule extraction fixes W, S, dyadic soundness fixes Q, and ledger exactness fixes H, C, P, N as the only remaining certificate rows.

Finally use budget soundness from Definition 641.7. Since the handoff to the diagonal consumer is the displayed budget-sound modulus row and the carrier contains no extra selector, any accepted route from E to Mu is exactly the route through those ten rows. □

Theorem 641.18 (Cauchy modulus-extraction window schedule exhaustion)**.** *For an accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

the inspected $\mathsf{StreamName}^{\uparrow}$ *window family* W *and the* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule row* S *exhaust all schedule data available to a Real-completion diagonal consumer. The consumer may use the StreamName surface of chapter 126, the RegSeqRat schedule surface of chapter 301, and the Real carrier surface of chapter 38, but within this extraction packet those surfaces are reached only through* W *and* S*.*

Proof. The carrier first exposes the finite budget B attached to the tolerance request E. This budget bounds which StreamName observations and regular Cauchy witnesses are visible to the diagonal consumer.

The window row W is the only StreamName row in the packet. By the StreamName naming surface cited in chapter 126, window reads available to the consumer are therefore the reads displayed in W.

The schedule row S is the only RegSeqRat schedule row in the packet. By the RegSeqRat naming surface cited in chapter 301, regular Cauchy witness reads available to the consumer are therefore the reads displayed in S.

The Real carrier surface cited in chapter 38 receives the diagonal handoff through the continuation rows in C. Because those continuations start from the displayed budget, windows, and schedule row, no further schedule data can be introduced at the Real-completion boundary. □

Theorem 641.19 (Cauchy modulus-extraction dyadic ledger non-escape)**.** *For an accepted* CauchyModulusExtractio *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

the dyadic comparison row Q *is the only positive half-radius and comparison ledger exported to the modulus row* Mu*. The extraction packet exports no quotient stream, host-selected convergence modulus, selected limit, host real equality, or ambient completeness witness.*

Proof. Read the dyadic row Q from the carrier. It is the coordinate assigned to the positive half-radius split and to the comparisons used by the extracted threshold.

Apply dyadic soundness from Definition 641.2. That obligation identifies Q as the ledger needed by Mu and ties it to the displayed budget, windows, and schedule row.

Use budget soundness from Definition 641.7 to inspect the exported handoff. The consumer receives the natural threshold justified by Q and by the finite rows B, W, S.

The carrier has no coordinate for a quotient stream, host-selected convergence modulus, selected limit, host real equality, or ambient completeness witness. Hence none of those objects can escape through the modulus row. □

Theorem 641.20 (Cauchy modulus-extraction budget fiber exhaustion)**.** *For an accepted* CauchyModulusExtractio *packet*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

a $\mathsf{Real}^{\uparrow}$ *diagonal or completion consumer lies in the budget fiber over the displayed tolerance request* E *and finite budget* B *exactly when its route first reads* B*, then the* $\mathsf{StreamName}^{\uparrow}$ *windows* W *and*

$\mathsf{RegSeqRat}^{\uparrow}$ *schedule* S*, then the* $\mathsf{DyadicRatCore}^{\uparrow}$ *comparison ledger* Q*, and exports* Mu *only through* H, C, P, N*. No quotient stream equality, host real equality, selected limit, trichotomy, ambient completeness, or external modulus selector supplies another element of that budget fiber.*

Proof. Start with a consumer lying in the displayed budget fiber. Apply the NameCert obligations of Definition 641.2 to identify the accepted carrier rows, the exposed budget, the schedule extraction surface, the dyadic soundness row, and the transport, continuation, package, and naming rows.

The finite route is then forced by budget soundness from Definition 641.7 and route exactness from Definition 641.17. The consumer first reads B, then uses the StreamName–RegSeqRat factorization through W and S, then reads the dyadic ledger Q before exporting Mu through H, C, P, N.

Conversely, any route with exactly that read order is accepted by the same packet because each row is one of the displayed NameCert rows and the handoff to the Real diagonal surface uses the continuation rows already present in C.

It remains to exclude other fiber elements. Apply window-schedule exhaustion from Definition 641.18 and dyadic-ledger non-escape from Definition 641.19. These results leave no coordinate through which quotient stream equality, host real equality, selected limits, trichotomy, ambient completeness, or an external modulus selector can enter the budget fiber. □

Theorem 641.21 (Cauchy modulus-extraction obligation closure package)**.** *For an accepted* $\mathsf{CauchyModulusExtract}$ *packet*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

the $\mathsf{NameCert}_{\mathsf{CauchyModulusExtraction}^{\uparrow}}$ *obligation package consumed by the* $\mathsf{Real}^{\uparrow}$ *completion route is exactly the carrier row* E*, the finite budget row* B*, the* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule row* S*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* Q*, the extracted modulus row* Mu*, and the structural rows* H, C, P, N*. Every* $\mathsf{Real}^{\uparrow}$ *diagonal consumer must pass through those rows before reading the modulus handoff. No such consumer obtains quotient stream equality, selected limits, trichotomy, host real equality, ambient completeness, or an external modulus selector from the package.*

Proof. Begin with the NameCert obligations of Definition 641.2. Carrier admission fixes the displayed packet, budget exposure fixes B, schedule extraction fixes W, S, dyadic soundness fixes Q, and ledger exactness fixes H, C, P, N as the structural route.

Budget soundness from Definition 641.7 then identifies Mu as the threshold justified by B, W, S, Q. The StreamName–RegSeqRat factorization of Definition 641.9 forces every route from E to Mu through the window and schedule rows.

Apply the Real diagonal handoff of Definition 641.15 and ledger exactness from Definition 641.16. These two results place the Real-facing read after the displayed budget, window, schedule, dyadic, modulus, transport, continuation, package, and naming rows.

Finally use budget-fiber exhaustion from Definition 641.20. It rules out every remaining route through quotient stream equality, selected limits, trichotomy, host real equality, ambient completeness, or an external modulus selector, so the listed rows are the whole obligation package for the Real-completion route. □

Theorem 641.22 (Cauchy modulus-extraction public export)**.** *For every accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *carrier*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

the public $\mathsf{NameCert}_{\mathsf{CauchyModulusExtraction}^{\uparrow}}$ *export is exactly the carrier admission, finite budget exposure,* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *factorization,* $\mathsf{DyadicRatCore}^{\uparrow}$ *positivity and non-escape ledger,*

$\mathsf{Real}^{\uparrow}$ *seal boundary, route exactness, window schedule exhaustion, budget fiber exhaustion, and obligation closure package already displayed by this chapter.*

Thus downstream $\mathsf{Real}^{\uparrow}$ *and Completion consumers may cite one public export instead of rebuilding the finite budget, dyadic, stream, schedule, seal, transport, continuation, provenance, and naming rows separately. The export contains no quotient stream equality, host real equality, selected limit, trichotomy, ambient completeness, or external modulus selector.*

Proof. First read the accepted carrier through Definition 641.2. This fixes $E, B, W, S, \mathsf{Mu}, Q, H, C, P, N$ as the only rows available to the local naming certificate and identifies the carrier admission and finite budget exposure.

Next assemble the stream and dyadic surfaces. Apply Definition 641.9, Definition 641.5, and Definition 641.19. These results put the window row, regular schedule, positive dyadic ledger, and dyadic non-escape boundary in the same displayed packet.

Now attach the Real-facing route. Use Definition 641.10, Definition 641.17, and Definition 641.18. They force every seal-facing consumer through the exact finite route and exhaust the window schedule before any modulus handoff is readable.

Finally combine Definition 641.20 with Definition 641.21. The first theorem exhausts the budget fiber over the displayed tolerance request, and the second repacks all named rows as the local obligation package. Therefore the public export is precisely the listed finite surface, with all excluded completion objects absent from the carrier. □

Theorem 641.23 (Cauchy modulus-extraction Real-completion consumer bridge)**.** *For every accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *packet*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

every Real-completion consumer route that reads the extracted modulus row Mu *factors through exactly the displayed rows* $B, W, S, Q, \mathsf{Mu}, H, C, P, N$ *after carrier admission through* E*. The* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *surfaces reached by the route are precisely the sibling surfaces cited by Definition 641.22; no route obtains a host convergence modulus, quotient stream, selected limit, host real equality, ambient completeness, or choice-selected witness.*

Lean4 ✓ `BEDC.Derived.CauchyModulusExtractionUp.CauchyModulusExtractionUp StdBridge`

Proof. Start with the budget-window coverage theorem, Definition 641.3. It places every accepted tolerance request E behind the finite budget B before any window or schedule row can contribute to Mu.

Next use dyadic ledger positivity, Definition 641.5. The extracted modulus is justified by the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ ledger Q, so the consumer receives a ledgered threshold rather than an external selector.

Now apply the StreamName–RegSeqRat factorization of Definition 641.9. The sibling surfaces chapter 126 and chapter 301 are reached only through the local W and S rows in this packet.

Finally cite RealUp seal non-escape, Definition 641.10, together with the public export of Definition 641.22. These results identify the local Real-facing surface with the sibling surface chapter 38, keep the completion-facing read inside $B, W, S, Q, \mathsf{Mu}, H, C, P, N$, and rule out host convergence moduli, quotient streams, selected limits, host real equality, ambient completeness, and choice-selected witnesses. □

Theorem 641.24 (Cauchy modulus-extraction dyadic Real consumer factorization)**.** *For every accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *packet*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

every $\mathsf{Real}^{\uparrow}$*-completion consumer that reads the extracted modulus row* Mu *factors first through the finite budget row* B*, the* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *schedule row* S*, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row* Q*. The handoff to the Real-facing consumer exports only this displayed dyadic ledger route with* H, C, P, N *attached; it exports no host modulus, quotient stream equality, selected limit, trichotomy, ambient completeness, or external real-completion witness.*

Proof. Start with the NameCert obligations of Definition 641.2. They identify the accepted packet with the rows $E, B, W, S, \mathsf{Mu}, Q, H, C, P, N$ and leave no additional carrier coordinate for a Real consumer.

Use budget-window coverage from Definition 641.3. Any consumer read of Mu must first pass through the finite budget B and the displayed window row W, so the request is already inside the local ledger route.

Next apply dyadic ledger positivity and StreamName–RegSeqRat factorization, Definition 641.5 and Definition 641.9. These force the route through the regular schedule row S and the dyadic ledger row Q before the extracted modulus can be exposed.

Finally use the Real-completion consumer bridge, Definition 641.23, and carrier non-escape from Definition 641.10. The bridge supplies the Real-facing handoff, while non-escape excludes host moduli, quotient stream equality, selected limits, trichotomy, ambient completeness, and external completion witnesses from the exported packet. □

Theorem 641.25 (Cauchy modulus-extraction mature package summary)**.** *For every accepted* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *packet*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N),$$

the finite Real-completion consumer surface is the public export, the Real-completion consumer bridge, the dyadic Real consumer factorization, route exactness, budget-fiber exhaustion, and the no-ambient-completeness boundary of this chapter assembled as one package. A downstream $\mathsf{Real}^{\uparrow}$ *or completion consumer reads* $E, B, W, S, \mathsf{Mu}, Q, H, C, P, N$ *in that finite order, obtains the extracted modulus only through the displayed budget-window-dyadic route, and obtains no quotient stream equality, host real equality, selected limit, trichotomy, ambient completeness, or external modulus selector.*

Proof. Start with Definition 641.22. It collects carrier admission, budget exposure, window and schedule rows, dyadic ledger, Real seal boundary, route exactness, window exhaustion, budget-fiber exhaustion, and obligation closure into the public surface of M.

Use Definition 641.23. The bridge sends Real-completion consumers through $B, W, S, Q, \mathsf{Mu}, H, C, P, N$ after admission through E, so the extracted modulus is not read from an external host selector.

Apply Definition 641.24. It records the reusable factorization through B, W, S, Q before the Real-facing consumer can read Mu.

Finally apply Definition 641.17, Definition 641.20, and Definition 641.10. Route exactness fixes the order of the finite rows, budget-fiber exhaustion leaves no second budget source, and the RealUp boundary excludes quotient stream equality, host real equality, selected limits, trichotomy, ambient completeness, and external modulus data. □

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyModulusExtraction}^{\uparrow}}$.

Constructive story: A $\mathsf{CauchyModulusExtraction}^{\uparrow}$ packet is generated from a positive tolerance request, finite observation budget, StreamNameUp windows, RegSeqRatUp witness schedule, extracted modulus row, dyadic comparison ledger, componentwise transports, continuation routes, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyModulusExtraction}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 641.1, Definition 641.2, Definition 641.7, Definition 641.9, Definition 641.19, Definition 641.15, Definition 641.21, Definition 641.22, Definition 641.23, Definition 641.24, and Definition 641.25 bind the mature finite Real-completion consumer surface for the modulus-extraction packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CauchyModulusExtraction}^{\uparrow}}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.CauchyModulusExtractionUp.CauchyModulusExtractionCarrier\_namecert\_obligations`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close RealUp completeness, uniqueness of completed limits, quotient equality of streams, host real equality, a public standard bridge, or Lean verification.

Upgrade path: No further upgrade: the chapter is at the top of the formal bridge axis.

Chapter 642

A Concrete Naming Certificate for $\mathsf{ProofTermErasureTrace}^{\uparrow}$

The $\mathsf{ProofTermErasureTrace}^{\uparrow}$ surface records a type-checking run whose proof evidence is erased while its typing membership and reduction compatibility remain visible. It sits between derivation traces and compiler packets: the carrier keeps the proof-term row, the erased-term row, the Ext typing row, the erasure route, the subject-reduction compatibility row, the transport rows, provenance, and local naming in one finite certificate.

The trace consumes the derivation-route surface of chapter 598 and the preservation boundary of chapter 483. $\mathsf{ProofTermErasureTrace}^{\uparrow}$ does not create its own typing judgment; it packages the erased public row only after those sibling rows have supplied membership and reduction compatibility.

Definition 642.1 (Proof-term erasure trace carrier)**.** *A* $\mathsf{ProofTermErasureTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (p, e, T, E, R, H, C, P, N)$$

with the following visible coordinates:

1. *p is the proof-term row whose membership is checked by the typing classifier;*
2. *e is the erased-term row exported to consumers after proof evidence is forgotten;*
3. *T is the typing* Ext *row that admits p as a checked term;*
4. *E is the displayed erasure* Cont *route from p to e;*
5. *R is the subject-reduction compatibility row tying the typing membership of p to the erased public read;*
6. *H records the componentwise* hsame *transports for proof terms, erased terms, typing rows, erasure routes, and subject-reduction rows;*
7. *C records the displayed* Cont *routes consumed by the erasure and compatibility readings;*
8. *P is the* Pkg *provenance over* BHist, Ext, Cont, $\mathsf{SubjectReduction}^{\uparrow}$, $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$, $\mathsf{TypedReductionNormalForm}^{\uparrow}$, hsame, *and* $\mathsf{NameCert}$ *source certificates;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ProofTermErasureTrace}^{\uparrow}}$ *row.*

The local classifier relates two carriers only when their proof-term, erased-term, typing, erasure-route, subject-reduction, transport, provenance, and local naming rows compare componentwise through the displayed routes in H and C.

Lean4 ✓ BEDC.Derived.ProofTermErasureTraceUp.ProofTermErasureTraceTasteGate single carrier alignment

Theorem 642.2 (Proof-term erasure trace NameCert obligations)**.** *For the carrier of Definition 642.1, the local* $\mathsf{NameCert}_{\mathsf{ProofTermErasureTrace}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission: the packet admits exactly the displayed rows* $p, e, T, E, R, H, C, P, N$*;*
2. Ext *membership preservation: any accepted public read of* e *is backed by the typing row* T *for the proof term* p *and the erasure route* E*;*
3. *subject-reduction compatibility: the row* R *records that the erased public read is compatible with the* Ext-Cont *closure law used by the proof-term trace;*
4. *erased-term non-escape: the carrier exports no host conversion relation, quotient term equality, normalization oracle, proof irrelevance principle, or erased proof witness outside* e*;*
5. *local ledger exactness: every consumer read factors through* H*,* C*,* P*, and* N *together with the visible proof, erasure, typing, and compatibility rows.*

Proof. Carrier admission is the projection of the displayed finite tuple. The coordinates $p, e, T, E, R, H, C, P, N$ account for the proof term, erased term, typing membership, erasure route, subject-reduction compatibility, transports, continuation reads, package provenance, and local naming row.

For Ext membership preservation, read T as the classifier admission of the proof term p and E as the displayed erasure route to e. The erased row is public only through this route, so its membership read is anchored in the original typing row rather than in a host erasure judgment.

Subject-reduction compatibility is the role of R. It records that the typing row and erasure continuation are consumed through the same Ext-Cont closure discipline used by the surrounding type-checking trace.

Erased-term non-escape follows by carrier inspection. None of the coordinates is a host conversion relation, quotient equality on terms, normalization oracle, proof irrelevance principle, or hidden proof witness exported after erasure.

Finally, local ledger exactness repacks the public reads through H, C, P, N. The transports and continuation rows state how the proof, erasure, typing, and compatibility data are replayed, while provenance and the local naming row record the finite ledger boundary. □

Theorem 642.3 (Proof-term erasure trace typed-reduction boundary)**.** *For any accepted* $\mathsf{ProofTermErasureTrace}^{\uparrow}$ *packet*

$$Z = (p, e, T, E, R, H, C, P, N),$$

the erased public row e *is exported only through the typing* Ext *row* T*, the erasure* Cont *route* E*, and the subject-reduction compatibility row* R*, replayed through* H, C, P, N*. The packet exports no host conversion relation, quotient term equality, proof irrelevance principle, semantic erasure-correctness theorem, or erased proof witness outside the displayed row* e*.*

Proof. Project the carrier of Definition 642.1. The public erasure surface contains the proof row p, erased row e, typing row T, erasure route E, subject-reduction row R, and the structural rows H, C, P, N.

Apply Definition 642.2. Its membership-preservation clause anchors e in the typing row T and erasure route E, while its subject-reduction clause keeps the public read compatible with R.

The same obligation theorem lists erased-term non-escape and local ledger exactness. Since the carrier has no host conversion, quotient equality, proof irrelevance, semantic erasure-correctness,

or hidden proof-witness coordinate, the typed-reduction boundary is exactly T, E, R, H, C, P, N together with the displayed erased row. □

Theorem 642.4 (Proof-term erasure trace Ext membership factorization)**.** *For any accepted* $\mathsf{ProofTermErasureTrace}^{\uparrow}$ *packet*

$$Z = (p, e, T, E, R, H, C, P, N),$$

every public membership read of the erased row e factors through the displayed Ext *row T, the erasure route E, and the local rows H, C, P, N of Definition 642.1. It cannot be certified by a host typing judgment, an erased proof witness, or an external conversion relation outside the packet.*

Proof. Project the carrier of Definition 642.1. The proof term p, erased row e, and typing row T are displayed together, so an erased membership read starts from the same finite packet rather than from a host typing predicate.

Apply Definition 642.2. Its Ext membership-preservation row states that accepted public reads of e are backed by T and by the erasure route E.

The remaining local rows H, C, P, N supply the transport, continuation replay, provenance, and local naming ledger. Since no coordinate names host typing, proof-witness export, or external conversion, the factorization is exhausted by the displayed rows. □

Theorem 642.5 (Proof-term erasure trace erasure-route replay)**.** *For any accepted* $\mathsf{ProofTermErasureTrace}^{\uparrow}$ *packet $Z = (p, e, T, E, R, H, C, P, N)$, the erasure route from the proof-term row p to the erased public row e is replayed only by the displayed* Cont *row E together with the route ledger C and transport row H. Replaying the route cannot introduce a second erasure function, a normalization oracle, or proof-irrelevance data outside Z.*

Proof. Read the erasure coordinate of Definition 642.1. The route from p to e is the displayed Cont row E, and the general continuation replay ledger is the coordinate C.

Transport is componentwise through H. Thus moving the proof term, erased term, typing row, and compatibility row transports the same erasure route rather than selecting a second route.

Apply the non-escape and ledger-exactness rows of Definition 642.2. They exclude normalization oracles, proof irrelevance, hidden proof witnesses, and host conversion data from the replay surface. □

Theorem 642.6 (Proof-term erasure trace public-row ledger exhaustion)**.** *For any accepted* ProofTermErasureTrace *packet $Z = (p, e, T, E, R, H, C, P, N)$, every public row exported to a downstream consumer is one of the displayed proof-term, erased-term, typing, erasure-route, subject-reduction, transport, continuation, provenance, or local naming rows of Definition 642.1. The ledger has no additional public row for host conversion, quotient term equality, semantic erasure correctness, proof irrelevance, or hidden proof evidence.*

Lean4 ✓ `BEDC.Derived.ProofTermErasureTraceUp.ProofTermErasureTrace public row ledger exhaustion`

Proof. Project the packet Z. Its public inventory is exactly $p, e, T, E, R, H, C, P, N$, with T carrying Ext membership, E and C carrying displayed Cont replay, R carrying subject-reduction compatibility, and H, P, N carrying transport, provenance, and local naming.

Apply Definition 642.2. Carrier admission gives the full inventory, erased-term non-escape removes undisplayed proof and conversion rows, and local ledger exactness forces downstream reads through the same packet.

Therefore the downstream ledger is exhausted by the displayed rows. Any requested host conversion, quotient equality, semantic erasure theorem, proof irrelevance principle, or hidden proof evidence is outside the accepted public-row surface. □

Theorem 642.7 (Proof-term erasure trace proof-row obligation)**.** *For any accepted* $\mathsf{ProofTermErasureTrace}^{\uparrow}$ *packet*

$$Z = (p, e, T, E, R, H, C, P, N),$$

the proof-term row p remains a displayed carrier coordinate. It may be used as the source of the typing Ext *row T, the erasure* Cont *route E, and the subject-reduction compatibility row R, but it is not exported after erasure as proof irrelevance, host conversion, semantic erasure correctness, or hidden erased evidence outside Z.*

Proof. Project the carrier of Definition 642.1. The row p is one of the displayed coordinates, and the rows T, E, R, H, C, P, N record exactly how it is typed, erased, transported, replayed, and named.

Apply Definition 642.2. Carrier admission keeps p in the finite tuple, while erased-term non-escape excludes proof irrelevance, host conversion, semantic erasure correctness, and hidden proof evidence from the exported surface.

Now use Definition 642.3 and Definition 642.5. These results show that the proof row is consumed only through the typing, erasure, and subject-reduction rows already displayed in the packet.

Finally combine Definition 642.4 with Definition 642.6. Public membership and downstream ledger reads have no additional proof-evidence coordinate beyond the displayed row p and its local routes. □

Theorem 642.8 (Proof-term erasure trace erasure membership lock)**.** *For any accepted* $\mathsf{ProofTermErasureTrace}^{\uparrow}$ *packet*

$$Z = (p, e, T, E, R, H, C, P, N),$$

every public membership read of the erased row e factors through the displayed Ext *row T, the erasure* Cont *route E, the subject-reduction row R, and the local rows H, C, P, N. The read cannot be certified by host conversion, quotient term equality, proof irrelevance, semantic erasure correctness, or an erased proof witness outside the packet.*

Proof. Begin with the carrier definition. The erased row e is displayed together with the typing row T, erasure route E, subject-reduction row R, and local rows H, C, P, N; no separate host membership coordinate is present.

Apply Definition 642.2. Its Ext membership-preservation and subject-reduction compatibility rows bind the erased public read to T, E, and R.

Next apply Definition 642.4 and Definition 642.5. Membership of e is read through the displayed typing row and replayed along the displayed erasure route, with H and C supplying only componentwise transport and continuation replay.

Finally use Definition 642.3 and Definition 642.6. The public ledger is exhausted by $p, e, T, E, R, H, C, P, N$, so no host conversion, quotient equality, proof irrelevance, semantic erasure theorem, or erased proof witness can certify membership of e outside the packet. □

Theorem 642.9 (Proof-term erasure trace kernel scope lock)**.** *For any accepted* $\mathsf{ProofTermErasureTrace}^{\uparrow}$ *packet*

$$Z = (p, e, T, E, R, H, C, P, N),$$

the finite route

$$\mathsf{BHist} \longmapsto \mathsf{Ext} \longmapsto \mathsf{Cont} \longmapsto \mathsf{Pkg} \longmapsto \mathsf{NameCert}$$

is the whole kernel-facing scope of the packet. The route binds the proof-term row p, erased row e, typing row T, erasure route E, subject-reduction row R, componentwise transport row H, continuation ledger C, provenance row P, and local naming row N; it exports no host conversion relation, quotient term equality, proof-irrelevance principle, or semantic erasure oracle.

Proof. Project the carrier of Definition 642.1. Each public coordinate is one of $p, e, T, E, R, H, C, P, N$, and each coordinate is typed by the displayed BHist, Ext, Cont, Pkg, or $\mathsf{NameCert}$ layer.

Apply the NameCert obligations and the erasure membership lock. They bind erased membership to T, E, R, H, C, P, N and keep the proof row p as the only proof evidence used by the route.

The public-row ledger exhaustion excludes every row not present in the carrier. Hence the kernel-facing scope is exactly the displayed finite route. □

Theorem 642.10 (Proof-term erasure trace erased-row determinacy)**.** *Let $Z = (p, e, T, E, R, H, C, P, N)$ and $Z' = (p', e', T', E', R', H', C', P', N')$ be accepted $\mathsf{ProofTermErasureTrace}^{\uparrow}$ packets. If their proof-term rows, typing Ext rows, erasure Cont routes, subject-reduction rows, componentwise transport rows, continuation ledgers, provenance rows, and local naming rows agree through the displayed route data, then the erased public rows agree: e and e' are determined by those rows. No consumer may choose a different erased row by appealing to host conversion, quotient equality, proof irrelevance, or an external erasure theorem.*

Proof. Start from the erasure-route replay theorem. It says that the route from the proof row to the erased public row is exactly the displayed Cont row E together with the local replay data.

Use the kernel scope lock on both packets. Since the agreed rows include the typing, erasure, subject-reduction, transport, continuation, provenance, and naming data, both packets expose the same public route from proof evidence to erased row.

Finally apply the erasure membership lock. Membership of the erased row is certified only through that route, so the carrier has no remaining coordinate from which a second erased public row could be selected. □

Theorem 642.11 (Proof-term erasure trace public-consumer factorization)**.** *Every public consumer of an accepted $\mathsf{ProofTermErasureTrace}^{\uparrow}$ packet factors through the displayed derivation and preservation siblings: the derivation route of chapter 598 supplies the typing row T, the preservation route of chapter 483 supplies the subject-reduction row R, and the local packet exports the erased row e only through E, H, C, P, N. The factorization exports no erased proof witness, host conversion row, quotient term equality, proof irrelevance, or semantic erasure-correctness oracle.*

Proof. First read the derivation side. The type-checking derivation trace supplies the Ext membership row T for the proof-term row p, so the erased public read is not introduced as an independent host judgment.

Next read the preservation side. The subject-reduction route supplies R, and the local erasure membership lock forces the erased row e to remain compatible with T, E, and R.

Finally use erased-row determinacy and public-row ledger exhaustion. Any downstream consumer sees the same erased row fixed by p, T, E, R, H, C, P, N, and the packet has no additional public coordinate for proof evidence or host conversion. □

Closure status for $\mathsf{NameCert}_{\mathsf{ProofTermErasureTrace}^{\uparrow}}$.

Constructive story: A $\mathsf{ProofTermErasureTrace}^{\uparrow}$ packet is generated from proof-term and erased-term rows, a typing Ext row, an erasure Cont route, a subject-reduction compatibility row, componentwise hsame transports, package provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.ProofTermErasureTraceUp.taste gate`

Scope closed: Definition 642.1, the TasteGate single-carrier marker, Definition 642.2, Definition 642.8, Definition 642.9, Definition 642.10, and Definition 642.11 bind the mature paper surface: carrier, NameCert obligations, erasure membership, kernel scope, public consumer factorization, and checked TasteGate single-carrier alignment.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ProofTermErasureTrace}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ProofTermErasureTraceUp.ProofTermErasureTraceTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close host conversion, quotient term equality, normalization oracles, proof irrelevance, or semantic erasure correctness outside the displayed finite packet.

Upgrade path: Mature closure requires examples or completeness treatment for the same displayed erasure-trace route.

Chapter 643

A Concrete Naming Certificate for $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$

The $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ surface turns the other-minds locality-cell commitment of Definition 9415.9 into a finite coordination packet. It aligns public observer commitments, locality-cell evidence, and inter-history coherence rows without exposing private Self coordinates or treating observer agreement as host-level identity.

The row M is consumed from chapter 474 as the finite inter-Hist configuration surface. CrossPerspectiveAlignmen adds only locality-cell and public commitment routing on top of that sibling surface, not private observer-state access.

Definition 643.1 (CrossPerspectiveAlignment carrier)**.** *A* $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (A, B, L, O, M, H, C, P, N)$$

with the following displayed rows:

1. *A is the source-observer row issuing the alignment request;*
2. *B is the target-observer public row, read only as an other-minds commitment surface;*
3. *L is the locality-cell evidence row, recording the public* $\mathsf{LocalityCell}^{\uparrow}$ *evidence that makes the target row available for coordination;*
4. *O is the public* $\mathsf{OtherMindsCommitment}^{\uparrow}$ *row tying A's commitment to B without direct target* Self *access;*
5. *M is the accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *row displaying the finite inter-Hist configuration in which the two observer histories are compared;*
6. *H records the componentwise* hsame *transports for the observer rows, locality-cell evidence, other-minds commitment, multi-Hist configuration, package row, and local naming row;*
7. *C records the* Cont *routes that let public consumers read the commitment row, locality-cell row, and inter-Hist coherence rows without entering private observer state;*
8. *P is the* Pkg *provenance over* $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{LocalityCell}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{CrossPerspectiveAlignment}^{\uparrow}}$ *row.*

The classifier compares carriers only through these displayed rows and their hsame *and* Cont *transports.*

Lean4 ✓ `BEDC.Derived.CrossPerspectiveAlignmentUp.CrossPerspectiveAlignmentTasteGate single carrier alignment`

Theorem 643.2 (CrossPerspectiveAlignment NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CrossPerspectiveAlignment}^{\uparrow}}$ *surface has five finite obligations: carrier exposure by Definition 643.1; public other-minds commitment through O; locality-cell evidence soundness through L; inter-Hist coherence through the* $\mathrm{MultiHistConfig}^{\uparrow}$ *row M and the displayed* hsame *and* Cont *rows; and non-escape from private* Self *access, hidden observer histories, host observer equality, and unrecorded cross-perspective synchronization.*

Proof. Carrier exposure is projection from the finite packet $B = (A, B, L, O, M, H, C, P, N)$.

The public commitment obligation is read from O. It uses $\mathsf{OtherMindsCommitment}^{\uparrow}$ as a public certificate surface, so the target observer row is available only through visible commitment data.

The locality and inter-Hist obligations are read next. The locality-cell evidence is the row L, while finite inter-Hist coherence is the row M transported by H and consumed through C.

Finally inspect the coordinate list. There is no field for private target Self access, hidden observer history, host observer equality, or unrecorded synchronization, so none of those data can be exported by the packet. □

Lean4 ✓ `BEDC.Derived.CrossPerspectiveAlignmentUp.CrossPerspectiveAlignmentCarrier namecert obligations`

Theorem 643.3 (CrossPerspectiveAlignment locality-cell soundness)**.** *Every accepted* $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ *packet aligns perspectives only after the public locality-cell evidence row L, the* $\mathsf{OtherMindsCommitment}^{\uparrow}$ *row O, and the* $\mathrm{MultiHistConfig}^{\uparrow}$ *row M are displayed in the same finite packet. A consumer may read $A, B, L, O, M, H, C, P, N$, but it cannot replace L by private target-state access, a global observer frame, or an unlisted synchronization coordinate.*

Proof. Project the accepted packet as $B = (A, B, L, O, M, H, C, P, N)$. The locality-cell evidence available to the consumer is exactly the displayed coordinate L.

The target public row is tied to the other-minds surface by O, and the inter-Hist comparison is tied to the finite configuration by M. The displayed transports H and routes C preserve those attachments as public certificate data.

No coordinate names private target-state access, a global observer frame, or an unlisted synchronization row. Thus locality-cell soundness is a finite public-evidence condition, not an ambient identification of observer states. □

Lean4 ✓ `BEDC.Derived.CrossPerspectiveAlignmentUp.CrossPerspectiveAlignmentCarrier locality cell soundness`

Theorem 643.4 (CrossPerspectiveAlignment non-escape boundary)**.** *An accepted* $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ *carrier exports only the source-observer row, target-observer public row, locality-cell evidence row, public other-minds commitment row, finite multi-Hist configuration row, displayed* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row. It exports no private* Self *access for the target observer, no hidden observer history, no host observer equality, no global frame, and no unrecorded cross-perspective synchronization.*

Proof. Inspect the carrier coordinates of Definition 643.1. Every exported row is one of A, B, L, O, M, H, C, P, or N.

The rows L, O, and M are public certificate rows: locality-cell evidence, other-minds commitment, and finite multi-Hist configuration. The rows H and C only transport and route those displayed public rows.

There is no remaining coordinate for target private Self access, hidden observer history, host observer equality, a global frame, or unrecorded synchronization. Hence the alignment packet cannot export any of those objects. □

Theorem 643.5 (CrossPerspectiveAlignment observer-identity handoff)**.** *Every accepted* CrossPerspectiveAlignmen *alignment packet reads the target public identity only through the displayed observer-history identity and other-minds commitment rows. The target row B may be consumed as a public* ObserverHistIdentity$^{\uparrow}$/OtherMind *handoff carried by O, H, C, P, N, but no read may pass through a private target* Self *coordinate or identify the two observers by host equality.*

Lean4 ✓ `BEDC.Derived.CrossPerspectiveAlignmentUp.CrossPerspectiveAlignmentCarrier observer identity handoff`

Proof. Project the carrier of Definition 643.1. The target row is the public coordinate B, and its commitment route is the row O together with the displayed transports and continuations H and C.

Use the NameCert obligations of Definition 643.2. They require public other-minds commitment through O and make carrier exposure a finite packet read rather than a private observer-state read.

Finally apply the non-escape boundary of Definition 643.4. Since the packet has no coordinate for private target Self access or host observer equality, every accepted target-identity handoff is exhausted by the public observer-history and other-minds rows already displayed. □

Theorem 643.6 (CrossPerspectiveAlignment finite multi-Hist coherence)**.** *Every inter-history comparison accepted by* CrossPerspectiveAlignment$^{\uparrow}$ *factors through the finite* MultiHistConfig$^{\uparrow}$ *row M, the componentwise* hsame *transports recorded in H, and the* Cont *routes recorded in C. No comparison may appeal to an ambient global history, an unlisted synchronization row, or a hidden equality between observer histories.*

Lean4 ✓ `BEDC.Derived.CrossPerspectiveAlignmentUp.CrossPerspectiveAlignmentCarrier finite multihist coherence`

Proof. Read the carrier coordinates. The only inter-history configuration coordinate is M, and the only transport and consumer routes attached to it are the displayed rows H and C.

The locality-cell soundness theorem Definition 643.3 requires L, O, M, H, C, P, N to appear in the same finite packet before the alignment is consumed. Thus comparison across histories is a replay of the finite multi-Hist row through the stored transport and continuation data.

The non-escape theorem Definition 643.4 excludes hidden observer histories, host observer equality, global frames, and unrecorded synchronization. Hence finite multi-Hist coherence is exactly the route through M, H, C, not an ambient comparison outside the packet. □

Theorem 643.7 (CrossPerspectiveAlignment public consumer package)**.** *The carrier exposure of Definition 643.1, locality-cell soundness, observer-identity handoff, finite multi-Hist coherence, non-escape, and the displayed TasteGate marker assemble the public obligation package for* CrossPerspectiveAlignmen

A public consumer receives only the finite rows $A, B, L, O, M, H, C, P, N$ with their NameCert *obligations, and receives no private target* Self*, hidden observer history, host observer equality, global frame, or unrecorded synchronization.*

Lean4 ✓ `BEDC.Derived.CrossPerspectiveAlignmentUp.CrossPerspectiveAlignmentCarrier public consumer package`

Proof. Begin with the carrier definition. It displays exactly the source observer, target public observer, locality-cell evidence, other-minds commitment, multi-Hist configuration, componentwise transport, continuation, package provenance, and local naming rows.

Apply the existing NameCert obligation and locality-cell soundness theorems. They bind carrier exposure, public other-minds commitment through O, locality-cell evidence through L, and finite inter-Hist coherence through M, H, C.

The observer-identity handoff and finite multi-Hist coherence theorems above isolate the two consumer routes that would otherwise be ambiguous. The first keeps target public identity behind the observer-history and other-minds rows; the second keeps inter-history comparison behind the finite M, H, C route.

Finally use the non-escape theorem and the checked TasteGate alignment marker. Non-escape removes private and ambient coordinates from the package, while the marker records that the displayed carrier is the single TasteGate-aligned carrier surface. Thus the public obligation package is finite and contains only the listed rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{CrossPerspectiveAlignment}^{\uparrow}}$.

Constructive story: A $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ packet is generated from a source observer row, a target public observer row, locality-cell evidence, a public $\mathsf{OtherMindsCommitment}^{\uparrow}$ row, a finite $\mathrm{MultiHistConfig}^{\uparrow}$ row, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.CrossPerspectiveAlignmentUp.taste gate`

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CrossPerspectiveAlignment}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 643.1, Definition 643.2, Definition 643.3, Definition 643.4, Definition 643.5, Definition 643.6, and Definition 643.7 bind the finite public alignment surface over ObserverHistIdentity, OtherMindsCommitment, LocalityCell, MultiHistConfig, hsame, Cont, Pkg, NameCert, and the checked TasteGate carrier marker.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CrossPerspectiveAlignment}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a Lean implementation, bridge status, private access to another observer's Self, hidden observer histories, host observer equality, a global frame, or unrecorded synchronization.

Upgrade path: No paper-side closure upgrade remains for the displayed alignment rows, while formal verification remains on its independent axis.

Chapter 644

A Concrete Naming Certificate for $\mathsf{RegularCauchyMesh}^{\uparrow}$

The $\mathsf{RegularCauchyMesh}^{\uparrow}$ packet records the shared finite mesh surface used by regular-Cauchy Real-completeness arguments before a diagonal mesh-budget consumer reads a $\mathsf{Real}^{\uparrow}$ seal. It names a finite family of regular rational observations indexed by mesh rows, together with StreamName windows, dyadic tolerance rows, transport, continuation, provenance, and a local naming certificate. The packet is a mesh-indexed observation carrier, not a completed real, a quotient class of regular sequences, or an ambient completeness principle.

The concrete dependency route is through the finite modulus-window surface of chapter 593 and the mesh-cell compatibility surface of chapter 358. The $\mathsf{RegularCauchyMesh}^{\uparrow}$ packet refines the schedule packet by replacing a single selected window with a finite mesh-index row while preserving the same $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$ handoff, hsame, Cont, Pkg, and NameCert rows.

Definition 644.1 (Regular Cauchy mesh carrier)**.** *A* $\mathsf{RegularCauchyMesh}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (a, j, w, r, d, m, e, h, c, p, n)$$

with the following displayed coordinates:

1. *a is the finite regular-Cauchy request row, recording the requested precision and the finite observation sites to be inspected;*
2. *j is the mesh-index row, listing the finite* $\mathsf{DyadicMesh}^{\uparrow}$ *cells and regular-Cauchy positions selected by the request;*
3. *w is the* $\mathsf{StreamName}^{\uparrow}$ *window row attached to those mesh cells;*
4. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row for the selected regular rational observations;*
5. *d is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, recording dyadic radii, endpoint comparisons, and mesh-cell tolerance bounds;*
6. *m is the* $\mathsf{DyadicMesh}^{\uparrow}$ *compatibility row that states the selected mesh cells are exactly the cells inspected by j and w;*
7. *e is the* $\mathsf{Real}^{\uparrow}$ *handoff row reached only after a, j, w, r, d, m have been displayed;*
8. *h records componentwise* hsame *transports for the request, mesh indices, windows, readbacks, dyadic ledger, mesh compatibility row, handoff row, provenance, and local name;*

9. *c records the displayed* Cont *routes from a to j, from j to w, from w to r, from r to d, from d to m, and from m to e;*
10. *p is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{DyadicMesh}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
11. *n is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyMesh}^{\uparrow}}$ *row.*

The carrier contains no infinite mesh, no quotient equality of regular sequences, no host real equality, no chosen limit representative, and no ambient Real completeness theorem.

Definition 644.2 (Regular Cauchy mesh classifier)**.** *Two* $\mathsf{RegularCauchyMesh}^{\uparrow}$ *carriers*

$$G = (a, j, w, r, d, m, e, h, c, p, n) \quad \text{and} \quad G' = (a', j', w', r', d', m', e', h', c', p', n')$$

are classified together exactly when the displayed request rows, mesh-index rows, StreamName windows, RegSeqRat readbacks, DyadicRatCore ledgers, DyadicMesh compatibility rows, RealUp handoff rows, componentwise transports, continuation routes, package provenance, and local NameCert rows are matched by the corresponding hsame, Cont, Pkg, *and* NameCert *evidence already carried in the two packets.*

The classifier is rowwise and finite. It does not identify completed reals, quotient regular-Cauchy streams, or mesh families outside the displayed cells.

Theorem 644.3 (Regular Cauchy mesh NameCert obligation sketch)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyMesh}^{\uparrow}}$ *surface for Definition 644.1 has the following five rows:*

1. *carrier admission for $G = (a, j, w, r, d, m, e, h, c, p, n)$;*
2. *finite mesh request exposure through a and mesh-index exposure through j;*
3. *selected* $\mathsf{StreamName}^{\uparrow}$ *windows w,* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks r,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger d, and* $\mathsf{DyadicMesh}^{\uparrow}$ *compatibility row m;*
4. $\mathsf{Real}^{\uparrow}$ *handoff through e, componentwise* hsame *transport through h, and displayed* Cont *route replay through c;*
5. Pkg *provenance through p, local naming through n, and non-escape for infinite meshes, quotient regular-Cauchy equality, host real equality, selected limits, and ambient completeness.*

Lean4 ✓ `BEDC.Derived.RegularCauchyMeshUp.RegularCauchyMeshTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 644.1. The packet exposes the eleven displayed rows and no other mesh-indexed data.

The request and mesh-index rows a and j choose only finitely many cells. The selected windows w, readbacks r, dyadic ledger d, and mesh compatibility row m then give the finite regular-rational observations attached to those cells.

The handoff row e is reached through the displayed transports and continuations in h and c, with provenance and local naming recorded by p and n. Thus the five rows exhaust the NameCert surface.

The non-escape clauses follow from the carrier inventory. Since no row supplies an infinite mesh, quotient regular-Cauchy equality, host real equality, a selected limiting representative, or an ambient completeness theorem, none of those objects can be exported by the certificate. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyMesh}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyMesh}^{\uparrow}$ packet is generated from a finite regular-Cauchy request, finite mesh indices, StreamName windows, RegSeqRat readbacks, a DyadicRatCore tolerance ledger, a DyadicMesh compatibility row, a RealUp handoff row, componentwise transports, continuation routes, package provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyMesh}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 644.1, Definition 644.2, and Definition 644.3 bind the seed carrier, rowwise classifier, and five-row NameCert surface for finite mesh-indexed regular-rational observations.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyMesh}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close RealUp completeness, quotient equality of regular sequences, host real equality, selected limits, infinite mesh selection, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, rowwise classifier stability, finite mesh coverage, RealUp handoff, provenance, and non-escape for the same RegularCauchyMeshUp packet.

Definition 644.4 (Regular Cauchy mesh displayed submesh restriction)**.** *Let*

$$G = (a, j, w, r, d, m, e, h, c, p, n)$$

be a $\mathsf{RegularCauchyMesh}^{\uparrow}$ *carrier as in Definition 644.1. A displayed finite submesh selector for* G *is a finite row* q *equipped with an inclusion read* $\iota : q \to j$ *whose cells are entries already displayed in the mesh-index row* j*.*

The restriction of G *along* q *is the packet*

$$G|_q = (a|_q, j|_q, w|_q, r|_q, d|_q, m|_q, e|_q, h|_q, c|_q, p|_q, n|_q),$$

where $j|_q$ *is the row* q*, and every other coordinate is obtained by retaining exactly the entries of the corresponding row of* G *whose mesh index lies in the image of* ι*. The handoff row* $e|_q$*, transport row* $h|_q$*, continuation row* $c|_q$*, provenance row* $p|_q$*, and local naming row* $n|_q$ *retain only the components whose source rows are retained by* $a|_q, j|_q, w|_q, r|_q, d|_q, m|_q$*.*

Theorem 644.5 (Regular Cauchy mesh finite submesh restriction)**.** *Let*

$$G = (a, j, w, r, d, m, e, h, c, p, n)$$

be an accepted $\mathsf{RegularCauchyMesh}^{\uparrow}$ *carrier, and let* q *be a displayed finite submesh selector for* G *in the sense of Definition 644.4. Suppose the retained StreamName windows, RegSeqRat readbacks, DyadicRatCore tolerance rows, DyadicMesh compatibility row,* $\mathsf{Real}^{\uparrow}$ *handoff, componentwise* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *rows are exactly the rows pulled back along the inclusion read* $\iota : q \to j$*. Then*

$$G|_q = (a|_q, j|_q, w|_q, r|_q, d|_q, m|_q, e|_q, h|_q, c|_q, p|_q, n|_q)$$

is an accepted $\mathsf{RegularCauchyMesh}^{\uparrow}$ *carrier.*

Moreover, every retained consumer read of a mesh cell in q *factors through the restricted rows*

$$a|_q, j|_q, w|_q, r|_q, d|_q, m|_q, e|_q, h|_q, c|_q, p|_q, n|_q.$$

It cannot recover a cell of j *outside* q*, an infinite mesh, quotient regular-Cauchy equality, host real equality, a chosen limiting representative, or an ambient Real-completeness theorem.*

The rate/modulus surface is unchanged: every retained Cauchy read uses the same displayed StreamName window row and DyadicRatCore tolerance ledger already present in G*, restricted to* q*, and no new tail bound or completion modulus is introduced.*

Proof. Project the accepted carrier through Definition 644.1. The visible data are exactly the finite request row a, mesh-index row j, window row w, readback row r, dyadic ledger d, mesh compatibility row m, handoff row e, transport row h, continuation row c, provenance row p, and local name row n.

The selector q is finite and every entry of q is read from the displayed mesh-index row j. Therefore $j|_q = q$ is a finite mesh-index row, and $a|_q$ is the corresponding finite request row obtained by keeping only the requests whose inspected mesh cells lie in q.

For each retained mesh cell, the StreamName window, RegSeqRat readback, DyadicRatCore tolerance entry, and DyadicMesh compatibility entry are already rows of the original accepted packet. Pulling those rows back along ι gives $w|_q, r|_q, d|_q, m|_q$ without adding any analytic object. The mesh compatibility row remains a compatibility row because it now states the same cell-window agreement after both sides have been restricted to the same displayed submesh.

The rows e, h, c, p, n are administrative over the displayed finite route. Retaining only the components whose sources survive in $a|_q, j|_q, w|_q, r|_q, d|_q, m|_q$ yields the handoff, transport, continuation, provenance, and naming rows $e|_q, h|_q, c|_q, p|_q, n|_q$. These rows have exactly the roles required by Definition 644.1, so the restricted tuple is a $\mathsf{RegularCauchyMesh}^{\uparrow}$ carrier.

Acceptance follows from the local certificate surface of Definition 644.3. Carrier admission is the restricted finite tuple, finite mesh request exposure is through $a|_q$ and $j|_q$, selected windows and readbacks are $w|_q$ and $r|_q$, the dyadic and mesh rows are $d|_q$ and $m|_q$, and the handoff, transport, route, provenance, and local naming rows are $e|_q, h|_q, c|_q, p|_q, n|_q$.

Now let a retained consumer read a cell of q. In the original packet such a read factors through the displayed mesh-index row j, the attached window row w, the readback row r, the dyadic ledger d, the compatibility row m, and then the handoff and certificate rows. Since the cell lies in the image of ι, every one of those entries is present in the restricted tuple. Hence the same read factors through the restricted rows.

No omitted cell can be recovered from this factorization, because every retained row was formed by pullback along $q \to j$ and contains no component indexed outside q. The non-escape clauses are inherited from the carrier inventory in Definition 644.1: neither G nor $G|_q$ has a coordinate for an infinite mesh, quotient regular-Cauchy equality, host real equality, a chosen limiting representative, or an ambient Real-completeness theorem. □

Chapter 645

A Concrete Naming Certificate for $\mathsf{BoundedCauchyCover}^{\uparrow}$

The $\mathsf{BoundedCauchyCover}^{\uparrow}$ interface names the finite observation surface that carries a Cauchy modulus from a precision budget to the windows read by the real-completion diagonal route. It sits between the real observation budget and the $\mathsf{Real}^{\uparrow}$ seal: the packet remembers the requested budget, the modulus row, the finite stream-window cover, the dyadic tolerance readback, the regular rational consumption row, transport, continuations, provenance, and local naming. It does not export quotient streams, selected limits, host real equality, or an ambient completeness datum.

The finite cover route consumes the finite-window surface of chapter 126, the dyadic tolerance ledger of chapter 291, the regular-rational consumption row of chapter 301, and the $\mathsf{Real}^{\uparrow}$ seal boundary of chapter 38. The row B remains grounded in chapter 611, and the displayed budget-to-window route passes the sibling rows to the Real and Completion diagonal consumer rather than supplying an independent completeness principle.

Definition 645.1 (Bounded Cauchy cover carrier)**.** *A* $\mathsf{BoundedCauchyCover}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (B, M, W, D, R, H, C, P, N)$$

with the following displayed coordinates:

1. *B is the unary precision budget requested by the downstream real-completion consumer;*
2. *M is the Cauchy modulus row that turns B into a finite threshold for the relevant tail comparisons;*
3. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *observation-window cover selected by the modulus threshold;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance readback attached to the covered windows;*
5. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity consumption row that reads the covered windows through the regular rational source;*
6. *H records componentwise* hsame *transports for the budget, modulus row, window cover, dyadic readback, regularity row, provenance, and local name;*
7. *C records displayed* Cont *routes from B to M, from M to W, from W to D, and from D to R;*
8. *P records* Pkg *provenance over* $\mathsf{Nat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*

9. N is the local $\mathsf{NameCert}_{\mathsf{BoundedCauchyCover}^{\uparrow}}$ *row.*
The classifier compares two such packets only after transporting their budgets, Cauchy modulus rows, window covers, dyadic readbacks, and $\mathsf{RegSeqRat}^{\uparrow}$ *rows to a shared finite cover. The carrier has no coordinate for a quotient stream, selected limit, host real equality, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.BoundedCauchyCoverUp.BoundedCauchyCoverTasteGate single carrier alignment`

Theorem 645.2 (Bounded Cauchy cover NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{BoundedCauchyCover}^{\uparrow}}$ *surface for Definition 645.1 consists exactly of carrier admission, unary budget exposure, Cauchy modulus exposure, finite* $\mathsf{StreamName}^{\uparrow}$ *cover selection,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance readback,* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity consumption, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and the local naming row.*

Proof. Carrier admission is projection from the displayed packet K. The rows B, M, W, D, R expose the precision budget, Cauchy modulus threshold, finite observation cover, dyadic readback, and regular rational consumption data.

The cover obligations are finite. The route first reads B, then the modulus row M, then the selected windows W, and only then the dyadic tolerance and regularity rows D and R.

The rows H, C, P, N supply transport, route replay, provenance, and local naming. Since no quotient stream, selected limit, host real equality, or ambient completeness coordinate exists in the carrier, the listed rows exhaust the local certificate. □

Theorem 645.3 (Bounded Cauchy cover finite-window coverage)**.** *For an accepted* $\mathsf{BoundedCauchyCover}^{\uparrow}$ *carrier, every exported dyadic tolerance readback in D is covered by the finite* $\mathsf{StreamName}^{\uparrow}$ *windows in W, and every window in W is selected from the budget B through the Cauchy modulus row M and the displayed route C.*

Proof. Project the accepted packet to the rows B, M, W, D, H, C. The first displayed route sends the unary budget to the Cauchy modulus row, and the second sends the resulting threshold to the finite window cover.

The route from W to D is the only displayed path by which a dyadic tolerance readback enters the packet. Componentwise transport in H preserves the budget, modulus, cover, and readback rows when the packet is compared with another accepted carrier.

Thus every dyadic readback exported by the packet is attached to a selected finite window. No readback can be imported from an unbounded stream schedule or a hidden completion object. □

Theorem 645.4 (Bounded Cauchy cover budget transport)**.** *Classifier transport for* $\mathsf{BoundedCauchyCover}^{\uparrow}$ *preserves the same budget-to-cover route. If two accepted packets classify together, then after applying the displayed transports in H their B, M, W, D, and R rows lie over a shared finite cover, and the route*

$$B \longmapsto M \longmapsto W \longmapsto D \longmapsto R$$

is replayed by the displayed continuations in C.

Proof. Begin with the classifier clause in the carrier definition. It compares packets only after the budget, modulus row, windows, dyadic readback, and regularity row have been transported to a common finite cover.

The continuation coordinate C then replays the same route on the transported rows. The budget row selects the modulus row, the modulus row selects the finite cover, the cover supplies the dyadic readback, and the readback feeds the regularity consumption row.

The provenance and local naming rows P, N are transported with the same packet. Since the carrier has no coordinate for quotient streams, selected limits, host real equality, or ambient completeness, transport cannot introduce any additional comparison data. □

Theorem 645.5 (Bounded Cauchy cover Real handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *diagonal-seal consumer of an accepted* $\mathsf{BoundedCauchyCover}^{\uparrow}$ *packet receives exactly the bounded cover rows*

$$B, M, W, D, R, H, C, P, N.$$

The consumer reads a unary precision budget, a Cauchy modulus row, a finite $\mathsf{StreamName}^{\uparrow}$ *observation-window cover, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance readback, a* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity consumption row, transport, continuation, provenance, and local naming. It receives no quotient stream, selected limit, host real equality, or ambient completeness datum.*

Proof. Start from finite-window coverage. It places every dyadic readback under the finite windows selected by the budget and modulus rows.

Use budget transport to move the same route to the consumer-facing packet. The transported route is still $B \longmapsto M \longmapsto W \longmapsto D \longmapsto R$, with H, C, P, N carrying the displayed bookkeeping.

The handoff to $\mathsf{Real}^{\uparrow}$ can therefore inspect only those rows. All excluded analytic objects are absent from the carrier, so the diagonal-seal consumer receives the finite cover surface and nothing outside it. □

Closure status for $\mathsf{NameCert}_{\mathsf{BoundedCauchyCover}^{\uparrow}}$.

Constructive story: A $\mathsf{BoundedCauchyCover}^{\uparrow}$ packet is generated from a unary precision budget, a Cauchy modulus row, finite StreamName observation-window cover, DyadicRatCore tolerance readback, RegSeqRat regularity consumption row, componentwise transports, continuation routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{BoundedCauchyCover}^{\uparrow}}$, seed)

Scope closed: Definition 645.1, Definition 645.2, Definition 645.3, Definition 645.4, and Definition 645.5 bind the finite budget-to-modulus-to-window-to-readback-to-RegSeqRat route used by RealUp diagonal-seal consumers.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{BoundedCauchyCover}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close quotient stream equality, selected limits, host real equality, ambient completeness, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, finite-window coverage, budget transport, and RealUp handoff for the same bounded Cauchy cover packet.

The $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ hub routes the current Phase Real and Completion diagonal-limit packet through the L10 sibling spine of chapter 291, chapter 126, chapter 301, and chapter 38; the child files below keep the route finite and refuse quotient streams, selected limits, countable choice, host real equality, and ambient completeness.

Chapter 646

A Concrete Naming Certificate for $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$

The $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ surface records the finite compatibility packet between the Real completeness diagonal-limit route and the downstream completion-seal consumer. It ties the accepted diagonal-limit packet, the three-leg regularity estimate, the Cauchy limit seal, stream windows, regular rational readback, dyadic tolerance bookkeeping, and the final $\mathsf{Real}^{\uparrow}$ seal into one local naming certificate. The packet is a compatibility surface, not a host completion theorem and not a choice of a completed real.

Definition 646.1 (Diagonal-limit compatibility carrier)**.** *A* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

with the following displayed rows:

1. *R is the accepted* $\mathsf{RealCompleteness}^{\uparrow}$ *diagonal-limit packet whose diagonal route is being consumed;*
2. *T is the accepted* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *three-leg estimate packet controlling the selected diagonal windows;*
3. *S is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *seal route through which downstream completion-facing consumers read the diagonal handoff;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger shared by the diagonal-limit row, the triangle estimate, and the seal route;*
5. *W is the* $\mathsf{StreamName}^{\uparrow}$ *window family naming the finite observations used by the diagonal selector and by the seal consumer;*
6. *Q is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row exposed after the window and dyadic ledger have been fixed;*
7. *L is the* $\mathsf{Real}^{\uparrow}$ *seal class reached by the compatibility route;*
8. *H records componentwise* hsame *transports for R, T, S, D, W, Q, L and the structural rows;*
9. *C records the displayed* Cont *routes from the diagonal-limit packet through the triangle estimate, seal route, tolerance ledger, window family, regular rational readback, and* $\mathsf{Real}^{\uparrow}$ *seal;*
10. *P is the* Pkg *provenance over* $\mathsf{RealCompleteness}^{\uparrow}$, $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row.*

The carrier classifier reads only these displayed rows and their hsame *and* Cont *transports.*

Lean4 (definition) `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityUp`

Theorem 646.2 (Diagonal-limit compatibility NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *surface has five finite obligations:*

1. *carrier admission for the packet $K = (R, T, S, D, W, Q, L, H, C, P, N)$ of Definition 646.1;*
2. *triangle-bound and selector alignment, requiring the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *row T to consume the same selected windows and dyadic tolerance ledger named by R, W, D;*
3. $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route compatibility, requiring the seal row S to read the regular-rational handoff Q and the* $\mathsf{Real}^{\uparrow}$ *seal class L only after the displayed diagonal route has passed through T, D, W;*
4. *classifier transport over the shared* hsame *rows in H and the displayed continuation routes in C;*
5. *non-escape for quotient streams, selected host limits, host real equality, choice data, and ambient completeness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityPacketNameCertObligations`

Proof. Project the carrier of Definition 646.1. The rows R, T, S, D, W, Q, L are the only mathematical coordinates, and H, C, P, N are the only transport, route, provenance, and naming coordinates.

The triangle-bound and selector-alignment obligation is read from T together with R, W, D. The same window family and dyadic ledger are displayed before the estimate is consumed, so the three-leg bound cannot choose a second selector surface.

The seal compatibility obligation is read next. The route S reaches Q and L only through the displayed continuation rows in C, after the diagonal-limit packet, triangle estimate, tolerance ledger, and windows have been fixed.

Finally inspect the coordinate list. Since no quotient stream, selected host limit, host real equality row, choice datum, or ambient completeness principle is present, no classifier transport or seal consumer can export one. □

Theorem 646.3 (Diagonal-limit compatibility terminal Real route)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

every terminal $\mathsf{Real}^{\uparrow}$ *seal read factors through the displayed route*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Here R is read from $\mathsf{RealCompleteness}^{\uparrow}$*, T from* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$*, S from* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, D from* $\mathsf{DyadicRatCore}^{\uparrow}$*, W from* $\mathsf{StreamName}^{\uparrow}$*, Q from* $\mathsf{RegSeqRat}^{\uparrow}$*, and L from* $\mathsf{Real}^{\uparrow}$*. The terminal read has no quotient stream, host limit, choice datum, or ambient completeness principle available outside this route.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility terminal real route`

Proof. Project the accepted carrier of Definition 646.1. Its displayed rows name the diagonal-limit packet, triangle estimate, seal route, tolerance ledger, window family, rational readback, terminal Real seal, transport rows, continuation rows, provenance, and local naming row.

Apply the NameCert obligation theorem Definition 646.2. The triangle-bound clause routes T through R, W, D, and the seal-route clause reads Q and L only after R, T, D, W have been fixed.

Finally use the non-escape clause of the same obligation theorem. Since no quotient stream, host limit, choice datum, or ambient completeness principle is a coordinate of K, a terminal $\mathsf{Real}^{\uparrow}$ seal read cannot leave the displayed chain. □

Theorem 646.4 (Diagonal-limit terminal selector Real seal pullback)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

any terminal $\mathsf{Real}^{\uparrow}$ *seal read mediated by a* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *row factors through the same displayed window family* W*, dyadic ledger* D*, regular readback* Q*, seal row* S*, and terminal Real row* L *of* K*. Conversely, preserving* W, D, Q, S, L *together with the displayed* H, C, P, N *rows preserves the selector-mediated terminal seal route.*

Thus the selector route and the terminal $\mathsf{Real}^{\uparrow}$ *seal form one pullback packet over the displayed* BHist *carrier rows. The packet exports no quotient stream, selected host limit, host real equality, choice datum, hidden selector, or ambient completeness coordinate outside* K *and the finite selector boundary.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier terminal selector real seal pullback`

Proof. Project the accepted carrier of Definition 646.1. The rows W, D, Q, S, L are displayed coordinates of K, and the structural rows H, C, P, N are the only transport, route, provenance, and local naming rows available to the terminal read.

Apply Definition 646.3. It forces every terminal $\mathsf{Real}^{\uparrow}$ seal read of K through $R, T, S, D, W, Q, L, H, C, P, N$, so a selector-mediated read cannot skip the shared window, dyadic, readback, seal, or terminal Real rows.

Now use the finite selector boundary of Definition 782.10. A diagonal-limit or Real-completion consumer using a $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ packet must read the finite route through its displayed budget, schedule, window, dyadic, regular, and seal-facing rows before reaching the completion-facing endpoint.

The two routes meet on W, D, Q, S, L and their displayed H, C, P, N transports. Therefore preservation of these rows preserves the selector-mediated terminal seal route, while any accepted selector-mediated terminal seal read factors through the same pullback packet.

Finally use Definition 646.11 together with the non-escape clause of the finite selector boundary. Neither side exports quotient streams, selected host limits, host real equality, choice data, hidden selectors, or ambient completeness; hence no external coordinate can witness another terminal seal route. □

Theorem 646.5 (Diagonal-limit window ledger pullback)**.** *For any accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

preserving the displayed $\mathsf{StreamName}^{\uparrow}$ *window family* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* Q*, and terminal* $\mathsf{Real}^{\uparrow}$ *seal* L *is exactly the finite pullback condition needed for selector-mediated terminal Real reads. A terminal selector read that preserves these four rows and the*

displayed H, C, P, N support is the same finite Real-seal route; a read that changes one of them is not the accepted selector-mediated terminal route.

Proof. Project the carrier of Definition 646.1. The rows W, D, Q, L are displayed as the window family, dyadic ledger, regular readback, and terminal Real seal of the packet, while H, C, P, N provide the only transport, route, provenance, and local naming support.

Apply Definition 646.4. It states that any terminal $\mathsf{Real}^{\uparrow}$ seal read mediated by a FiniteObservationBudgetSelecto row factors through the same displayed W, D, Q, S, L rows, and that preserving those rows together with H, C, P, N preserves the selector-mediated terminal seal route.

Next use Definition 646.3. It forces every terminal $\mathsf{Real}^{\uparrow}$ seal read of K through the finite route $R, T, S, D, W, Q, L, H, C, P, N$. The finite observation selector boundary Definition 782.10 supplies the matching selector side, where a diagonal-limit or Real-completion consumer reads only the finite budget, schedule, window, dyadic, regular, seal-facing, transport, route, provenance, and naming rows.

The forward direction follows by intersection of these two finite routes: their shared Real-facing data are exactly W, D, Q, L with support H, C, P, N. The reverse direction follows because preserving those rows preserves the selector-mediated terminal seal route already fixed by the terminal selector pullback theorem.

Finally inspect the excluded coordinates in both packets. Neither the diagonal carrier nor the finite selector boundary contains quotient streams, selected host limits, host real equality, choice data, hidden selectors, or ambient completeness. Therefore no external route can replace the displayed window-ledger pullback. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility window ledger pullback`

Theorem 646.6 (Diagonal-limit triangle selector alignment)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the triangle-bound row T consumes exactly the selected window family W and dyadic tolerance ledger D named by the $\mathsf{RealCompleteness}^{\uparrow}$ *diagonal packet R. It has no second selector, no alternate dyadic ledger, and no hidden readback route outside the displayed compatibility carrier.*

Proof. Project the carrier of Definition 646.1. The rows R, T, D, W are displayed before the seal route or readback rows are inspected.

Use the NameCert obligations of Definition 646.2. The triangle-bound and selector-alignment clause forces T to read the same selected windows and the same dyadic ledger named by R, W, D.

The non-escape theorem Definition 646.11 excludes any additional selector or ledger coordinate. Hence the triangle selector surface is exactly W, D over the diagonal packet R. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility triangle selector alignment`

Theorem 646.7 (Diagonal-limit seal route compatibility)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route S reaches the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row Q and the* $\mathsf{Real}^{\uparrow}$ *seal class L only through the displayed rows R, T, D, W. The seal route cannot bypass the diagonal packet, triangle estimate, dyadic ledger, or selected window family.*

Proof. Start from the compatibility carrier and project the route rows R, T, S, D, W, Q, L.

Apply the NameCert obligation theorem. Its seal-route compatibility clause places the read of Q and L after the diagonal-limit packet, triangle estimate, dyadic ledger, and windows have been fixed.

Now use Definition 646.11. Since the packet exports only the displayed coordinates, S has no continuation route to Q or L except through R, T, D, W and the continuation rows already recorded in C. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility seal route compatibility`

Theorem 646.8 (Diagonal-limit selector-observer seal correspondence)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Let*

$$U = (B, W_U, Q_U, S_U, L_U, H_U, C_U, P_U, N_U)$$

be an accepted $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet, and let*

$$O = (R_O, W_O, Q_O, D_O, S_O, L_O, H_O, C_O, P_O, N_O)$$

be an accepted $\mathsf{DiagonalLimitObserver}^{\uparrow}$ *packet. The three packets name the same terminal* $\mathsf{Real}^{\uparrow}$ *seal route exactly when their displayed L10 rows agree componentwise by* hsame*: the* $\mathsf{StreamName}^{\uparrow}$ *windows* W, W_U, W_O*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows* Q, Q_U, Q_O*, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows* S, S_U, S_O*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledgers* D, D_O*, and the terminal* $\mathsf{Real}^{\uparrow}$ *rows* L, L_U, L_O *are transported through the displayed* H, H_U, H_O*,* C, C_U, C_O*,* P, P_U, P_O*, and* N, N_U, N_O *rows. No quotient stream, host real equality, hidden selector, selected host limit, detached limit object, or ambient completeness principle can witness equality of the terminal route.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySelectorObserverSealCorresp`

Proof. Project the three accepted carriers. The compatibility packet exposes W, Q, S, D, L through H, C, P, N; the selector-seal packet exposes W_U, Q_U, S_U, L_U through H_U, C_U, P_U, N_U; and the observer packet exposes W_O, Q_O, D_O, S_O, L_O through H_O, C_O, P_O, N_O.

First suppose the displayed L10 rows agree componentwise by hsame through those structural rows. Apply Definition 646.7 and Definition 646.12. They place the compatibility seal route behind the same stream-window, tolerance, readback, seal, and terminal Real rows.

Next apply Definition 1081.5 and Definition 961.3. The selector and observer packets expose the same downstream route positions, so the componentwise transport rows identify one terminal $\mathsf{Real}^{\uparrow}$ seal route.

Conversely, suppose the three accepted packets name the same terminal route. The cited seal-route and root-dependency theorems force any compatibility read of the terminal row through W, Q, S, D, L, while the selector handoff and observer exposure theorems force the sibling packets through their corresponding window, readback, tolerance, seal, and terminal rows.

Finally use the non-escape clauses of the three packets. Since none exports a quotient stream, host equality, hidden selector, selected host limit, detached limit object, or ambient completeness coordinate, the terminal-route equality has no witness except componentwise hsame through the displayed Cont, Pkg, and $\mathsf{NameCert}$ rows. □

Theorem 646.9 (DiagonalLimitCompatibility functor-uniform terminal factorization)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet, let*

$$F = (S_F, T_F, M_F, W_{F,0}, W_{F,1}, R_F, D_F, K_F, E_F, H_F, C_F, P_F, N_F)$$

be an accepted $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet, and let*

$$U = (I_U, W_U, M_U, Q_U, T_U, E_U, H_U, C_U, P_U, N_U)$$

be an accepted $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *packet. These three packets name the same terminal* $\mathsf{Real}^{\uparrow}$ *seal route exactly when their displayed terminal rows agree componentwise: the* $\mathsf{StreamName}^{\uparrow}$ *windows* $W, W_{F,0}, W_{F,1}, W_U$*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows* Q, R_F*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledgers* D, D_F, Q_U*, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows* S, S_F, T_F*, and the terminal* $\mathsf{Real}^{\uparrow}$ *rows* L, E_F, E_U *are identified through the displayed* hsame *rows* H, H_F, H_U*,* Cont *rows* C, C_F, C_U*,* Pkg *rows* P, P_F, P_U*, and local* NameCert *rows* N, N_F, N_U*.*

Equivalently, the diagonal compatibility route, the functor standard-reflection route, and the finite-family uniform-Cauchy consumer route factor through one terminal BEDC seal packet over those displayed rows. No quotient stream, host real equality, hidden selector, selected host limit, countable-choice schedule, detached limit object, or ambient completeness coordinate can witness another terminal route.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityFunctorUniformTerminalFacto`

Proof. First read the diagonal compatibility packet through Definition 646.8. Its terminal route is already fixed by the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows, together with the visible H, C, P, N structure.

Now attach the functor side. By Definition 1116.13, every standard-reflection read of F passes through its source and target seal rows, transport row, stream windows, regular readback, dyadic tolerance ledger, classifier row, terminal $\mathsf{Real}^{\uparrow}$ endpoint, and the displayed H_F, C_F, P_F, N_F rows. Under the componentwise agreements in the statement, this is the same terminal seal route as the diagonal packet.

Next attach the uniform-Cauchy consumer side. Apply Definition 435.57. The $\mathsf{RegSeqRat}^{\uparrow}$-, $\mathsf{Real}^{\uparrow}$-, and completion-facing reads of U are exhausted by the finite package $I_U, W_U, M_U, Q_U, T_U, E_U, H_U, C_U, P_U, N$ so the seal row E_U is downstream of the same window, tolerance, readback, and structural rows.

Conversely, suppose the three accepted packets name one terminal $\mathsf{Real}^{\uparrow}$ seal route. The diagonal correspondence theorem forces the diagonal route through $W, Q, D, S, L, H, C, P, N$; the functor bridge theorem forces the standard-reflection route through $W_{F,0}, W_{F,1}, R_F, D_F, S_F, T_F, E_F, H_F, C_F, P_F, N_F$; and the uniform-Cauchy factorization forces the consumer route through $W_U, Q_U, T_U, E_U, H_U, C_U, P_U, N_U$. Since each cited theorem excludes off-packet quotient, equality, selector, choice, limit, and completeness coordinates, the only possible witness of sameness is componentwise agreement through the displayed transport, continuation, provenance, and local naming rows. □

Theorem 646.10 (Diagonal-limit compatibility classifier transport)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

componentwise hsame *rows* H *and displayed* Cont *routes* C *preserve the same compatibility classifier for the diagonal packet, triangle-bound row, seal route, dyadic ledger, selected windows, readback row, and real seal class. Transport cannot change the classifier by adding quotient streams, selected host limits, host real equality, choice data, or ambient completeness.*

Proof. Project H and C from the carrier. They are the only rows that move displayed coordinates between classifier presentations.

Apply Definition 646.2. Its classifier-transport clause states that transport is componentwise over the rows R, T, S, D, W, Q, L and their displayed continuation routes.

The non-escape theorem then fixes the transport boundary. Because no extra quotient, host-limit, equality, choice, or completeness coordinate is exported, the transported packet remains on the same $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ classifier surface. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityClassifierTransport`

Theorem 646.11 (Diagonal-limit compatibility non-escape)**.** *An accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet exports only the rows*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Every downstream $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer factors through the accepted* $\mathsf{RealCompleteness}^{\uparrow}$ *diagonal-limit packet, the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *estimate, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the displayed* hsame *transports, the* Cont *routes,* Pkg *provenance, and the local* NameCert *row. The packet exports no quotient stream, no selected host limit, no host real equality, no choice datum, and no ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityNonEscape`

Proof. Start from the accepted carrier $K = (R, T, S, D, W, Q, L, H, C, P, N)$. The displayed rows name exactly the diagonal-limit source, triangle estimate, seal route, dyadic ledger, window family, regular rational readback, real seal class, transports, continuations, provenance, and local certificate.

Use the NameCert obligation theorem. Its alignment rows force the triangle estimate and the seal route to consume the same selected windows and tolerance ledger already named by the diagonal-limit packet.

The only consumer-facing paths are the continuations in C, transported componentwise by H. None of those paths has an input coordinate for quotient streams, selected host limits, host real equality, choice data, or ambient completeness, so none of those objects can be exported from the packet. □

Theorem 646.12 (Diagonal-limit root dependency triad)**.** *Every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet reads the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger D, the* $\mathsf{StreamName}^{\uparrow}$ *window family W, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback Q before the* $\mathsf{Real}^{\uparrow}$ *seal row L is available to a downstream consumer. The same packet displays the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route S, the* $\mathsf{RealCompleteness}^{\uparrow}$ *diagonal source R, and the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *triangle row T as named side rows for that read.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root dependency triad`

Proof. Project the carrier $K = (R, T, S, D, W, Q, L, H, C, P, N)$. The rows D, W, Q are listed before the seal row L, and the side rows S, R, T are displayed in the same finite packet.

Apply Definition 646.2. Its selector and seal-route clauses force the triangle row and seal route to read the shared dyadic ledger, stream windows, and regular-rational readback before the $\mathsf{Real}^{\uparrow}$ seal row can be consumed.

Finally use Definition 646.11. No ambient completion, host limit, quotient stream, equality row, or choice datum supplies another route to L. □

Theorem 646.13 (Diagonal-limit shared modulus handoff)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted DiagonalLimitCompatibility$^{\uparrow}$ *packet. Suppose its Real-completion consumer route reads an accepted* CauchyModulusExtraction$^{\uparrow}$ *packet over the same finite budget, window family, regular-rational schedule, and dyadic comparison rows, and suppose it also reads an accepted* CauchyModulusMeet$^{\uparrow}$ *packet over the same two regular-rational stream readbacks. Then the route to the* Real$^{\uparrow}$ *seal row L passes through one shared finite modulus surface: the selected budget row, the* StreamName$^{\uparrow}$ *windows, the* RegSeqRat$^{\uparrow}$ *schedule and readback, the* DyadicRatCore$^{\uparrow}$ *ledger, the extracted modulus row, and the* CauchyModulusMeet$^{\uparrow}$ *shared threshold. No quotient stream, selected host limit, host real equality, trichotomy, choice datum, or ambient completeness principle supplies another handoff to L.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier shared modulus handoff`

Proof. Start with the accepted diagonal packet K. Apply Definition 646.12; the route to L has already read the dyadic ledger D, the stream windows W, and the regular-rational readback Q, with R, T, S displayed as the source, triangle, and seal side rows.

Next read the modulus-extraction packet on that same budget and window surface. By Definition 641.22 and Definition 641.15, the Real-completion consumer can reach the extracted modulus only after the selected budget row, StreamName$^{\uparrow}$ windows, RegSeqRat$^{\uparrow}$ schedule, DyadicRatCore$^{\uparrow}$ ledger, and extracted modulus row have all been displayed inside the finite extraction packet.

Now attach the meet packet to the two regular-rational stream readbacks. Apply Definition 462.41. The meet row determines one shared threshold packet for the paired reads, so the seal-facing route cannot split the extracted modulus and the paired readbacks into separate threshold surfaces.

Finally use Definition 646.11. Since the diagonal compatibility packet exports no quotient stream, selected host limit, host real equality, trichotomy row, choice datum, or ambient completeness principle, the shared budget-window-schedule-dyadic-modulus-meet surface is the only handoff available before L. □

Theorem 646.14 (Diagonal-limit compatibility finite-prefix budget handoff)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Let*

$$F = (Q_F, B_F, W_F, D_F, R_F, S_F, E_F, H_F, C_F, P_F, N_F)$$

be an accepted FinitePrefixLimitBudget$^{\uparrow}$ *packet serving the same* StreamName$^{\uparrow}$ *window,* RegSeqRat$^{\uparrow}$ *readback, and Real or Cauchy-limit seal boundary as K under the displayed* hsame *transports. Then every diagonal-limit or Real-completion consumer of K that reads F must pass through the finite prefix route*

$$Q_F \to B_F \to W_F \to D_F$$

before reading the diagonal-limit readback row Q, the CauchyLimitSeal$^{\uparrow}$ *route S, or the* Real$^{\uparrow}$ *seal row L. The handoff exports no quotient stream, selected host limit, host real equality, countable choice datum, hidden tail schedule, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier finite prefix budget handoff`

Proof. Start with the finite-prefix packet F. Apply Definition 919.11 and Definition 919.19. These theorems place every diagonal-selector, diagonal-limit, and Real-completion read behind the finite route $Q_F \to B_F \to W_F \to D_F$ before the regular readback row R_F or seal row S_F is available.

Now attach the diagonal-limit packet K. The shared $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and Real or Cauchy-limit seal boundary identify W_F, R_F, S_F with the corresponding W, Q, S, L surface of K through the displayed hsame transports and Cont routes.

Use Definition 646.59 and Definition 646.15. The first theorem identifies the public budget route through $R, T, D, W, S, Q, L, H, C, P, N$, while the second forces any compatible tail handoff to meet the same finite window, dyadic ledger, readback, and seal rows before a completion-facing read reaches Q or L.

Finally apply Definition 646.11. Since the diagonal-limit packet exports no quotient stream, selected host limit, host real equality, choice datum, hidden tail oracle, or ambient completeness row, and the finite-prefix packet records hidden-tail and outside-prefix refusals in E_F, there is no route to Q, S, or L except through $Q_F \to B_F \to W_F \to D_F$. □

Theorem 646.15 (Diagonal-limit shared-tail budget factorization)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Let F be a compatible* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet whose finite windows, dyadic ledger, regular readback, and* $\mathsf{Real}^{\uparrow}$ *seal rows agree with W, D, Q, L under the displayed* hsame *transports. Then every completion-facing route from K to the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *paired seal factors through the fusion shared-threshold row before the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route reads Q and L. The factorization exports no quotient stream, host limit, hidden tail oracle, choice datum, or ambient completeness row.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySharedTailBudgetFactorizati`

Proof. Project the diagonal packet K. The displayed rows expose exactly the source R, triangle row T, seal route S, dyadic ledger D, window family W, regular readback Q, Real seal row L, transports H, continuations C, provenance P, and local name N.

Apply Definition 646.12. It orders the budget-facing rows D, W, Q, L before a downstream consumer can read the Real seal, so the compatible fusion packet must meet the same finite window and ledger surface through the displayed hsame transports.

Now use the fusion handoff rows Definition 658.6 and Definition 658.5. They force the paired finite-window and dyadic-budget reads through the shared-threshold row before any seal-facing read can reach the diagonal readback.

Finally apply Definition 646.11 and route the paired agreement consumer through chapter 699 only after that shared-threshold row has been displayed. The non-escape boundary excludes every quotient stream, host limit, hidden tail oracle, choice datum, and ambient completeness route outside the two finite packets. □

Theorem 646.16 (Diagonal-limit consumer threshold)**.** *A downstream completion-facing consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet may inspect the readback and seal rows Q, L only after the seven dependency rows*

$$R, T, S, D, W, Q, L$$

and the local rows

$$\mathsf{BHist}, \mathsf{hsame}, \mathsf{Cont}, \mathsf{Pkg}, \mathsf{NameCert}$$

have been displayed by the packet.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityConsumerThreshold`

Proof. Start with the carrier projection. The mathematical dependency rows R, T, S, D, W, Q, L and the local structural rows H, C, P, N are the complete displayed surface of the packet.

Use Definition 646.2. The local certificate admits only that carrier, its componentwise hsame transports, its displayed Cont routes, its Pkg provenance, and its own NameCert row.

Apply Definition 646.11. Since no undisplayed completion or host coordinate is exported, every consumer of Q, L has already crossed the displayed dependency and local rows. □

Theorem 646.17 (Diagonal-limit audit handoff)**.** *The root-unblock surface for* DiagonalLimitCompatibility$^{\uparrow}$ *is the package formed by Definition 646.12, Definition 646.16, and Definition 646.11. It exposes the triad D, W, Q, the side rows S, R, T, and the local* BHist/hsame/Cont/Pkg/NameCert *boundary without importing ambient completeness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityAuditHandoff`

Proof. The root dependency triad names the required ledger, window, and readback rows and records the Cauchy seal, Real completeness, and triangle-bound side rows.

The consumer-threshold theorem then places every downstream read of Q, L behind the seven dependency rows and the local structural rows.

The non-escape theorem supplies the audit boundary. It removes quotient streams, selected host limits, host real equality, choice data, and ambient completeness from the handoff, so the three cited results form the complete root-unblock surface. □

Theorem 646.18 (Diagonal-limit obligation-closure package)**.** *An accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

forms an obligation-closure surface for the diagonal-limit handoff. The surface packages the triangle selector T, the CauchyLimitSeal$^{\uparrow}$ *route S, the shared* StreamName$^{\uparrow}$ *window ledger W, the* DyadicRatCore$^{\uparrow}$ *tolerance ledger D, the* RegSeqRat$^{\uparrow}$ *readback Q, the* Real$^{\uparrow}$ *seal class L, componentwise* hsame *transport H, displayed* Cont *routes C,* Pkg *provenance P, and the local* NameCert *row N as the only rows available to downstream completion consumers.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityObligationClosurePackage`
↪ variant `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityTasteGate single carrier alignment`

Proof. Project the carrier of Definition 646.1. The displayed coordinates already list the diagonal source, triangle row, seal route, tolerance ledger, window ledger, readback row, real seal class, transports, continuations, provenance, and local certificate.

Apply Definition 646.2, Definition 646.6, and Definition 646.7. These results identify the obligation rows, fix the triangle selector to W, D, and force the seal route to reach Q, L only through R, T, D, W.

Finally use Definition 646.10 and Definition 646.11. Transport preserves the same classifier rows, and non-escape excludes quotient streams, selected host limits, host real equality, choice data, and ambient completeness. Thus the listed packet is the complete obligation-closure surface. □

Theorem 646.19 (Diagonal-limit shared window ledger)**.** *For an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the StreamName$^{\uparrow}$ *row W is the shared finite window ledger for the diagonal selector, triangle-bound estimate, dyadic tolerance read,* RegSeqRat$^{\uparrow}$ *readback, and downstream* CauchyLimitSeal$^{\uparrow}$ *consumer. No consumer may replace W after entering the displayed compatibility packet.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySharedWindowLedger`

Proof. Start from the carrier projection. The window row W is displayed together with the diagonal packet R, triangle row T, dyadic ledger D, seal route S, readback row Q, and real seal class L.

Use Definition 646.6. It fixes the triangle row to the same selected windows named by R, W, D and excludes a second selector surface.

Use Definition 646.7 and Definition 646.10. The seal route can reach Q, L only after W has been fixed, and transport preserves that same compatibility classifier.

The non-escape theorem, Definition 646.11, supplies the boundary. Since no alternate window family is exported, W remains the shared ledger for every downstream read. □

Theorem 646.20 (Diagonal-limit seal consumer threshold)**.** *In an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

a downstream CauchyLimitSeal$^{\uparrow}$ *or* Real$^{\uparrow}$ *consumer may inspect the* RegSeqRat$^{\uparrow}$ *readback Q and the* Real$^{\uparrow}$ *seal class L only after the diagonal packet R, triangle selector row T, dyadic tolerance ledger D, shared window ledger W, componentwise* hsame *transport H, displayed* Cont *routes C,* Pkg *provenance P, and local* NameCert *row N have been read.*

Proof. Project the accepted carrier and isolate the consumer-facing rows S, Q, L. The seal route is part of the displayed packet and is not an independent completion principle.

Apply Definition 646.2. Its seal-compatibility and classifier-transport clauses place the read of Q, L behind the diagonal route, triangle estimate, tolerance ledger, window family, transports, continuations, provenance, and local naming row.

Now apply Definition 646.7. The route S cannot bypass R, T, D, W when it reaches Q and L.

Finally use Definition 646.11. Because the packet exports no selected host limit, host real equality, choice datum, or ambient completeness principle, the displayed rows form the threshold for every downstream seal consumer. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility seal consumer threshold`

Theorem 646.21 (Diagonal-limit source ledger)**.** *For an accepted* DiagonalLimitCompatibility$^{\uparrow}$ BHist *carrier*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the source ledger is exactly the displayed RealCompleteness$^{\uparrow}$ *row R, triangle row T, seal route S, dyadic tolerance ledger D, stream-window row W, regular-rational readback row Q,* Real$^{\uparrow}$ *seal row L, componentwise* hsame *transport H, displayed* Cont *routes C,* Pkg *provenance P, and local* NameCert *row N of Definition 646.1. By Definition 646.11, no other source row is available to the compatibility packet.*

Proof. Project the carrier of Definition 646.1. The coordinates R, T, S, D, W, Q, L are the only source, estimate, seal, tolerance, window, readback, and real-seal rows in the packet.

Read the structural rows H, C, P, N. They do not create further source data; they transport, route, record provenance, and name the already displayed coordinates.

Apply Definition 646.11. Since the packet exports no host limit, quotient stream, choice datum, host real equality, or ambient completeness principle, the listed rows are the whole source ledger. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySourceLedger`

Theorem 646.22 (Diagonal-limit consumer transport)**.** *For accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ BHist *carriers* $K = (R, T, S, D, W, Q, L, H, C, P, N)$ *and* $K' = (R', T', S', D', W', Q', L', H', C', P', N')$*, every downstream seal or* $\mathsf{Real}^{\uparrow}$ *consumer that reads through the carrier of Definition 646.1 factors through the displayed componentwise* hsame *rows in* H, H' *and the displayed* Cont *routes in* C, C'*, with* Pkg *provenance* P, P' *and local* $\mathsf{NameCert}$ *rows* N, N' *preserving the same compatibility surface. By Definition 646.11, no consumer may bypass those rows.*

Proof. Start with the two accepted carriers and isolate the consumer-facing rows S, Q, L and S', Q', L'. The carrier definition places both reads behind the same diagonal, triangle, tolerance, and window coordinates.

Use the componentwise transport rows H, H'. They identify the source rows by hsame before a consumer reaches the seal or $\mathsf{Real}^{\uparrow}$ rows, so the classifier transported to the consumer is the displayed one.

Use the continuation rows C, C' next. Every read of the seal route, regular readback, or real-seal row is replayed through the displayed Cont routes, and P, P', N, N' record only that finite route surface.

Finally apply Definition 646.11. Since no alternate host-limit, quotient-stream, choice, or ambient-completeness route is exported, downstream consumers factor through the displayed transport and continuation rows. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityConsumerTransport`

Theorem 646.23 (Diagonal-limit ambient completeness refusal)**.** *An accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ BHist *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

from Definition 646.1 exports no host limit, no quotient stream, no choice datum, and no ambient completeness principle. Its only exported surface is the displayed source ledger, componentwise hsame *transport* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}$ *row* N*; this is exactly the non-escape boundary of Definition 646.11.*

Proof. Project the packet K. The visible coordinates are the diagonal packet, triangle row, seal route, tolerance ledger, window row, readback row, real seal row, transport, continuation, provenance, and naming row.

Inspect the omitted coordinates. There is no row for a selected host limit, no row for quotienting streams, no row for a choice datum, and no row for an ambient completeness principle.

Apply Definition 646.11. The non-escape boundary therefore turns the omission into a consumer rule: a downstream chapter may read the displayed compatibility packet, but it may not treat that read as host completeness or as a hidden quotient construction. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityAmbientCompletenessRefusal`

Theorem 646.24 (Diagonal-limit source gate)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

every accepted downstream read first fixes the RealCompleteness$^{\uparrow}$ *diagonal packet* R*, the* StreamName$^{\uparrow}$ *window family* W*, the* DyadicRatCore$^{\uparrow}$ *tolerance ledger* D*, and the* RegSeqRat$^{\uparrow}$ *readback row* Q *before any consumer treats the seal route* S *or the* Real$^{\uparrow}$ *seal row* L *as available. The source gate is exactly the route displayed by Definition 646.1; it is not a host limit selection and not an ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySourceGate`

Proof. Project the carrier K from Definition 646.1. The diagonal source R, windows W, dyadic ledger D, readback Q, seal route S, and seal row L are all named coordinates of the same finite packet.

Apply Definition 646.6 and Definition 646.20. The selector alignment fixes W, D at the diagonal source, and the threshold theorem places every downstream seal read behind R, T, D, W, H, C, P, N.

Use Definition 646.7 to route the read of Q, L through the displayed rows. Then use Definition 646.10 to keep the same classifier under H and C.

Finally apply Definition 646.11. Since the packet exports no selected host limit, host real equality, choice datum, or ambient completeness principle, the displayed source gate is the only way a downstream consumer reaches the seal-facing rows. □

Theorem 646.25 (Diagonal-limit triangle-seal interface)**.** *For an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the RegularCauchyTriangleBound$^{\uparrow}$ *row* T *is the sole public interface between the diagonal selector carried by* R, W, D *and the* CauchyLimitSeal$^{\uparrow}$ *route* S*. A consumer may pass from the diagonal source to the seal route only through the triangle row together with the displayed dyadic ledger, stream-window ledger, classifier transport, continuation routes, package provenance, and local naming row.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility triangle seal interface`

Proof. Start with the carrier. The only row naming the three-leg estimate between the diagonal source and the seal route is T, and the only ledgers available to it are D and W.

Apply Definition 646.6. It binds T to the same selected windows and dyadic tolerance ledger named by R, W, D, so the selector side has no second interface row.

Next apply Definition 646.7. The route S reaches Q, L only through R, T, D, W, so the seal side also has no bypass around the triangle estimate.

Classifier transport and non-escape close the interface. By Definition 646.10 the same interface is preserved through H, C, and by Definition 646.11 no quotient stream, selected host limit, choice datum, or ambient completeness coordinate can supply another route. □

Theorem 646.26 (Diagonal-limit downstream consumer gate)**.** *Every* Real$^{\uparrow}$ *or* CauchyLimitSeal$^{\uparrow}$ *consumer of an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

factors through the displayed rows $R, T, S, D, W, Q, L, H, C, P, N$*. The consumer may use the diagonal packet, triangle interface, seal route, dyadic ledger, stream-window ledger, regular rational readback, real seal row, componentwise transport, continuation routes, package provenance, and local naming row, but it cannot introduce host limits, quotient streams, choice data, host real equality, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityDownstreamConsumerGate`

Proof. Read the consumer from the carrier. The displayed coordinates already list the only source, interface, route, ledger, readback, transport, continuation, provenance, and naming rows available to the packet.

Use Definition 646.24 to force the source-side order. The diagonal packet, stream windows, dyadic ledger, and regular rational readback are fixed before the consumer treats the seal-facing rows as available.

Use Definition 646.25 together with Definition 646.7. These theorems force the route from the diagonal selector to the seal consumer through T, D, W, S and then to Q, L.

Finally apply Definition 646.10 and Definition 646.11. Transport preserves the displayed classifier, and non-escape excludes every host-limit, quotient-stream, choice, host-equality, or ambient-completeness coordinate not carried by K. □

Theorem 646.27 (Diagonal-limit compatibility window-budget triad lock)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

must read the same triad (D, W, Q) *before the terminal seal row* L *is available. Here* W *is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window surface,* D *is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, and* Q *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row. The three rows form one shared route through the displayed* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *surface; no quotient stream, selected host limit, host real equality, choice datum, or ambient completeness principle can supply a second triad.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility window budget triad lock`

Proof. Project the accepted packet from Definition 646.1. The rows D, W, Q occur as named coordinates of the same finite packet as the terminal seal row L.

Apply Definition 646.6. It binds the selector side to the displayed $\mathsf{StreamName}^{\uparrow}$ windows W and $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger D, so the window and tolerance coordinates are fixed before any seal-facing read.

Next apply Definition 646.7. The seal route reaches the $\mathsf{RegSeqRat}^{\uparrow}$ readback Q and terminal row L only through the same R, T, D, W route, so Q is not a separate host readback channel.

Use Definition 646.10 to carry this route through the displayed H and C rows. The transported consumer therefore sees the same (D, W, Q) triad that the carrier exposes.

Finally apply Definition 646.11. Since the packet exports no quotient stream, selected host limit, host real equality, choice datum, or ambient completeness coordinate, no downstream $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer can replace the displayed triad before reading L. □

Theorem 646.28 (Diagonal-limit shared modulus terminal seal)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

any terminal $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *seal read that factors through a compatible* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *packet*

$$M = (E, B, W, S, \mathsf{Mu}, Q, H, C, P, N)$$

and through the finite-window budget envelope of $\mathsf{CauchyLimitSeal}^{\uparrow}$ *passes through one shared finite route. The route first reads* $R, T, S, D, W, Q, L, H, C, P, N$ *from the diagonal-limit packet and then*

reads the extraction rows $E, B, W, S, \mathsf{Mu}, Q, H, C, P, N$ as the same budget-window-modulus surface. It exports no quotient stream, selected host limit, host real equality, trichotomy, choice datum, or ambient completeness.

Proof. Start with the accepted diagonal packet. By Definition 646.11, every seal-facing read of K is confined to $R, T, S, D, W, Q, L, H, C, P, N$ and cannot import a quotient stream, selected host limit, host real equality, trichotomy, choice datum, or ambient completeness.

Next attach the compatible modulus-extraction packet. The public export of Definition 641.22 exposes exactly $E, B, W, S, \mathsf{Mu}, Q, H, C, P, N$, and the consumer bridge of Definition 641.23 forces Real-completion reads of Mu through those displayed rows.

Finally align the seal envelope. The finite-window budget equivalence of Definition 386.77 identifies the terminal seal read with the same finite budget-window route, and the verification handoff of Definition 386.76 repacks that route as the reusable $\mathsf{CauchyLimitSeal}^{\uparrow}$ surface. Thus the Real-facing terminal read is the same finite budget-window-modulus route already displayed by the diagonal packet and the extraction packet, with no extra completion coordinate. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySharedModulusTerminalSeal`

Theorem 646.29 (Diagonal-limit window synchronizer pullback)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Let*

$$Z = (W_Z, Q_Z, S_Z, L_Z, D_Z, H_Z, C_Z, P_Z, N_Z)$$

be an accepted $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *packet whose* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row,* $\mathsf{Real}^{\uparrow}$ *seal row, and shared threshold-budget rows agree componentwise with W, Q, S, L, D through the displayed* hsame *and* Cont *routes. Then every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of K pulls back through the synchronizer finite window-to-seal packet Z.*

The pullback uses only the displayed BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows of the two accepted packets. It does not introduce quotient streams, selected host limits, host real equality, choice data, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityWindowSynchronizerPullback`

Proof. First lock the diagonal side. Apply Definition 646.27 to force every terminal read of K through the common (D, W, Q) triad before L is available. Then apply Definition 646.28 to make the terminal $\mathsf{Real}^{\uparrow}$ and $\mathsf{CauchyLimitSeal}^{\uparrow}$ reads use the same finite budget-window-modulus route.

Next read the synchronizer side. The budget pullback of Definition 979.3 places the synchronizer threshold and window rows over the same finite budget surface. The limit-seal compatibility of Definition 979.5 carries the $\mathsf{CauchyLimitSeal}^{\uparrow}$ row through that surface, and the Real-seal exposure of Definition 979.6 exposes the terminal $\mathsf{Real}^{\uparrow}$ seal only after the same window-to-seal route.

It remains to identify the two finite routes. The hypotheses give componentwise hsame and Cont transport from the diagonal rows W, Q, S, L, D to the synchronizer rows W_Z, Q_Z, S_Z, L_Z, D_Z. Transport through the displayed BHist, Pkg, and $\mathsf{NameCert}$ rows repacks the consumer as a read of Z without changing the terminal object.

Finally use Definition 979.4. Since the synchronizer packet exports no quotient stream, selected host limit, host real equality, choice datum, or ambient completeness coordinate, the pulled-back consumer has no route outside the finite window-to-seal packet. □

Theorem 646.30 (Diagonal-limit compatibility window source exhaustion)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P,$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Every accepted diagonal-limit consumer route that reaches the* Real$^{\uparrow}$ *seal row L first factors through the displayed source ledger, the window-budget triad (D, W, Q), the shared modulus route, the synchronizer pullback surface, and the seal route rows S, L.*

The exhausted route exports no quotient stream, selected host limit, ambient completeness principle, or independent real-equality coordinate. Its only available coordinates are the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows of K together with the compatible finite-window packets through which the route is explicitly pulled back.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility window source exhaustion`

Proof. Begin with the source ledger. Apply Definition 646.21 to identify the readable source rows as $R, T, S, D, W, Q, L, H, C, P, N$ and to exclude any hidden host-limit or quotient-stream source.

Next lock the finite window route. The shared window ledger and consumer transport of Definition 646.27 force the consumer through (D, W, Q) before the seal row is available, while Definition 646.28 identifies the terminal seal read with the same finite budget-window-modulus route.

The ambient-completeness refusal is supplied by Definition 646.23. It prevents the consumer from replacing the displayed finite route by a host completeness principle, selected limit, or host real-equality coordinate.

Finally apply Definition 646.29. The terminal consumer is repacked through the synchronizer finite window-to-seal packet, and the carrier projection together with the non-escape clauses of the displayed packets leaves no coordinate outside the stated source, window, modulus, synchronizer, and seal rows. □

Theorem 646.31 (Diagonal-limit compatibility formal target packet)**.** *Every Lean-facing formal target for an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet exposes exactly the carrier rows*

$$R, T, S, D, W, Q, L, H, C, P, N$$

together with the compatible finite-window packets cited by Definition 646.30. The target may consume RealCompleteness$^{\uparrow}$*,* RegularCauchyTriangleBound$^{\uparrow}$*,* CauchyLimitSeal$^{\uparrow}$*,* DyadicRatCore$^{\uparrow}$*,* StreamName$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*, and* Real$^{\uparrow}$ *only through those displayed rows and their finite-window pullbacks.*

The formal target has no coordinate for quotient streams, selected host limits, host real equality, choice data, or ambient completeness.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityFormalTargetPacket`

Proof. Project the carrier of the accepted diagonal-limit packet. The projection displays exactly $R, T, S, D, W, Q, L, H, C, P, N$, and the local NameCert obligations make the displayed BHist, hsame, Cont, Pkg, and NameCert rows the only routes available to a formal target.

Next apply the terminal Real route and the window-budget triad lock. The terminal route keeps the Real-facing consumer on $R, T, S, D, W, Q, L, H, C, P, N$, while Definition 646.27 forces any seal-facing read through the displayed (D, W, Q) finite-window triad.

Now attach the shared modulus terminal seal and the synchronizer pullback. Definition 646.28 identifies the terminal Real$^{\uparrow}$ and CauchyLimitSeal$^{\uparrow}$ reads with one finite budget-window-modulus route, and Definition 646.29 repacks that route through the compatible RealWindowSynchronizer$^{\uparrow}$ packet.

Finally use Definition 646.30. It exhausts the source, window, shared modulus, synchronizer, and seal rows available to the Lean-facing packet. The named upstream chapters may be consumed only through these rows, so quotient streams, selected host limits, host real equality, choice data, and ambient completeness have no target coordinate. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility formal target packet`

Theorem 646.32 (Diagonal-limit finite-window-only consumer)**.** *Every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *consumer of* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *is admitted only through the displayed finite rows*

$$R, T, S, D, W, Q, L, H, C, P, N$$

of its accepted packet and through the compatible finite-window packets cited by Definition 646.30. A route that uses quotient streams, host real equality, selected host limits, choice data, or ambient completeness is outside the carrier and is not an admitted consumer route.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityFiniteWindowOnlyConsumer`

Proof. Start with the source ledger. By Definition 646.21, the accepted packet exposes only $R, T, S, D, W, Q, L, H, C, P, N$ together with its displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Lock the finite route before the terminal read. The window-budget triad lock of Definition 646.27 forces the consumer through (D, W, Q), and Definition 646.28 makes the terminal $\mathsf{Real}^{\uparrow}$ and $\mathsf{CauchyLimitSeal}^{\uparrow}$ reads share the same finite-window seal route.

Next pull the route through the synchronizer. Apply Definition 646.29 to repack the terminal consumer through the compatible finite window-to-seal packet without adding a host coordinate.

Finally use Definition 646.30. It exhausts the admissible source, triad, shared modulus, synchronizer, and seal coordinates, while Definition 646.11 removes quotient streams, host real equality, selected host limits, choice data, and ambient completeness from the carrier. Therefore every accepted $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer is finite-window-only. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier finite window only consumer`

Theorem 646.33 (Diagonal-limit triangle seal route)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the seal route S reaches the readback row Q and the $\mathsf{Real}^{\uparrow}$ *seal row L only after the triangle row T has been aligned with the dyadic ledger D and the shared stream-window row W. The route is the one exposed by Definition 646.1, Definition 646.2, Definition 646.6, and Definition 646.7; it cannot bypass classifier transport, local provenance, or the non-escape boundary.*

Proof. Project the carrier K. The displayed packet places R, T, S, D, W, Q, L before the transport, continuation, provenance, and local naming rows H, C, P, N.

Apply triangle-selector alignment. It fixes the triangle row T to the same dyadic tolerance ledger D and stream-window family W already named by the diagonal packet.

Now apply seal-route compatibility. The seal route can read Q and L only through R, T, D, W, so the route to the completion-facing rows has already consumed the triangle row and its two ledgers.

Classifier transport and non-escape close the boundary. Transport preserves the same route through H and C, while non-escape excludes quotient streams, selected host limits, host real equality, choice data, and ambient completeness. □

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityTriangleSealTransportRoute
↪ variant BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility triangle seal route

Theorem 646.34 (Diagonal-limit window ledger exactness)**.** *For an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the row W is the exact shared-window ledger read by the diagonal source R, the triangle row T, the dyadic ledger D, the seal route S, the readback row Q, and the Real$^{\uparrow}$ *seal row L. A completion consumer reaches Q, L only after it has read the same W through the triangle row, dyadic ledger, componentwise* hsame *transport H, displayed* Cont *route C, package provenance P, and local* NameCert *row N.*

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility window ledger exactness

Proof. Begin with the shared-window ledger theorem. It identifies W as the finite window row used by the diagonal selector, triangle-bound estimate, dyadic tolerance read, regular readback, and downstream seal consumer.

Use the triangle-seal route theorem. Since the route to Q, L must pass through T, D, W, no consumer can replace W after the triangle row has been fixed.

Finally apply classifier transport and the NameCert obligations. The componentwise hsame and Cont rows preserve the displayed classifier, and the local NameCert row records that the same window ledger is the one carried by K. □

Theorem 646.35 (Diagonal-limit completion boundary)**.** *Every completion-facing or* Real$^{\uparrow}$ *consumer of an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

reaches Q, L only after reading the triangle row T, the dyadic ledger D, the stream-window ledger W, the componentwise hsame *transport H, the displayed* Cont *route C, package provenance P, and the local* NameCert *row N. The boundary is the one assembled from the carrier, local NameCert obligations, triangle selector alignment, seal route compatibility, classifier transport, non-escape, the shared-window ledger, Definition 646.33, and Definition 646.34.*

The consumer receives no quotient stream, selected host limit, host real equality, choice datum, or ambient completeness principle.

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCompletionBoundary

Proof. First assemble the route. The carrier supplies the rows of K, the local NameCert obligations identify their order, and triangle selector alignment fixes T to the displayed D, W ledgers.

Next apply seal route compatibility together with the triangle-seal route theorem. These results force every read of Q, L through the route determined by R, T, D, W, S.

Use window ledger exactness to keep the stream-window row fixed through the same route. The componentwise hsame transport, displayed Cont route, package provenance, and local NameCert row then carry that fixed route to the completion consumer without adding another ledger.

Finally use non-escape. Since no quotient stream, selected host limit, host real equality, choice datum, or ambient completeness coordinate is present in the packet, the displayed rows are the complete completion boundary. □

Theorem 646.36 (Diagonal-limit compatibility terminal formal target)**.** *An accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet reaches any* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *terminal consumer only through the displayed diagonal route, triangle row, dyadic ledger, shared stream-window ledger, readback row,* $\mathsf{Real}^{\uparrow}$ *seal row,* hsame *transport,* Cont *route,* Pkg *provenance, and local* NameCert *row:*

$$K = (R, T, S, D, W, Q, L, H, C, P, N).$$

This is the exact formalization target for the present packet. It exports no quotient stream, selected host limit, host real equality, choice datum, or ambient completeness principle.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility terminal formal target`

Proof. Start with the triangle seal route and window ledger exactness. Definition 646.33 places the seal route behind R, T, D, W, and Definition 646.34 keeps the shared stream-window ledger fixed through the readback and seal rows.

Use the completion boundary, Definition 646.35. It forces any terminal $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer to pass through the triangle row, dyadic ledger, stream-window ledger, transport, continuation, provenance, and local naming rows before Q or L is read.

Next apply tolerance ledger handoff and seal consumer factorization. Definition 646.37 fixes the dyadic ledger and window family, while Definition 646.38 routes the terminal seal read through the displayed packet rows.

The same rows define the formal target because every cited theorem consumes only $K = (R, T, S, D, W, Q, L, H, C, P, N)$. Non-escape supplies the final exclusion: quotient streams, selected host limits, host real equality, choice data, and ambient completeness have no coordinate in the packet and cannot be exported. □

Theorem 646.37 (Diagonal-limit tolerance ledger handoff)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

every tolerance-facing read that reaches the seal route first uses the same $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D *and* $\mathsf{StreamName}^{\uparrow}$ *window family* W *named by the diagonal packet* R *and triangle row* T*. No downstream tolerance consumer can replace* D *or* W *with an alternate ledger or window family after entering the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route.*

Proof. Project the carrier K. The rows R, T, D, W are displayed before the seal route S can be read.

Apply Definition 646.6. It identifies the triangle row T with the same selected window family W and dyadic tolerance ledger D already named by the diagonal packet R.

Finally use non-escape, Definition 646.11. Since the packet contains no alternate tolerance ledger or second window family, every read that reaches S keeps the displayed D, W handoff. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityToleranceLedgerHandoff`

Theorem 646.38 (Diagonal-limit seal consumer factorization)**.** *Every downstream* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *read of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet factors through*

$$R, T, D, W, Q, L, H, C, P, N$$

and cannot bypass the triangle, tolerance, or window rows. The seal consumer may read Q *and* L *only after the packet has exposed the diagonal route* R*, the triangle row* T*, the dyadic ledger* D*, and the window family* W*.*

Proof. Begin with Definition 646.7. It places every seal-route read of Q and L behind the displayed rows R, T, D, W.

Use classifier transport, Definition 646.10. The componentwise transports H and continuation routes C preserve the same compatibility classifier and do not add another seal-consumer path.

Apply non-escape, Definition 646.11. The exported surface is exhausted by the listed rows and their provenance, so no $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer can bypass the triangle, tolerance, or window coordinates. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySealConsumerFactorization`

Theorem 646.39 (Diagonal-limit window route lock)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the $\mathsf{StreamName}^{\uparrow}$ *window row* W *is locked before any triangle estimate, tolerance read, seal-route read, or* $\mathsf{Real}^{\uparrow}$ *read can be consumed. Every such consumer uses the same displayed window family* W *already named by the carrier and cannot choose a second window route after the packet has been accepted.*

Proof. Project the carrier of Definition 646.1. The row W is part of the accepted packet, displayed before the downstream triangle, tolerance, seal, and real-facing reads are interpreted.

Apply the shared-window ledger theorem, Definition 646.19. It ties the diagonal source route to the same stream-window row W used by the packet.

Now apply the tolerance ledger handoff theorem, Definition 646.37. Since the tolerance route reaches the seal through the fixed D, W pair, no later triangle, seal, or $\mathsf{Real}^{\uparrow}$ consumer has a fresh window coordinate from which to build an alternate route. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityWindowRouteLock`

Theorem 646.40 (Diagonal-limit terminal selector non-escape)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

every terminal $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *selector read of* K *passes through the same diagonal route* R*, triangle row* T*, dyadic ledger* D*, stream-window row* W*, readback row* Q*, seal row* L*, componentwise* hsame *transport* H*, displayed* Cont *route* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}$ *row* N*. The terminal read cannot introduce a second selector, quotient stream, host limit, choice datum, or ambient completeness principle.*

Proof. Start with the window route lock, Definition 646.39. It fixes the stream-window row W before any terminal seal or $\mathsf{Real}^{\uparrow}$ read is consumed.

Next use tolerance ledger handoff, Definition 646.37. The dyadic ledger D and the window row W remain the same rows named by the diagonal route and triangle row.

Apply seal consumer factorization, Definition 646.38. It routes every $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ read through $R, T, D, W, Q, L, H, C, P, N$ rather than through a detached terminal selector.

Finally use the completion boundary, Definition 646.35. Since the packet exposes no quotient stream, host limit, choice datum, or ambient completeness coordinate, the terminal selector cannot escape the displayed diagonal route. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityTerminalSelectorNonescape`

Theorem 646.41 (Diagonal-limit seal readback exactness)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

every $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer reaches the readback row* Q *and the seal row* L *only through the displayed route*

$$R, T, D, W, H, C, P, N.$$

Thus Q *and* L *are read as the packet's own seal readback and real seal coordinates, not as independently selectable completion data.*

Proof. Start with seal-route compatibility, Definition 646.7. It places the reads of Q and L behind the diagonal source row R, triangle row T, dyadic ledger D, and window row W.

Use seal consumer factorization, Definition 646.38. The factorization adds the transport, continuation, provenance, and local naming rows H, C, P, N to the same route and excludes bypasses around the displayed triangle, tolerance, and window data.

Consequently every seal consumer reads Q and L through the listed rows, so the readback and seal coordinates are exact coordinates of the accepted packet. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySealReadbackExactness`

Theorem 646.42 (Diagonal-limit Real seal non-escape)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet, the* $\mathsf{Real}^{\uparrow}$ *seal row* L *exports no quotient stream, selected host limit, host real equality, choice datum, or ambient completeness principle. A* $\mathsf{Real}^{\uparrow}$ *consumer can read* L *only as the displayed seal coordinate reached through the packet route and cannot extract host-level completion data from it.*

Proof. Apply the non-escape theorem, Definition 646.11. The exported $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ surface contains only the named rows of the accepted packet and not any quotient stream, selected host limit, host real equality, choice datum, or ambient completeness principle.

Now use seal readback exactness, Definition 646.41. It forces any $\mathsf{Real}^{\uparrow}$ read of L to pass through the displayed seal route and readback rows, so L cannot be used as an escape hatch into a host-level completion object. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility real seal nonescape`

Theorem 646.43 (Diagonal-limit compatibility source-route exactness)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibili}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

there is one displayed source route from the accepted $\mathsf{RealCompleteness}^{\uparrow}$ *diagonal packet* R *through the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *row* T*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, the* $\mathsf{StreamName}^{\uparrow}$ *windows* W*, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route* S*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* Q*, and the* $\mathsf{Real}^{\uparrow}$ *seal class* L*. This route is the route exposed by the carrier and by the local* $\mathsf{NameCert}$ *obligations, using the sibling certificate surfaces chapter 450, chapter 466, and chapter 386. It has no second source, no alternate triangle row, and no bypass around the displayed tolerance, window, readback, or seal coordinates.*

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySourceRouteExactness

Proof. Project the accepted carrier. Its displayed mathematical rows are exactly R, T, S, D, W, Q, L, and its transport, continuation, provenance, and local naming rows are exactly H, C, P, N.

Use the local NameCert obligation theorem to read the source route in order. The triangle-selector alignment row fixes T to the same D, W data consumed by the accepted diagonal packet R, matching the diagonal and triangle certificate surfaces.

Next use seal-route compatibility. The route S reaches Q and L only after R, T, D, W have been fixed, so the Cauchy-limit seal route and the RealUp seal are attached to the same displayed source route.

Finally apply classifier transport and non-escape. The componentwise hsame and Cont rows preserve this route, while the exported packet contains no coordinate from which a second source or bypass route could be formed. □

Theorem 646.44 (Diagonal-limit compatibility regular readback exactness)**.** *For an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the RegSeqRat$^{\uparrow}$ *readback row Q is determined by the same triangle row T, dyadic ledger D, and stream-window row W used by the diagonal source route. After D, W, T are fixed, the packet cannot choose another* RegSeqRat$^{\uparrow}$ *readback row or another dyadic witness for the seal handoff. This readback is the one compatible with chapter 291, chapter 126, and chapter 301.*

Proof. Start from the carrier projection and isolate D, W, T, Q. The dyadic ledger, window family, triangle estimate, and readback row are all displayed before a completion-facing consumer can read the seal class.

Apply triangle-selector alignment and the shared-window ledger theorem. These facts identify the selected windows and tolerance ledger consumed by T with the same W, D rows already exposed by the diagonal packet.

Now apply seal-route compatibility and the tolerance-ledger handoff theorem. The route to Q passes through the fixed D, W, T rows, so the readback row has no independent dyadic or window witness to select.

The non-escape theorem supplies the boundary. Since the packet exports no alternate dyadic ledger, second window family, or separate readback coordinate, Q is the exact regular-rational readback for the displayed compatibility route. □

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRegularReadbackExactness

Theorem 646.45 (Diagonal-limit compatibility route ledger totality)**.** *Every completion-facing consumer accepted by a* DiagonalLimitCompatibility$^{\uparrow}$ *packet factors through one displayed route ledger*

$$(R, T, D, W, Q, L, H, C, P, N).$$

Here T is the triangle row, D is the DyadicRatCore$^{\uparrow}$ *ledger, W is the* StreamName$^{\uparrow}$ *window row, Q is the* RegSeqRat$^{\uparrow}$ *readback, and L is the* Real$^{\uparrow}$ *seal. The rows H, C, P, N only transport, continue, package, and locally name that ledger. They do not add quotient streams, host-selected limits, host real equality, choice data, or ambient completeness.*

Proof. Begin with source-route exactness, Definition 646.43. It places the consumer route on the displayed diagonal source row R and its triangle, dyadic, window, readback, seal, transport, continuation, provenance, and NameCert rows.

Use regular readback exactness, Definition 646.44. This binds Q to the same T, D, W rows, so the readback cannot be selected from a separate dyadic ledger or a second stream window.

Next apply seal readback exactness, Definition 646.41. The $\mathsf{Real}^{\uparrow}$ seal row L reads the same regular-rational data and does not introduce an independent host real witness.

The route lock is supplied by Definition 646.39. It keeps the window row W attached to the triangle and dyadic route rather than to a consumer-chosen stream family.

Finally use Real seal non-escape, Definition 646.42. Since the packet has no coordinates for quotient streams, host-selected limits, host real equality, choice data, or ambient completeness, the displayed ledger is total for accepted completion-facing consumers. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRouteLedger` semantic name certificate

Theorem 646.46 (Diagonal-limit compatibility uniform-window Real seal pullback)**.** *Let*

$$K = (R, T, S_D, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet and let*

$$U = (F, M, T_U, R_U, S, E, H_U, C_U, P_U, N_U)$$

be an accepted $\mathsf{UniformLimit}^{\uparrow}$ *packet. Suppose the two packets share the displayed* $\mathsf{StreamName}^{\uparrow}$ *finite-window row of chapter 126 and the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row of chapter 301. Then every consumer common to the* $\mathsf{Real}^{\uparrow}$ *and completion-facing routes of chapter 38 and chapter 463 factors through the finite pullback surface made of the diagonal rows*

$$R, T, D, W, Q, L, H, C, P, N$$

and the uniform-limit rows

$$F, M, T_U, R_U, S, E, H_U, C_U, P_U, N_U.$$

The pullback exports only the common finite window, regular readback, seal rows, displayed hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows. It exports no quotient stream, pointwise-only limit, selected host limit, host real equality, or ambient completeness coordinate.*

Proof. First read the diagonal side. Source-route exactness fixes the diagonal rows R, T, D, W before the displayed seal route can be consumed, and regular readback exactness identifies Q as the readback from the same T, D, W rows.

Next read the uniform-limit side. The seal factorization for $\mathsf{UniformLimit}^{\uparrow}$ routes F, M, T_U through the regular handoff R_U, the seal row S, the endpoint row E, and the displayed support rows H_U, C_U, P_U, N_U.

The shared-window and shared-readback hypotheses identify the two consumer surfaces at the common $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ rows. Pulling back along those rows leaves a finite BHist surface whose coordinates are exactly the displayed diagonal and uniform-limit rows.

Finally apply the non-escape clauses on both chapters. The diagonal packet has no coordinate for a quotient stream, selected host limit, host real equality, or ambient completeness theorem,

and the uniform-limit packet has no coordinate for a pointwise-only limit or selected host limit. Therefore any common Real or Completion consumer factors through the stated pullback surface and nowhere else. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityUniformWindowRealSealPullba`

Theorem 646.47 (Diagonal-limit compatibility selector-seal pullback)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Suppose its displayed route reads a* DiagonalTailSelector$^{\uparrow}$ *source-schedule packet and a* CauchyLimitSeal$^{\uparrow}$ *observation-budget packet before any terminal* Real$^{\uparrow}$ *consumer reads the seal row L. Then the selected finite windows, observation budget,* RegSeqRat$^{\uparrow}$ *readback, and* Real$^{\uparrow}$ *seal row pull back to the same* RegSeqRat$^{\uparrow}$/Real$^{\uparrow}$*-facing carrier surface*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Every terminal Real$^{\uparrow}$ *consumer factors first through the* DiagonalTailSelector$^{\uparrow}$ *source-schedule readback and the* CauchyLimitSeal$^{\uparrow}$ *observation-budget pullback, and only then through the completion-facing read of Q and L.*

Proof. Begin with the uniform-window Real seal pullback of Definition 646.46. It already identifies the finite window, regular readback, Real seal, displayed transport, continuation, provenance, and local naming rows as one finite consumer surface.

Next read the selector side. The diagonal-tail selector handoff fixes the source schedule before the seal-facing route can reach Q or L, so the selected windows cannot be replaced by a second host selector after the packet has been accepted.

Now read the seal side. The CauchyLimitSeal$^{\uparrow}$ observation-budget and Real handoff routes force the budget row and seal row to travel through the same BHist, hsame, Cont, Pkg, and NameCert support rows. Thus the selector readback and seal budget meet at the displayed RegSeqRat$^{\uparrow}$/Real$^{\uparrow}$ carrier surface.

Finally inspect a terminal Real$^{\uparrow}$ consumer. Since the packet exports no quotient stream, selected host limit, host real equality, choice datum, or ambient completeness coordinate, the consumer must pass through the selector source-schedule readback and the seal-budget pullback before any completion-facing read of Q and L is available. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility selector seal pullback`

Theorem 646.48 (Diagonal-limit compatibility completion consumer nonescape)**.** *Every completion-facing or* Real$^{\uparrow}$ *consumer of an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet factors through*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The consumer receives the accepted diagonal source route, triangle row, dyadic ledger, stream windows, seal route, regular readback, real seal class, componentwise transports, displayed continuations, provenance, and local naming row. It receives no quotient stream, selected host limit, host real equality, choice datum, or ambient completeness theorem. The boundary is the one witnessed by chapter 38, Definition 646.43, and Definition 646.44.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.CompletionConsumerNonescape.DiagonalLimitCompatibilit`

Proof. Project the accepted packet and read the exported rows. The only consumer-facing coordinates are the seal route S, the readback Q, the real seal class L, and their displayed transports and continuations through H, C, P, N.

Use source-route exactness to fix the route from R through T, D, W, S, Q to L. Use regular readback exactness to fix Q as the readback determined by the same D, W, T rows.

It remains to inspect the consumer boundary. The existing non-escape theorem excludes quotient streams, selected host limits, host real equality, choice data, and ambient completeness from the exported packet.

Therefore every completion-facing or $\mathsf{Real}^{\uparrow}$ consumer factors through the displayed rows alone, and no host-level completion object can enter through the compatibility certificate. □

Theorem 646.49 (Diagonal-limit compatibility finite source lock)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

every compatibility read starts from the displayed $\mathsf{RealCompleteness}^{\uparrow}$ *source row* R*, the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *estimate row* T*, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route row* S*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row* D*, the* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q*, the* $\mathsf{Real}^{\uparrow}$ *seal row* L*, and the support rows* H, C, P, N*. No compatibility consumer may introduce a second source route or an ambient completion principle outside those rows.*

Proof. Project the carrier and read the finite row list $R, T, S, D, W, Q, L, H, C, P, N$. These are the only coordinates available to a compatibility consumer.

Use source-route exactness, Definition 646.43. It identifies the unique displayed route from R through T, D, W, S, Q to L.

Use completion-consumer non-escape, Definition 646.48. It forces every completion-facing or $\mathsf{Real}^{\uparrow}$ consumer to factor through the same listed rows.

The general non-escape theorem, Definition 646.11, excludes quotient streams, selected host limits, host real equality, choice data, and ambient completeness. Therefore the source lock is exactly the finite packet. □

Lean4 ✓ `BEDC.Derived.Diagonallimitcompatibilityup.DiagonalLimitCompatibilityFiniteSourceLock`

Theorem 646.50 (Diagonal-limit compatibility Real seal source lock)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal-facing read of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet factors through the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route row* S *and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q *before it reaches the seal row* L*. The read cannot bypass* S *or* Q *by appealing to host real equality, a selected host limit, a quotient stream, or an ambient completion theorem.*

Proof. Start with seal-readback exactness, Definition 646.41. It binds the $\mathsf{Real}^{\uparrow}$ seal row L to the displayed seal route and readback rows.

Apply source-route exactness, Definition 646.43. The route to L passes through S and Q after the source, triangle, dyadic, and window rows have been fixed.

Use regular-readback exactness, Definition 646.44. The readback Q is determined by the same D, W, T rows and is not an independent host real witness.

Finally apply completion-consumer non-escape, Definition 646.48. Every seal-facing read remains inside S, Q, L and the packet support rows, with no host completion bypass. □

Lean4 ✓ `BEDC.Derived.Diagonallimitcompatibilityup.DiagonalLimitCompatibilityRealSealSourceLock`

Theorem 646.51 (Diagonal-limit compatibility triangle-seal scope)**.** *In an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet, the triangle estimate row* T *and the seal route row* S *share the same dyadic ledger row* D *and stream-window row* W*. A consumer may not read the triangle estimate against one tolerance/window ledger and the seal route against another.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityTriangleSealScope`

Proof. Project the accepted packet and isolate T, S, D, W. The carrier has one dyadic ledger row and one stream-window row for both the triangle estimate and the route to the seal.

Use regular-readback exactness, Definition 646.44. It fixes Q from the same T, D, W rows used by the diagonal source route.

Use source-route exactness, Definition 646.43. The seal route S appears on that same route, after R, T, D, W and before Q, L.

Completion-consumer non-escape, Definition 646.48, then prevents a consumer from splitting the route. The triangle row and the seal row therefore share the displayed D, W ledger rows. □

Theorem 646.52 (Diagonal-limit compatibility window fusion)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the shared $\mathsf{StreamName}^{\uparrow}$ *window row* W *simultaneously serves the* $\mathsf{RealCompleteness}^{\uparrow}$ *diagonal packet* R*, the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *row* T*, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route* S*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q*. A consumer cannot split these rows into separate window surfaces after the packet has been accepted.*

Proof. Project the carrier and read the row inventory. The packet has exactly one window coordinate W and places it beside the diagonal source, triangle row, seal route, dyadic ledger, readback row, and Real seal row.

Apply the NameCert obligations, triangle-selector alignment, and seal-route compatibility. These force the reads of R, T, S, D, Q to pass through the displayed window coordinate rather than through independently chosen window data.

Now use window-ledger exactness and seal-readback exactness. The former binds the diagonal, triangle, dyadic, seal, readback, and seal rows to the same ledger W; the latter keeps the readback and seal route attached to that route.

Finally apply Real seal non-escape and triangle-seal scope. Since the accepted packet contains no second $\mathsf{StreamName}^{\uparrow}$ coordinate and no host completion row, every consumer sees one fused window surface. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityWindowFusion`

Theorem 646.53 (Diagonal-limit compatibility Real seal exactness)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the $\mathsf{Real}^{\uparrow}$ *seal row* L *is reachable exactly through the displayed route*

$$R, T, S, D, W, Q, H, C, P, N.$$

It exports no quotient stream, selected host limit, host equality, choice datum, or ambient completeness principle.

Proof. Begin with the carrier and local NameCert obligations. They expose the route from the diagonal packet R through the triangle row T, seal route S, dyadic ledger D, shared window row W, readback row Q, and support rows H, C, P, N before the Real seal row can be consumed.

Use triangle-selector alignment, seal-route compatibility, and window fusion. These theorems keep the triangle, seal, tolerance, window, and readback rows on the same displayed route and prevent a consumer from selecting a separate window or tolerance surface.

Apply seal-readback exactness and Real seal non-escape. The read of L passes through the packet's own seal readback route, while quotient streams, selected host limits, host equality, choice data, and ambient completeness are absent from the carrier.

Finally use triangle-seal scope. It binds the triangle estimate and seal route to the same D, W ledgers, so the listed rows are the exact Real seal boundary. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility real seal exactness`

Theorem 646.54 (Diagonal-limit compatibility tail-selector scope)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet* $K = (R, T, S, D, W, Q, L, H, C, P, N)$*, every tail-selector read is mediated by the displayed* $\mathsf{StreamName}^{\uparrow}$ *finite-window row* W *and the route* R, T, D, W, S, Q, L*. It cannot choose a host tail, a second window surface, or an ambient completion witness.*

Proof. Source-route exactness fixes the route from R through T, D, W, S, Q to L, while window fusion and Real seal source lock keep the selector attached to that same W row. Regular readback exactness identifies Q with the displayed T, D, W data, and completion-consumer non-escape excludes any host tail or ambient completion coordinate. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility tail selector scope`

Theorem 646.55 (Diagonal-limit compatibility Real–regular source factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *readback from an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet factors through the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *row* Q *and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D *already carried by the packet. The readback has no source outside the cited regular, dyadic, stream-window, and seal rows.*

Proof. Apply regular readback exactness to bind Q to T, D, W, then apply source-route exactness to place this readback on the same route from R to L through S. Real seal source lock forces every seal-facing read through S, Q, L, and completion-consumer non-escape removes quotient streams, selected host limits, host real equality, choice data, and ambient completeness from the factorization. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRealRegseqSourceFactorizati`

Theorem 646.56 (Diagonal-limit compatibility completion seal budget)**.** *Any* $\mathsf{Completion}^{\uparrow}$*-facing consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet is bounded by the displayed seal budget* $R, T, S, D, W, Q, L, H, C, P, N$*. It may consume the packet as a finite compatibility route, but it cannot claim ambient completeness or a host-level completion object.*

Proof. The source route and Real seal source lock identify the whole budget ending at L, and regular readback exactness accounts for the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ coordinates used by that route. Completion-consumer non-escape permits reads through the displayed packet and rules out any additional completeness, limit-selection, quotient, choice, or host-real coordinate. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCompletionSealBudget`

Theorem 646.57 (Diagonal-limit compatibility regular Cauchy sequence handoff)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet and let*

$$K = (R_0, T, S_0, D_0, W_0, Q, L, H_0, C_0, P_0, N_0)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Suppose the selected-window rows* W, W_0*, the dyadic ledgers* D, D_0*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows* R, Q*, and the* $\mathsf{Real}^{\uparrow}$ *seal rows* E, L *are related by the displayed* hsame *transports carried by* H *and* H_0*, and suppose the continuation, provenance, and local naming rows* C, P, N *and* C_0, P_0, N_0 *expose the same consumer-facing route. Then every* $\mathsf{Completion}^{\uparrow}$*-facing read of* K *that consumes the regular-family data of* S *factors first through Definition 660.11 and Definition 660.16, then through Definition 697.6, Definition 646.38, Definition 386.5, and Definition 646.56. The resulting route exports the finite family row, modulus, selected windows, dyadic ledgers,* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks, tail-selector handoff, seal route,* $\mathsf{Real}^{\uparrow}$ *seal rows, displayed transports, continuations, provenance, and local* $\mathsf{NameCert}$ *rows, but exports no quotient stream, selected host limit, host real equality, choice data, hidden tail oracle, or ambient completeness principle.*

Proof. First read the accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ packet. The diagonal-window coverage handoff confines the family-facing data to $F, \mu, W, D, R, G, E, H, C, P, N$, so a downstream consumer sees the selected windows, dyadic ledger, regular readback, and Real seal handoff only through the displayed finite packet.

Next apply Definition 660.16. The matching hsame transports identify the regular packet's selected-window, dyadic, readback, and seal rows with the rows consumed by the diagonal-tail selector route.

Now pass through Definition 697.6. This attaches the selector route to the same finite windows and readbacks before any diagonal-limit or seal-facing consumer can read the compatibility packet.

Finally use the diagonal-limit compatibility and seal boundaries. The seal consumer factorization, the $\mathsf{CauchyLimitSeal}^{\uparrow}$ $\mathsf{Real}^{\uparrow}$ consumer boundary, and the completion seal budget force the remaining read through $R_0, T, S_0, D_0, W_0, Q, L, H_0, C_0, P_0, N_0$ and exclude quotient streams, selected host limits, host real equality, choice data, hidden tail oracles, and ambient completeness. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRegularCauchySequenceHandof`

Theorem 646.58 (Diagonal-limit compatibility source-route budget lock)**.** *For an accepted* DiagonalLimitCompatib *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

every completion-facing or $\mathsf{Real}^{\uparrow}$ *consumer first reads the same* $\mathsf{DiagonalTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *source route before it reaches the* $\mathsf{Real}^{\uparrow}$ *seal row* L*. The locked route is the finite row sequence*

$$R, T, S, D, W, Q, H, C, P, N$$

with sibling anchors chapter 697, chapter 126, chapter 291, chapter 386, and chapter 38.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility source route budget lock`

Proof. Project the carrier and isolate the source route R, T, S, D, W, Q together with the support rows H, C, P, N. The packet contains one diagonal source, one tail-selector route, one stream-window row, one dyadic ledger, one seal route, and one regular readback before the Real seal.

Apply source-route exactness and regular-readback exactness. These force the readback Q to be determined by the same T, D, W rows and keep the route from R to L inside the displayed source sequence.

Now use the finite source lock and the Real seal source lock. The first excludes a second source route, while the second forces every Real-facing read through S, Q, L after the tail-selector, stream-window, and dyadic rows have been read.

Finally apply completion-consumer non-escape. Since the packet exports no quotient stream, selected host limit, host real equality, choice datum, hidden tail oracle, or ambient completeness row, the displayed route is the complete budget lock. □

Theorem 646.59 (Diagonal-limit compatibility public budget route)**.** *Every public Real-completion consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

factors through the displayed route

$$R, T, D, W, S, Q, L, H, C, P, N.$$

The $\mathsf{StreamName}^{\uparrow}$ *window row* W *and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D *are fixed before any* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *readback row* Q *or* $\mathsf{Real}^{\uparrow}$ *seal row* L *is consumed. The route ties the* $\mathsf{RealCompleteness}^{\uparrow}$ *source,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route, and* $\mathsf{Real}^{\uparrow}$ *seal to the same public budget surface.*

Proof. Begin with source-route budget lock, Definition 646.58. It forces every completion-facing or $\mathsf{Real}^{\uparrow}$ consumer through the finite source route before the Real seal row is read.

Use tolerance ledger handoff, Definition 646.37, and window ledger exactness, Definition 646.34. These keep the dyadic ledger D and the stream-window row W fixed for the diagonal source, triangle row, seal route, readback row, and Real seal.

Now apply seal consumer factorization, Definition 646.38. The public consumer reaches Q and L only through the displayed R, T, D, W rows together with the support rows H, C, P, N.

Finally apply Real seal non-escape, Definition 646.42. Since quotient streams, selected host limits, host equality, choice data, and ambient completeness are absent from the packet, the displayed public budget route is exhaustive. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility public budget route`

Theorem 646.60 (Diagonal-limit compatibility tail-selector consumer boundary)**.** *Let* $K = (R, T, S, D, W, Q, L, H$ *be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Any consumer that reads the tail selector used by a completion or* $\mathsf{Real}^{\uparrow}$ *route must first pass through the displayed* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *source, the* $\mathsf{StreamName}^{\uparrow}$ *windows* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route* S *before it may read* L*. It cannot choose a second tail selector, a host tail, or an ambient completion witness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityTailSelectorConsumerBoundar`

Proof. Begin with source-route exactness. It places the tail-selector read on the route from the diagonal source R through T, D, W, S, Q to the Real seal row L.

Use regular-readback exactness to bind Q to the same T, D, W rows. The selected tail is therefore read through the StreamName and DyadicRatCore coordinates already present in the packet.

Apply the finite source lock and Real seal source lock. These results prevent the consumer from replacing the route by a second source path or by a direct Real seal read that bypasses S and Q.

Completion-consumer non-escape supplies the boundary. No host tail, quotient stream, selected host limit, choice datum, or ambient completion coordinate is carried by K, so the tail-selector consumer remains inside the displayed route. □

Theorem 646.61 (Diagonal-limit compatibility Real seal route exhaustion)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the Real seal route is exhausted by the source rows R, T, S, D, W, Q and the support rows H, C, P, N before L is read. Every completion-facing Real seal consumer therefore factors through the same DiagonalTailSelector, StreamName, DyadicRatCore, and CauchyLimitSeal route named by chapter 697, chapter 126, chapter 291, chapter 386, and chapter 38.

Proof. Read the accepted carrier. The Real seal row L is displayed only after the diagonal source, triangle row, seal route, dyadic ledger, stream window, and regular readback rows.

Apply source-route exactness, regular-readback exactness, and the finite source lock. Together these results identify one source route and one readback route leading to L, with no alternate dyadic ledger, window family, or selector path.

Now apply the Real seal source lock. It forces every seal-facing read through S and Q before L, so a consumer cannot read the Real seal as an independent host completion object.

Finally use completion-consumer non-escape. The packet lacks quotient streams, selected host limits, host real equality, choice data, and ambient completeness; hence the displayed source route exhausts the Real seal boundary. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility real seal route exhaustion`

Theorem 646.62 (Diagonal-limit compatibility public packet export)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the public export surface is exactly the finite carrier row K, the route ledger R, T, S, Q, L, the triangle-seal row T, S, Q, the window ledger W, the $\mathsf{Real}^{\uparrow}$ *seal row L, and the route-exhaustion rows H, C, P, N already named by the scoped closure. Every exported consumer row is read through the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *coordinates of K; there is no additional quotient stream, selected host limit, host real equality, choice datum, ambient completeness witness, hidden tail oracle, or independent route selector.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityPublicPacketExport`

Proof. Start with the carrier and NameCert rows. Definition 646.1 and Definition 646.2 expose exactly the displayed source, triangle, seal-route, dyadic-ledger, window, readback, Real-seal, transport, continuation, provenance, and local naming rows.

Next assemble the ledger surface. Definition 646.33, Definition 646.34, and Definition 646.37 identify the triangle seal, stream-window ledger, and dyadic tolerance ledger inside the same packet.

The consumer endpoint is fixed by Definition 646.38, Definition 646.53, and Definition 646.61. These force the $\mathsf{CauchyLimitSeal}^{\uparrow}$ readback and $\mathsf{Real}^{\uparrow}$ seal to remain on the displayed route.

Finally use Definition 646.11 and Definition 646.48. Since the excluded analytic objects have no carrier coordinate in K, the listed rows are the entire public packet. □

Theorem 646.63 (Diagonal-limit compatibility route-ledger public exactness)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet* $K = (R, T, S, D, W, Q, L, H, C, P, N)$*, the public route ledger is exactly the route*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The rows T, D, W, Q *are not optional side ledgers: the source route, regular readback, window fusion, and Real seal exactness theorems force them to be the same rows used by every public completion-facing or* $\mathsf{Real}^{\uparrow}$ *consumer.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRouteLedgerPublicExactness`

Proof. Read source-route exactness first. Definition 646.43 places the route from R through the selector, seal, dyadic, window, readback, and Real rows, and Definition 646.44 binds Q to the same T, D, W data.

Use the ledger theorems to remove side choices. Definition 646.52 and Definition 646.34 keep the window row W fixed, while Definition 646.53 keeps L attached to that same route.

The public route then follows from Definition 646.59 and Definition 646.61. They identify the displayed ledger as the route read by public consumers and exhaust the remaining support rows H, C, P, N. □

Theorem 646.64 (Diagonal-limit compatibility downstream public boundary)**.** *Downstream* $\mathsf{RealCompleteness}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and regular-Cauchy consumers of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet may consume only the public route*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

They may transport that route through the displayed hsame*,* Cont*,* Pkg*, and* NameCert *rows, but they cannot introduce quotient streams, selected limits, host equality, ambient completeness, hidden tail oracles, or independent route selectors.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityDownstreamPublicBoundary`

Proof. Begin with the public packet export, Definition 646.62. It fixes the finite carrier, route ledger, triangle seal, window ledger, Real seal, and route-exhaustion rows as one exported packet.

Attach the downstream consumers with Definition 646.35, Definition 646.38, and Definition 646.60. These theorems route completion, seal, and regular-tail reads through the same displayed packet.

Finally apply Definition 646.48 and Definition 646.42. The excluded objects are not part of the exported carrier or support rows, so no downstream consumer can supply them from this public boundary. □

Theorem 646.65 (DiagonalLimitCompatibility standard bridge surface)**.** *For an accepted* DiagonalLimitCompatibil *packet* $K = (R, T, S, D, W, Q, L, H, C, P, N)$*, the public diagonal-limit compatibility packet bridges the displayed budget, selector, limit-seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows to the standard reflection schema. The bridge surface is the same finite public route*

$$R, T, S, D, W, Q, L, H, C, P, N,$$

with no quotient stream, selected host limit, host real equality, choice datum, hidden tail oracle, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityStandardBridgeSurface`

Proof. Start from the public route of Definition 646.64. It already exposes the budget, selector, seal, dyadic, window, readback, Real seal, transport, continuation, package, and local name rows as the only rows available to completion-facing consumers.

Synchronize the seal source with Definition 646.69 and Definition 646.50. These theorems keep the limit-seal route attached to the same diagonal source and force every Real-facing read through the displayed seal and readback rows.

Lock the source and budget rows with Definition 646.58 and Definition 646.49. The selector-budget package rows supplied by Definition 646.190 and Definition 646.191 then give the standard reflection input without adding a second selector or analytic coordinate.

Finally repack the same finite tuple as the bridge surface. The BHist, hsame, Cont, Pkg, and NameCert rows are already displayed by K, and the non-escape theorems exclude every quotient, selected-limit, host-equality, choice, and ambient-completeness row not present in that tuple. □

Theorem 646.66 (DiagonalLimitCompatibility bridge support minimality)**.** *For an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet* $K = (R, T, S, D, W, Q, L, H, C, P, N)$*, every standard-reflection or completion-facing bridge read must retain the finite support rows*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Deleting D *loses the dyadic tolerance ledger, deleting* W *loses the* StreamName$^{\uparrow}$ *window ledger, deleting* Q *loses the* RegSeqRat$^{\uparrow}$ *readback row, deleting* L *loses the* Real$^{\uparrow}$ *seal, and deleting one of* H, C, P, N *loses componentwise transport, displayed route, package provenance, or local naming. No quotient stream, selected host limit, host real equality, choice datum, hidden tail oracle, or ambient completeness row can replace any missing support row.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityBridgeSupportMinimality`

Proof. First lock the route that any bridge consumer may read. Definition 646.58 forces completion-facing and Real$^{\uparrow}$ consumers through the source, selector, seal, dyadic, window, readback, and Real rows before L is available. Definition 646.59 identifies this same route as the public budget route, and Definition 646.63 records it as exactly $R, T, S, D, W, Q, L, H, C, P, N$.

Next attach the bridge consumer to that route. Definition 646.64 makes downstream completion and regular-Cauchy reads factor through the same displayed packet, while Definition 646.65 repacks that packet as the standard reflection surface. Thus a standard-reflection or completion-facing bridge read has no support beyond the listed rows.

It remains to check that no listed row is eliminable. Removing D breaks the tolerance handoff used before readback; removing W breaks the stream-window ledger used by the seal and readback rows; removing Q removes the regular rational readback; removing L removes the Real seal read

by the bridge; and removing one of H, C, P, N removes the transport, route, provenance, or local naming row that makes the packet public.

Finally apply Definition 646.11, Definition 646.48, and Definition 646.42. These clauses exclude quotient streams, selected host limits, host equality, choice data, hidden tail oracles, and ambient completeness from the carrier, so none of them can supply a substitute for a deleted finite support row. □

Theorem 646.67 (Diagonal-limit compatibility budget-selector route meet)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet, and let B be an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packet using the same* $\mathsf{StreamName}^{\uparrow}$ *window row W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row Q, and* $\mathsf{Real}^{\uparrow}$ *seal row L. The completion-facing route of K and the finite observation budget-selector route of B meet at the same displayed budget surface*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Every completion-facing, $\mathsf{Real}^{\uparrow}$*-facing, or selector-facing consumer that preserves those shared rows must read the same budget surface, with no quotient stream, selected host limit, host real equality, choice datum, hidden tail oracle, independent selector, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityBudgetSelectorRouteMeet`

Proof. First lock the diagonal-limit route. Apply Definition 646.58 and Definition 646.59. These theorems force the accepted packet K to expose the completion-facing budget through $R, T, S, D, W, Q, L, H, C, P, N$

Next identify the public ledger. The route-ledger public exactness theorem Definition 646.63 states that the displayed budget surface is the exact public ledger for K, and Definition 646.65 repacks the same rows for bridge-facing consumers.

Now attach the selector side through chapter 782. Its accepted carrier and budget-route determinacy use the same $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal rows, so the selector route has no separate budget surface once it shares W, D, Q, L with K.

The two routes therefore meet at the displayed tuple. The non-escape clauses for the diagonal-limit packet and for the finite observation budget selector exclude quotient streams, selected host limits, host real equality, choice data, hidden tail oracles, independent selectors, and ambient completeness from the shared surface. □

Theorem 646.68 (Diagonal-limit compatibility budget-selector bridge-meet exactness)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet, and let B be an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packet using the same* $\mathsf{StreamName}^{\uparrow}$ *window row W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row Q, and* $\mathsf{Real}^{\uparrow}$ *seal row L. Then every bridge-facing, completion-facing, or selector-facing consumer preserving those rows reads the same standard-reflection support surface*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

No quotient stream, host real equality, countable choice, hidden selector, independent selected limit, or ambient completeness coordinate refines this bridge meet.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityBudgetSelectorBridgeMeetExa`

Proof. First apply the budget-selector route meet, Definition 646.67. It places the diagonal route and selector route on the same displayed budget surface whenever W, D, Q, L are shared.

Next identify the public ledger. The route-ledger public exactness theorem Definition 646.63 says that this surface is exactly $R, T, S, D, W, Q, L, H, C, P, N$ for accepted diagonal-limit consumers.

Now pass to bridge-facing consumers. The standard bridge surface theorem Definition 646.65 repacks the same rows as the standard-reflection support, and bridge support minimality Definition 646.66 prevents deletion or replacement of any listed row.

Finally use the non-escape clauses from the route meet and the bridge support theorem. Quotient streams, host real equality, countable choice, hidden selectors, selected limits, and ambient completeness are absent from both packets, so they cannot refine the common bridge meet. □

Closure status for $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$.

Constructive story: A $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ packet is generated from an accepted $\mathsf{RealCompleteness}^{\uparrow}$ diagonal-limit packet, a $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ three-leg estimate, a $\mathsf{CauchyLimitSeal}^{\uparrow}$ seal route, a $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, $\mathsf{StreamName}^{\uparrow}$ windows, a $\mathsf{RegSeqRat}^{\uparrow}$ readback row, a $\mathsf{Real}^{\uparrow}$ seal class, displayed hsame transports, Cont routes, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 646.1, Definition 646.2, Definition 646.11, Definition 646.33, Definition 646.34, Definition 646.35, Definition 646.37, Definition 646.38, Definition 646.39, Definition 646.41, Definition 646.42, Definition 646.43, Definition 646.44, Definition 646.48, Definition 646.49, Definition 646.50, Definition 646.51, Definition 646.52, Definition 646.53, Definition 646.61, Definition 646.62, Definition 646.65, and Definition 646.66 bind the finite carrier, route ledger, triangle seal, stream-window ledger, RegSeqRat readback, Real seal, completion boundary, route exhaustion, bridge support, and standard bridge surface to the displayed BHist, hsame, Cont, Pkg, and NameCert rows of the public packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: paperBridge

Origin: human

Not claimed: This chapter does not close Lean verification, bridge checking, quotient stream equality, selected host limits, host real equality, choice, or ambient completeness.

Upgrade path: The remaining work is formal-axis checking of the displayed bridge route.

Theorem 646.69 (Diagonal-limit seal source synchronization)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

any seal-facing read first fixes the diagonal packet R, the triangle row T, the dyadic ledger D, the window ledger W, the regular readback row Q, and the seal row L through the displayed hsame *transports H,* Cont *routes C,* Pkg *provenance P, and local* NameCert *row N. The read cannot inspect Q or L through a second source route, alternate window ledger, host limit, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySealSourceSynchronization`

Proof. Project the carrier of Definition 646.1. The accepted packet exposes exactly the source rows R, T, S, D, W, Q, L together with H, C, P, N.

Use triangle selector alignment, Definition 646.6, to bind the triangle row T to the same dyadic ledger D and window ledger W already named by the diagonal packet R.

Now apply seal route compatibility, Definition 646.7. The seal route can read Q and L only after the displayed source, triangle, tolerance, and window rows have been fixed.

Finally apply non-escape, Definition 646.11. Since no second source route, alternate window ledger, host limit, host equality, choice datum, or ambient completeness row is exported, the seal-facing read is synchronized to the displayed packet rows. □

Theorem 646.70 (Diagonal-limit triangle readback lock)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q *is locked behind the same triangle row* T*, dyadic ledger* D*, and window ledger* W *that support the seal route. After* T, D, W *have been displayed,* Q *cannot be selected from a second regular readback route or from a tolerance row outside the packet.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility triangle readback lock`

Proof. Start with window ledger exactness, Definition 646.34. The row W is the exact shared-window ledger read by the diagonal source, triangle row, dyadic ledger, seal route, readback row, and real seal row.

Next use the triangle seal route, Definition 646.33. It places the seal route to Q behind the displayed T, D, W rows.

Apply regular readback exactness, Definition 646.44. That theorem identifies Q as the readback determined by the same T, D, W route and excludes another regular readback or dyadic witness.

The non-escape boundary then removes any remaining hidden source. The packet has no coordinate from which a second readback route or alternate tolerance surface could be selected. □

Theorem 646.71 (Diagonal-limit real seal factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet factors through*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The consumer receives the displayed diagonal source, triangle row, seal route, dyadic ledger, window ledger, regular readback, real seal row, componentwise transports, continuations, provenance, and local naming row. It receives no quotient stream, selected host limit, host real equality, choice datum, or ambient completeness theorem.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility real seal factorization`

Proof. First read the seal source synchronization theorem, Definition 646.69. It fixes the source, triangle, dyadic, window, readback, seal, transport, route, provenance, and naming rows before a seal-facing consumer can proceed.

Then apply the triangle readback lock, Definition 646.70. The regular readback row Q is tied to the same T, D, W route as the seal row, so a $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer has no independent readback surface.

Finally use completion consumer nonescape, Definition 646.48. Every completion-facing read remains inside the displayed packet rows and exports none of the omitted quotient, host, choice, or completeness data. □

Theorem 646.72 (Diagonal-limit Real seal consumer scope)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

first reads the synchronized source rows R, T, D, W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q*, and the real seal row* L *through* H, C, P, N*. Such a consumer cannot obtain a host limit, quotient stream, choice datum, ambient completeness row, or second source route.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility real seal consumer scope`

Proof. Apply Definition 646.69. It fixes the displayed source rows R, T, D, W, the readback row Q, the seal row L, and the structural rows H, C, P, N before any seal-facing read can continue.

Next use Definition 646.70. The readback row Q is locked behind the same triangle, dyadic, and window rows T, D, W, so the consumer has no independent readback or tolerance route.

Finally apply Definition 646.71. The factorization routes every $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer through the displayed packet rows and exports none of the host limit, quotient stream, choice, ambient completeness, or second-source data excluded in the statement. □

Theorem 646.73 (Diagonal-limit seal source scope row)**.** *Every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

exposes a seal-facing $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer only after the finite budget-selector route, synchronized triangle row, dyadic ledger, stream window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, Real seal, transports, continuations, provenance, and* $\mathsf{NameCert}$ *rows have been fixed. Thus the consumer reads only the displayed rows* $R, T, S, D, W, Q, L, H, C, P, N$ *and cannot obtain a second source route, quotient stream, host limit, choice datum, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility seal source scope row`

Proof. Project the carrier of Definition 646.1. The accepted packet displays the finite route rows R, T, S, D, W, Q, L and the structural rows H, C, P, N before any seal-facing consumer can be addressed.

Apply seal source synchronization, Definition 646.69. It fixes the source route, triangle row, dyadic ledger, stream window, readback row, seal row, transport, continuation, provenance, and local naming rows as one packet.

Use the triangle readback lock, Definition 646.70. The readback row Q is tied to the same T, D, W route as the seal row L, so a $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer has no separate tolerance or regular-sequence source.

Finally apply the Real seal consumer scope theorem, Definition 646.72. It routes the consumer through the displayed rows and excludes second source routes, quotient streams, host limits, choice data, and ambient completeness. □

Theorem 646.74 (Diagonal-limit seal source determinacy)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packets. Suppose their displayed rows agree componentwise by* hsame*:*

$$\mathsf{hsame} RR', \quad \mathsf{hsame} TT', \quad \mathsf{hsame} SS', \quad \mathsf{hsame} DD', \quad \mathsf{hsame} WW', \quad \mathsf{hsame} QQ', \quad \mathsf{hsame} LL',$$
$$\mathsf{hsame} HH', \quad \mathsf{hsame} CC', \quad \mathsf{hsame} PP', \quad \mathsf{hsame} NN'.$$

If two $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumers both pass through Definition 646.73, then they determine the same seal-facing finite route. In particular, they cannot be distinguished by a host limit, quotient stream, choice datum, ambient completeness principle, or second source route.*

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySealSourceDeterminacy

Proof. Apply seal source synchronization, Definition 646.69, to both accepted packets. Each seal-facing read is first confined to the displayed rows $R, T, S, D, W, Q, L, H, C, P, N$ and $R', T', S', D', W', Q', L', H', C',$

Use the triangle readback lock, Definition 646.70. The readback coordinate is tied to the same triangle, dyadic, and window rows as the seal coordinate, so the componentwise hsame hypotheses identify the finite route through T, D, W, Q, L on both sides.

Next apply real seal factorization, Definition 646.71, and real seal consumer scope, Definition 646.72. The consumer route factors through exactly the displayed coordinates and exports no host limit, quotient stream, choice datum, ambient completeness row, or second source route.

It remains only to exhaust the coordinates. The hypotheses identify every displayed source, structural, provenance, and naming row by hsame, while the factorization and scope theorems leave no hidden coordinate outside those rows. Thus the two consumers determine the same seal-facing finite route and admit no remaining distinguishing datum of the kinds named in the statement. □

Theorem 646.75 (Diagonal-limit four-face budget ownership)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted DiagonalLimitCompatibility$^{\uparrow}$ *packets whose displayed rows agree componentwise by* hsame*. Any* Real$^{\uparrow}$ *or* CauchyLimitSeal$^{\uparrow}$ *consumer that passes through the synchronized seal source of K and K' decomposes its finite budget into exactly four owned faces. The* StreamName$^{\uparrow}$ *face owns the finite window/source row S and window ledger W; the* DyadicRatCore$^{\uparrow}$ *face owns the dyadic tolerance ledger D; the* RegSeqRat$^{\uparrow}$ *face owns the readback row Q behind the synchronized T, D, W route; and the* Real$^{\uparrow}$ *face owns the seal row L. The support rows H, C, P, N are shared BEDC support rows for* hsame*,* Cont*,* Pkg*, and* NameCert*, not a fifth mathematical face.*

Consequently the finite budget carries no quotient stream equality, host sequence equality, selected limit, ambient Real$^{\uparrow}$ *completeness theorem, metric-completeness datum, countable-choice datum, or standard bridge row. The same four faces are the Phase Real and Completion boundary faces named by Definition 126.500.*

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier four face budget ownership

Proof. First apply seal source synchronization, Definition 646.69. It confines every seal-facing read to the displayed rows $R, T, S, D, W, Q, L, H, C, P, N$ and their componentwise hsame partners in K'.

Next use the triangle readback lock, Definition 646.70. The readback row Q is available only behind the same synchronized T, D, W route, so it cannot supply an independent tolerance ledger, regular source, or host sequence equality.

Apply real seal factorization and real seal consumer scope, Definition 646.71 and Definition 646.72. These identify the seal consumer with the displayed finite packet and exclude quotient stream equality, selected limits, ambient completeness, choice data, and any second source route. Then apply seal source determinacy, Definition 646.74, to see that the componentwise hsame agreement leaves no additional coordinate on which two consumers can differ.

It remains to name the ownership boundary. The row S together with W is the StreamName finite window/source face, D is the DyadicRatCore tolerance ledger, Q is the RegSeqRat readback

face behind T, D, W, and L is the Real seal face. The rows H, C, P, N only transport, continue, package, and certify these four faces. Finally Definition 126.500 identifies exactly the same four faces with the current Phase Real and Completion exit route, so the diagonal seal packet contributes no fifth mathematical face or standard bridge row. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility four face budget ownership`

Theorem 646.76 (Diagonal-limit four-face budget determinacy)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packets. Suppose the* $\mathsf{StreamName}^{\uparrow}$ *window/source face, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance face, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback face, the* $\mathsf{Real}^{\uparrow}$ *seal face, and the support rows* H, C, P, N *agree by* hsame*:*

$$\mathsf{hsame}SS', \quad \mathsf{hsame}WW', \quad \mathsf{hsame}DD', \quad \mathsf{hsame}QQ', \quad \mathsf{hsame}LL',$$
$$\mathsf{hsame}HH', \quad \mathsf{hsame}CC', \quad \mathsf{hsame}PP', \quad \mathsf{hsame}NN'.$$

Then every $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer that passes through the two accepted packets reads the same finite seal route. The route has exactly the four faces owned by* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, with* H, C, P, N *as support rows, and it has no second source route, quotient stream, host limit, choice datum, ambient completeness row, metric completion row, or standard bridge row.*

Proof. Start with seal source synchronization, Definition 646.69. It places each seal-facing read behind the displayed diagonal source, triangle, dyadic, window, readback, seal, transport, continuation, provenance, and naming rows.

Use the triangle readback lock, Definition 646.70. The readback row Q cannot move independently of the synchronized triangle, dyadic, and window rows, so the hsame agreement on D, W, Q fixes the tolerance and readback part of the route seen by either consumer.

Next apply real seal factorization, Definition 646.71, and real seal consumer scope, Definition 646.72. These results force the $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer to pass through the displayed seal row L and prevent any hidden host limit, quotient stream, choice datum, ambient completeness row, or second source route from entering the consumer route.

Now invoke seal source determinacy, Definition 646.74. Together with the stated hsame agreement on $S, W, D, Q, L, H, C, P, N$, it identifies all coordinates that the consumer can read after synchronization and factorization.

Finally use four-face budget ownership, Definition 646.75. The only owned mathematical faces are the $\mathsf{StreamName}^{\uparrow}$ window/source face, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance face, the $\mathsf{RegSeqRat}^{\uparrow}$ readback face, and the $\mathsf{Real}^{\uparrow}$ seal face, while H, C, P, N only support transport, continuation, packaging, and naming. Hence both consumers read the same finite seal route and no additional completion, bridge, choice, quotient, or host row remains. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier four face budget determinacy`

Theorem 646.77 (Diagonal-limit four-face pullback exactness)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packets whose displayed rows agree componentwise by* hsame*. A* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer classifies through the diagonal seal source of* K *and* K' *if and only if its four projections classify componentwise on the* $\mathsf{StreamName}^{\uparrow}$ *window/source face* (S, W)*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance face* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback face* Q *behind the synchronized* T, D, W *route, and the* $\mathsf{Real}^{\uparrow}$ *seal face* L*.*

The only gluing data are the displayed support rows H, C, P, N *and* H', C', P', N'*, read respectively as* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support. The exact pullback exports no quotient stream, host equality, selected limit, ambient completeness theorem, metric-completeness datum, countable-choice row, or standard bridge row.*

Proof. For the forward direction, start with a consumer that classifies through the diagonal seal source. Apply seal source synchronization, Definition 646.69, to confine the read to the displayed rows of K and K'.

Use the triangle readback lock, Definition 646.70, to keep the readback coordinate Q behind the same synchronized T, D, W route. Then apply real seal factorization, Definition 646.71, so the $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer reads the seal row only after the displayed source, tolerance, window, and readback rows have been fixed.

Now project the synchronized packet to its four faces. Four-face budget ownership, Definition 646.75, names exactly the $\mathsf{StreamName}^{\uparrow}$ window/source face, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance face, the $\mathsf{RegSeqRat}^{\uparrow}$ readback face, and the $\mathsf{Real}^{\uparrow}$ seal face. The componentwise hsame hypotheses therefore give componentwise classification of those four projections, with H, C, P, N and H', C', P', N' as the only support rows.

For the reverse direction, assume the four projected faces classify componentwise through the displayed support rows. Apply Definition 301.58 to repack the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces as one finite terminal pullback surface.

Next apply Definition 38.413. The compatible open-phase faces determine a single consumer-visible seal-source handoff, and the comparison uses only hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Finally use seal source determinacy, Definition 646.74. The componentwise agreement of the accepted packets leaves no hidden coordinate outside the displayed finite route, so the repacked four-face surface is exactly the diagonal seal source classification for K and K'.

The exclusion clauses come from the same cited pullback and factorization results together with four-face budget ownership. None of the accepted rows contains quotient stream equality, host equality, selected limits, ambient completeness, metric-completeness data, countable-choice rows, or standard bridge rows, so none can be part of the exact pullback. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility four face pullback exactness`

Theorem 646.78 (Diagonal-limit tail-seal source uniqueness)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Any terminal* $\mathsf{Real}^{\uparrow}$ *seal read using the displayed* $\mathsf{StreamName}^{\uparrow}$ *window row* W *and source row* S*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q*, the*

$\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger D, and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route has a unique displayed tail-seal source up to componentwise* hsame *through the support rows H, C, P, N.*

Equivalently, two terminal seal reads whose $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *faces are accepted by the same packet determine the same consumer-visible source route after transport through H, replay through C, packaging through P, and local naming through N. The uniqueness statement exports no quotient stream, host real equality, hidden selector, selected host limit, detached completion object, or ambient completeness principle.*

Proof. Start with two terminal $\mathsf{Real}^{\uparrow}$ seal reads of the accepted packet. Seal source synchronization, Definition 646.69, places both reads behind the displayed $R, T, S, D, W, Q, L, H, C, P, N$ rows.

The triangle readback lock, Definition 646.70, fixes Q behind the same T, D, W route. Hence neither read can choose a separate regular readback, tolerance witness, or window source while still being a read of K.

Next use real seal factorization, Definition 646.71. A $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer reaches the terminal seal only after the displayed source, window, tolerance, readback, and seal rows have already been fixed.

Four-face budget determinacy, Definition 646.76, identifies the consumer-visible mathematical faces as the $\mathsf{StreamName}^{\uparrow}$ window/source face, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance face, the $\mathsf{RegSeqRat}^{\uparrow}$ readback face, and the $\mathsf{Real}^{\uparrow}$ seal face. The support rows H, C, P, N only transport, replay, package, and name those same faces.

Finally apply four-face pullback exactness, Definition 646.77. The four accepted faces repack as one terminal pullback surface, and seal source determinacy identifies the resulting source route. Thus any two terminal seal reads have the same displayed tail-seal source up to componentwise hsame through H, C, P, N.

The refusal clauses are inherited from the cited synchronization, factorization, budget, and pullback results. Since no accepted row contains a quotient stream, host real equality, hidden selector, selected host limit, detached completion object, or ambient completeness theorem, none can be used to produce another terminal tail-seal source. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityTailSealSourceUniqueness`

Theorem 646.79 (Diagonal-limit compatibility root budget source)**.** *Every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet reads its root budget source through the displayed finite rows*

$$\mathsf{BHist}, \mathsf{hsame}, \mathsf{Cont}, \mathsf{Pkg}, \mathsf{NameCert}.$$

The budget source is the same source exposed to $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *consumers: the diagonal row, dyadic ledger, stream window, regular-rational handoff, seal route, componentwise transport, route table, provenance, and local name must already be visible before the compatibility packet is accepted.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root budget source`

Proof. Project the accepted compatibility carrier. The displayed packet contains the diagonal source, triangle estimate, seal route, dyadic ledger, stream window, regular readback, Real seal row, transports, continuations, provenance, and local naming row.

Apply the NameCert obligation theorem and the window-ledger exactness theorem. They force the budget-facing reads to use the same carrier, hsame rows, Cont routes, Pkg provenance, and $\mathsf{NameCert}$ row rather than an undisplayed budget source.

Finally use completion-boundary and non-escape. Since no host limit, quotient stream, choice datum, host real equality, or ambient completeness coordinate is exported, the accepted packet can source its budget only through the displayed finite rows shared with the selector-budget route. □

Theorem 646.80 (Diagonal-limit compatibility terminal modulus-budget comparison)**.** *Let an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *terminal route be consumed both by a* UniformCauchyCriterion$^{\uparrow}$ *route and by a* CauchyModulusRefinement$^{\uparrow}$ *selector route. Then the terminal budget comparison factors through the same displayed rows*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The two consumers therefore agree on the finite StreamName *window, dyadic ledger, regular-Cauchy readback,* Real$^{\uparrow}$ *seal handoff, route, provenance, and local* NameCert *rows. The comparison introduces no quotient stream, selected host limit, choice datum, host real equality, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier terminal modulus budget comparison`

Proof. First bind the diagonal terminal route. Apply Definition 646.79, Definition 646.81, and Definition 646.82. These rows expose the finite stream window, dyadic ledger, diagonal readback, Real seal handoff, consumer route, provenance, and local NameCert data before any terminal consumer acts.

Next route the uniform consumer through Definition 646.95. The uniform finite-family seal can read the terminal prefix only after the displayed diagonal budget rows are visible, so its window and ledger data are not separate host-level selections.

Now route the selector consumer through Definition 646.91. The Cauchy-modulus-refinement selector reads the same diagonal prefix before it reaches its selector rows, while Definition 885.22 and Definition 885.23 keep the regular-Cauchy readback and Real$^{\uparrow}$ handoff tied to the displayed finite window.

Finally compare the two consumers using Definition 646.96. Both branches have already entered through $R, T, S, D, W, Q, L, H, C, P, N$, so the terminal budget comparison has no coordinate from which to extract a quotient stream, selected host limit, choice datum, host real equality, or ambient completeness claim. □

Theorem 646.81 (Diagonal-limit compatibility root window route)**.** *For an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet, the* StreamName$^{\uparrow}$ *finite-window route is selected before any* RegSeqRat$^{\uparrow}$ *readback or* Real$^{\uparrow}$ *seal handoff is available. A downstream consumer reaches the regular-rational row and the Real-facing seal only after reading the displayed window row, dyadic ledger, transport rows, continuation rows, provenance row, and local naming row.*

Proof. Start with the carrier projection. The window row W and dyadic ledger D are displayed before the readback row Q and seal row L are consumed.

Use window-ledger exactness together with the triangle-seal route theorem. These results place the route to Q, L behind the same StreamName$^{\uparrow}$ window row used by the diagonal source, triangle row, dyadic ledger, and seal route.

Apply completion boundary. It adds the componentwise hsame transport, displayed Cont route, Pkg provenance, and local NameCert rows to the same finite-window route, so no RegSeqRat or Real handoff precedes the window selection. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root window route`

Theorem 646.82 (Diagonal-limit compatibility root seal boundary)**.** *Every Real-facing read of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet passes through the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row and seal rows before it reaches the* $\mathsf{Real}^{\uparrow}$ *coordinate. The read is a route through* $R, T, S, D, W, Q, L, H, C, P, N$*, not a read through host real equality, a selected host limit, quotient stream equality, choice data, or ambient completeness.*

Proof. Read the packet through seal-route compatibility. The seal route can reach the regular readback and Real seal only after the diagonal source, triangle row, dyadic ledger, and stream window have been fixed.

Now apply Real-seal exactness. It identifies the displayed route through $R, T, S, D, W, Q, H, C, P, N$ as the boundary through which L is reached.

The Real-seal non-escape theorem removes the possible host-side bypasses. Thus the Real-facing read is exactly a finite regular-readback and seal-route read inside the accepted compatibility packet. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root seal boundary`

Theorem 646.83 (Diagonal-limit compatibility root consumer non-escape)**.** *Every downstream* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Completion}^{\uparrow}$*, or completion-seal consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet can inspect only the displayed budget, window, diagonal, seal, transport, route, provenance, and local-name rows. In packet notation the consumer-visible surface is exhausted by*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Proof. Project the accepted packet and list the consumer-facing coordinates. The budget and window information is carried by the dyadic ledger and stream window, the diagonal and seal information by the source, triangle, seal, readback, and Real rows, and the structural information by the transport, route, provenance, and local-name rows.

Use the completion-consumer non-escape theorem. It already requires every completion-facing or $\mathsf{Real}^{\uparrow}$ consumer to factor through the same listed rows.

Finally replay the root budget source, root window route, and root seal boundary results. Together they show that the consumer has no coordinate outside the displayed budget, window, diagonal, seal, transport, route, provenance, and local-name surface. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root consumer nonescape`

Theorem 646.84 (Diagonal-limit compatibility root budget-seal factorization)**.** *Every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root consumer reaches a* $\mathsf{Real}^{\uparrow}$ *or completion-seal read only after the displayed budget source,* $\mathsf{StreamName}^{\uparrow}$ *finite-window route,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal rows, transports, continuations, provenance, and local* $\mathsf{NameCert}$ *rows have been read. In packet notation the consumer route is*

$$R, T, S, D, W, Q, L, H, C, P, N,$$

and it excludes host real equality, selected host limits, quotient stream equality, choice data, and ambient completeness.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root budget seal factorization`

Proof. Start with the root budget source. Definition 646.79 identifies the budget-facing source with the displayed diagonal row, dyadic ledger, stream window, regular-rational handoff, Real seal route, transports, continuations, provenance, and local name.

Next apply the root window route. Definition 646.81 forces the $\mathsf{StreamName}^{\uparrow}$ finite-window row to be read before the $\mathsf{RegSeqRat}^{\uparrow}$ readback or the $\mathsf{Real}^{\uparrow}$ seal handoff is available.

Then use the root seal boundary. Definition 646.82 places each Real-facing read behind the regular readback and seal rows Q, L on the displayed route through $R, T, S, D, W, Q, L, H, C, P, N$.

Finally apply root consumer non-escape. Definition 646.83 exhausts downstream Real, completion, and completion-seal consumers by the displayed packet rows, so none of the excluded host or quotient objects has a route into the accepted consumer surface. □

Theorem 646.85 (Diagonal-limit compatibility root provenance exhaustion)**.** *Every root budget, window, readback, seal, and consumer route in an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet is exhausted by the displayed rows*

$$R, T, S, D, W, Q, L, H, C, P, N$$

together with the Pkg *provenance and the local* $\mathsf{NameCert}$ *row. No host limit, quotient stream equality, choice datum, host real equality, or ambient completeness coordinate is added to the accepted root-budget surface.*

Proof. First use root budget source, root window route, and root seal boundary. These three route theorems identify the budget source, the $\mathsf{StreamName}^{\uparrow}$ finite-window route, the $\mathsf{RegSeqRat}^{\uparrow}$ readback, and the $\mathsf{Real}^{\uparrow}$ seal boundary with the same displayed packet rows.

Next apply root consumer non-escape. It says that every downstream Real, completion, or completion-seal consumer is confined to the visible budget, window, diagonal, seal, transport, route, provenance, and local-name rows.

Finally use root budget-seal factorization. The factorization composes the preceding routes into the consumer-facing tuple $R, T, S, D, W, Q, L, H, C, P, N$, and the tuple already contains the Pkg provenance row and local $\mathsf{NameCert}$ row as P, N. Therefore the accepted packet has no remaining route through host limits, quotient stream equality, choice data, host real equality, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root provenance exhaustion`

Theorem 646.86 (Diagonal-limit compatibility root-window selector exhaustion)**.** *Every root finite-window selector read of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet is exhausted by the displayed rows*

$$R, T, S, D, W, Q, L, H, C, P, N$$

before any $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *or completion-seal consumer can read the route. The selector cannot add quotient stream equality, selected host limits, hidden selector data, host real equality, choice data, or ambient completeness.*

Proof. Begin with the root budget source and root window route, Definition 646.79 and Definition 646.81. These identify the budget source, dyadic ledger, stream window, diagonal row, window row, and regular handoff as the finite selector-facing packet.

Next apply the root seal boundary and root consumer non-escape, Definition 646.82 and Definition 646.83. The seal boundary keeps $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and completion-facing reads behind the displayed Q, L, H, C, P, N rows, while non-escape prevents a branch to host limits, quotient streams, selected host data, choice data, host equality, or ambient completeness.

Finally use budget-seal factorization and root provenance exhaustion, Definition 646.84 and Definition 646.85. Their composite exhausts the selector route by $R, T, S, D, W, Q, L, H, C, P, N$ together with the displayed provenance and local naming rows. Since the accepted packet has no hidden selector coordinate, every root finite-window selector read is consumed before the downstream regular, Real, or completion-seal route is available. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root window selector exhaustion`

Theorem 646.87 (Diagonal-limit compatibility selector-budget common refinement)**.** *Every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet whose terminal route is consumed by a* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *route, a* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *selector route, and a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal route factors all three reads through the same displayed finite rows*

$$R, T, S, D, W, Q, L, H, C, P, N$$

before any selector or seal consumer can inspect the route. The shared route first exposes the diagonal root budget, stream-name window, regular-rational readback, dyadic ledger, Real seal boundary, componentwise transport, continuation replay, package provenance, and local $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row. It admits no hidden selector budget, no quotient stream equality, no selected host limit, no host real equality, no choice datum, and no ambient completeness row.*

Proof. Start with the root budget source, root window route, and root seal boundary. Theorems 646.79, 646.81, and 646.82 identify the diagonal source, $\mathsf{StreamName}^{\uparrow}$ finite-window row, $\mathsf{RegSeqRat}^{\uparrow}$ readback row, dyadic ledger, and $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal boundary as one displayed packet.

Next attach the selector-facing consumers. The root-window selector exhaustion theorem, Definition 646.86, forces every selector-budget read to pass through the same $R, T, S, D, W, Q, L, H, C, P, N$ rows before any regular, Real, or completion-seal route is visible.

Finally close the route against escape. Root consumer non-escape, budget-seal factorization, and root provenance exhaustion, Definition 646.83, Definition 646.84, and Definition 646.85, keep Pkg provenance and the local $\mathsf{NameCert}$ row attached to the same carrier. Thus the $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$, $\mathsf{CauchyModulusRefinement}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumers share the common refinement before any selector or seal consumer inspects the route. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget common refinement`

Theorem 646.88 (DiagonalLimitCompatibility finite-tail-filter handoff)**.** *Let* $K = (R, T, S, D, W, Q, L, H, C, P, N)$ *be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Let*

$$F = (S_F, D_F, R_F, B_F, Q_F, E_F, H_F, C_F, P_F, N_F)$$

be an accepted FiniteTailFilter$^{\uparrow}$ *packet whose stream-window, dyadic, regular-readback, and Real-seal rows agree with the displayed rows of* K *by* hsame(S_F, W), hsame(D_F, D), hsame(R_F, Q), *and* hsame(E_F, L).

Then every finite-tail-filter consumer of F *reads the same* StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, Cont, Pkg, *and* NameCert *route supplied by* K *before any completion-facing read. The handoff introduces no hidden tail selector, quotient stream, selected host limit, host real equality, choice datum, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget finite tail filter handoff`

Proof. First apply the selector-budget common refinement of Definition 646.87. It places the diagonal root budget, stream-name window, regular-rational readback, dyadic ledger, Real seal boundary, continuation replay, package provenance, and local naming row on the single displayed route $R, T, S, D, W, Q, L, H, C, P, N$.

Next read the finite-tail-filter carrier through the four shared rows. The hsame identifications force the FiniteTailFilter$^{\uparrow}$ window, dyadic, readback, and Real-seal faces to be W, D, Q, L as seen by the diagonal packet, while the carrier obligations keep the tail-budget, comparison, transport, continuation, provenance, and local NameCert rows inside the same finite packet.

Finally use the finite-tail-filter non-escape and Real-seal handoff rows. They make every Real-facing or completion-facing consumer pass through the finite packet before it can read the completion boundary. Since the common refinement already fixes the corresponding diagonal route and its Pkg and NameCert rows, the composite handoff has no coordinate left for a hidden tail selector, quotient stream, selected host limit, host real equality, choice datum, or ambient completeness. □

Theorem 646.89 (DiagonalLimitCompatibility CauchyTailWitnessEnvelope factorization)**.** *Let an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet have a terminal* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *route consumed by an accepted* CauchyTailWitnessEnvelope$^{\uparrow}$ *packet. Then the terminal consumer route factors first through the displayed diagonal budget rows*

$$R, T, S, D, W, Q, L, H, C, P, N$$

and then through the envelope rows

$$S, F, Q, A, R, H, C, P, N.$$

The composite route introduces no quotient stream, selected host limit, host equality, choice datum, hidden tail oracle, or ambient completeness row.

Proof. Begin with the diagonal budget side. The root budget source, root window route, and root seal boundary of Definition 646.79, Definition 646.81, and Definition 646.82 place the terminal Real$^{\uparrow}$ or Completion$^{\uparrow}$ read behind the displayed rows $R, T, S, D, W, Q, L, H, C, P, N$.

Next use the consumer and provenance boundary. By Definition 646.83, Definition 646.84, and Definition 646.85, no downstream consumer can leave the diagonal budget packet for a host limit, quotient stream, choice datum, host equality, or ambient completeness coordinate.

Now attach the Cauchy tail witness envelope. The selector handoff of Definition 898.3 sends the consumed diagonal-tail route through the selected window S, finite-window envelope F, and tail-comparison row Q. The exactness results of Definition 898.5 and Definition 898.6 keep the selected window and endpoint ledger on the same finite envelope surface.

Finally apply the Real-tail seal boundary and non-escape results of Definition 898.7 and Definition 898.4. They force the envelope read to pass through $S, F, Q, A, R, H, C, P, N$ and exclude hidden tail oracles together with the same host, quotient, choice, and ambient-completeness bypasses. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier cauchy tail envelope factorization`

Theorem 646.90 (Diagonal-limit selector-budget MonotoneCauchy handoff)**.** *Let $K = (R, T, S, D, W, Q, L, H, C,$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet, and let an accepted* $\mathsf{MonotoneCauchy}^{\uparrow}$ *packet read its finite-window, modulus, located-interval, regular-readback, and* $\mathsf{Real}^{\uparrow}$ *seal rows through the same W, D, Q, L selector-budget surface of K. Then every* $\mathsf{Real}^{\uparrow}$*- or* $\mathsf{Completion}^{\uparrow}$*-facing monotone-Cauchy consumer factors through the displayed diagonal selector-budget route before it reads the monotone ledger or located upper-bound row.*

The handoff exports no quotient stream, selected host limit, host real equality, trichotomy row, ambient completeness coordinate, metric-completeness datum, bridge row, or choice datum.

Proof. First lock the diagonal selector source. Apply Definition 646.193 and Definition 646.198. These identify the only selector-budget route of K as the displayed diagonal source together with the rows W, D, Q, L, H, C, P, N.

Next attach the terminal diagonal consumer. The Cauchy-tail envelope factorization, Definition 646.89, shows that any $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read first passes through $R, T, S, D, W, Q, L, H, C, P, N$ before a downstream tail-facing packet can inspect its own rows.

Now read the monotone-Cauchy packet through the same selector surface. By Definition 438.27, the finite-window, modulus, located-interval, regular-readback, and $\mathsf{Real}^{\uparrow}$ seal rows of the accepted monotone packet are read as the cofinal criterion seal surface. Since those rows are assumed to be the W, D, Q, L selector-budget surface of K, the monotone ledger and located upper-bound row occur only after the diagonal selector route has already been fixed.

Finally apply the diagonal completion-consumer non-escape boundary, Definition 646.48. It removes every route through quotient streams, selected host limits, host real equality, trichotomy, ambient completeness, metric-completeness data, bridge rows, and choice, so the monotone-Cauchy consumer receives only the displayed selector-budget handoff. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySelectorBudgetMonotoneCauch`

Theorem 646.91 (DiagonalLimitCompatibility CauchyModulusRefinement route)**.** *Let an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet have a terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *route consumed through an accepted* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *packet. Then the terminal consumer route factors first through the displayed diagonal rows*

$$R, T, S, D, W, Q, L, H, C, P, N$$

and then through the refinement rows

$$M_0, M_1, U, V, T, W, Q, E, H, C, P, N.$$

The composite route exports no quotient stream, selected host limit, hidden selector, second meet row, host real equality, choice datum, or ambient completeness coordinate.

Proof. Start with the diagonal root budget. The root budget source, root window route, and root seal boundary of Definition 646.79, Definition 646.81, and Definition 646.82 place every terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read behind $R, T, S, D, W, Q, L, H, C, P, N$.

Next use the diagonal consumer boundary. By Definition 646.83, Definition 646.84, and Definition 646.85, the terminal read cannot leave the displayed diagonal route for a quotient stream, selected host limit, host real equality, choice datum, or ambient completeness coordinate.

Now pass the terminal route into the refinement packet. The source-window lock of Definition 885.110 forces the consumed route to expose M_0, M_1, U, V before any selected-window or tolerance-readback row is available.

Finally apply root window exhaustion and Real-seal source conservation, Definition 885.113 and Definition 885.116. These results place the refinement consumer on $M_0, M_1, U, V, T, W, Q, E, H, C, P, N$ and exclude quotient streams, selected host limits, hidden selectors, second meet rows, host real equality, choice data, ambient completeness coordinates, and detached completion witnesses. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier cauchy modulus refinement route`

Theorem 646.92 (Diagonal-limit compatibility shared terminal consumer comparison)**.** *Let an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet have a terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer routed through either an accepted* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *packet or an accepted* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *packet. In both cases the terminal consumer first reads the same diagonal budget, window, readback, seal, transport, route, provenance, and local-name boundary*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Only after this shared boundary do the two routes differ: the $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *route continues through its envelope rows, while the* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *route continues through its refinement rows. The comparison introduces no quotient stream equality, selected host limit, hidden tail oracle, hidden selector, host real equality, choice datum, or ambient completeness coordinate.*

Proof. First form the shared diagonal boundary. Apply Definition 646.79, Definition 646.81, and Definition 646.82. These force every terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read to pass through the diagonal budget, stream window, regular readback, Real seal, transport, continuation, package, and local-name rows.

Next close that boundary against escape. Use Definition 646.83, Definition 646.84, and Definition 646.85. The reusable consumer-facing tuple is therefore exactly $R, T, S, D, W, Q, L, H, C, P, N$, with no route to host limits, quotient stream equality, choice data, host real equality, or ambient completeness.

Now compare the two terminal consumers. The $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ case follows from Definition 646.89, which begins with the same diagonal tuple before entering the envelope rows. The $\mathsf{CauchyModulusRefinement}^{\uparrow}$ case follows from Definition 646.91, which begins with that same tuple before entering the refinement rows. Thus the routes differ only after the shared diagonal terminal-consumer boundary has been read. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier shared terminal consumer comparison`

Theorem 646.93 (DiagonalLimitCompatibility envelope-refinement pullback)**.** *Let an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet have a terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer routed through*

either an accepted CauchyTailWitnessEnvelope$^{\uparrow}$ *packet or an accepted* CauchyModulusRefinement$^{\uparrow}$ *packet. Both terminal-consumer routes pull back to the same displayed diagonal boundary*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The envelope-specific rows $S, F, Q, A, R, H, C, P, N$ *and the refinement-specific rows* $M_0, M_1, U, V, T, W, Q, E, H, C,$ *are read only after that boundary. Neither branch introduces quotient streams, selected host limits, hidden tail oracles, hidden selectors, host real equality, choice data, or ambient completeness.*

Proof. First read the root budget source, root window, and root seal boundary of Definition 646.79, Definition 646.81, and Definition 646.82. These place the terminal Real$^{\uparrow}$ or Completion$^{\uparrow}$ consumer behind $R, T, S, D, W, Q, L, H, C, P, N$ before any downstream packet can expose its own rows.

Next close that boundary under root consumer non-escape. Apply Definition 646.83; the terminal read cannot leave the displayed diagonal packet for a quotient stream, selected host limit, hidden selector, host real equality, choice datum, or ambient completeness coordinate.

Now attach the two branch factorizations. The envelope branch is Definition 646.89, which reads $S, F, Q, A, R, H, C, P, N$ only after the same diagonal boundary. The refinement branch is Definition 646.91, which reads $M_0, M_1, U, V, T, W, Q, E, H, C, P, N$ only after that boundary.

Finally use Definition 646.92. Since both branches have the same terminal-consumer prefix and all branch-specific rows occur downstream, the displayed tuple $R, T, S, D, W, Q, L, H, C, P, N$ is the classifier-visible pullback for either accepted terminal route. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier envelope refinement pullback`

Theorem 646.94 (DiagonalLimitCompatibility terminal budget readback)**.** *Let an accepted* DiagonalLimitCompati *packet have a terminal* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *consumer read, and suppose that this read is later consumed by either an accepted* CauchyTailWitnessEnvelope$^{\uparrow}$ *packet or an accepted* CauchyModulusRefinement$^{\uparrow}$ *packet. Then the terminal read first factors through the same displayed diagonal budget prefix*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Only after this prefix may the route branch: the envelope case proceeds through

$$S, F, Q, A, R, H, C, P, N,$$

while the refinement case proceeds through

$$M_0, M_1, U, V, T, W, Q, E, H, C, P, N.$$

The common readback exports no quotient stream equality, selected host limit, hidden tail oracle, hidden selector, host real equality, choice datum, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier terminal budget readback`

Proof. First build the common diagonal prefix. Apply Definition 646.79, Definition 646.81, and Definition 646.82 to place the terminal Real$^{\uparrow}$ or Completion$^{\uparrow}$ read behind the root budget, window, seal, transport, route, provenance, and local-name rows.

Next close the prefix against escape. Use Definition 646.83, Definition 646.84, and Definition 646.85. These identify the reusable consumer-facing tuple as $R, T, S, D, W, Q, L, H, C, P, N$

and rule out quotient stream equality, selected host limits, host real equality, choice data, and ambient completeness before any downstream branch is inspected.

Now split by the downstream consumer. If the read is consumed by CauchyTailWitnessEnvelope$^{\uparrow}$, apply Definition 646.89; the remaining route is exactly $S, F, Q, A, R, H, C, P, N$, and hidden tail oracles are excluded.

If the read is consumed by CauchyModulusRefinement$^{\uparrow}$, apply Definition 646.91; the remaining route is exactly $M_0, M_1, U, V, T, W, Q, E, H, C, P, N$, and hidden selectors are excluded. Thus both terminal branches share the same diagonal budget readback boundary before they diverge. □

Theorem 646.95 (DiagonalLimitCompatibility uniform Cauchy terminal handoff)**.** *Let an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet have a terminal* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *consumer read, and suppose that the read is later consumed by an accepted* UniformCauchyCriterion$^{\uparrow}$ *packet. Then the terminal read first factors through the same diagonal budget prefix*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Only after this prefix may it enter the uniform Cauchy finite-family seal rows: the finite family index ledger, shared StreamName$^{\uparrow}$ *window family, uniform* CauchyModulus$^{\uparrow}$ *schedule,* DyadicRatCore$^{\uparrow}$ *tolerance row,* DyadicTailBound$^{\uparrow}$ *tail ledger,* Real$^{\uparrow}$ *seal handoff, and the displayed* BHist/hsame/Cont/Pkg/NameCert *rows. The handoff exports no quotient stream equality, selected host limit, hidden tail selector, host real equality, choice datum, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier uniform cauchy terminal handoff`

Proof. First bind the diagonal terminal prefix. Apply Definition 646.79, Definition 646.81, and Definition 646.82. These place the terminal Real$^{\uparrow}$ or Completion$^{\uparrow}$ read behind the displayed budget source, window, readback, Real seal, transport, route, provenance, and local naming rows.

Next close that prefix against bypass. Use Definition 646.83; the terminal consumer can inspect only $R, T, S, D, W, Q, L, H, C, P, N$ before it reaches a downstream packet. Hence quotient stream equality, selected host limits, host real equality, choice data, and ambient completeness are unavailable at the handoff boundary.

Now read the accepted UniformCauchyCriterion$^{\uparrow}$ consumer through its finite family seal surface. The public export, downstream consumer boundary, and seal completion boundary of chapter 435 force the uniform criterion read to pass through the finite index ledger, shared window family, uniform modulus, dyadic tolerance, finite tail ledger, Real seal handoff, and structural BHist/hsame/Cont/Pkg/NameCert rows.

Combining the two surfaces gives the claimed order: the diagonal terminal prefix is read first, and only then can the finite-family uniform Cauchy seal rows be consumed. Since neither side exposes hidden tail selectors, quotient streams, selected host limits, host real equality, choice data, or ambient completeness, the composite handoff exports none of them. □

Theorem 646.96 (DiagonalLimitCompatibility uniform Cauchy three-way terminal comparison)**.** *Let an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet have a terminal* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *consumer read, and suppose that this read is routed through one of the accepted terminal consumers* CauchyTailWitnessEnvelope$^{\uparrow}$, CauchyModulusRefinement$^{\uparrow}$, *or* UniformCauchyCriterion$^{\uparrow}$. *Then all three routes first factor through the same displayed diagonal budget prefix*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Only after this common prefix may the route enter the respective terminal surface: the envelope rows for CauchyTailWitnessEnvelope$^{\uparrow}$*, the refinement rows for* CauchyModulusRefinement$^{\uparrow}$*, or the uniform finite-family seal rows for* UniformCauchyCriterion$^{\uparrow}$*. The comparison introduces no quotient stream equality, selected host limit, hidden tail oracle, hidden selector, host real equality, choice datum, or ambient completeness coordinate.*

Proof. First bind the diagonal budget prefix. Apply Definition 646.79, Definition 646.81, and Definition 646.82. These place the terminal Real$^{\uparrow}$ or Completion$^{\uparrow}$ read behind the budget source, stream window, diagonal readback, Real seal, transport, continuation, package, and local-name rows.

Next close the prefix against nonlocal exits. Use Definition 646.83, Definition 646.84, and Definition 646.85. The consumer-facing boundary is therefore exactly $R, T, S, D, W, Q, L, H, C, P, N$, and the route has no access to host limits, quotient stream equality, choice data, host real equality, or ambient completeness before any terminal consumer row is entered.

Now compare the three terminal consumers. The CauchyTailWitnessEnvelope$^{\uparrow}$ branch is Definition 646.89; the CauchyModulusRefinement$^{\uparrow}$ branch is Definition 646.91; and the UniformCauchyCriterion$^{\uparrow}$ branch is Definition 646.95. Each begins with the same diagonal prefix and only afterward enters its own envelope, refinement, or uniform finite-family rows. Thus the shared diagonal budget prefix is the common terminal-consumer boundary for the current Real$^{\uparrow}$ and Completion$^{\uparrow}$ routes. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityUniformCauchyThreeWayTermin`

Theorem 646.97 (DiagonalLimitCompatibility Real-completion terminal pullback)**.** *Let an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet have a terminal route read by a* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *consumer, and suppose that this read is then consumed by one of* CauchyTailWitnessEnvelope$^{\uparrow}$*,* CauchyModulusRefinement$^{\uparrow}$*, or* UniformCauchyCriterion$^{\uparrow}$*. The Real-completion-facing terminal read pulls back first to the same displayed diagonal tuple*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The branch-specific rows are downstream-only: envelope, refinement, and uniform finite-family data may be read only after the tuple above has been fixed. No quotient stream, selected host limit, host real equality, choice datum, ambient completeness coordinate, hidden tail oracle, or hidden selector is exported by the pullback boundary.

Proof. First bind the Real-completion terminal read to the root diagonal route. Apply Definition 646.79, Definition 646.81, and Definition 646.82. These identify the budget source, finite stream window, regular-rational readback, Real seal, transport, continuation, package, provenance, and local-name rows with $R, T, S, D, W, Q, L, H, C, P, N$.

Next close the route under the consumer boundary. Use Definition 646.83 and Definition 646.85. The accepted packet has no coordinate from which a Real or completion consumer can leave the displayed diagonal tuple for a quotient stream, selected host limit, host real equality, choice datum, ambient completeness coordinate, hidden tail oracle, or hidden selector.

It remains to compare the downstream consumers. The envelope branch is Definition 646.89, the refinement branch is Definition 646.91, and the uniform finite-family branch is Definition 646.95. Each branch starts only after the same diagonal tuple has already been read.

Finally apply Definition 646.96. The three-way comparison makes the shared tuple the terminal-consumer boundary for all three downstream routes, so the Real-completion terminal read pulls back to that tuple before any branch-specific rows are available. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier real completion terminal pullback`

Theorem 646.98 (DiagonalLimitCompatibility terminal branch exhaustion)**.** *Let an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet have a terminal* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *read consumed by the current terminal branch surface. Then the read first factors through the displayed diagonal terminal prefix*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

After this prefix the only admitted branch rows are the CauchyTailWitnessEnvelope$^{\uparrow}$ *rows, the* CauchyModulusRefinement$^{\uparrow}$ *rows, or the* UniformCauchyCriterion$^{\uparrow}$ *finite-family seal rows. The terminal surface exports no quotient stream, selected host limit, host equality, choice datum, ambient completeness coordinate, hidden tail oracle, hidden selector, or fourth terminal branch.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityTerminalBranchExhaustion`

Proof. First bind the root prefix. Apply Definition 646.79, Definition 646.81, and Definition 646.82. These place the terminal Real$^{\uparrow}$ or Completion$^{\uparrow}$ read behind the budget, window, readback, seal, transport, route, provenance, and local-name rows $R, T, S, D, W, Q, L, H, C, P, N$.

Next close the prefix against nonlocal escape. Use Definition 646.83, Definition 646.84, and Definition 646.85. The accepted carrier has no coordinate for quotient streams, selected host limits, host equality, choice data, ambient completeness, hidden tail oracles, or hidden selectors before a displayed branch surface is read.

Now enumerate the admitted terminal branches. The envelope route is Definition 646.89; the refinement route is Definition 646.91; and the uniform finite-family route is Definition 646.95. Each begins only after the same diagonal prefix and then reads its own displayed branch rows.

Finally apply the three-way comparison and terminal pullback, Definition 646.96 and Definition 646.97. They make the three displayed consumers exhaustive for the current terminal surface: any accepted terminal branch is one of those rows after $R, T, S, D, W, Q, L, H, C, P, N$, and no fourth branch or hidden terminal export remains. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier terminal branch exhaustion`

Theorem 646.99 (Diagonal-limit compatibility root budget coherence)**.** *For an accepted* DiagonalLimitCompatibilit *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

the root-budget route is the same displayed route used by the rows D, W, Q, L, H, C, P, N. It reads the DyadicRatCore$^{\uparrow}$ *ledger D, the* StreamName$^{\uparrow}$ *window row W, the* RegSeqRat$^{\uparrow}$ *readback row Q, the* Real$^{\uparrow}$ *seal row L, the componentwise* hsame *transports H, the displayed* Cont *routes C, the* Pkg *provenance P, and the local* NameCert *row N through the carrier of Definition 646.1. It has no root-budget source outside that* BHist/hsame/Cont/Pkg/NameCert *surface.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root budget coherence`

Proof. Project the accepted carrier. The only root-facing data in the packet are the displayed rows $R, T, S, D, W, Q, L, H, C, P, N$, with D, W, Q, L carrying the budget, window, readback, and seal coordinates and H, C, P, N carrying transport, route, provenance, and naming.

Apply the root budget source theorem, Definition 646.79. It identifies the budget source with the same finite structural surface used by the selector-budget route, rather than with a hidden host-side source.

Now use the root window route and root seal boundary theorems, Definition 646.81 and Definition 646.82. They keep the route through W, Q, L after the displayed ledger and window rows and before any Real-facing handoff.

Finally apply root consumer non-escape, Definition 646.83. Since no additional budget coordinate is exported, the root-budget route is exactly the route already used by D, W, Q, L, H, C, P, N. □

Theorem 646.100 (Diagonal-limit compatibility root selector budget exhaustion)**.** *Every selector-budget consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet factors through*

$$R, T, S, D, W, Q, L.$$

It must first read the accepted diagonal source R, the triangle selector row T, the seal route S, the dyadic ledger D, the finite window row W, the regular readback row Q, and the Real seal row L, transported by the same H, C, P, N support rows. No selector-budget consumer can introduce a second diagonal route, alternate window route, alternate dyadic ledger, selected host limit, quotient stream, choice datum, or ambient completeness input.

Proof. Start with the carrier projection. A selector-budget consumer sees one diagonal source row R, one triangle selector row T, one seal route S, one dyadic ledger D, one stream-window row W, one regular readback Q, and one Real seal row L.

Use triangle selector alignment together with source-route exactness, Definition 646.6 and Definition 646.43. These theorems attach the selector route to the same R, T, D, W rows and place the route to Q, L on that displayed source path.

Next apply the root budget carrier and classifier rows, Definition 646.111 and Definition 646.112. The carrier row supplies the finite packet surface, and the classifier row keeps componentwise hsame transport and Cont replay on that same route.

The exhaustion claim follows from root budget ledger row and completion consumer non-escape, Definition 646.113 and Definition 646.48. Together they leave no selector-budget coordinate outside $R, T, S, D, W, Q, L, H, C, P, N$. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootSelectorBudgetExhaustio`

Theorem 646.101 (Diagonal-limit compatibility Real seal readback lock)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal read of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet reaches L only after the* $\mathsf{StreamName}^{\uparrow}$ *window row W, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row Q, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D, and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route S have been fixed on the displayed compatibility route. The read is therefore locked to the carrier route*

$$R, T, S, D, W, Q, L, H, C, P, N$$

and cannot be replaced by a host real equality, selected limit, quotient stream, choice datum, or ambient completeness principle.

Proof. First read the seal source synchronization theorem, Definition 646.69. It fixes R, T, S, D, W, Q, L together with H, C, P, N before a seal-facing consumer can inspect the readback or seal rows.

Next apply the triangle readback lock and regular readback exactness, Definition 646.70 and Definition 646.44. These results place Q behind the same T, D, W route used by the seal row and exclude an independent regular readback source.

Now use seal readback exactness and Real seal exactness, Definition 646.41 and Definition 646.53. They identify the route to L with the displayed seal, dyadic, window, readback, transport, continuation, provenance, and local naming rows.

Finally apply the completion consumer gate, Definition 646.149. Every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read remains downstream of the same finite budget-source and seal-budget routes, so no host-side completion data can replace the locked readback route. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root real seal readback lock`

Theorem 646.102 (Diagonal-limit compatibility finite-window handoff boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet reaches the public handoff only through the displayed finite route*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The handoff consumes the root-budget route, the selector-budget route, and the Real seal readback lock as one carrier boundary. It cannot be replaced by host real equality, a quotient stream, a selected limit, choice data, or ambient completeness.

Proof. First apply Definition 646.99. This fixes the root-budget route on the same D, W, Q, L, H, C, P, N surface that the accepted carrier exposes to downstream consumers.

Next apply Definition 646.100. The selector-budget read is exhausted by R, T, S, D, W, Q, L and the structural rows, so no second diagonal route, second window route, alternate ledger, or choice datum is available.

Finally apply Definition 646.101. The seal read reaches L only after S, D, W, Q have been fixed on the displayed compatibility route.

The non-escape clauses Definition 646.83 and Definition 646.48 remove host real equality, quotient streams, selected limits, and ambient completeness from the public handoff. Therefore the finite route $R, T, S, D, W, Q, L, H, C, P, N$ is the complete boundary for $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumers. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier finite window handoff boundary`

Theorem 646.103 (Diagonal-limit compatibility root budget public boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet is confined to the single displayed route*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The route simultaneously consumes the root-budget coherence, selector-budget exhaustion, Real-seal readback lock, and finite-window handoff boundary. It admits no host real equality, quotient stream, choice datum, selected limit, or ambient completeness input.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root budget public boundary`

Proof. Begin with root-budget coherence, Definition 646.99. It places the root-facing budget read on the same D, W, Q, L, H, C, P, N surface exposed by the accepted carrier.

Next apply selector-budget exhaustion, Definition 646.100. The selector route has already consumed R, T, S, D, W, Q, L together with the same transport, continuation, provenance, and naming rows.

Then apply the Real-seal readback lock, Definition 646.101. This locks every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal read to L only after the displayed S, D, W, Q route has been fixed.

Use the finite-window handoff boundary, Definition 646.102, to package these three reads as one public consumer boundary for the route $R, T, S, D, W, Q, L, H, C, P, N$.

Finally, the non-escape clauses Definition 646.83 and Definition 646.48 close coordinate exhaustion. They leave no host real equality, quotient stream, choice datum, selected limit, or ambient completeness input outside the displayed packet route. □

Theorem 646.104 (Diagonal-limit compatibility root-budget handoff totality)**.** *Every root-budget handoff from an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet to a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer is exhausted by the ordered route*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The handoff is already the finite Real and Completion route carried by the packet. It exposes no host real equality, quotient stream, selected limit, choice data, ambient completeness, or second budget source.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root budget handoff totality`

Proof. Begin with Definition 646.99. It fixes the root budget on the displayed D, W, Q, L, H, C, P, N carrier rows before any downstream consumer can read the packet.

Next apply Definition 646.100. This consumes the selector contribution on R, T, S, D, W, Q, L and leaves only the displayed transport, continuation, provenance, and naming rows available to the handoff.

Now use Definition 646.101. The Real-facing read reaches L only after the public selector and budget rows have already been fixed on the same route.

Apply Definition 646.102 and Definition 646.103. These two public-boundary theorems package the root budget, selector budget, Real seal lock, and finite-window handoff as one route for $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumers.

The non-escape clauses attached to those five rows remove every remaining off-route coordinate. Hence the root-budget handoff is total for the displayed finite route, with no host real equality, quotient stream, selected limit, choice data, ambient completeness, or second budget source. □

Theorem 646.105 (Diagonal-limit compatibility budget coherence terminal lock)**.** *For every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet* $K = (R, T, S, D, W, Q, L, H, C, P, N)$*, every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer that reads the root-budget handoff passes through the single ordered route*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The terminal route is the displayed $\mathsf{BHist}/\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}/\mathsf{NameCert}$ *packet. It admits no host real equality, quotient stream, selected limit, choice datum, ambient completeness input, alternate dyadic ledger, alternate* $\mathsf{StreamName}^{\uparrow}$ *window, or second budget source.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility budget coherence terminal lock`

Proof. Begin with root-budget coherence, Definition 646.99. It places the budget read on the same D, W, Q, L, H, C, P, N rows carried by the accepted packet.

Next use selector-budget exhaustion, Definition 646.100. The selector contribution consumes R, T, S, D, W, Q, L on the same packet surface, so no alternate dyadic ledger or alternate $\mathsf{StreamName}^{\uparrow}$ window can sit between the root budget and the public selector read.

Apply the Real-seal readback lock, Definition 646.101. It forces every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ readback to reach L only through the already fixed selector, window, dyadic, and regular readback rows.

The finite-window handoff boundary Definition 646.102 and the root-budget public boundary Definition 646.103 package these rows as one public consumer route. The handoff totality theorem, Definition 646.104, then exhausts the route for every root-budget handoff.

All cited route coordinates are therefore identical:

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Since the displayed BHist/hsame/Cont/Pkg/NameCert packet has already consumed the budget, selector, window, readback, and seal rows, no host real equality, quotient stream, selected limit, choice datum, ambient completeness, alternate dyadic ledger, alternate $\mathsf{StreamName}^{\uparrow}$ window, or second budget source remains available to a $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer. □

Theorem 646.106 (Diagonal-limit compatibility root budget consumer chain)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet reaches the public read only through the ordered chain*

root-budget coherence → *selector-budget exhaustion* → *Real-seal readback lock* → *finite-window handoff* → *public b*

on the displayed route

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Thus the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{Completion}^{\uparrow}$*-facing reads consume one ordered BEDC route rather than a host limit, quotient stream, choice datum, host real equality, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootBudgetConsumerChain`

Proof. First apply Definition 646.99. It fixes the root-budget read on the same D, W, Q, L, H, C, P, N surface carried by the accepted packet.

Next apply Definition 646.100. It places the selector budget behind R, T, S, D, W, Q, L and rules out a second diagonal source, alternate window route, alternate dyadic ledger, selected host limit, quotient stream, choice datum, or ambient completeness input between the root-budget read and the selector read.

Then apply Definition 646.101. The seal read reaches L only after S, D, W, Q have been fixed on the displayed compatibility route, so no host real equality can enter between the selector budget and the $\mathsf{Real}^{\uparrow}$ read.

Now use Definition 646.102. It packages the root-budget route, selector-budget route, and Real-seal lock as one finite handoff on $R, T, S, D, W, Q, L, H, C, P, N$.

Finally apply Definition 646.103. The public boundary is downstream of those four links on the same route, so every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer reaches the public read without inserting a host limit, quotient stream, choice datum, host real equality, or ambient completeness coordinate between any two links of the chain. □

Theorem 646.107 (Diagonal-limit compatibility TailMeet refinement seal route)**.** *Every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet whose root budget route enters through* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*, whose refinement read is governed by* $\mathsf{CauchyModulusRefinement}^{\uparrow}$*, and whose endpoint seal is consumed by* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *factors through the single displayed L10 route*

$$R, T, S, D, W, Q, L, H, C, P, N$$

followed by the TailMeet budget-seal rows, the refinement rows, and the agreement-seal rows. The composed route exports no quotient stream, host real equality, selected limit, choice datum, side-channel completion carrier, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root tailmeet refinement seal route`

Proof. Begin with the local diagonal packet. Apply Definition 646.106. It places every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer of the accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ carrier on the ordered route $R, T, S, D, W, Q, L, H, C, P, N$ before the public read.

Next attach the TailMeet entry and refinement handoff. Use Definition 885.156. A consumer entering through the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ root budget-seal package must consume the displayed TailMeet rows and then the refinement route before any endpoint seal is exported.

The route is unique at the refinement surface. Apply Definition 885.157. It identifies the exported $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ handoff as the same public route under the displayed hsame rows, with no side-channel completion carrier or ambient completeness coordinate.

Finally use Definition 699.79. The $\mathsf{RealTailAgreementSeal}^{\uparrow}$ endpoint is reached through the finite completion lattice after the selector, window, dyadic readback, regular readback, and agreement-seal rows have been consumed.

These four route certificates exhaust the available $\mathsf{BHist}/\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}/\mathsf{NameCert}$ coordinates. Since the diagonal packet, TailMeet package, refinement read, and agreement seal each expose only their displayed rows, no quotient stream, host real equality, selected limit, choice datum, side-channel completion carrier, or ambient completeness coordinate can be exported by the composed route. □

Theorem 646.108 (Root TailMeet refinement Real-seal correspondence)**.** *For every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet entering through* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*, refined by* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *and read by* $\mathsf{RealTailAgreementSeal}^{\uparrow}$*, the endpoint* $\mathsf{Real}^{\uparrow}/\mathsf{Completion}^{\uparrow}$ *consumer route is equivalent to the staged public read obtained by first consuming the displayed diagonal route*

$$R, T, S, D, W, Q, L, H, C, P, N,$$

then the TailMeet budget-seal rows, then the refinement rows, and then the agreement-seal rows. Under this correspondence the endpoint route exports no quotient stream, host real equality, selected limit, choice datum, side-channel completion carrier, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootTailmeetRefinementRealS`

Proof. For the forward direction, start from an endpoint $\mathsf{Real}^{\uparrow}/\mathsf{Completion}^{\uparrow}$ consumer of the accepted diagonal packet. Apply Definition 646.106 to place the consumer on the displayed $R, T, S, D, W, Q, L, H, C, P, N$ spine. Then use Definition 885.156 to force the TailMeet budget-seal entry and the refinement handoff before the endpoint seal can be read.

The refinement part has no alternate public route. Apply Definition 885.157; it identifies the TailMeet-to-refinement handoff with the same exported $\mathsf{Real}^{\uparrow}/\mathsf{Completion}^{\uparrow}$ read. Finally apply Definition 699.79 to finish the endpoint through the agreement-seal lattice, so the original consumer has exactly the staged diagonal, TailMeet, refinement, and agreement-seal presentation.

For the reverse direction, begin with a staged public read in that order. The diagonal root-budget chain supplies the $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ consumer spine, the route-exhaustion theorem supplies the TailMeet and refinement rows, and the uniqueness theorem prevents a second

refinement handoff from being inserted. The Real-tail agreement lattice then repacks the last rows as the endpoint $\mathsf{Real}^{\uparrow}/\mathsf{Completion}^{\uparrow}$ seal read.

Both directions use only the exposed BHist/hsame/Cont/Pkg/NameCert rows named by the four cited route theorems. Their exhaustion clauses remove the remaining possible coordinates, so the correspondence carries no quotient stream, host real equality, selected limit, choice datum, side-channel completion carrier, or ambient completeness input. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootTailMeetRefinementRealS`

Theorem 646.109 (Diagonal-limit compatibility root transport replay exactness)**.** *Any root-budget consumer entering the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *refinement route from an accepted* DiagonalLimitCompatibility *packet is transported and replayed through the same ordered rows*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The replayed route cannot split into a second diagonal selector, detached TailMeet object, host limit, quotient stream, or ambient completion coordinate.

Proof. Begin with the root budget consumer chain, Definition 646.106. It places every root-facing consumer on the displayed $R, T, S, D, W, Q, L, H, C, P, N$ route before any TailMeet refinement handoff is read.

Then apply Definition 646.108. The TailMeet refinement and Real-seal endpoint consume the same root spine and do not introduce a second diagonal selector or detached TailMeet coordinate.

The transported replay is therefore exact at the public surface. Since both cited routes expose only the listed BHist/hsame/Cont/Pkg/NameCert rows, there is no host limit, quotient stream, or ambient completion coordinate left for the replay to branch through. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root transport replay exactness`

Theorem 646.110 (Diagonal-limit compatibility root-budget public-route cover)**.** *Every public root-budget consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet reaches a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *endpoint exactly through the displayed diagonal rows*

$$R, T, S, D, W, Q, L, H, C, P, N,$$

then the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *refinement route, then the* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *budget route, and finally the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *completion lattice. No public endpoint consumer can factor through host real equality, quotient streams, choice selectors, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root budget public route cover`

Proof. Start from a public root-budget consumer of the accepted diagonal packet. Apply Definition 646.106; it places the consumer on the displayed diagonal route $R, T, S, D, W, Q, L, H, C, P, N$ before any public endpoint read is available.

Next attach the TailMeet and refinement stages. The correspondence of Definition 646.108 identifies the root-budget route with the staged read through $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{CauchyModulusRefinement}^{\uparrow}$, and the agreement seal. The replay exactness of Definition 646.109 keeps that route on the same transported diagonal spine.

It remains to cover the public endpoints. Apply Definition 885.156 and Definition 885.157. These force every TailMeet-entering budget consumer through the displayed refinement handoff and exclude a second public route or side-channel completion carrier.

Finally use Definition 699.79. The $\mathsf{Real}^{\uparrow}/\mathsf{Completion}^{\uparrow}$ endpoint is read only after the selector, window, dyadic readback, regular readback, and agreement-seal rows of the completion lattice have been consumed.

The composed certificates exhaust the available BHist/hsame/Cont/Pkg/NameCert rows. Since none of the displayed diagonal, TailMeet, refinement, or agreement-seal rows contains host real equality, quotient streams, choice selectors, or ambient completeness, no public root-budget endpoint consumer can reach such a coordinate. □

Theorem 646.111 (Diagonal-limit compatibility root budget carrier row)**.** *The root budget carrier row of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet is the finite packet surface over* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *already displayed by the compatibility packet. In packet notation, the root budget route may read only the displayed diagonal source, triangle estimate, seal route, dyadic ledger, stream window, regular readback, Real seal row, componentwise transport, continuation route, provenance, and local naming rows.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root budget carrier row`

Proof. Project the accepted compatibility packet. The carrier rows already list the budget-facing source, window, seal, transport, route, provenance, and local name.

Apply the root budget source theorem. Definition 646.79 identifies the budget source with the same BHist, hsame, Cont, Pkg, and NameCert surface used by the selector-budget route.

Since the carrier exports no extra budget coordinate, the root budget carrier row is exactly the displayed finite packet surface. □

Theorem 646.112 (Diagonal-limit compatibility root budget classifier row)**.** *The root budget classifier of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet is stable under componentwise* hsame *transport of the same displayed packet rows and under replay of the displayed* Cont *routes. A downstream route that transports the diagonal source, dyadic ledger, stream window, regular readback, seal row, provenance, and local name by the recorded* hsame *rows reaches the same root budget surface after replaying the recorded* Cont *rows.*

Proof. Begin with the displayed transport rows. Componentwise hsame movement changes only the representation of each listed coordinate and leaves the packet inventory fixed.

Replay the displayed continuation rows. The root window route theorem Definition 646.81 places the $\mathsf{StreamName}^{\uparrow}$ window before the $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{Real}^{\uparrow}$ seal handoff, so replay follows the same budget order after transport.

The classifier therefore has no second route on which to branch. It reads the transported packet through the same finite root budget surface. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root budget classifier row`

Theorem 646.113 (Diagonal-limit compatibility root budget ledger row)**.** *The root budget route of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet has exact ledger boundary and non-escape. Its source is fixed by Definition 646.79, its window order by Definition 646.81, its seal boundary by Definition 646.82, and its consumer boundary by Definition 646.83. The route also consumes the*

sibling L10 surfaces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *before any completion-facing handoff is available.*

Proof. First read the source and window rows. The root budget source theorem fixes the finite budget surface, and the root window route theorem orders the $\mathsf{StreamName}^{\uparrow}$ window before the regular readback and Real seal.

Next read the seal boundary. The root seal boundary theorem forces every Real-facing read through the displayed $\mathsf{RegSeqRat}^{\uparrow}$ readback and seal rows.

Finally apply consumer non-escape. Definition 646.83 exhausts the downstream surface by the displayed packet rows, so no host limit, quotient stream, choice datum, host real equality, or ambient completeness coordinate can enter the root budget route. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootBudget ledger row`

Theorem 646.114 (Diagonal-limit compatibility root budget triad exactness)**.** *For every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet, the carrier row, classifier row, and ledger row jointly exhaust the root-budget route seen by any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer. Every such consumer read through the root budget factors through the displayed diagonal source, dyadic ledger,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row. No host limit, quotient stream, choice datum, host real equality, or ambient completeness coordinate is part of this route.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root budget triad exactness`

Proof. First read the carrier and classifier rows. The carrier row Definition 646.111 fixes the finite packet surface, and the classifier row Definition 646.112 keeps componentwise hsame transport and Cont replay on that same surface.

Next impose the ordered window and seal boundaries. The root window route theorem Definition 646.81 places the $\mathsf{StreamName}^{\uparrow}$ window before the $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{Real}^{\uparrow}$ seal, while the root seal boundary theorem Definition 646.82 prevents a Real-facing read from bypassing those rows.

Finally apply the ledger and consumer boundaries. The ledger row Definition 646.113 records the exact route inventory, and consumer non-escape Definition 646.83 excludes host limits, quotient streams, choice data, host real equality, and ambient completeness. Thus every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read through the root budget factors through the displayed diagonal packet and no additional coordinate. □

Theorem 646.115 (Diagonal-limit compatibility root budget terminal route uniqueness)**.** *Let* R_0 *and* R_1 *be* $\mathsf{Real}^{\uparrow}$*- or* $\mathsf{Completion}^{\uparrow}$*-facing consumers of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Suppose both consumers preserve the displayed diagonal source, dyadic ledger,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row. Then* R_0 *and* R_1 *determine the same root-budget terminal route through those rows. There is no second seal, quotient stream, host real equality, selected limit, or ambient completeness coordinate through which either consumer can factor a distinct terminal read.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootBudget terminal route uniqueness`

Proof. First read the root-budget carrier. By Definition 646.111, both consumers see only the displayed finite packet surface over BHist, hsame, Cont, Pkg, and the local NameCert row.

Next transport the classifier. The classifier row of Definition 646.112 says that componentwise hsame movement and replay of the displayed Cont routes keep the diagonal source, ledger, window, readback, seal, provenance, and name on the same root-budget surface.

Now apply the ledger row. Definition 646.113 orders the source, window, readback, and seal boundary and excludes any route coordinate beyond the displayed packet inventory.

Finally use triad exactness. Definition 646.114 states that every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read through the root budget factors through exactly this carrier, classifier, and ledger triad. Since R_0 and R_1 preserve the same triad rows, there is no remaining coordinate from which a second terminal route could be formed. □

Theorem 646.116 (Diagonal-limit compatibility root-budget Real completion factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-budget packet factors through the displayed diagonal source, dyadic ledger,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row. The factorization has no quotient stream, selected limit, host real equality, choice datum, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root budget real completion factorization`

Proof. First apply triad exactness. By Definition 646.114, every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read through the root budget is already exhausted by the carrier, classifier, and ledger rows over the displayed diagonal source, dyadic ledger, $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal, transports, routes, provenance, and local name.

Next use terminal-route uniqueness. Definition 646.115 says that two consumers preserving this same displayed packet inventory determine the same terminal route, so a consumer has no second terminal read through a quotient stream, selected limit, host real equality, choice datum, or ambient completeness coordinate.

The carrier row, classifier row, and ledger row therefore exhaust the visible factorization surface. Any $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer of the accepted root-budget packet factors through exactly those displayed rows. □

Theorem 646.117 (Diagonal-limit compatibility Cauchy limit functor handoff)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-budget packet, and let a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of* K *be routed through the terminal Real-completion surface of Definition 646.116. Suppose the same route also supplies an accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet*

$$F = (S_0, S_1, M, W_0, W_1, Q', D', K', E, H', C', P', N')$$

whose source seal S_0 *is the displayed source seal read by the root-budget route and whose rows preserve the displayed source seal, target seal,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* RealCompletionSealClassifierUp *row, terminal* $\mathsf{Real}^{\uparrow}$ *endpoint, componentwise* hsame *transports, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchyLimitFunctor}^{\uparrow}}$ *row. Then the consumer factors through the same finite terminal route already fixed by the root-budget factorization. No quotient stream, selected host limit, host real equality, choice row, detached completion object, or independent completion route remains after the functor packet is consumed.*

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility cauchy limit functor handoff

Proof. First apply the root-budget Real-completion factorization. Definition 646.116 places the consumer on the displayed route through the diagonal source, dyadic ledger, stream window, regular readback, Real seal, componentwise transports, continuations, provenance, and local name.

Next read the $\mathsf{CauchyLimitFunctor}^{\uparrow}$ surface. The NameCert obligations of Definition 1116.3 force the functor packet through its source-to-target seal route, finite observation rows, completion-consumer rows, componentwise transports, continuation replay, provenance, and local name. The Real-completion consumer boundary of Definition 1116.7 prevents that packet from exporting quotient stream equality, host real equality, selected limits, detached completion objects, ambient completeness, countable-choice selectors, or a second transport route.

Finally insert the functor packet into the terminal route. Root-budget terminal-route uniqueness from Definition 646.115 identifies every Real- or Completion-facing read that preserves the displayed packet rows, and selector-synchronizer exactness in Definition 646.121 keeps the finite observation surface on the same route. Since the functor preserves the displayed source seal and its terminal Real endpoint, it is consumed on that route rather than opening an independent completion endpoint. □

Theorem 646.118 (Diagonal-limit compatibility Cauchy functor selector admission lock)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-budget packet, and let a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of* K *consume an accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet along the route of Definition 646.117. Then terminal admission for that consumer is equivalent to preservation of both the displayed* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *rows and the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *request, seal, and budget rows named in Definition 646.123. In the admitted case the route is the unique terminal route of Definition 646.121. It exports no quotient stream, host real equality, selected host limit, choice row, hidden observation budget, detached completion object, or ambient completeness coordinate.*

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility cauchy functor selector admission lock

Proof. First consume the functor packet through Definition 646.117. The handoff keeps the $\mathsf{CauchyLimitFunctor}^{\uparrow}$ source seal, target seal, finite observation rows, completion-consumer rows, transports, continuation replay, provenance, and local name on the finite terminal route already fixed by the root-budget factorization.

Next expose the finite selector and synchronizer gates. Apply Definition 646.119 and Definition 646.120 to place the selector rows and the synchronizer request, seal, and budget rows on the same displayed packet route.

For admission, use Definition 646.123. It identifies terminal admission exactly with joint factorization through the displayed selector rows and synchronizer rows, and it sends every request outside those two gates to the visible refusal boundary.

Finally apply Definition 646.121 together with Definition 646.122. Exactness gives the unique terminal selector-synchronizer route, while refusal exactness removes quotient streams, host real equality, selected host limits, choice rows, hidden observation budgets, detached completion objects, and ambient completeness coordinates from every non-admitted completion-facing request. □

Theorem 646.119 (Diagonal-limit compatibility carrier finite observation-budget factorization)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *carrier as in Definition 646.1. Suppose the displayed* Cont *rows factor through*

$$R \to W \to \mathit{selector} \to D \to \mathit{synchronizer} \to Q$$
$$\to \mathit{request} \to L \to \mathit{budget} \to N \to \mathit{terminal}$$

and suppose the terminal row is carried by the same Pkg *bundle as the carrier provenance. Then the carrier exposes unary histories for the selector, synchronizer, request, budget, and terminal rows, preserves each displayed continuation in the chain, and carries both the provenance package row and the terminal package row.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier finite observation budget factorization`

Proof. Project the accepted carrier of Definition 646.1. Its displayed rows give unary histories for the diagonal source, dyadic ledger, window family, readback row, $\mathsf{Real}^{\uparrow}$ seal, certificate row, and provenance package.

Apply unary closure for Cont along the displayed route. The row $R \to W \to$ selector gives a unary selector history; the row from the selector through D gives a unary synchronizer history; the row from the synchronizer through Q gives a unary request history; the row from the request through L gives a unary budget history; and the row from the budget through N gives a unary terminal history.

Finally repack the data in carrier order. Keep the five continuation rows unchanged, keep the provenance Pkg row projected from the carrier, and keep the terminal Pkg row supplied at the terminal endpoint. □

Theorem 646.120 (Diagonal-limit compatibility finite observation-budget factorization)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-budget packet. Suppose a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of* K *also consumes an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packet and an accepted* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *packet on the displayed route. Then the consumer factors through the same finite packet rows: the diagonal source, dyadic ledger* D*,* $\mathsf{StreamName}^{\uparrow}$ *window* W*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* Q*,* $\mathsf{Real}^{\uparrow}$ *seal* L*, the finite observation-budget selector rows, the synchronizer request, seal, and budget rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row. The factorization exports no quotient stream, selected host limit, host real equality, countable-choice row, hidden observation budget, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility finite observation budget factorization`

Proof. First use Definition 646.116. It places the $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer on the root-budget route through the displayed diagonal source, dyadic ledger, stream window, regular readback, Real seal, componentwise transports, continuations, provenance, and local name.

Next insert the finite observation-budget selector. The route theorem Definition 646.191 says that the selector handoff is mediated only by the displayed BHist, hsame, Cont, Pkg, and NameCert support rows, and Definition 782.6 excludes quotient streams, host real equality, countable-choice data, hidden limit selectors, and ambient completeness from the selector packet.

Now insert the seal-budget synchronizer. By Definition 646.138, the accepted $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ request, seal, budget, selector, compatibility, transport, route, provenance, and local naming rows are read before Q and L are available to the consumer.

Finally apply Definition 646.140 and root-budget terminal route uniqueness from Definition 646.115. The synchronizer and selector are inserted on the same finite packet route, and terminal uniqueness leaves no second route through a quotient stream, selected host limit, host real equality, countable-choice row, hidden observation budget, or ambient completeness coordinate. □

Theorem 646.121 (Diagonal-limit compatibility root-budget selector synchronizer exactness)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-budget packet. Any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of K that preserves the displayed diagonal source, dyadic ledger D,* $\mathsf{StreamName}^{\uparrow}$ *window W,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback Q,* $\mathsf{Real}^{\uparrow}$ *seal L, the finite observation-budget selector rows, the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *request, seal, and budget rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row determines the same terminal root-budget route through the selector and synchronizer. No quotient stream, selected host limit, host real equality, choice row, hidden observation budget, or ambient completeness coordinate remains on the terminal path.*

Proof. First apply finite observation-budget factorization. Definition 646.120 places the consumer, selector, and synchronizer on the same displayed finite packet route through the diagonal source, ledger, stream window, regular readback, Real seal, transports, continuations, provenance, and local name.

Next use root-budget terminal route uniqueness. Definition 646.115 identifies all $\mathsf{Real}^{\uparrow}$- and $\mathsf{Completion}^{\uparrow}$-facing reads that preserve this displayed route, so the selector and synchronizer cannot open a second terminal path.

Finally combine triad exactness with consumer non-escape. The triad exactness theorem Definition 646.114 exhausts the carrier, classifier, and ledger rows, while Definition 646.83 excludes quotient streams, selected host limits, host real equality, choice rows, hidden observation budgets, and ambient completeness coordinates. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootBudgetSelectorSynchroni`

Theorem 646.122 (Diagonal-limit compatibility finite observation-budget refusal exactness)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-budget packet. Any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of K that requests quotient stream identity, a selected host limit, host real equality, a countable-choice row, a hidden observation budget, an independent seal-budget route, or ambient completeness is routed to the visible refusal boundary unless that request first factors through the finite observation-budget selector rows and the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *rows named in Definition 646.120. Thus the only admitted completion-facing route through K is the displayed*

finite route through D, W, Q, L, the selector packet, the synchronizer request, seal, and budget rows, componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row.*

Proof. Start with the finite factorization theorem. Definition 646.120 names the admitted route for any $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer that has already consumed the accepted $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ packet and the accepted $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ packet on the displayed route.

The selector route gives the first boundary. By Definition 646.191, the selector handoff reads only the visible BHist, hsame, Cont, Pkg, and NameCert support rows. The selector non-escape theorem Definition 782.6 refuses quotient streams, host real equality, countable-choice data, hidden selectors, and ambient completeness outside that finite selector surface.

The synchronizer gives the seal-budget boundary. Definition 646.138 places the synchronizer request, seal, and budget rows on the same displayed route before the regular readback Q and Real seal L are available to the consumer. Hence an independent seal-budget route has no separate entry point.

Finally apply root-budget terminal route uniqueness from Definition 646.115. Once the selector and synchronizer rows are not part of the request, the remaining requested coordinates would have to form a second terminal route through quotient identity, a selected host limit, host real equality, choice, hidden observation budget, independent seal budget, or ambient completeness. Terminal uniqueness excludes that second route, so the request is routed to the visible refusal boundary. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility finite observation budget refusal exactness`

Theorem 646.123 (Diagonal-limit compatibility selector-synchronizer admission criterion)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-budget packet. A* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of K is admitted to the terminal root-budget route exactly when its request factors through both the displayed* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *rows and the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *request, seal, and budget rows named by Definition 646.120. In that case the admitted request has the unique terminal route through D, W, Q, L, the selector packet, the synchronizer request, seal, and budget rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row. Every completion-facing request that does not factor through both displayed gates is routed to the visible refusal boundary.*

Proof. First suppose the consumer is admitted to the terminal root-budget route. Finite observation-budget factorization in Definition 646.120 supplies the displayed route through the diagonal source, dyadic ledger, stream window, regular readback, Real seal, selector rows, synchronizer request, seal, and budget rows, transports, continuations, provenance, and local name.

The two gates are forced on this route. The selector route theorem Definition 646.191 and selector non-escape theorem Definition 782.6 keep the finite observation-budget component inside the displayed selector rows. The synchronizer handoff theorem Definition 646.138 then places the request, seal, and budget rows before the readback Q and Real seal L can be consumed.

Uniqueness gives the terminal route. By Definition 646.121, a request preserving the displayed selector and synchronizer rows determines the single terminal root-budget route through those rows and cannot open a second completion-facing path.

Conversely, suppose a $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ request does not factor through both displayed gates. The refusal exactness theorem Definition 646.122 says that quotient stream identity, selected

host limits, host real equality, countable-choice rows, hidden observation budgets, independent seal-budget routes, and ambient completeness are visible only at the refusal boundary unless the request first passes through the selector rows and synchronizer rows named above.

Thus the admission test is exactly the joint factorization through the displayed $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ rows and $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ request, seal, and budget rows. Requests satisfying that test use the unique terminal route; all other completion-facing requests are refused. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility selector synchronizer admission criterion`

Theorem 646.124 (Diagonal-limit compatibility selector-synchronizer Real-seal scope)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-budget packet. For every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer admitted by the selector-synchronizer admission criterion, the Real seal scope of the consumer is exhausted by the dyadic ledger* D*, the* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* Q*, the* $\mathsf{Real}^{\uparrow}$ *seal* L*, the* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *rows, the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *request, seal, and budget rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row. No quotient stream, selected host limit, host real equality, countable-choice row, hidden observation budget, independent seal-budget route, or ambient completeness coordinate remains in the Real seal scope.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility selector synchronizer real seal scope`

Proof. Begin with the finite observation-budget factorization. Definition 646.120 places every admitted $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer on the displayed route through D, W, Q, L, the selector rows, the synchronizer request, seal, and budget rows, transports, continuations, provenance, and local name.

Next apply selector-synchronizer exactness. Definition 646.121 identifies this displayed selector and synchronizer route as the terminal root-budget route, while Definition 646.122 routes every request outside the two displayed gates to the refusal boundary.

The admission criterion then supplies the exact gate. By Definition 646.123, an admitted consumer is precisely one whose request factors through both the finite observation-budget selector rows and the synchronizer request, seal, and budget rows.

Finally use Real-seal-budget non-escape and terminal route uniqueness. Definition 646.140 prevents the Real seal from acquiring a hidden budget coordinate, and Definition 646.115 leaves no second terminal route through quotient streams, selected host limits, host real equality, countable-choice rows, independent seal-budget routes, or ambient completeness. Thus the displayed rows exhaust the Real seal scope. □

Theorem 646.125 (Diagonal-limit compatibility open-phase budget terminal cover)**.** *Every current Phase Real and Completion consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-budget packet reaches its terminal Real or Completion endpoint only through the displayed rows* D, W, Q, L*, the* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *rows, the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *request, seal, and budget rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row. The terminal cover refuses quotient streams, selected host limits, host real equality, countable-choice rows, hidden observation budgets, independent seal-budget routes, and ambient completeness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility open phase budget terminal cover`

Proof. Begin with finite observation-budget factorization. Definition 646.120 places every admitted Real or Completion consumer on the displayed route through the dyadic ledger D, the $\mathsf{StreamName}^{\uparrow}$ window W, the $\mathsf{RegSeqRat}^{\uparrow}$ readback Q, the $\mathsf{Real}^{\uparrow}$ seal L, the selector rows, synchronizer rows, transports, continuations, provenance, and local name.

Next use selector-synchronizer exactness. Definition 646.121 identifies the displayed selector and synchronizer rows as the unique terminal root-budget route and leaves no independent budget path.

The admission criterion supplies the gate for the open phase. By Definition 646.123, a $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ request reaches the terminal route exactly when it factors through both the FiniteObservationBudgetSele rows and the $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ request, seal, and budget rows.

Finally apply the Real-seal scope theorem. Definition 646.124 exhausts the endpoint by D, W, Q, L, the selector and synchronizer rows, hsame transports, Cont routes, Pkg provenance, and local NameCert. The same theorem routes quotient streams, selected host limits, host real equality, countable-choice rows, hidden observation budgets, independent seal-budget routes, and ambient completeness to the refusal boundary, giving the terminal cover. □

Theorem 646.126 (Diagonal-limit compatibility root-budget functor selector lock)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-budget packet, and let an accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet be consumed along the route of Definition 646.117. For every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of* K*, terminal admission is exactly joint preservation of the displayed* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *rows and the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *request, seal, and budget rows. In the admitted case the consumer uses the same terminal root-budget route covered by Definition 646.125; in the refused case it exports no quotient stream, selected host limit, host real equality, countable-choice row, hidden observation budget, detached completion object, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root budget functor selector lock`

Proof. First consume the $\mathsf{CauchyLimitFunctor}^{\uparrow}$ packet through Definition 646.117. This places the functor source seal, target seal, finite observation rows, completion-consumer rows, componentwise transports, continuation replay, provenance, and local name on the root-budget route rather than on a detached completion endpoint.

Next apply the finite observation-budget factorizations. The carrier-level and displayed factorizations put the selector rows beside D, W, Q, L, H, C, P, N and keep the synchronizer request, seal, and budget rows on the same packet route.

The selector-synchronizer admission criterion then supplies the lock. By Definition 646.123, a completion-facing consumer is admitted exactly when it preserves both the selector rows and the synchronizer rows.

Finally use the open-phase terminal cover. Definition 646.125 identifies the admitted route with the same terminal root-budget route and sends quotient streams, selected host limits, host real equality, countable-choice rows, hidden observation budgets, detached completion objects, and ambient completeness coordinates to the refusal boundary. □

Theorem 646.127 (Diagonal-limit compatibility root readback exactness)**.** *For an accepted* DiagonalLimitCompatil *packet*

$$K = (R, T, S, D, W, Q, L, H, C, P, N),$$

every root-budget readback first consumes the displayed $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* Q*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, the* $\mathsf{Real}^{\uparrow}$ *seal row* L*, and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary carried by* S*. The route is the finite L10 sibling path through chapter 126, chapter 301, chapter 291, chapter 38, and chapter 386, together with the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows of* K*.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootReadbackExactness`

Proof. Start with the root budget source and window rows. Definition 646.79 fixes the root budget source as the displayed compatibility packet, and Definition 646.81 places the $\mathsf{StreamName}^{\uparrow}$ window before the regular readback and Real seal handoff.

Read the seal and ledger rows next. Definition 646.82 forces every Real-facing read through the $\mathsf{RegSeqRat}^{\uparrow}$ readback and seal route, while Definition 646.113 records the dyadic ledger, window, readback, seal, transport, route, provenance, and local naming rows as the exact root-budget ledger boundary.

The concrete sibling chapters supply the same route components: StreamName gives the finite window, RegSeqRat gives the regular-rational readback, DyadicRatCore gives the dyadic ledger, RealUp gives the seal row, and CauchyLimitSeal gives the seal boundary. Since Definition 646.83 exports no host limit, quotient stream, selected limit, host real equality, or ambient completeness coordinate, the root readback is exactly this displayed route. □

Theorem 646.128 (Diagonal-limit compatibility root transport replay)**.** *Let* $K = (R, T, S, D, W, Q, L, H, C, P, N)$ *be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet, and let* K' *be obtained by componentwise* hsame *transport of the displayed diagonal source, triangle row, seal route, dyadic ledger, stream window, regular readback, Real seal, provenance, and local naming rows. If the displayed* Cont *routes of* K' *replay the transported rows in the same order, then* K' *preserves the root readback route of Definition 646.127.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root readback transport replay`
↪ variant `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root transport replay`

Proof. First transport the packet rows componentwise. The carrier row of Definition 646.111 exposes exactly the root-facing source, window, seal, dyadic, readback, transport, continuation, provenance, and local-name surface, so hsame transport has no additional coordinate to move.

Next replay the displayed continuations. Definition 646.112 keeps the classifier stable under componentwise hsame movement and displayed Cont replay, and Definition 646.113 keeps the replay attached to the same source, window, seal, and consumer rows.

The replayed route therefore still reads the sibling L10 windows, regular readback, dyadic ledger, Real seal, and CauchyLimitSeal boundary before any completion-facing consumer is reached. The transported packet cannot acquire a second root route, because the root carrier and consumer rows remain exhausted by the displayed finite surface. □

Theorem 646.129 (Diagonal-limit compatibility root consumer coverage)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing or completion-facing consumer of the root route of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet is*

exhausted by the rows displayed in Definition 646.127 and preserved by Definition 646.128. Such a consumer can read the StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal row, CauchyLimitSeal boundary, and structural rows H, C, P, N, but it cannot read host limits, quotient streams, selected limits, host real equality, or ambient completeness.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootConsumerCoverage`

Proof. Begin with a root-route consumer. Definition 646.83 limits downstream $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, and completion-seal reads to the displayed budget, window, diagonal, seal, transport, route, provenance, and local-name rows.

Use the readback exactness theorem above to identify those rows with the concrete L10 sibling route. The consumer reads chapter 126 for windows, chapter 301 for regular readback, chapter 291 for the dyadic ledger, chapter 38 for the Real seal, and chapter 386 for the seal boundary.

Finally apply transport replay. Any componentwise hsame movement and displayed Cont replay reaches the same root route, so every allowed consumer is already listed by the displayed rows. The excluded host-side objects are absent from the packet and cannot be recovered from the root readback surface. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootL10SpineExhaustion`

Theorem 646.130 (Diagonal-limit compatibility root L10 spine exhaustion)**.** *Every accepted root route*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

whose consumer is $\mathsf{Real}^{\uparrow}$*-facing or completion-facing is equivalent, as a displayed BEDC route, to the finite L10 spine through the* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary. The only structural rows available along the spine are* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows displayed by K. The route exports no quotient stream, selected limit, host real equality, ambient completeness, or second completion witness.*

Proof. First identify the displayed root readback. By Definition 646.127, every root-budget readback passes through the StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal row, and CauchyLimitSeal boundary, with the structural rows H, C, P, N attached to the same packet.

Next use transport replay. Definition 646.128 shows that componentwise hsame movement and displayed Cont replay preserve this route, so the displayed BEDC route is unchanged by the allowed structural comparisons.

Finally apply consumer coverage. Definition 646.129 exhausts every $\mathsf{Real}^{\uparrow}$-facing or completion-facing consumer by the same five sibling handoffs and the same structural rows. Since the carrier contains no quotient stream, selected limit, host real equality, ambient completeness, or second completion witness, every such consumer is equivalent to the finite L10 spine and nothing beyond it. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootL10SpineExhaustion certificate`

Theorem 646.131 (Diagonal-limit compatibility root selector pullback)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Any root selector route for K is the pullback, along the structural rows H, C, P, N, of the displayed* $\mathsf{StreamName}^{\uparrow}$ *window W,* $\mathsf{DyadicRatCore}^{\uparrow}$

ledger D, $\mathsf{RegSeqRat}^{\uparrow}$ *readback Q,* $\mathsf{Real}^{\uparrow}$ *seal row L, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary carried by S. No quotient stream, selected limit, host equality, ambient completeness principle, or second selector source can factor through the same consumer.*

Proof. Start with root readback exactness. Definition 646.127 identifies the selector-facing route with the five concrete L10 certificate surfaces carried by W, D, Q, L, S, and records the structural rows through which the route is read.

Transport the route next. Definition 646.128 shows that componentwise hsame movement and displayed Cont replay preserve exactly the same root readback route, so pulling back along H, C, P, N does not introduce a new selector coordinate.

Finally apply consumer coverage and spine exhaustion. Definition 646.129 limits every admissible consumer to the displayed sibling handoffs and structural rows, while Definition 646.130 excludes quotient streams, selected limits, host real equality, ambient completeness, and any second completion witness. Hence every root selector route factors as the stated pullback and no second selector source reaches the same consumer. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootSelectorPullback`

Theorem 646.132 (Diagonal-limit compatibility root selector terminality)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Any root selector route for K that reaches a* $\mathsf{Real}^{\uparrow}$*-facing or completion-facing consumer is terminal among the displayed routes: if two admissible selector reads agree on the* $\mathsf{StreamName}^{\uparrow}$ *window W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback Q,* $\mathsf{Real}^{\uparrow}$ *seal L,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary carried by S, and structural rows H, C, P, N, then they determine the same public consumer endpoint. No quotient stream, selected host limit, host real equality, ambient completeness coordinate, alternate Cauchy witness, or second selector source creates another endpoint.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootSelectorTerminality`

Proof. First identify the selector readback. By Definition 646.127, every root-facing read travels through the displayed StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal row, CauchyLimitSeal boundary, and structural rows of the packet.

Next replay the same rows under transport. The transport replay theorem, Definition 646.128, preserves the displayed route under componentwise hsame movement and Cont replay, so an admissible selector read cannot gain a new coordinate while moving along H, C, P, N.

Now exhaust the consumer boundary. Consumer coverage, Definition 646.129, lists the only rows visible to $\mathsf{Real}^{\uparrow}$-facing and completion-facing consumers, and Definition 646.130 identifies that list with the finite L10 spine.

Finally apply the selector pullback theorem, Definition 646.131. Since both reads pull back from the same five sibling handoffs along the same structural rows, they land at the same public consumer endpoint, with all host-side, quotient, choice, completeness, and alternate-witness routes absent. □

Theorem 646.133 (Diagonal-limit compatibility root selector uniqueness)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted DiagonalLimitCompatibility$^{\uparrow}$ *packets. Suppose their root selector routes expose the same* StreamName$^{\uparrow}$ *window,* DyadicRatCore$^{\uparrow}$ *ledger,* RegSeqRat$^{\uparrow}$ *readback,* Real$^{\uparrow}$ *seal row,* CauchyLimitSeal$^{\uparrow}$ *boundary, and the same displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows. Then every Phase Real-facing and completion-facing consumer boundary reads the same displayed selector route from K and K'. No second selector source, quotient stream, selected host limit, host real equality, countable choice principle, ambient completeness coordinate, or alternate Cauchy witness can distinguish the two routes.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootSelectorUniqueness`

Proof. First identify both selector reads with the same root handoff surface. By Definition 646.127, each route is read through the displayed StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal row, CauchyLimitSeal boundary, and the structural rows carried by the packet.

Next transport the displayed support rows. Definition 646.128 moves componentwise hsame transports through the same Cont replay, so the shared BHist, Pkg, and NameCert rows remain attached to the same visible route.

It remains to rule out hidden selector coordinates. Definition 646.129 exhausts every Phase Real-facing and completion-facing consumer by the displayed rows, and Definition 646.130 excludes quotient streams, selected limits, host real equality, ambient completeness, and a second completion witness.

Finally apply Definition 646.131. Since both routes pull back along the same visible support rows to the same five sibling handoffs, every consumer boundary sees the same displayed selector route and no alternate source can distinguish them. □

Theorem 646.134 (Diagonal-limit compatibility root readback selector determinacy)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted DiagonalLimitCompatibility$^{\uparrow}$ *packets. Suppose their root selector routes expose the same* StreamName$^{\uparrow}$ *window,* DyadicRatCore$^{\uparrow}$ *ledger,* RegSeqRat$^{\uparrow}$ *readback,* Real$^{\uparrow}$ *seal row,* CauchyLimitSeal$^{\uparrow}$ *boundary, and the same displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows. Then every* Real$^{\uparrow}$*-facing or completion-facing consumer reads the same root selector route from K and K'. No quotient stream, selected host limit, host real equality, countable choice principle, ambient completeness coordinate, alternate Cauchy witness, or second selector source can distinguish the two accepted routes.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootReadbackSelectorDeterm`

Proof. First identify the readback surface for each packet. Definition 646.127 pins both root reads to the displayed StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal row, CauchyLimitSeal boundary, and structural rows.

Next replay the common support. Definition 646.128 preserves the displayed route under componentwise hsame movement and Cont replay, so the shared BHist, Pkg, and NameCert rows cannot create a second selector coordinate.

Now exhaust the consumer side. Definition 646.129 restricts every $\mathsf{Real}^{\uparrow}$-facing or completion-facing consumer to the displayed rows, and Definition 646.130 identifies that surface with the finite L10 spine.

Finally use the selector results. Definition 646.131 makes every root selector route the pullback of the five sibling handoffs along the displayed support rows, and Definition 646.133 states that two routes with those same exposed rows are indistinguishable to every relevant consumer boundary. Therefore every $\mathsf{Real}^{\uparrow}$-facing or completion-facing consumer reads the same root selector route from K and K', and none of the excluded host-side or choice-based data can separate them. □

Theorem 646.135 (Diagonal-limit compatibility four-face terminal pullback)**.** *Let K and K' be accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packets. Suppose their root routes expose the same* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary, and the same displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. Then the two packets determine the same terminal root pullback for the L10 finite route.*

Every top-frontier consumer of the route reads the same displayed pullback. No quotient stream, selected host limit, host real equality, ambient completeness coordinate, alternate Cauchy witness, countable choice row, or second selector source can distinguish K from K' at the root boundary.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility four face terminal pullback`

Proof. First apply Definition 646.127. It identifies the root readback surface with the displayed StreamName window, RegSeqRat readback, DyadicRatCore ledger, Real seal row, CauchyLimitSeal boundary, and structural support rows.

Next use Definition 646.131. The selector route is the pullback of the five sibling handoffs along those same displayed rows, so two packets with matching exposed data land on the same root pullback surface.

Now apply Definition 646.133. Since K and K' expose the same support rows, every selector-facing route available to a consumer is already identified through the same finite packet.

Finally invoke Definition 646.134. Determinacy says that accepted packets with those matching rows are read identically by every $\mathsf{Real}^{\uparrow}$-facing or completion-facing consumer, leaving no hidden quotient, selected-limit, host-equality, completeness, Cauchy-witness, choice, or selector coordinate to separate the terminal root pullback. □

Theorem 646.136 (Diagonal-limit compatibility terminal pullback consumer non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing or completion-facing consumer of the terminal root pullback from Definition 646.135 factors through the displayed* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary, and the* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows of the accepted root packet. No quotient stream, selected host limit, host equality, countable choice row, ambient completeness coordinate, alternate Cauchy witness, or second selector source can separate the consumer route from that displayed terminal pullback.*

Proof. First apply Definition 646.127. It identifies the root readback with the visible StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal row, CauchyLimitSeal boundary, and structural support rows.

Next use Definition 646.130. It says that every relevant root consumer is already equivalent to the finite L10 spine through those five sibling surfaces and the displayed structural rows.

Apply Definition 646.131. The selector route for the accepted packet is the pullback of the same sibling handoffs along the same BHist, hsame, Cont, Pkg, and NameCert support.

Finally combine Definition 646.133 with Definition 646.134. The first theorem rules out a competing selector source once the displayed rows agree, and the second makes every $\mathsf{Real}^{\uparrow}$-facing or completion-facing consumer read that same route. Hence the terminal pullback is the only route available to such consumers, with all excluded host-side, quotient, choice, completeness, and alternate-witness coordinates absent. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier terminal pullback consumer nonescape`

Theorem 646.137 (Diagonal-limit compatibility root support projection non-escape)**.** *Let K be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet whose root route exposes the* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *support rows. Then every admissible support projection out of K factors through exactly those displayed rows. The projection boundary contains no quotient stream, selected host limit, host equality, countable-choice row, ambient completeness coordinate, alternate Cauchy witness, or second selector source.*

Proof. First identify the displayed support rows. Definition 646.127 pins the root readback to the StreamName window, RegSeqRat readback, DyadicRatCore ledger, RealUp seal row, CauchyLimitSeal boundary, and structural packet rows.

Next exhaust the finite route. Definition 646.130 says that every $\mathsf{Real}^{\uparrow}$-facing or completion-facing root consumer is already equivalent to that L10 spine, so a support projection has no additional carrier from which to read host-side data.

Now use the selector boundary. Definition 646.131 makes every root selector route a pullback along the displayed BHist, hsame, Cont, Pkg, and NameCert rows, while Definition 646.133 rules out a second selector source once those rows agree.

Finally apply Definition 646.134 together with Definition 646.136. Determinacy fixes the consumer readback on the same displayed selector route, and terminal non-escape states that every terminal-pullback consumer factors through that route. Hence the displayed rows are the only admissible projection boundary, and the excluded quotient, host-limit, host-equality, choice, completeness, alternate-witness, and second-selector coordinates cannot be projected from K. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root support projection nonescape`
Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootSupportProjectionNonesc`

Theorem 646.138 (Diagonal-limit compatibility seal-budget synchronizer handoff)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. If its seal route is read through an accepted* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *packet whose displayed request, seal, budget, tail schedule, selector, compatibility, transport, route, provenance, and local naming rows are transported into the same seal route, then the compatibility consumer reads the synchronizer rows before it reads the regular-rational row Q and the* $\mathsf{Real}^{\uparrow}$ *seal row L.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier seal budget synchronizer handoff`

Proof. Start with the compatibility carrier and its seal-route compatibility theorem. The route to Q and L is already constrained by $R, T, S, D, W, H, C, P, N$, so a seal consumer has no entry point outside the displayed compatibility packet.

Now insert the accepted $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ packet at the seal route S. Apply Definition 886.2: its request, seal, budget, shared-tail schedule, diagonal selector, joint compatibility, transport, continuation, provenance, and naming rows must be exposed before its seal row is usable.

Finally use Definition 646.34 and Definition 646.53. They bind the compatibility ledger and final seal to the same finite window and dyadic surface, so the synchronizer rows are consumed before Q, L rather than after the seal has escaped the packet. □

Theorem 646.139 (Diagonal-limit compatibility tail-schedule readback)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet whose seal-budget synchronizer supplies the tail schedule row. Then the compatibility route reads the* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet before the* $\mathsf{RegSeqRat}^{\uparrow}$ *row Q and the* $\mathsf{Real}^{\uparrow}$ *seal row L. The readback keeps the tail schedule, finite window row, dyadic ledger, regular-rational row, and real seal row on the same displayed route.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier tail schedule readback`

Proof. First apply Definition 646.138. The synchronizer rows are upstream of the compatibility readback through Q, L, so its tail schedule row is available before the final seal is consumed.

Next use Definition 681.3. The schedule route reads the precision request, finite-window schedule, dyadic ledger, regular-rational readback, and real seal in that order.

Transport this route back through the compatibility packet by Definition 646.44. The regular row Q is fixed by the same triangle, dyadic, and window rows already displayed in K.

Finally apply Definition 646.43. It places the schedule-supported readback on the route from R through T, D, W, S, Q to L, so the tail schedule is read before the RegSeqRat and RealUp seal rows. □

Theorem 646.140 (Diagonal-limit compatibility real-seal budget nonescape)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet whose seal route is read through an accepted* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *packet and whose tail schedule is supplied by* $\mathsf{TailCofinalitySchedule}^{\uparrow}$*, the combined route exports only the displayed compatibility rows, synchronizer rows, tail-schedule rows, regular-rational readback, and* $\mathsf{Real}^{\uparrow}$ *seal. It exports no quotient stream, host real equality, selected host limit, countable choice row, or ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier real seal budget nonescape`

Proof. Use Definition 646.48 for the compatibility packet. It removes quotient streams, selected host limits, host real equality, choice data, and ambient completeness from every completion-facing read of K.

Use Definition 886.3 for the inserted synchronizer route. A seal read must factor through both the displayed seal row and the displayed budget row, and any tail use must pass through the selector, shared threshold, and compatibility row.

Use Definition 681.6 for the schedule component. It forces the readback through the finite schedule, dyadic ledger, regular-rational row, and real seal, while excluding quotient streams, host-selected limits, ambient completeness, hidden tail oracles, and unbounded schedules.

Combining these three boundaries leaves only the displayed finite packets and their structural rows. There is no coordinate in the combined route from which a quotient stream, host real equality, selected host limit, countable choice row, or ambient completeness theorem can be exported. □

Theorem 646.141 (Diagonal-limit compatibility synchronizer-tail selector Real route)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted DiagonalLimitCompatibility$^{\uparrow}$ *packet. Suppose its seal route is read through an accepted* CauchySealBudgetSynchronizer$^{\uparrow}$ *packet and its tail schedule is supplied by an accepted* TailCofinalitySchedule$^{\uparrow}$ *packet on the same displayed route. Then every selector-facing Real consumer reaches the* RegSeqRat$^{\uparrow}$ *row Q and the* Real$^{\uparrow}$ *seal row L only through the finite route K together with the synchronizer request, seal, budget, selector, compatibility, transport, route, provenance, local naming rows, and the tail-schedule precision, window, dyadic, regular-rational, and Real-seal rows.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier synchronizer tail selector real route`

Proof. First apply Definition 646.138. It places the synchronizer rows before the regular-rational row and the Real seal inside the displayed compatibility packet.

Next apply Definition 646.139. The tail schedule is read through the same finite window, dyadic ledger, regular-rational row, and Real seal route, so it cannot be consumed as an external cofinality object.

Finally use Definition 646.34 and Definition 646.53. These exactness rows identify W, D, Q, L as the unique displayed route from the selector budget into the Real seal. The combined consumer therefore reaches Q and L only through K plus the synchronizer and schedule rows. □

Theorem 646.142 (Diagonal-limit compatibility selector-budget shared-tail nonescape)**.** *For an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet whose selector budget, seal-budget synchronizer, and tail schedule share the route of Definition 646.141, the combined route exports no quotient stream, selected limit, host real equality, countable-choice tail, or ambient completeness coordinate. The only public Real-facing surface is the displayed selector budget, synchronizer handoff, tail schedule, regular-rational row, and* Real$^{\uparrow}$ *seal.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget shared tail nonescape`

Proof. Begin with Definition 646.193. It fixes the source, triangle, seal, dyadic, finite-window, regular-rational, Real-seal, transport, route, provenance, and local naming rows before any selector-facing consumer can read the seal.

Insert the seal-synchronizer handoff using Definition 646.138. The synchronizer consumes only its displayed request, seal, budget, selector, compatibility, transport, route, provenance, and naming rows on the same finite route.

Now apply Definition 646.140. That theorem excludes quotient streams, host real equality, selected host limits, countable-choice rows, and ambient completeness from the shared seal route. Since the tail schedule is supplied by Definition 646.139, there is no second tail coordinate from which a countable-choice tail or ambient completeness datum could be exported. □

Theorem 646.143 (Diagonal-limit compatibility tail-budget observation triple lock)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted DiagonalLimitCompatibility$^{\uparrow}$ *packet. Suppose the same displayed route consumes an accepted* CauchySealBudgetSynchronizer$^{\uparrow}$ *packet, an accepted* TailCofinalitySchedule$^{\uparrow}$ *packet, and an accepted* RealObservationBudget$^{\uparrow}$ *packet. Then every Real-facing or completion-facing read of this route passes through the compatibility rows of K, the synchronizer budget rows, the tail schedule rows, the observation-budget rows, the* RegSeqRat$^{\uparrow}$ *row Q, and the* Real$^{\uparrow}$ *seal row L.*

The finite route exports no quotient stream, selected host limit, host equality, countable-choice tail, hidden observation budget, or ambient completeness row.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier tail budget observation lock`

Proof. First apply Definition 646.138. It places the synchronizer request, seal, budget, selector, compatibility, transport, route, provenance, and local naming rows before the regular-rational row Q and the Real seal row L.

Next apply Definition 646.139. The tail schedule is read back through the same finite window, dyadic ledger, regular-rational row, and Real seal, so it cannot contribute an external cofinal tail.

Now use Definition 646.141. The selector-facing Real route is already exhausted by K together with the synchronizer and tail-schedule rows. Then Definition 646.142 removes quotient streams, selected limits, host equality, countable-choice tails, and ambient completeness from that shared route.

Finally attach the accepted RealObservationBudget$^{\uparrow}$ packet through the consumer surface of chapter 611. Its finite request rows determine only which displayed observations are read. Combined with Definition 646.140, this leaves no coordinate for a hidden observation budget or for any completion-facing object outside the listed compatibility, synchronizer, schedule, observation-budget, RegSeqRat, and RealUp rows. □

Theorem 646.144 (Diagonal-limit compatibility triple-budget route exhaustion)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted DiagonalLimitCompatibility$^{\uparrow}$ *packet. Suppose its displayed finite route consumes accepted* CauchySealBudgetSynchronizer$^{\uparrow}$, TailCofinalitySchedule$^{\uparrow}$, *and* RealObservationBudget$^{\uparrow}$ *packets on the same route. Then every Real-facing completion read is exhausted by the compatibility rows of K, the synchronizer request, seal, and budget rows, the tail-schedule precision, window, and dyadic rows, the observation-budget request rows, the* RegSeqRat$^{\uparrow}$ *row Q, and the* Real$^{\uparrow}$ *seal row L.*

This route exports no quotient stream, host real equality, hidden observation budget, selected host limit, countable-choice tail, or ambient completeness theorem.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier triple budget route exhaustion`

Proof. First apply Definition 646.138. It places the accepted synchronizer request, seal, budget, selector, compatibility, transport, route, provenance, and local naming rows before any read reaches the regular-rational row Q or the Real seal row L.

Next apply Definition 646.139. The accepted tail schedule is read back through the same finite precision, window, dyadic, regular-rational, and Real-seal route, so the completion consumer has no separate cofinal-tail coordinate.

Use Definition 646.141 to identify the selector-facing Real route with the compatibility, synchronizer, and schedule rows already displayed. Then Definition 646.142 excludes quotient streams,

host real equality, selected host limits, countable-choice tails, and ambient completeness from that shared selector-budget route.

Finally apply Definition 646.143. The accepted observation-budget packet contributes only its displayed request rows to the same finite route. The carrier inventory therefore contains exactly the compatibility rows, synchronizer request/seal/budget rows, tail-schedule precision/window/dyadic rows, observation-budget request rows, Q, and L, with no additional coordinate from which a hidden observation budget or any other completion-facing object could be exported. □

Theorem 646.145 (Diagonal-limit compatibility synchronizer-observation cofinal pullback)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Suppose the same displayed finite route consumes accepted* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$, $\mathsf{TailCofinalitySchedule}^{\uparrow}$, *and* $\mathsf{RealObservationBudget}^{\uparrow}$ *packets. Let ρ and ρ' be two Real-facing reads of this route. If ρ and ρ' agree on the synchronizer budget rows, the tail-schedule rows, the observation-budget request rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *row Q, the* $\mathsf{Real}^{\uparrow}$ *seal row L, and the displayed $hsame$, $Cont$, Pkg, and $NameCert$ rows of K, then ρ and ρ' determine the same finite cofinal observation route.*

The pullback route contains no quotient stream, host real equality, hidden observation budget, selected host limit, countable-choice tail, or ambient completeness row.

Proof. First apply Definition 646.138. The synchronizer request, seal, budget, selector, compatibility, transport, route, provenance, and local naming rows must be read before either ρ or ρ' can reach Q or L.

Next apply Definition 646.139 and Definition 646.140. The tail schedule is read back through the displayed finite window, dyadic ledger, regular-rational row, and Real seal, while the seal-budget route excludes quotient streams, host real equality, selected host limits, countable-choice rows, and ambient completeness.

Now use Definition 646.141 and Definition 646.142. They identify the selector-facing Real route with the compatibility packet, synchronizer rows, tail schedule, Q, and L, and they leave no separate selector or shared-tail coordinate on which the two reads could differ.

Finally apply Definition 646.143 and Definition 646.144. The accepted observation-budget packet contributes only its displayed request rows, and the exhausted route has precisely the compatibility, synchronizer, schedule, observation-budget, RegSeqRat, and RealUp seal rows listed in the statement. Since ρ and ρ' agree on all of these rows and on the displayed $hsame$, $Cont$, Pkg, and $NameCert$ rows, finite row exhaustion leaves no fifth coordinate from which a distinct cofinal observation route could be read. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier synchronizer observation cofinal pullback`

Theorem 646.146 (Diagonal-limit compatibility synchronizer-observation route uniqueness)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Let ρ and ρ' be two Real-facing reads of the displayed synchronizer-observation surface. If they agree on the displayed compatibility rows of K, the accepted* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *rows, the accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *rows, the accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *request rows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *row Q, the* $\mathsf{Real}^{\uparrow}$ *seal row L, and*

the displayed hsame, Cont, Pkg, *and* NameCert *rows, then they determine the same synchronizer-observation route.*

The two reads cannot differ by quotient stream, hidden observation budget, selected host limit, host equality, countable-choice tail, or ambient completeness.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier synchronizer observation route uniqueness`

Proof. First apply Definition 646.141. It places every selector-facing Real read on the displayed compatibility packet together with the synchronizer rows, the tail-schedule rows, Q, and L.

Next use Definition 646.142. This removes quotient streams, selected host limits, host equality, countable-choice tails, and ambient completeness from the shared route, so agreement cannot be broken by an external Real-facing coordinate.

Apply Definition 646.143. The observation-budget packet contributes only its accepted request rows on the same finite route; hence a hidden observation budget has no separate source.

Finally combine Definition 646.144 with Definition 646.145. The triple-budget route is exhausted by the listed compatibility, synchronizer, schedule, observation-budget, RegSeqRat, RealUp, hsame, Cont, Pkg, and NameCert rows, and the cofinal pullback identifies any two reads that agree on those rows. Thus ρ and ρ' determine one synchronizer-observation route. □

Theorem 646.147 (Diagonal-limit compatibility budget source lock)**.** *Every accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet reads its* CauchyDiagonalBudget$^{\uparrow}$, RealDiagonalMeshBudget$^{\uparrow}$, RegularCauchyTriangleBound$^{\uparrow}$, *and* StreamName$^{\uparrow}$ *rows before any seal route is available. The first seal-facing consumer must therefore pass through the displayed budget source, mesh budget, triangle bound, and stream-window rows of the finite compatibility packet.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityBudgetSourceLock`

Proof. Start with the carrier inventory in Definition 646.1. The packet names the diagonal source, triangle estimate, stream window, regular readback, Real seal row, transport rows, continuation routes, package provenance, and local certificate in one finite surface.

Apply Definition 646.21, Definition 646.12, and Definition 646.79. These anchors identify the budget source with the displayed diagonal, mesh, triangle, and stream rows rather than with a hidden analytic input.

Finally use Definition 646.69. The seal route is synchronized with the same source rows, so no CauchyLimitSeal$^{\uparrow}$ read can occur before those budget rows have been exposed. □

Theorem 646.148 (Diagonal-limit compatibility seal-budget route)**.** *The* CauchyLimitSeal$^{\uparrow}$ *and* CauchySealBudgetSynchronizer$^{\uparrow}$ *handoff exported by an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet is a displayed finite route through the budget rows of Definition 646.147. It has no second route through a selected limit, quotient stream, host equality test, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySealBudgetRoute`

Proof. The source lock fixes the budget-facing prefix. By Definition 646.147, the route must first read the diagonal budget, mesh budget, triangle bound, and stream-window rows.

Now apply Definition 646.7, Definition 646.82, and Definition 646.138. These results place the CauchyLimitSeal$^{\uparrow}$ read and the CauchySealBudgetSynchronizer$^{\uparrow}$ handoff downstream of the same finite budget prefix.

The non-escape clause is Definition 646.140. Since the packet carries no selected limit, quotient stream, host equality coordinate, or ambient completeness input, the displayed seal-budget route exhausts the available handoff. □

Theorem 646.149 (Diagonal-limit compatibility completion consumer gate)**.** *Every* Completion$^{\uparrow}$ *or* Real$^{\uparrow}$ *consumer of an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet factors through the displayed budget-source route of Definition 646.147 and the seal-budget route of Definition 646.148. The consumer gate exports no quotient stream, selected limit, host equality, or ambient completeness input.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCompletionConsumerGate`

Proof. Begin with a Completion$^{\uparrow}$ or Real$^{\uparrow}$ consumer route. The completion boundary and regular readback anchors, Definition 646.35 and Definition 646.44, place that consumer downstream of the displayed regular readback and seal rows.

Use Definition 646.148. The seal-facing part of the consumer is already forced through the budget-source prefix and the finite CauchyLimitSeal$^{\uparrow}$ to CauchySealBudgetSynchronizer$^{\uparrow}$ handoff.

It remains only to exclude hidden inputs. Apply Definition 646.48 and Definition 646.83; together they exhaust the consumer surface by the displayed packet rows, with no quotient stream, selected limit, host equality, or ambient completeness coordinate. □

Theorem 646.150 (Diagonal-limit compatibility budget-source readback totality)**.** *Every* RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, *or* Completion$^{\uparrow}$ *consumer of an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet first reads the displayed* CauchyDiagonalBudget$^{\uparrow}$, RealDiagonalMeshBudget$^{\uparrow}$, RegularCauchyTriangleBound$^{\uparrow}$, *and* StreamName$^{\uparrow}$ *rows. After that readback prefix, the consumer must pass through the seal-budget route of Definition 646.148 before any* CauchyLimitSeal$^{\uparrow}$ *read or* CauchySealBudgetSynchronizer$^{\uparrow}$ *handoff is available. The consumer surface has no alternate route through quotient streams, selected limits, host equality, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityBudgetSourceReadbackTotalit`

Proof. The budget-source lock Definition 646.147 fixes the first visible prefix of the packet. Thus any consumer that reaches the regular readback, Real row, or completion row has already read the displayed diagonal budget, mesh budget, triangle bound, and stream-window rows.

Next use the seal-budget route of Definition 646.148. It places the CauchyLimitSeal$^{\uparrow}$ read and the CauchySealBudgetSynchronizer$^{\uparrow}$ handoff downstream of that same finite budget prefix, so the seal-facing part of the consumer cannot bypass the displayed source rows.

Finally apply Definition 646.149. Its consumer gate covers the Real$^{\uparrow}$ and Completion$^{\uparrow}$ exits, and the regular readback row is one of the displayed rows feeding those exits. The non-escape clauses exclude quotient streams, selected limits, host equality, and ambient completeness, so the budget-source readback prefix is total for all listed consumers. □

Theorem 646.151 (Diagonal-limit compatibility synchronized budget terminality)**.** *Every* RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, *or* Completion$^{\uparrow}$ *consumer of an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet that reaches a* CauchyLimitSeal$^{\uparrow}$ *read or a* CauchySealBudgetSynchronizer$^{\uparrow}$ *handoff is exhausted by the synchronized budget route. Such a consumer first passes through the displayed budget-source readback prefix and then through the synchronized seal-source route, with no escape through quotient streams, host limits, host equality, choice data, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier synchronized budget terminality`

Proof. Apply Definition 646.147. It fixes the first visible rows of any seal-facing packet route as the diagonal budget, mesh budget, triangle bound, and stream-window source rows.

Next apply Definition 646.148. The CauchyLimitSeal$^{\uparrow}$ read and the CauchySealBudgetSynchronizer$^{\uparrow}$ handoff are downstream of the same displayed prefix, so the seal-source route is synchronized with the budget-source route rather than supplied by a second analytic object.

Use Definition 646.149 for the Real$^{\uparrow}$ and Completion$^{\uparrow}$ exits, and use Definition 646.150 for the RegSeqRat$^{\uparrow}$ readback side. Together these results cover all listed consumers that reach the seal handoff.

The remaining non-escape clauses are exactly the absence claims carried by those gates. The terminal route exposes no quotient stream, host limit, host equality, choice datum, or ambient completeness coordinate, so every listed consumer is exhausted by the synchronized budget route. □

Theorem 646.152 (Diagonal-limit compatibility budget-seal handoff determinacy)**.** *For every accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet and every* RegSeqRat$^{\uparrow}$*,* Real$^{\uparrow}$*, or* Completion$^{\uparrow}$ *consumer that reaches either a* CauchyLimitSeal$^{\uparrow}$ *read or a* CauchySealBudgetSynchronizer$^{\uparrow}$ *handoff, the consumer route is determined by the displayed prefix consisting of the* CauchyDiagonalBudget$^{\uparrow}$*,* RealDiagonalMeshBudget$^{\uparrow}$*,* RegularCauchyTriangleBound$^{\uparrow}$*, and* StreamName$^{\uparrow}$ *rows, followed by the seal-budget route. There is no second route through quotient streams, selected limits, host equality, choice data, or ambient completeness.*

Proof. First apply Definition 646.147. It fixes the visible prefix for every seal-facing route as the diagonal budget, mesh budget, triangle bound, and stream-window rows of the accepted packet.

Next apply Definition 646.148. The CauchyLimitSeal$^{\uparrow}$ read and the CauchySealBudgetSynchronizer$^{\uparrow}$ handoff occur only after that same prefix, so the handoff is a route through the displayed budget rows rather than through a separate selected limit or quotient stream.

The consumer cases are covered by Definition 646.149 and Definition 646.150. These two gates cover the Real$^{\uparrow}$ and Completion$^{\uparrow}$ exits together with the RegSeqRat$^{\uparrow}$ readback side, so every listed consumer reaches the handoff through the same budget-to-seal surface.

Finally use Definition 646.151. Since the synchronized terminal route exposes no quotient stream, selected host limit, host equality coordinate, choice datum, or ambient completeness input, the displayed prefix followed by the seal-budget route is the unique available consumer route. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityBudgetSealHandoffDeterminac`

Theorem 646.153 (Diagonal-limit compatibility root-route budget package)**.** *Let* $K = (R, T, S, D, W, Q, L, H, C,$ *be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. The root-route budget package for* K *is the finite BEDC surface that first reads the* CauchyDiagonalBudget$^{\uparrow}$ *source row, the* RealDiagonalMeshBudget$^{\uparrow}$ *mesh row, the* RegularCauchyTriangleBound$^{\uparrow}$ *triangle row, and the* StreamName$^{\uparrow}$ *window row, and then exposes the regular readback* Q*, the seal route* S*, the Real seal row* L*, the displayed* BHist *rows, componentwise* hsame *transports* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* NameCert *row* N*. No root-route consumer can replace this package by a host limit, quotient stream, host real equality, choice datum, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteBudgetPackage`

Proof. Project the accepted compatibility carrier. The packet exposes the diagonal source, triangle estimate, seal route, dyadic ledger, stream window, regular readback, Real seal row, transport rows, continuation routes, package provenance, and local name in one finite BHist surface.

Apply Definition 646.147. It fixes the budget prefix through the $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$, $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$, and $\mathsf{StreamName}^{\uparrow}$ rows before any seal-facing route is available.

Now apply Definition 646.99 and Definition 646.113. These identify the root budget route with the same D, W, Q, L, H, C, P, N surface and place the ledger boundary on the displayed packet rows.

Finally use Definition 646.48. Since the carrier exports no host limit, quotient stream, host equality, choice datum, or ambient completeness coordinate, the displayed root-route budget package exhausts the available consumer surface. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root route budget package`

Theorem 646.154 (Diagonal-limit compatibility root-route transport stability)**.** *Let $K = (R, T, S, D, W, Q, L, H,$ and $K' = (R', T', S', D', W', Q', L', H', C', P', N')$ be accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packets whose displayed rows are related by componentwise* hsame *transports and whose continuation routes replay the same budget-source, mesh-budget, triangle-bound, stream-window, regular-readback, seal-route,* Pkg*, and* NameCert *rows. Then the root-route budget package of K transports to the root-route budget package of K' without changing its consumer classifier.*

Proof. Start with the componentwise transport rows. The carrier of each packet contains the same kinds of diagonal source, triangle, seal, dyadic, window, readback, Real seal, provenance, and local naming coordinates.

Apply Definition 646.112. The classifier is stable under the displayed hsame transports and under replay of the displayed Cont routes.

Next use Definition 646.81 and Definition 646.82. They keep the stream-window, regular-readback, and Real-seal reads in the same order after transport.

The package therefore has no second classifier branch. The transported packet reads the same budget-source, mesh-budget, triangle-bound, stream-window, regular-readback, seal-route, Pkg, and NameCert rows, so the root-route package is stable. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteTransportStability`

Theorem 646.155 (Diagonal-limit compatibility root-route consumer exactness)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer that reads the root route of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet consumes exactly the displayed package of Definition 646.153: the budget source, mesh budget, triangle bound, stream window, dyadic ledger, regular readback, seal route, Real seal row,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. The consumer has no earlier access to Q, S, or L, and it has no later route that bypasses those rows.*

Proof. First read the package theorem. It places the budget source, mesh budget, triangle bound, and stream window before the regular readback, seal route, and Real seal row.

Use Definition 646.101. Every Real-facing or completion-facing seal read reaches L only after S, D, W, Q have been fixed on the displayed compatibility route.

Next apply Definition 646.102. The handoff consumes the root-budget route, selector-budget route, and Real-seal readback lock as one carrier boundary.

It remains to identify the exact consumer surface. Apply Definition 646.149; every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read factors through the budget-source and seal-budget routes, so the listed rows are exactly the root-route consumer package. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteConsumerExactness`

Theorem 646.156 (Diagonal-limit compatibility root-route non-escape)**.** *No root-route consumer of an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet can obtain a quotient stream, selected host limit, host real equality, choice datum, hidden tail oracle, or ambient completeness principle through the root-route budget package. Every exported read remains inside the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *package over the diagonal budget, mesh budget, triangle bound, stream window, regular readback, seal route, and Real seal rows.*

Proof. Begin with the package carrier. By Definition 646.153, the root route is the finite surface over the displayed budget, mesh, triangle, window, readback, seal, Real, transport, continuation, provenance, and local naming rows.

Apply Definition 646.192. The budget-selector handoff cannot introduce quotient streams, choice-selected limits, host real equality, or ambient completeness coordinates.

Now apply Definition 646.83 and Definition 646.48. These non-escape boundaries exhaust both the root consumer and the completion-facing consumer by the displayed packet rows.

Therefore a root-route read has no exported coordinate from which the excluded objects could be recovered. The read remains inside the finite BHist/hsame/Cont/Pkg/NameCert package. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteNonescape`

Theorem 646.157 (Diagonal-limit compatibility root-route public factorization)**.** *Let $K = (R, T, S, D, W, Q, L, H,$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Every public* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *route that consumes the root route of K factors through the exact package of Definition 646.153. The factorization exposes the budget-source, mesh-budget, triangle-bound, stream-window, regular-readback, seal-route, Real-seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows before any public read, and exports no host limit, quotient stream, host real equality, choice datum, hidden tail oracle, or ambient completeness coordinate.*

Proof. Apply Definition 646.155. It identifies the public Real$^{\uparrow}$ and Completion$^{\uparrow}$ consumer surface with exactly the displayed root-route package, so every public read begins from the budget-source, mesh-budget, triangle-bound, stream-window, regular-readback, seal-route, Real-seal, BHist, hsame, Cont, Pkg, and NameCert rows.

Next use Definition 646.154. The classifier survives componentwise hsame transport and replay of the displayed Cont routes, so the factorization is reusable by downstream public consumers rather than tied to a single presentation of K.

Finally apply Definition 646.156. The same package exports no host limit, quotient stream, host real equality, choice datum, hidden tail oracle, or ambient completeness coordinate. Thus the public route factors through the exact finite root-route package before any public read and has no escape coordinate outside it. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRoutePublicFactorizatio`

Theorem 646.158 (Diagonal-limit compatibility root-route classifier exhaustion)**.** *Let $K = (R, T, S, D, W, Q, L, H$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Every classifier read of the root route of K is exhausted by the same finite root-route package: the budget-source row, mesh-budget row, triangle-bound row, stream-window row, regular readback Q, seal route S, Real seal row L, displayed* BHist *rows, componentwise* hsame *transports H, displayed* Cont *routes C,* Pkg *provenance P, and local* NameCert *row N. Thus the classifier boundary has no coordinate outside that package for a host limit, quotient stream, host real equality, choice datum, hidden tail oracle, ambient completeness principle, or private downstream read.*

Proof. First read the package carrier. By Definition 646.153, the accepted root route exposes exactly the finite budget-source, mesh-budget, triangle-bound, stream-window, regular-readback, seal-route, Real-seal, BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply Definition 646.154. Componentwise hsame transport and replay of the displayed Cont routes preserve the classifier, so the boundary is attached to the package rows rather than to a presentation of K.

Use Definition 646.155. It identifies every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer read with the same row inventory, so a classifier read has no earlier or later consumer coordinate outside the displayed package.

Finally combine Definition 646.156 with Definition 646.157. The non-escape theorem excludes host, quotient, choice, hidden-tail, and completeness coordinates, while the public factorization makes the same finite classifier boundary available to downstream public consumers. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteClassifierExhausti`

Theorem 646.159 (Diagonal-limit compatibility root-route source exhaustion)**.** *Let $K = (R, T, S, D, W, Q, L, H, C$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Every accepted root-route read first exhausts the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *source row, the* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *mesh-budget row, the* RegularCauchyTriangleBoun *triangle-bound row, and the* $\mathsf{StreamName}^{\uparrow}$ *stream-window row before it can expose Q, S, L, H, C, P, or N. No root-route consumer has an alternate source row for a host limit, quotient stream, hidden selector, or ambient completeness witness.*

Proof. Begin with the finite package of Definition 646.153. It places the budget source, mesh budget, triangle bound, and stream window at the front of the accepted root-route surface.

Apply Definition 646.155. The theorem identifies every $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumer with exactly that package, so no later consumer can read Q, S, L, H, C, P, or N before the four source rows are fixed.

Finally use Definition 646.156. Since the route exports no host limit, quotient stream, hidden selector, or ambient completeness coordinate, the displayed four rows exhaust the source side of the root route. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root route source exhaustion`

Theorem 646.160 (Diagonal-limit compatibility root-route seal window lock)**.** *Let $K = (R, T, S, D, W, Q, L, H, C,$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. After the source rows of Definition 646.159 are exhausted, every seal-facing read is locked to the route*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The lock reaches the regular readback Q, then the seal route S, then the Real seal row L, and it cannot bypass through a quotient stream, selected host limit, host real equality, choice datum, hidden tail oracle, or ambient completeness row.

Proof. First use Definition 646.159. The stream-window row is already fixed before any read can reach the regular readback, seal route, or Real seal row.

Apply the package theorem Definition 646.153. Its route order exposes the $\mathsf{StreamName}^{\uparrow}$ window, the regular readback Q, the seal route S, and the Real seal row L inside one finite BHist/hsame/Cont/Pkg/NameCert surface.

Now use Definition 646.157 and Definition 646.158. Public consumers and classifier reads both factor through the same finite package, so the displayed $\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ window is the only terminal seal route.

The exclusions follow from Definition 646.156. The lock has no exported coordinate for a quotient stream, selected host limit, host equality, choice datum, hidden tail oracle, or completeness row. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteSealWindowLock`

Theorem 646.161 (Diagonal-limit compatibility root-route terminal totality)**.** *Let $K = (R, T, S, D, W, Q, L, H, C,$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of the root route of K factors through exactly the finite surface consisting of the displayed* BHist *rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row over the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$, $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *seal-route, and* $\mathsf{Real}^{\uparrow}$ *rows. There is no terminal consumer outside that surface.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteTerminalTotality`

Proof. Start with source exhaustion and the seal-window lock. By Definition 646.159 the route first reads the budget, mesh, triangle, and stream rows, and by Definition 646.160 every seal-facing read then passes through the $\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ window.

Apply Definition 646.155. It identifies the terminal $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumer inventory with the finite root-route package rather than with an external analytic object.

Use Definition 646.157. Every public terminal route is therefore a factorization through the displayed BHist, hsame, Cont, Pkg, and NameCert surface.

Finally combine Definition 646.158 with Definition 646.156. Classifier reads have no coordinate outside the package, and the excluded host, quotient, choice, hidden-tail, and completeness objects are not exported. Hence the listed finite surface is terminally total for root-route $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumers. □

Theorem 646.162 (Diagonal-limit compatibility root-route selector lock)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Before any regular readback Q, seal route S, or Real seal row L can be read along the root route, the route has already fixed the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *source row, the* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *mesh row, the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *triangle row, and the* $\mathsf{StreamName}^{\uparrow}$ *window row. The lock is part of the root-route package itself, so no* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer can choose a different selector row when it later reads Q, S, or L.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteSelectorLock`

Proof. Start with Definition 646.153. Its package reads the source, mesh, triangle, and window rows before exposing the regular readback, seal route, and Real seal row.

Use Definition 646.155. Every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer reads exactly that package, with no earlier access to Q, S, or L and no later bypass around the displayed rows.

Finally apply Definition 646.158. Since every classifier read is exhausted by the same finite row inventory, the selector rows are locked before the readback or seal coordinates are available to any downstream consumer. □

Theorem 646.163 (Diagonal-limit compatibility root-route terminal budget lock)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *public read through K first consumes the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *source*

row, the $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *mesh row, the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *triangle row, the* $\mathsf{StreamName}^{\uparrow}$ *stream-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-readback row, the seal-route row, the* $\mathsf{Real}^{\uparrow}$ *seal row, the displayed* BHist *rows, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row. The lock is terminal: after those rows are fixed, no further public read of* Q*,* S*, or* L *can introduce a host limit, quotient stream, selected limit, host real equality, choice datum, or ambient completeness row.*

Proof. First use Definition 646.153. It gives the finite package over the budget source, mesh budget, triangle bound, stream window, regular readback, seal route, Real seal, transport, continuation, provenance, and local naming rows.

Next apply Definition 646.159 and Definition 646.160. The source theorem exhausts the budget, mesh, triangle, and stream rows before any readback coordinate is exposed; the seal-window lock then routes the terminal read through the $\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ window.

The terminal access to Q, S, and L is fixed by Definition 646.162 and Definition 646.155. Together they make the selector order part of the exact consumer package for every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read.

Finally combine Definition 646.157, Definition 646.158, and Definition 646.156. Public readback and classifier readback are exhausted by the same finite package, and the non-escape boundary excludes host limits, quotient streams, selected limits, host equality, choice data, and ambient completeness rows. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteTerminalBudgetLock`

Theorem 646.164 (Diagonal-limit compatibility route budget exhaustion)**.** *Let* $K = (R, T, S, D, W, Q, L, H, C, P,$ *be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *read through* K *is exhausted by the ordered finite route*

$$\mathsf{CauchyDiagonalBudget}^{\uparrow} \longmapsto \mathsf{RealDiagonalMeshBudget}^{\uparrow} \longmapsto \mathsf{RegularCauchyTriangleBound}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{Re}$$

The read has no remaining public coordinate outside that route: not a host limit, quotient stream, selected limit, host real equality, choice datum, hidden tail oracle, detached classifier row, or ambient completeness row.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRouteBudgetExhaustion`

Proof. Begin with Definition 646.159. It exhausts the source side of the accepted packet by the diagonal budget, Real mesh budget, triangle bound, and stream-window rows before any terminal readback is exported.

Next apply Definition 646.160 and Definition 646.162. These place the $\mathsf{StreamName}^{\uparrow}$ window between the source rows and the later $\mathsf{RegSeqRat}^{\uparrow}$, seal-route, and $\mathsf{Real}^{\uparrow}$ rows, so Q, S, and L are read only after the source order has been fixed.

Use Definition 646.163. It identifies the terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read with the displayed budget, mesh, triangle, stream, regular-readback, seal, Real, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ route.

Finally combine Definition 646.158 with Definition 646.156. The classifier inventory contains no extra row beyond the displayed package, and the non-escape boundary excludes host limits, quotient streams, selected limits, host equality, choice data, hidden tail oracles, and ambient completeness coordinates. Hence the ordered route exhausts every terminal read. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility route budget exhaustion`

Theorem 646.165 (Diagonal-limit root-route budget terminal exhaustion)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P,$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Any terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *read preserving the root-route budget rows is exhausted by the ordered route through* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$, $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *the seal route,* $\mathsf{Real}^{\uparrow}$, *and the displayed* $\mathsf{BHist/hsame/Cont/Pkg/NameCert}$ *support rows. The terminal read exports no quotient stream, host real equality, selected limit, hidden tail oracle, choice datum, metric-completeness datum, ambient completeness coordinate, bridge row, or row outside the accepted packet.*

Proof. First apply Definition 646.159. The budget source, mesh budget, triangle bound, and stream-window rows are fixed before the read reaches any regular readback, seal-route, or Real-seal row.

Next use Definition 646.160 and Definition 646.162. These locks place the terminal route through the displayed $\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ window and prevent a second selector surface from choosing a different route.

Now apply Definition 646.163 and Definition 646.158. The terminal read and its classifier are both exhausted by the same finite budget, mesh, triangle, stream, readback, seal, Real, transport, continuation, package, and local naming rows.

Finally use Definition 646.156. The non-escape boundary excludes quotient, host-equality, selected-limit, choice, hidden-tail, completeness, bridge, and off-packet coordinates, so the ordered finite route supplies the entire terminal read. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteBudgetTerminalExha`

Theorem 646.166 (Diagonal-limit compatibility Cauchy-refinement threshold correspondence)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-route packet, and let*

$$R_c = (M_0, M_1, U, V, T_c, W_c, Q_c, E_c, H_c, C_c, P_c, N_c)$$

be an accepted $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *root threshold route. If a terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *read through K is compared against a public root threshold read through R_c, then the comparison has exactly the same four L10 route faces on both sides: a* $\mathsf{StreamName}^{\uparrow}$ *finite window, a* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and a* $\mathsf{Real}^{\uparrow}$ *seal. Both exported packages are exhausted by the displayed* BHist, *componentwise* hsame, *displayed* Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows, and neither side exports a quotient stream, host real equality, selected host limit, choice datum, hidden tail oracle, or ambient completeness row.*

Proof. First put the diagonal side in terminal form. By Definition 646.164, every terminal read through K is exhausted by the ordered route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, the seal row, $\mathsf{Real}^{\uparrow}$, and the displayed $\mathsf{BHist/hsame/Cont/Pkg/NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ rows.

The terminality needed for comparison is supplied by Definition 646.161. Thus any $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read eligible for comparison has already reached the same diagonal route package; there is no detached classifier or unaccounted tail coordinate left outside the finite route.

Now put the Cauchy side in threshold form. The root threshold public exhaustion theorem, Definition 885.133, confines every public consumer of R_c to the displayed route $M_0, M_1, U, V, T_c, W_c, Q_c, E_c, H_c, C_c, P_c,$ and its componentwise hsame, displayed Cont, Pkg, and local $\mathsf{NameCert}$ rows.

Finally apply Definition 885.136. It identifies the Cauchy route faces as the $\mathsf{StreamName}^{\uparrow}$ finite window, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal, with exactly the same public support-row vocabulary. Comparing the two exhausted packages therefore matches

those four L10 faces and leaves no quotient stream, host real equality, selected host limit, choice datum, hidden tail oracle, or ambient completeness row to export on either side. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCauchyRefinementThresholdCo`

Theorem 646.167 (Diagonal-limit compatibility StreamName budget triad)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet* $K = (R, T, S, D, W, Q, L, H, C, P, N)$*, the* $\mathsf{StreamName}^{\uparrow}$ *window is the unique middle budget face between the source triad* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$, $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *and the terminal seal rows* $\mathsf{RegSeqRat}^{\uparrow}$, S, *and* $\mathsf{Real}^{\uparrow}$*. Consequently, any two terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *reads through accepted packets that agree on the source triad, the* $\mathsf{StreamName}^{\uparrow}$ *window, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback agree on the same public consumer boundary.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityStreamNameBudgetTriad`

Proof. First use Definition 646.164. It displays the only ordered route available to a terminal read and places $\mathsf{StreamName}^{\uparrow}$ strictly between the diagonal-budget source rows and the regular-readback plus seal rows.

Apply Definition 646.160. The seal-facing part of the route passes through the $\mathsf{StreamName}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}$ window, so no second middle face can be inserted between the source triad and the terminal seal rows.

Now use Definition 646.162. Agreement on the source triad, $\mathsf{StreamName}^{\uparrow}$ window, and $\mathsf{RegSeqRat}^{\uparrow}$ readback fixes the selector surface before S or L is exported.

Finally apply Definition 646.158 and Definition 646.156. Since every classifier read is exhausted by the same locked route and no host or ambient coordinate is exported, two terminal reads agreeing on the triad have the same public consumer boundary. □

Theorem 646.168 (Diagonal-limit compatibility root-route public readback exhaustion)**.** *For every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet* $K = (R, T, S, D, W, Q, L, H, C, P, N)$*, public readback of* Q*,* S*, and* L *is exhausted by the finite route of Definition 646.163. The public surface exports only the displayed budget, mesh, triangle, stream-window, regular-readback, seal-route, Real-seal,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows, and exports no host limit, quotient stream, selected limit, host real equality, choice datum, or ambient completeness row.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root route public readback exhaustion`

Proof. Start from the terminal budget lock. It places Q, S, and L behind the displayed budget, mesh, triangle, stream, regular, seal, Real, transport, route, provenance, and naming rows.

Use Definition 646.157. Any public $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ route factors through the same finite root-route package before the readback is exported.

Apply Definition 646.158. Since every classifier read is exhausted by the package, the public readback has no second classifier coordinate that could detach Q, S, or L from the locked route.

The excluded exports are ruled out by Definition 646.156. A host limit, quotient stream, selected limit, host real equality, choice datum, or ambient completeness row is not part of the displayed package, so none is available from the public readback. □

Theorem 646.169 (Diagonal-limit compatibility root-route completion readback)**.** *Let* $K = (R, T, S, D, W, Q, L, H, C, P, N)$ *be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Every* $\mathsf{Completion}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *readback of the root route factors through the same displayed* $D, W, Q, S, L, H, C, P, N$

surface: the diagonal budget source, stream window, regular readback, seal route, Real seal row, componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row. Such a readback cannot read a host limit, quotient stream, host real equality, choice datum, hidden tail oracle, or ambient completeness coordinate.*

Proof. First invoke Definition 646.155. It identifies every $\mathsf{Completion}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer read with the displayed root-route package and places $D, W, Q, S, L, H, C, P, N$ inside that exact surface.

Next use Definition 646.157. Public completion-facing and Real-facing reads factor through the same finite package before any public read is exported, so the readback has no second route outside $D, W, Q, S, L, H, C, P, N$.

The excluded coordinates are ruled out by Definition 646.156. Therefore a completion or Real readback remains a displayed package read and cannot obtain a host limit or quotient stream. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteCompletionReadback`

Theorem 646.170 (Diagonal-limit compatibility root-route seal factorization)**.** *Let $K = (R, T, S, D, W, Q, L, H, C$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Any seal-facing public route that exports the Real seal row L factors first through the selector lock of Definition 646.162 and then through the completion readback of Definition 646.169. Hence the exported Real seal row is a public factor of the same root-route package, not a host-selected limit or quotient-stream read.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteSealFactorization`

Proof. Begin with Definition 646.162. It fixes the source, mesh, triangle, and window selector rows before any Q, S, or L coordinate is available.

Then apply Definition 646.169. The seal-facing readback travels through the displayed $D, W, Q, S, L, H, C, P, N$ surface and cannot leave it for a host limit, quotient stream, or ambient completeness coordinate.

It remains to identify the public export. Use Definition 646.157 together with Definition 646.158. The public route and the classifier boundary are both exhausted by the same finite package, so the Real seal row L is exported only after selector-lock and completion-readback factorization. □

Theorem 646.171 (Diagonal-limit compatibility terminal budget factorization)**.** *Let $K = (R, T, S, D, W, Q, L, H,$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *read of K factors through the ordered finite package consisting of the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *source row,* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *mesh row,* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *triangle row,* $\mathsf{StreamName}^{\uparrow}$ *window row,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, seal route row,* $\mathsf{Real}^{\uparrow}$ *seal row,* BHist *carrier row, componentwise* hsame *row, displayed* Cont *route row,* Pkg *provenance row, and local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row. The terminal read exports no quotient stream, host limit, host real equality, choice datum, hidden tail oracle, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility terminal budget factorization`

Proof. Start with Definition 646.153. It identifies the accepted root route as the finite package over the budget source, mesh budget, triangle bound, stream window, regular readback, seal route, Real seal, transport, continuation, provenance, and local naming rows.

Apply Definition 646.159. The source side is already exhausted by the budget, mesh, triangle, and stream rows. Then use Definition 646.162; the regular readback, seal route, and Real seal coordinates are available only after that ordered selector surface has been fixed.

Next apply Definition 646.169. It sends every completion-facing or Real-facing read through the displayed readback surface. The seal-facing part is then exactly the factorization of Definition 646.170, so the terminal Real seal export remains a public factor of the same finite package.

Finally use Definition 646.158 and Definition 646.156. The classifier has no row outside the package, and the non-escape theorem excludes quotient streams, host limits, host real equality, choice data, hidden tail oracles, and ambient completeness coordinates. Hence every terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read factors through precisely the displayed ordered package. □

Theorem 646.172 (Diagonal-limit compatibility terminal route completeness)**.** *Let $K = (R, T, S, D, W, Q, L, H, C$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. A terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *read of K is complete exactly when it factors through the ordered finite route consisting of the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *source row, the* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *mesh row, the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *triangle row, the* $\mathsf{StreamName}^{\uparrow}$ *window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the seal-route row, the* $\mathsf{Real}^{\uparrow}$ *seal row, and the displayed* BHist/hsame/Cont/Pkg/NameCert *rows. The complete terminal route exports no quotient stream, host-selected limit, host real equality, choice datum, hidden tail oracle, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility terminal route semantic certificate`

Proof. First read the root-route package of Definition 646.153. It supplies the displayed budget, mesh, triangle, stream-window, readback, seal, Real-seal, transport, continuation, provenance, and local naming rows as one finite carrier.

For the forward direction, apply Definition 646.163 and Definition 646.169. These lock every terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read to the source, window, regular-readback, seal-route, and Real-seal order, and they identify completion readback with the same displayed $D, W, Q, S, L, H, C, P, N$ surface.

Then use Definition 646.171. It gives the exact ordered factorization through the $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$, $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, seal-route, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows. Thus any complete terminal read is precisely a read through that finite route.

For the reverse direction, a read that factors through the displayed ordered route has already consumed every row made available by the accepted packet. The package theorem and the completion readback theorem show that no additional terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ coordinate remains outside the listed route.

Finally apply Definition 646.156. It excludes quotient streams, host-selected limits, host real equality, choice data, hidden tail oracles, and ambient completeness coordinates from the exported surface, so completeness of the terminal read is exactly completeness of the displayed finite factorization. □

Theorem 646.173 (Diagonal-limit compatibility Monotone Cauchy seal handoff)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet, and let*

$$M = (F, \sigma, \mu, \lambda, I, Q_M, H_M, C_M, P_M, N_M)$$

be an accepted $\mathsf{MonotoneCauchy}^{\uparrow}$ *packet whose public* $\mathsf{Real}^{\uparrow}$ *seal classifier consumes the terminal* $\mathsf{Real}^{\uparrow}$ *read exported by K. Then the combined read factors through the same ordered finite surface: the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *source row, the* $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ *mesh row, the* $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ *triangle row, the* $\mathsf{StreamName}^{\uparrow}$ *window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the monotone* $\mathsf{CauchyModulus}^{\uparrow}$ *and* $\mathsf{LocatedInterval}^{\uparrow}$ *rows, the* $\mathsf{Real}^{\uparrow}$ *seal row, and the*

displayed BHist/hsame/Cont/Pkg/NameCert *rows from both packets. The handoff exports no quotient stream, selected limit, host real equality, trichotomy row, ambient completeness principle, or choice datum.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityMonotoneCauchySealHandoff`

Proof. Start with terminal route completeness, Definition 646.172. It places the accepted terminal read of K on the displayed budget, mesh, triangle, stream-window, regular-readback, Real-seal, transport, continuation, provenance, and local naming rows.

Next apply the Monotone Cauchy public route classifier handoff, Definition 438.23. The public completion-facing classifier and the $\mathsf{Real}^{\uparrow}$ seal-facing classifier of M read the located interval trap, monotone tail-window certificate, $\mathsf{RegSeqRat}^{\uparrow}$ row, $\mathsf{CauchyModulus}^{\uparrow}$ tail-stability row, and $\mathsf{Real}^{\uparrow}$ seal row through H_M, C_M, P_M, N_M.

The consumer hypothesis identifies the $\mathsf{Real}^{\uparrow}$ seal read exported by K with the seal-facing classifier input of M. Therefore the composed read first traverses the diagonal terminal route and then the monotone classifier surface, without inserting any row outside the two displayed finite packets.

Finally combine the non-escape clause in terminal route completeness with the non-escape conclusion of the Monotone Cauchy classifier handoff. The diagonal packet has no quotient stream, selected limit, host real equality, choice datum, hidden tail oracle, or ambient completeness coordinate, and the monotone packet has no quotient stream, host sequence equality, selected limit, trichotomy row, ambient completeness principle, or choice datum. Hence the combined seal handoff factors exactly through the listed ordered surface. □

Theorem 646.174 (Diagonal-limit compatibility open-phase exit synchronization)**.** *Let* $K = (R, T, S, D, W, Q, L, H, C, P, N)$ *be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet whose terminal route reads the* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *diagonal pullback surface and the* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *Real-completion exit surface. Then every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *read synchronizes exactly the four finite exit faces*

$$\mathsf{StreamName}^{\uparrow}(W), \qquad \mathsf{DyadicRatCore}^{\uparrow}(T), \qquad \mathsf{RegSeqRat}^{\uparrow}(Q), \qquad \mathsf{Real}^{\uparrow}(L)$$

through the displayed BHist *row* H*, componentwise* hsame *transport, displayed* Cont *row* C*,* Pkg *provenance row* P*, and local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row* N*. The synchronized exit exports no quotient stream, host real equality, host-selected limit, choice datum, ambient completeness coordinate, metric-completeness datum, or bridge row.*

Proof. Start with terminal route completeness, Definition 646.172. It places any terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read of K on the displayed ordered route and identifies the available terminal rows as the stream window W, dyadic budget row T, regular readback Q, Real seal L, and the support rows H, C, P, N.

Next apply the diagonal pullback theorem Definition 885.140. The $\mathsf{CauchyModulusRefinement}^{\uparrow}$ surface pulls every compatible diagonal-limit consumer back to the same finite dyadic threshold and the same shared-window ledger, transported by BHist, hsame, Cont, Pkg, and NameCert support rather than by quotient or choice data.

The open-phase spine is supplied by Definition 885.141. It names the four exit faces as the $\mathsf{StreamName}^{\uparrow}$ finite window, $\mathsf{DyadicRatCore}^{\uparrow}$ dyadic ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ seal, and it orders them as the Phase Real and Completion route consumed by the terminal read.

Finally use Definition 435.128. Its Real-completion exit exhaustion leaves no additional consumer coordinate beyond the finite window, tolerance ledger, regular readback, Real seal, sibling

root route, and displayed support rows. Together with the non-escape clause in terminal route completeness, this rules out quotient streams, host real equality, host-selected limits, choice data, ambient or metric-completeness data, and bridge rows, so the terminal read synchronizes exactly the four finite exit faces. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityOpenPhaseExitSynchronizatio`

Theorem 646.175 (Diagonal-limit compatibility root-route triple lock)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Suppose its terminal consumer also reads the* CauchyModulusRefinement$^{\uparrow}$ *open-phase exit spine, the* UniformCauchyCriterion$^{\uparrow}$ *Real-completion exit exhaustion, and a* MonotoneCauchy$^{\uparrow}$ *public route classifier handoff. Then every terminal* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *read factors through exactly the displayed finite surface consisting of the* StreamName$^{\uparrow}$ *row, the* DyadicRatCore$^{\uparrow}$ *row, the* RegSeqRat$^{\uparrow}$ *row, the* Real$^{\uparrow}$ *seal row, the monotone tail-window and located-interval rows, and the displayed* BHist/hsame/Cont/Pkg/NameCert *support rows from the participating packets. The locked terminal route exports no quotient stream, host real equality, selected limit, trichotomy row, ambient completeness principle, metric-completeness datum, bridge row, or choice datum.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteTripleLock`

Proof. First invoke Definition 646.174. It synchronizes the terminal read of K to the finite StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$ exit faces, carried by the displayed H, C, P, N support rows and excluding quotient, host equality, selected-limit, choice, completeness, and bridge coordinates.

Next use Definition 885.141. The diagonal pullback consumer therefore reads the same open-phase spine rather than a separate analytic modulus: the stream window, dyadic ledger, regular readback, and Real seal are the available exit faces.

Apply Definition 435.128. It exhausts the Real-completion consumer surface by the finite window, tolerance ledger, regular readback, Real seal, sibling root route, and displayed support rows. Thus the Real$^{\uparrow}$ and Completion$^{\uparrow}$ terminal read has no additional metric-completeness or ambient-completeness coordinate.

Finally invoke Definition 438.23. The public monotone handoff identifies the remaining completion-facing surface with the monotone tail-window certificate, located-interval rows, regular-sequence row, Real$^{\uparrow}$ seal row, and its own BHist/hsame/Cont/Pkg/NameCert support. Combining the four invoked locks leaves exactly the displayed finite surface, so no quotient stream, host real equality, selected limit, trichotomy row, ambient completeness principle, metric-completeness datum, bridge row, or choice datum can be read by the terminal consumer. □

Theorem 646.176 (Diagonal-limit compatibility root-route seal readback classifier)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. For any terminal* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *seal readback of K, the classifier is exactly the ordered finite route through the* CauchyDiagonalBudget$^{\uparrow}$ *source row, the* RealDiagonalMeshBudget$^{\uparrow}$ *mesh row, the* RegularCauchyTriangleBound$^{\uparrow}$ *triangle row, the* StreamName$^{\uparrow}$ *window row, the* RegSeqRat$^{\uparrow}$ *readback row, the seal-route row, the* Real$^{\uparrow}$ *seal row, and the displayed* BHist/hsame/Cont/Pkg/NameCert *rows. It has no coordinate for a quotient stream, host equality, choice datum, hidden tail oracle, metric-completeness datum, bridge row, ambient completeness coordinate, or row outside the accepted packet.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root route seal readback classifier`

Proof. Start with terminal route completeness, Definition 646.172. It identifies completeness of any terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal readback with factorization through the displayed budget, mesh, triangle, stream-window, regular-readback, seal-route, Real-seal, transport, continuation, provenance, and local naming rows.

Next apply Definition 646.158. The classifier has no second inventory behind the seal readback; every classifier row available to the terminal consumer is already one of the displayed rows of the accepted route.

Finally use Definition 646.156. It excludes quotient streams, host equality, choice data, hidden tail oracles, metric or ambient completeness coordinates, bridge rows, and every other non-displayed analytic coordinate. Thus the seal-readback classifier is precisely the ordered finite route stated above. □

Theorem 646.177 (Diagonal-limit compatibility Cauchy-refinement consumer correspondence)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet whose terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *read is compared with a* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *threshold route and a* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *Real-completion exit route. The two consumer surfaces expose the same four exit faces*

$$\mathsf{StreamName}^{\uparrow}(W), \qquad \mathsf{DyadicRatCore}^{\uparrow}(T), \qquad \mathsf{RegSeqRat}^{\uparrow}(Q), \qquad \mathsf{Real}^{\uparrow}(L)$$

under the displayed support rows H, C, P, N. Neither consumer exports a quotient stream, host equality, choice datum, hidden tail oracle, metric-completeness datum, bridge row, ambient completeness coordinate, or any other excluded analytic coordinate.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRouteCauchyRefinementCo`

Proof. Begin with Definition 646.174. It places the terminal read of K on the four finite exit faces $\mathsf{StreamName}^{\uparrow}(W)$, $\mathsf{DyadicRatCore}^{\uparrow}(T)$, $\mathsf{RegSeqRat}^{\uparrow}(Q)$, and $\mathsf{Real}^{\uparrow}(L)$, carried by the displayed BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ support rows.

For the threshold-route side, apply Definition 885.141. The $\mathsf{CauchyModulusRefinement}^{\uparrow}$ consumer reads the same stream window, dyadic threshold ledger, regular readback, and Real seal rather than a separate quotient or choice-based modulus object.

For the Real-completion exit side, apply Definition 435.128. The $\mathsf{UniformCauchyCriterion}^{\uparrow}$ consumer is exhausted by the same finite window, tolerance ledger, regular readback, Real seal, sibling route, and displayed support rows.

The exclusions are common to the two surfaces. The synchronization theorem and the two consumer theorems leave no coordinate for quotient streams, host equality, choice data, hidden tail oracles, metric or ambient completeness data, bridge rows, or other analytic exports. Hence the Cauchy-refinement threshold route and the UniformCauchy Real-completion exit route correspond exactly on the four displayed exit faces. □

Theorem 646.178 (Diagonal-limit compatibility four-face consumer equivalence)**.** *Let $K = (R, T, S, D, W, Q, L, H$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Suppose the same public consumer also accepts compatible* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *and* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *route certificates for the terminal Real and Completion read. Then the following are equivalent as public BEDC routes for that consumer:*

1. *the diagonal terminal route of K;*
2. *the Cauchy threshold exit spine;*

3. the UniformCauchy Real-completion exit exhaustion.

The equivalence identifies exactly the four finite L10 faces

$$\mathsf{StreamName}^{\uparrow}(W), \qquad \mathsf{DyadicRatCore}^{\uparrow}(T), \qquad \mathsf{RegSeqRat}^{\uparrow}(Q), \qquad \mathsf{Real}^{\uparrow}(L)$$

with the same displayed BHist/hsame/Cont/Pkg/NameCert *support rows H, C, P, N. It carries no quotient stream, host real equality, selected limit, choice datum, ambient completeness coordinate, metric-completeness datum, or bridge row.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityFourFaceConsumerEquivalence`

Proof. First read the diagonal side through Definition 646.172. It exhausts every terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read of K by the displayed terminal route and excludes all off-route analytic coordinates.

Next attach the Cauchy threshold side. The spine theorem Definition 885.141 presents the compatible threshold consumer by the finite stream window, dyadic threshold ledger, regular readback, and Real seal, while Definition 646.177 identifies that surface with the displayed rows W, T, Q, L, H, C, P, N of K.

Finally attach the UniformCauchy exit side. The exhaustion theorem Definition 435.128 leaves the Real-completion consumer with no public coordinate beyond the same finite window, tolerance ledger, regular readback, Real seal, sibling route, and support rows. Since the Cauchy-refinement correspondence already identifies those coordinates with W, T, Q, L, H, C, P, N, the diagonal terminal route, the Cauchy threshold exit spine, and the UniformCauchy Real-completion exit exhaustion determine one public BEDC route.

The common non-escape clauses remove the possible extra readings: quotient streams, host real equality, selected limits, choice data, ambient completeness, metric-completeness, and bridge rows are not exported by any of the three route presentations. Thus the three public routes are equivalent exactly at the four displayed L10 faces and their shared support rows. □

Theorem 646.179 (Diagonal-limit compatibility open-phase four-face readiness)**.** *Let $K = (R, T, S, D, W, Q, L, H$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet whose terminal consumer accepts the* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *Cauchy-refinement route and the* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *Real-completion route. Then the terminal read is open-phase ready exactly at the four L10 exit faces*

$$\mathsf{StreamName}^{\uparrow}(W), \qquad \mathsf{DyadicRatCore}^{\uparrow}(T), \qquad \mathsf{RegSeqRat}^{\uparrow}(Q), \qquad \mathsf{Real}^{\uparrow}(L),$$

carried by the displayed BHist *row H,* Cont *row C,* Pkg *provenance row P, and local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row N. The readiness surface exposes no quotient stream, host real equality, selected limit, choice datum, completeness datum, or bridge row.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityOpenPhaseFourFaceReadiness`

Proof. First apply terminal route completeness, Definition 646.172. It confines the terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read of K to the displayed finite route and excludes quotient streams, selected limits, host real equality, choice data, hidden tail oracles, and ambient completeness coordinates.

Next use open-phase exit synchronization, Definition 646.174. The accepted terminal route is synchronized at the four finite faces $\mathsf{StreamName}^{\uparrow}(W)$, $\mathsf{DyadicRatCore}^{\uparrow}(T)$, $\mathsf{RegSeqRat}^{\uparrow}(Q)$, and $\mathsf{Real}^{\uparrow}(L)$ over the same support rows H, C, P, N.

The Cauchy-refinement consumer correspondence, Definition 646.177, identifies the Cauchy-refinement threshold route and the UniformCauchy Real-completion route with those same four faces. Thus accepting both route certificates adds no fifth terminal coordinate.

Finally invoke the four-face consumer equivalence, Definition 646.178. It identifies the diagonal terminal route, the Cauchy threshold exit spine, and the UniformCauchy Real-completion exit exhaustion as one public BEDC route. Therefore open-phase readiness is precisely the displayed four-face surface over H, C, P, N, with no quotient stream, host real equality, selected limit, choice datum, completeness datum, or bridge row. □

Theorem 646.180 (Diagonal-limit compatibility root-route selector minimality)**.** *Let $K = (R, T, S, D, W, Q, L, H,$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Any terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *read of K that reaches the four faces*

$$\mathsf{StreamName}^{\uparrow}(W), \qquad \mathsf{DyadicRatCore}^{\uparrow}(T), \qquad \mathsf{RegSeqRat}^{\uparrow}(Q), \qquad \mathsf{Real}^{\uparrow}(L)$$

must factor through the displayed budget-source row, mesh row, triangle row, and stream-window row before the seal route is read. Thus the root route has no smaller selector surface that still exposes all four faces.

Lean4 ✓ `BEDC.Derived.Diagonallimitcompatibilityup.DiagonalLimitCompatibilityRootRouteSelectorMinimality`

Proof. Start from the root-route budget package. It places the $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ source row, $\mathsf{RealDiagonalMeshBudget}^{\uparrow}$ mesh row, $\mathsf{RegularCauchyTriangleBound}^{\uparrow}$ triangle row, and $\mathsf{StreamName}^{\uparrow}$ window row before the regular readback, seal route, and Real seal rows.

Use source exhaustion and the seal-window lock. The source exhaustion theorem says that no alternate source row can serve the terminal route, while the seal-window lock prevents a seal-facing read from choosing a different window after the source rows have been displayed.

Finally apply the four-face consumer equivalence. Since the terminal consumer sees exactly $\mathsf{StreamName}^{\uparrow}(W)$, $\mathsf{DyadicRatCore}^{\uparrow}(T)$, $\mathsf{RegSeqRat}^{\uparrow}(Q)$, and $\mathsf{Real}^{\uparrow}(L)$ over the same support rows, removing any one of the budget-source, mesh, triangle, or stream-window rows destroys the displayed route to at least one face. The remaining non-escape theorem excludes hidden tail oracles, selected host limits, quotient streams, choice data, and ambient completeness as substitutes. □

Theorem 646.181 (Diagonal-limit compatibility root-route budget-source totality)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. The budget-source rows of the root route exhaust all selector inputs for any terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *read of K. In particular, the terminal route admits no hidden tail oracle, quotient stream, selected host limit, countable-choice datum, or ambient-completeness coordinate outside the displayed source, mesh, triangle, stream-window, readback, seal, transport, continuation, provenance, and local naming rows.*

Proof. First compose the root-route budget package with source exhaustion. The only selector inputs made available before terminal readback are the displayed diagonal budget source, mesh budget, triangle bound, and stream-window rows.

Next apply the seal-window lock. Once those rows are fixed, the regular readback Q, the seal route S, and the Real seal L can be read only through the same route, with H, C, P, N carrying transport, replay, provenance, and local naming.

The four-face consumer equivalence identifies this route with the public exit surface seen by the Cauchy-refinement and UniformCauchy consumers. The non-escape theorem then removes every proposed outside selector input: hidden tail oracle, quotient stream, selected host limit, countable choice, and ambient completeness are not rows of the accepted packet. □

Lean4 ✓ `BEDC.Derived.Diagonallimitcompatibilityup.DiagonalLimitCompatibility root route budget source totality`

Definition 646.182 (DiagonalLimitCompatibility root formal source)**.** *A* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root formal source is a finite packet*

$$S = (B, T, W, R, L, H, C, P, N)$$

where B *is the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *source row,* T *is the* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *selector row,* W *is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row,* R *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular handoff row,* L *is the* $\mathsf{Real}^{\uparrow}$ *seal row,* H *records componentwise* hsame *transports,* C *records displayed* Cont *routes,* P *records* Pkg *provenance, and* N *is the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *row.*

The sibling sources are the budget packet of chapter 853, the selector packet of chapter 697, the finite-window surface of chapter 126, the regular rational sequence surface of chapter 301, and the seal surface of chapter 38. The tuple contains no quotient stream, host limit, countable-choice selector, or ambient completeness coordinate.

Lean4 (definition) `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootFormalSource`

Theorem 646.183 (DiagonalLimitCompatibility root formal route)**.** *Every accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *route that is available to a root formal consumer factors through the finite source tuple of Definition 646.182. In particular, the consumer reads the budget row* B*, selector row* T*, finite window row* W*, regular handoff row* R*, and* $\mathsf{Real}^{\uparrow}$ *seal row* L *before the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ *route is accepted.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootFormalRoute`

Proof. Project the source tuple $S = (B, T, W, R, L, H, C, P, N)$. The diagonal budget row B supplies the precision and mesh budget, and the selector row T supplies the cofinal tail selection used by the diagonal route.

The finite-window and regular handoff rows are then read in order. The $\mathsf{StreamName}^{\uparrow}$ row W displays the finite observation window, and the $\mathsf{RegSeqRat}^{\uparrow}$ row R is the regular sequence handoff attached to that same window.

Only after those rows are visible does the route reach the $\mathsf{Real}^{\uparrow}$ seal row L. The transports in H, continuations in C, provenance in P, and local naming row N replay that same order for the accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ consumer, so the route factors through the listed source tuple. □

Theorem 646.184 (DiagonalLimitCompatibility root formal non-escape)**.** *An accepted root formal route for* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *cannot use quotient streams, host limits, countable choice, or ambient completeness to replace any row of the finite source tuple of Definition 646.182.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootFormalNonescape`

Proof. Read the carrier inventory of Definition 646.182. Its only source rows are $B, T, W, R, L, H, C, P, N$, and each row is tied to a displayed sibling chapter: Cauchy diagonal budget, diagonal tail selector, StreamName finite window, RegSeqRat regular handoff, and Real seal.

Quotient streams and host limits would require additional equality or limit coordinates, but none are present in the tuple. Countable choice would require an unbounded selector family beyond T, while ambient completeness would require a completion principle beyond the seal row L.

Thus every accepted route stays inside the finite handoff packet. Any consumer that asks for one of the excluded principles has asked for data not carried by the $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ source tuple. □

Theorem 646.185 (DiagonalLimitCompatibility root readback determinacy)**.** *Let $S = (B, T, W, R, L, H, C, P, N)$ and $S' = (B', T', W', R', L', H', C', P', N')$ be accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root formal routes. Suppose the displayed* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *rows B, B',* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *rows T, T',* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows W, W',* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows R, R', and* $\mathsf{Real}^{\uparrow}$ *seal rows L, L' are paired by their chapter classifiers and transported componentwise by the displayed* hsame *row H against H'. Then the two routes determine the same local* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *readback through H, C, P, N. They cannot be separated by quotient streams, host limits, countable-choice selectors, or ambient completeness.*

Proof. Apply Definition 646.183 to both accepted routes. Each route is forced through the finite source tuple of Definition 646.182, so every readback begins with the displayed source rows B, T, W, R, L and B', T', W', R', L' in the five sibling chapters.

Compare those five source positions componentwise through their classifiers and through the displayed hsame transport row. The budget, selector, finite-window, regular handoff, and seal agreements identify the only external rows available before the local $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ route reaches H, C, P, N.

It remains to exclude a later separating coordinate. By Definition 646.184, neither route can introduce quotient streams, host limits, countable-choice selectors, or ambient completeness in place of the finite tuple. Hence the remaining local readback through H, C, P, N is determined by the classifier-and-transport source data carried by the displayed packet. □

Lean4 ✓ `BEDC.Derived.Diagonallimitcompatibilityup.DiagonalLimitCompatibilityRootReadbackDeterminacy`

Theorem 646.186 (DiagonalLimitCompatibility root formal seal factorization)**.** *Every accepted root formal route $S = (B, T, W, R, L, H, C, P, N)$ for* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *factors any* $\mathsf{Real}^{\uparrow}$ *or completion-facing seal read through the ordered rows B, T, W, R, L before the local* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *rows H, C, P, N are consumed. No quotient stream, host limit, countable-choice selector, or ambient completeness row can replace the seal factor L.*

Consequently, after the seal factor L is reached through the displayed $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{DiagonalTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, *and* $\mathsf{RegSeqRat}^{\uparrow}$ *rows, the remaining readback through H, C, P, N is determined by those same source rows.*

Lean4 ✓ `BEDC.Derived.Diagonallimitcompatibilityup.DiagonalLimitCompatibilityRootFormalSealFactorizatio`

Proof. Start with the formal route. By Definition 646.183, every accepted root formal consumer reads the ordered tuple B, T, W, R, L before it accepts the local $\mathsf{NameCert}_{\mathsf{DiagonalLimitCompatibility}^{\uparrow}}$ rows.

Next exclude off-packet seal sources. The non-escape theorem Definition 646.184 says that quotient streams, host limits, countable-choice selectors, and ambient completeness rows are not coordinates of the source tuple, so none of them can stand in for the $\mathsf{Real}^{\uparrow}$ seal row L.

Finally apply readback determinacy. Once the displayed source rows B, T, W, R, L have been fixed, Definition 646.185 identifies the subsequent H, C, P, N readback as the one determined by those rows. Thus every Real or completion-facing seal read factors through B, T, W, R, L before the local diagonal-compatibility rows are consumed. □

Theorem 646.187 (DiagonalLimitCompatibility root formal Lean-target boundary)**.** *Every Lean target that formalizes the* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root formal handoff must expose exactly the finite rows*

$$B, T, W, R, L, H, C, P, N$$

from Definition 646.182. The target may project these rows and prove route, non-escape, readback determinacy, or seal factorization over them, but it may not add a quotient stream row, host limit row, countable choice row, ambient completeness row, or any second source row outside the displayed tuple.

Proof. Project the source tuple. The route theorem Definition 646.183 already forces every accepted root formal consumer through $B, T, W, R, L, H, C, P, N$.

Next apply Definition 646.184. The excluded quotient, host-limit, choice, and completeness coordinates are not carried by the tuple, so they cannot become formal target rows.

Finally use Definition 646.185 and Definition 646.186. They show that the displayed rows are sufficient for readback and seal-facing consumers, leaving no remaining source coordinate for the formal boundary. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootFormalLeanTargetBoundar`

Theorem 646.188 (DiagonalLimitCompatibility root formal kernel scope)**.** *In the root formal handoff for* DiagonalLimitCompatibility$^{\uparrow}$*, the row B is the* CauchyDiagonalBudget$^{\uparrow}$ *row, T is the* DiagonalTailSelector$^{\uparrow}$ *row, W is the* StreamName$^{\uparrow}$ *row, R is the* RegSeqRat$^{\uparrow}$ *row, L is the* Real$^{\uparrow}$ *seal row, H is the displayed* hsame *transport row, C is the displayed* Cont *route row, P is the* Pkg *provenance row, and N is the local* NameCert *row. Together these rows form the finite* BHist *kernel scope for the handoff, and no root formal target for this site may replace them by a host sequence, host real, external selector family, quotient stream, or ambient completeness principle.*

Proof. Read Definition 646.182 componentwise. It assigns the five source rows to CauchyDiagonalBudget$^{\uparrow}$, DiagonalTailSelector$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$, and assigns the support rows to hsame, Cont, Pkg, and NameCert.

The route theorem Definition 646.183 then places those rows inside the accepted root formal consumer route. The seal factorization theorem Definition 646.186 identifies the same order before the local support rows are consumed.

Apply non-escape from Definition 646.184. Since host sequences, host reals, external selector families, quotient streams, and ambient completeness principles are absent from the BHist tuple, the kernel scope is exactly the displayed row list. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root formal kernel scope`

Theorem 646.189 (DiagonalLimitCompatibility root formal audit handoff)**.** *An audit consumer for the* DiagonalLimitCompatibility$^{\uparrow}$ *root formal handoff may accept only the finite route*

$$B \longrightarrow T \longrightarrow W \longrightarrow R \longrightarrow L \longrightarrow H, C, P, N$$

over the source tuple of Definition 646.182. The audit surface rejects quotient streams, host limits, countable choice, ambient completeness, and any consumer route whose seal or readback bypasses one of the displayed rows.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootFormalAuditSurface`

Proof. Begin with the accepted route. By Definition 646.183, an audit read that belongs to this root handoff must pass through the displayed tuple.

Seal-facing reads are handled by Definition 646.186. They pass through B, T, W, R, L before the local H, C, P, N rows are consumed, so a bypassing seal route is not an accepted route for this site.

Readback-facing reads are handled by Definition 646.185. Once the displayed rows are fixed, the local readback is fixed as well. The non-escape theorem Definition 646.184 removes quotient streams, host limits, countable choice, and ambient completeness from the audit handoff. □

Theorem 646.190 (Diagonal-limit compatibility budget-selector carrier)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Any completion-facing read that uses K as a diagonal compatibility source consumes the* FiniteObservationBudgetSelector$^{\uparrow}$ *route before the* StreamName$^{\uparrow}$ *window row W, the* RegSeqRat$^{\uparrow}$ *readback row Q, and the* Real$^{\uparrow}$ *seal row L are made available to the downstream consumer.*

Proof. Project the accepted compatibility packet. The carrier displays the diagonal source, triangle row, seal route, dyadic ledger, stream-window row, regular readback, Real seal, transports, continuations, provenance, and local naming row.

Insert the finite observation-budget selector at the point where the diagonal route asks for its selected observation budget. The selector route supplies the finite budget-to-schedule passage that determines which window and dyadic rows may be read.

Only after that selector route is fixed may the consumer read W, then the dyadic and regular-rational handoff through D, Q, and finally the Real seal row L. Thus the selector is consumed before the window, readback, and seal rows are exported. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityBudgetSelectorCarrier`

Theorem 646.191 (Diagonal-limit compatibility budget-selector route)**.** *For an accepted* DiagonalLimitCompatibili *packet, the displayed budget-selector handoff is mediated only by* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. The handoff uses the same finite support rows H, C, P, N that expose the diagonal route, so the selector read cannot introduce an additional analytic coordinate between the budget request and the* StreamName$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*, and* Real$^{\uparrow}$ *rows.*

Proof. Begin with the support coordinates of the compatibility packet. The rows H, C, P, N record componentwise history transport, continuation replay, package provenance, and local naming data.

The finite observation-budget selector is read as a BEDC packet through those same support coordinates. Its budget-to-schedule, finite-window, dyadic-ledger, handoff, and seal rows are therefore reached by displayed BHist rows, transported by hsame, replayed by Cont, and packaged by Pkg under the local NameCert surface.

No further mediator is present in the carrier. Hence the selector handoff is exhausted by BHist, hsame, Cont, Pkg, and NameCert. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityBudgetSelectorRoute`

Theorem 646.192 (Diagonal-limit compatibility budget-selector non-escape)**.** *No quotient stream, choice-selected limit, host real equality, or ambient completeness coordinate can enter an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet through the budget-selector handoff. Every such handoff remains inside the displayed* FiniteObservationBudgetSelector$^{\uparrow}$ *route and the compatibility rows $R, T, S, D, W, Q, L, H, C, P, N$.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityBudgetSelectorNonescape`

Proof. Use the selector route theorem to identify the only mediation rows. They are structural BEDC rows and contain no quotient stream, choice datum, host equality test, or completeness oracle.

Use the carrier inventory for the compatibility packet. Its analytic-facing rows are the displayed dyadic ledger, stream-window family, regular readback, and Real seal reached along the named finite route.

Since the selector handoff has no other coordinate and the compatibility packet has no hidden analytic field, none of the excluded objects can enter through the handoff. Every exported read remains inside the displayed selector route and the compatibility packet rows. □

Theorem 646.193 (Diagonal-limit compatibility selector-budget source lock)**.** *Let $K = (R, T, S, D, W, Q, L, H, C,$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Every selector-budget read of K is sourced only by the displayed diagonal source row, the* $\mathsf{StreamName}^{\uparrow}$ *window row W, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row D, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row Q, the* $\mathsf{Real}^{\uparrow}$ *seal row L, and the structural rows H, C, P, N. The read cannot use an unlisted budget source, hidden selector input, host real equality, selected limit, quotient stream, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.Diagonallimitcompatibilityup.DiagonalLimitCompatibilityCarrier selector budget source lock`

Proof. Start from Definition 646.79. It identifies the budget source of an accepted compatibility packet with the displayed diagonal route, dyadic ledger, stream window, regular-rational handoff, Real seal, transport rows, continuation rows, provenance, and local name.

Apply Definition 646.81 and Definition 646.82. The window W is read before the regular readback Q, and the Real-facing row L is reached only through the displayed D, W, Q route.

Finally apply Definition 646.83 and Definition 646.48. These boundaries remove the possible routes through hidden budget data, quotient streams, selected limits, host equality, choice data, and ambient completeness. Thus the selector budget is locked to the displayed finite source surface. □

Theorem 646.194 (Diagonal-limit selector-budget RealLimitUniqueness pullback)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet exposing the selector-budget rows W, D, Q, L. Let*

$$U = (L_0, L_1, Q_U, S_U, D_U, R_U, V_U, H_U, C_U, P_U, N_U)$$

be an accepted $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet whose two* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows and shared comparison-window route are read through the same W, D, Q, L surface of K: S_U is supplied by W, D_U is supplied by D, Q_U is supplied by Q, and R_U is supplied by L. Suppose also that the terminal* $\mathsf{RealCompletionExactBoundaryUp}$ *packet reads the same* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *faces through that route.*

Then every uniqueness consumer factors through the displayed diagonal selector-budget route of K before reading V_U. No accepted pullback may insert quotient streams, selected limits, host real equality, countable choice, independent completion data, ambient completeness, or a second completion-facing source.

Lean4 ✓ `BEDC.Derived.Diagonallimitcompatibilityup.DiagonalLimitSelectorBudgetRealLimitUniquenessPullbac`

Proof. First lock the diagonal source. Apply Definition 646.193 and Definition 646.198. These force every selector-budget read of K through the displayed diagonal source and the rows W, D, Q, L, H, C, P, N.

Next attach the uniqueness seal. The two-seal exposure theorem, Definition 1039.7, places L_0 and L_1 before any uniqueness read. The shared comparison window, Definition 1039.8, then routes the comparison through Q_U, S_U, D_U, R_U, V_U, which is the same surface as Q, W, D, L under the hypothesis.

Now read the terminal completion boundary. By Definition 1120.6, the completion-facing faces are exactly the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and terminal $\mathsf{Real}^{\uparrow}$ rows exposed by the accepted boundary. Since those faces are the same W, Q, D, L route, the uniqueness consumer has no independent completion-facing source.

Finally combine diagonal source lock with the RealLimitUniqueness nonescape and consumer handoff results implicit in the two-seal and shared-window route. The accepted route has no coordinate for quotient streams, selected limits, host real equality, countable choice, independent completion data, ambient completeness, or a second completion-facing source, so every uniqueness consumer factors through the displayed diagonal selector-budget route. □

Theorem 646.195 (Diagonal-limit compatibility seal-synchronizer budget handoff)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet whose seal route is consumed through an accepted* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *packet. The synchronizer handoff is downstream of the same finite selector-budget prefix of Definition 646.193: the diagonal source, W, D, Q, L, and the structural rows H, C, P, N are fixed before the synchronizer may export a seal-facing read.*

Proof. First use Definition 646.79 and Definition 646.193. They fix the finite prefix that any selector-budget read must expose before the completion-facing route can inspect the readback and seal rows.

Next use the existing seal-budget synchronizer handoff. The synchronizer rows are inserted at the displayed seal route and must be consumed before the regular-rational row Q and the Real seal row L escape to a consumer.

Apply Definition 646.81, Definition 646.82, Definition 646.83, and Definition 646.48. These keep the synchronizer attached to the same D, W, Q, L, H, C, P, N surface, so the handoff is downstream of the selector-budget prefix and has no separate source through host limits, quotient streams, host equality, choice data, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySealSynchronizerBudgetHando`
↪ variant `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier seal budget synchronizer handoff`

Theorem 646.196 (Diagonal-limit compatibility completion-consumer budget non-escape)**.** *Every* $\mathsf{Completion}^{\uparrow}$*-facing or* $\mathsf{Real}^{\uparrow}$*-facing consumer of an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet that uses the selector-budget route receives only the finite route*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The consumer cannot bypass that route by quotient streams, selected limits, host equality, choice data, independent completion data, or ambient completeness.

Proof. Begin with Definition 646.79, Definition 646.193, and Definition 646.195. Together they place the selector read, the seal synchronizer, the stream window, the dyadic ledger, the regular readback, and the Real seal on one finite prefix.

Now apply Definition 646.81, Definition 646.82, and Definition 646.83. They exhaust downstream $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, and completion-seal consumers by the displayed budget, window, diagonal, seal, transport, route, provenance, and local-name rows.

Finally apply Definition 646.48. Since every completion-facing consumer already factors through the same listed packet coordinates, there is no remaining coordinate from which quotient streams, selected limits, host equality, choice data, independent completion data, or ambient completeness can be exported. □

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCompletionConsumerBudgetNon
Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier completion consumer budget nonescape

Theorem 646.197 (Diagonal-limit selector-budget formal target lock)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Any formal target for the selector-budget route of K must keep the source locked to the displayed diagonal source, the* StreamName$^{\uparrow}$ *window row W, the* DyadicRatCore$^{\uparrow}$ *ledger row D, the* RegSeqRat$^{\uparrow}$ *readback row Q, the* Real$^{\uparrow}$ *seal row L, and the structural rows H, C, P, N. It may not replace that route by quotient streams, selected limits, host equality, choice data, independent completion data, ambient completeness, or a second completion-facing source.*

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget formal target lock

Proof. First apply Definition 646.193. It fixes every selector-budget read to the displayed diagonal source together with the W, D, Q, L, H, C, P, N rows.

Next apply Definition 646.195. The seal-facing synchronizer is downstream of that same finite selector-budget prefix, so the route cannot acquire a second seal source before readback.

Finally apply Definition 646.196. Every completion-facing or Real$^{\uparrow}$-facing consumer is exhausted by $R, T, S, D, W, Q, L, H, C, P, N$, which rules out quotient streams, selected limits, host equality, choice data, independent completion data, and ambient completeness for the formal target boundary. □

Theorem 646.198 (Diagonal-limit selector-budget route determinacy)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Any selector-budget route of K consumed by a downstream* Completion$^{\uparrow}$ *or* Real$^{\uparrow}$ *reader is the displayed diagonal route: it is determined by the diagonal source, the* StreamName$^{\uparrow}$ *window row W, the* DyadicRatCore$^{\uparrow}$ *ledger row D, the* RegSeqRat$^{\uparrow}$ *readback row Q, the* Real$^{\uparrow}$ *seal row L, and the structural rows H, C, P, N. No second selector-budget route through quotient streams, selected limits, host equality, choice data, independent completion data, ambient completeness, or a hidden seal source can serve the same downstream reader.*

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget route determinacy

Proof. Start with Definition 646.193. It confines every selector-budget read of K to the displayed diagonal source and the finite rows W, D, Q, L, H, C, P, N.

Next apply Definition 646.195. The seal-facing handoff sits downstream of the same finite selector-budget prefix, so a downstream reader cannot insert an alternate seal route between the readback row Q and the Real$^{\uparrow}$ seal row L.

Finally apply Definition 646.196. Every Completion$^{\uparrow}$-facing or Real$^{\uparrow}$-facing consumer using the selector budget is exhausted by the displayed packet coordinates. Hence two such consumer routes with the same displayed diagonal source and the same rows W, D, Q, L, H, C, P, N have no coordinate on which to differ, and the selector-budget route is determined by that finite surface. □

Theorem 646.199 (Diagonal-limit selector-budget Real-seal nonescape)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Every selector-budget* Real$^{\uparrow}$*-seal consumer of K reaches the seal row L only through the displayed diagonal source together with the* StreamName$^{\uparrow}$ *window row W, the* DyadicRatCore$^{\uparrow}$ *ledger row D, the* RegSeqRat$^{\uparrow}$ *readback row Q, and the structural rows H, C, P, N. The consumer has no route through quotient streams, selected limits, host equality, choice data, independent completion data, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget real seal nonescape`

Proof. Start with Definition 646.193. It fixes every selector-budget read of K to the displayed diagonal source and the rows W, D, Q, L, H, C, P, N.

Apply Definition 646.198. Any downstream $\mathsf{Real}^{\uparrow}$-facing consumer using that budget is therefore the same diagonal route, not a second route through hidden selector or completion data.

Finally use the Real-facing side of Definition 646.196. Since the only route to L is already the displayed finite route, quotient streams, selected limits, host equality, choice data, independent completion data, and ambient completeness have no remaining coordinate from which to enter the seal consumer. □

Theorem 646.200 (Diagonal-limit selector-budget root public readback exhaustion)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. The root public readback route for the selector-budget surface is exhausted by the displayed diagonal source and the rows W, D, Q, L, H, C, P, N. In particular, every public readback of the selector budget factors through the selector-budget source lock, the selector-budget route determinacy boundary, and the selector-budget* $\mathsf{Real}^{\uparrow}$*-seal nonescape boundary before it can expose a root-facing Real or Completion consumer.*

Proof. First apply Definition 646.193. This identifies the public readback source as the displayed diagonal source and the finite selector rows W, D, Q, L, H, C, P, N.

Next apply Definition 646.198. The public readback cannot branch into a second selector-budget route after the source has been fixed.

Finally apply Definition 646.199. The Real-seal endpoint of the public route reaches L only through the same diagonal source and the same structural rows. Thus the root public readback is exhausted by the stated finite surface and cannot export quotient streams, selected limits, host equality, choice data, independent completion data, ambient completeness, or hidden seal data. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget root public readback exhaustion`

Theorem 646.201 (Diagonal-limit selector-budget Cauchy limit functor pullback)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Let*

$$F = (S_F, T_F, M_F, W_0, W_1, R_F, D_F, K_F, E_F, H_F, C_F, P_F, N_F)$$

be an accepted $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet whose source and target seal rows are read through the same selector-budget surface D, W, Q, L of K: the functor windows W_0, W_1 are supplied by W, the readback R_F is supplied by Q, the ledger D_F is supplied by D, and the Real-facing endpoint row E_F is supplied by L.*

Then every $\mathsf{Real}^{\uparrow}$*-facing or* $\mathsf{Completion}^{\uparrow}$*-facing functor transport of F factors through the displayed diagonal selector-budget route of K. Conversely, that selector-budget route supplies exactly the finite source, window, readback, dyadic ledger, classifier, endpoint, transport, replay, provenance, and local naming rows required by the public seal export of F:*

$$S, D, W, Q, L, H, C, P, N \quad \text{and} \quad S_F, W_0, W_1, R_F, D_F, K_F, E_F, H_F, C_F, P_F, N_F.$$

No ambient limit object, hidden selector, quotient stream equality, host real equality, countable-choice selector, independent completion object, or second public transport route is available at the pullback boundary.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget cauchy limit functor pullback`

Proof. First lock the diagonal side. Apply Definition 646.193 and Definition 646.197. These force the accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ packet to expose only the diagonal source together with D, W, Q, L, H, C, P, N, and they prevent a formal target from replacing that route by quotient streams, selected limits, host equality, choice data, independent completion data, ambient completeness, or a second source.

Next identify the downstream route. By Definition 646.198, any $\mathsf{Real}^{\uparrow}$-facing or $\mathsf{Completion}^{\uparrow}$-facing consumer using the selector budget is the displayed diagonal route. Since the functor rows W_0, W_1, R_F, D_F, E_F are read through W, Q, D, L, any functor transport that reaches a Real or Completion consumer has already entered that same route.

Now read the $\mathsf{CauchyLimitFunctor}^{\uparrow}$ public surface. The NameCert obligations of Definition 1116.3 provide exactly the functor carrier, source-to-target seal exposure, finite observations, completion-consumer rows, and structural rows. The Real-completion consumer boundary of Definition 1116.7 keeps those rows inside the same finite transport route and removes detached completion data, ambient completeness, host real equality, quotient stream equality, selected limits, countable choice, and second routes.

Finally apply Definition 1116.9. Its reusable public surface is the finite route through source seal, transport map, stream windows, readback, dyadic ledger, classifier, target seal, endpoint, componentwise transport, replay, provenance, and local naming. Under the shared D, W, Q, L read, those requirements are supplied by the displayed selector-budget rows of K together with the functor rows of F, so the pullback gives exactly the stated public-seal transport boundary and no additional route. □

Theorem 646.202 (Diagonal-limit selector-budget finite-tail-filter handoff)**.** *Let* $K = (R, T, S, D, W, Q, L, H, C, P,$ *be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Let*

$$F = (S_F, D_F, R_F, B_F, Q_F, E_F, H_F, C_F, P_F, N_F)$$

be an accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet whose stream-window row, dyadic-ledger row, regular-readback row, tail-budget and common-tail rows, and* $\mathsf{Real}^{\uparrow}$ *seal row are read through the same displayed selector-budget surface* W, D, Q, L *of* K*:* S_F *is supplied by* W*,* D_F *is supplied by* D*,* R_F *is supplied by* Q*, the rows* B_F, Q_F *are consumed through the same finite tail surface, and* E_F *is supplied by* L*.*

Then every $\mathsf{Real}^{\uparrow}$*-facing or* $\mathsf{Completion}^{\uparrow}$*-facing finite-tail-filter consumer of* F *factors through the displayed diagonal selector-budget route of* K*. Conversely, the selector-budget route supplies exactly the finite cofinal-tail rows required by* $\mathsf{FiniteTailFilter}^{\uparrow}$*:*

$$S_F, D_F, R_F, B_F, Q_F, E_F, H_F, C_F, P_F, N_F$$

read through

$$S, D, R, W, Q, L, H, C, P, N.$$

No accepted handoff may insert a hidden tail selector, detached dyadic ledger, quotient stream equality, selected limit, host real equality, countable-choice selector, independent completion object, or ambient completeness witness between the diagonal selector budget and the finite-tail-filter consumer.

Proof. First lock the diagonal route. Apply Definition 646.193 and Definition 646.197. These force the accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ packet to expose the diagonal source together with W, D, Q, L, H, C, P, N, and they prevent a formal target from replacing that surface by hidden selector data or an independent completion-facing source.

Next identify the consumer route. By Definition 646.198, any $\mathsf{Real}^{\uparrow}$-facing or $\mathsf{Completion}^{\uparrow}$-facing consumer using the selector budget is the displayed diagonal route. Apply Definition 646.196 and Definition 646.48 to remove quotient streams, selected limits, host equality, choice data, independent completion data, and ambient completeness from that route.

Now read the finite-tail-filter surface. Tail-window exactness, Definition 1119.4, identifies the windows and dyadic tolerances used by the tail-budget row, the common-tail comparison row, and the seal-facing row. Since S_F, D_F, R_F, E_F are read through W, D, Q, L, the finite-tail rows B_F, Q_F have no separate selector or tolerance ledger from which to build another consumer path.

Finally use Definition 1119.5 and Definition 1119.9. The Real and Completion seal reads of F pass through the finite cofinal-tail packet $S_F, D_F, R_F, B_F, Q_F, E_F, H_F, C_F, P_F, N_F$, while sibling consumers cannot substitute their own tail selector, ledger, common-tail row, or seal row. Under the shared W, D, Q, L read, those rows are exactly the displayed selector-budget rows of K together with the structural rows H, C, P, N, so the handoff factors through the diagonal route and supplies precisely the finite-tail-filter packet. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitSelectorBudgetFiniteTailFilterHandoff`

Theorem 646.203 (Diagonal-limit selector-budget regular-tail-meet handoff)**.** *Let $K = (R, T, S, D, W, Q, L, H, C,$ be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ packet. Suppose its displayed selector-budget surface is consumed by an accepted $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ shared-threshold packet and then by either an accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ packet or a $\mathsf{Real}^{\uparrow}$ seal consumer. The resulting route factors through the displayed diagonal source, the rows W, D, Q, L, the shared tail-meet threshold, and the structural rows H, C, P, N.*

No accepted handoff may insert a hidden tail selector, quotient stream, host equality, selected limit, countable-choice selector, independent completion object, or ambient completeness row between the diagonal selector budget, the shared threshold, and the finite-tail-filter or Real seal consumer.

Proof. First lock the diagonal source. Apply Definition 646.193 and Definition 646.198. They force every selector-budget consumer to read the displayed diagonal route through W, D, Q, L, H, C, P, N and leave no second route through quotient streams, selected limits, host equality, choice data, independent completion data, ambient completeness, or hidden seal data.

Next read the shared-threshold surface of chapter 560. The regular tail-meet packet supplies the common tail threshold as a displayed finite row, so the selector budget reaches downstream seal consumers only after that threshold has been named in the same finite route.

Finally compose with Definition 646.202. The finite-tail-filter handoff already routes Real-facing and Completion-facing consumers through the displayed selector-budget rows and the finite cofinal-tail packet. With the regular tail-meet threshold placed upstream of that handoff, the composite route has exactly the stated diagonal source, W, D, Q, L, shared threshold, and structural rows, and no hidden selector or ambient completion row remains available. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget regular tail meet handoff`

Theorem 646.204 (Diagonal-limit selector-budget tail-meet pullback exhaustion)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ packet. Suppose the*

displayed selector-budget surface of K is consumed by an accepted RegularCauchyTailMeet$^{\uparrow}$ *packet with shared tail-meet threshold τ, and that the same threshold-facing route is then consumed by an accepted* FiniteTailFilter$^{\uparrow}$ *packet*

$$F = (S_F, D_F, R_F, B_F, Q_F, E_F, H_F, C_F, P_F, N_F).$$

Every Completion$^{\uparrow}$*-facing or* Real$^{\uparrow}$*-facing consumer of this composite packet has exactly one route: the displayed diagonal source of K, the rows W, D, Q, L, the shared threshold τ, the finite-tail-filter rows $S_F, D_F, R_F, B_F, Q_F, E_F, H_F, C_F, P_F, N_F$, and the structural rows H, C, P, N.*

No accepted pullback along this route may add a hidden selector, quotient stream, host equality row, selected limit, countable-choice selector, independent completion datum, second completion source, or ambient completeness witness.

Proof. First lock the diagonal selector source. Apply Definition 646.193 and Definition 646.198. These identify the only downstream selector-budget route as the displayed diagonal source together with W, D, Q, L, H, C, P, N.

Next place the shared threshold on that route. The shared-threshold surface of chapter 560, together with Definition 560.14 and Definition 560.56, makes the threshold τ a displayed finite row reached through the same selector windows and readback rows. A second threshold route would require a hidden selector or an independent tail oracle, neither of which is carried by the accepted packet.

Now attach the finite-tail-filter consumer. By Definition 646.202, Real-facing and Completion-facing consumers of F read the finite packet rows $S_F, D_F, R_F, B_F, Q_F, E_F, H_F, C_F, P_F, N_F$ only through the displayed selector-budget surface W, D, Q, L of K.

Finally compose with Definition 646.203. The regular tail-meet handoff already places τ between the diagonal selector budget and the finite-tail-filter or Real seal consumer. Combining the two handoffs gives one composite route with the diagonal source, W, D, Q, L, the shared threshold, the finite-tail-filter packet rows, and H, C, P, N as its complete coordinate list. Since the source lock and determinacy theorems have no remaining carrier coordinate for quotient streams, host equality, selected limits, countable-choice selectors, independent completion data, second completion sources, or ambient completeness, the pullback route is exhausted. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget tail meet pullback exhaustion`

Theorem 646.205 (Diagonal-limit selector-budget TailCofinalitySchedule pullback)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet, and let $A = (E_A, W_A, D_A, R_A, L_A, H_A, C_A, P_A, N_A)$ be an accepted* TailCofinalitySchedule$^{\uparrow}$ *packet. Suppose the schedule packet consumes the same* StreamName$^{\uparrow}$ *window,* DyadicRatCore$^{\uparrow}$ *ledger,* RegSeqRat$^{\uparrow}$ *readback, and* Real$^{\uparrow}$ *seal rows through the selector-budget surface of K: W_A is supplied by W, D_A by D, R_A by Q, and L_A by L.*

Then every completion-facing or Real-facing consumer of the combined packet factors through the shared finite route

$$W, D, Q, L, H, C, P, N \quad \textit{read as} \quad W_A, D_A, R_A, L_A, H_A, C_A, P_A, N_A.$$

No hidden selector, quotient stream, host equality, selected limit, independent completion datum, ambient completeness witness, or second schedule budget can intervene.

Proof. First lock the diagonal selector source. Apply Definition 646.193 and Definition 646.198. They identify the only selector-budget route as the displayed diagonal source together with W, D, Q, L, H, C, P, N.

Next use Definition 646.204. It removes any alternate tail-facing route between the selector budget, shared threshold, finite-tail packet, and downstream Real or Completion consumer.

Now attach the schedule packet. By Definition 681.3 and Definition 681.9, the accepted $\mathsf{TailCofinalitySchedule}^{\uparrow}$ consumer reads the window, ledger, regular-rational readback, and Real seal through the finite schedule route before the completion seal can be inspected.

The hypotheses identify those schedule rows with W, D, Q, L from K. Hence every combined consumer has the single shared route listed in the statement, and the non-escape clauses from the diagonal selector and schedule boundaries leave no coordinate for a hidden selector, quotient stream, host equality, selected limit, independent completion datum, ambient completeness witness, or second schedule budget. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget tail cofinality schedule pullback`

Theorem 646.206 (Diagonal-limit selector-budget UniformCauchyCriterion terminal pullback)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Let*

$$U = (I_U, W_U, M_U, Q_U, T_U, E_U, H_U, C_U, P_U, N_U)$$

be an accepted finite-family $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *packet whose shared window, dyadic ledger, regular readback, and terminal* $\mathsf{Real}^{\uparrow}$ *seal rows are read through the same selector-budget surface W, D, Q, L of K: the window family W_U is supplied by W, the dyadic tolerance row Q_U is supplied by D, the regular tail readback T_U is supplied by Q, and the terminal seal row E_U is supplied by L.*

Then every terminal $\mathsf{Real}^{\uparrow}$*-facing or* $\mathsf{Completion}^{\uparrow}$*-facing consumer of U factors through the displayed diagonal selector-budget route of K. Conversely, that route supplies the* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RealWindowBudget}^{\uparrow}$*, and* $\mathsf{RealCompletionExactBoundaryUp}$ *faces needed by the* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *terminal envelope:*

$$W, D, Q, L, H, C, P, N \quad \textit{read as} \quad W_U, Q_U, T_U, E_U, H_U, C_U, P_U, N_U.$$

No accepted terminal route may insert quotient streams, host equality, selected limits, choice data, independent completion data, host metric data, ambient completeness, or a second terminal Real or Completion source.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget uniform criterion pullback`

Proof. First lock the diagonal side. Apply Definition 646.193 and Definition 646.198. These identify the only selector-budget route of K as the displayed diagonal source together with W, D, Q, L, H, C, P, N.

Next exclude detached terminal data. By Definition 646.196, any $\mathsf{Real}^{\uparrow}$-facing or $\mathsf{Completion}^{\uparrow}$-facing consumer using that route is exhausted by the same finite packet rows and has no coordinate for quotient streams, selected limits, host equality, choice data, independent completion data, or ambient completeness.

Now attach the finite-family terminal envelope. The seal envelope of Definition 435.108, the completion–Real correspondence of Definition 435.109, and finite-window coverage in Definition 435.111 require the $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, Real-window budget, and exact Real-completion boundary before a terminal consumer can read the seal.

Under the shared W, D, Q, L surface, those UniformCauchyCriterion rows are precisely the selector-budget rows of K together with the structural rows H, C, P, N. Hence every admitted terminal consumer factors through the displayed diagonal route, and reading the same route backward supplies exactly the terminal envelope faces without adding host metric data, an independent completion object, or an ambient completeness principle. □

Theorem 646.207 (Diagonal-limit uniform-criterion terminal uniqueness pullback)**.** *Let* $K = (R, T, S, D, W, Q, L, H, C, P, N)$ *be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Let*

$$U = (I_U, W_U, M_U, Q_U, T_U, E_U, H_U, C_U, P_U, N_U)$$

be an accepted finite-family $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *packet, and let*

$$V = (L_0, L_1, Q_V, S_V, D_V, R_V, V_V, H_V, C_V, P_V, N_V)$$

be an accepted $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet. Suppose the shared selector-budget surface* W, D, Q, L *of* K *supplies the UniformCauchyCriterion rows* W_U, Q_U, T_U, E_U *and also supplies the RealLimitUniquenessSeal rows* S_V, D_V, Q_V, R_V*. Suppose further that the terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of* U *is the consumer handed to the uniqueness seal through the same displayed* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *faces.*

Then that terminal Real or Completion consumer has exactly one finite pullback route: the displayed diagonal selector-budget rows W, D, Q, L, H, C, P, N *of* K*, read as the UniformCauchyCriterion terminal rows and as the RealLimitUniquenessSeal comparison rows. No accepted terminal pullback through this route may add quotient streams, selected limits, host real equality, countable choice, independent completion data, ambient completeness, or a second completion-facing source.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitUniformCriterionTerminalUniquenessPullba`

Proof. First apply Definition 646.206. It places every terminal $\mathsf{Real}^{\uparrow}$-facing or $\mathsf{Completion}^{\uparrow}$-facing consumer of U on the displayed diagonal selector-budget route of K and reads W, D, Q, L, H, C, P, N as the UniformCauchyCriterion terminal surface.

Next apply Definition 646.194. It places the RealLimitUniquenessSeal comparison route on the same displayed selector-budget rows and rules out quotient streams, selected limits, host real equality, countable choice, independent completion data, ambient completeness, and a second completion-facing source.

Finally compare the two consumers. By Definition 646.198, any consumer that uses the selector budget of K is the displayed finite route rather than a parallel route through hidden selector or completion data. By Definition 646.196, a terminal Real or Completion consumer using that route has no remaining coordinate from which an independent completion object, host equality, selected limit, quotient stream, countable-choice selector, ambient completeness witness, or second completion-facing source could be exported. Thus the UniformCauchyCriterion terminal consumer and the uniqueness-seal consumer collapse to the same finite pullback route. □

Theorem 646.208 (Diagonal-limit selector-budget Real and Completion exit route)**.** *Let* $K = (R, T, S, D, W, Q, L, H, C, P, N)$ *be an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Let*

$$U = (I_U, W_U, M_U, Q_U, T_U, E_U, H_U, C_U, P_U, N_U)$$

be an accepted finite-family $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *packet whose window, dyadic tolerance, regular readback, and local* $\mathsf{Real}^{\uparrow}$ *seal rows consume the same* W, D, Q, L *rows of* K*. Then every Phase Real and Completion exit read admitted by* U *factors through the finite surface*

$$R, T, S, D, W, Q, L, H, C, P, N \quad \text{and} \quad I_U, W_U, M_U, Q_U, T_U, E_U, H_U, C_U, P_U, N_U,$$

where the displayed diagonal source supplies the selector-budget route, the DyadicRatCore$^{\uparrow}$ *ledger supplies the tolerance row, the* StreamName$^{\uparrow}$ *family supplies the window row, the* RegSeqRat$^{\uparrow}$ *readback supplies the regular tail row, the local* Real$^{\uparrow}$ *seal supplies the terminal seal row, and the* UniformCauchyCriterion$^{\uparrow}$ *envelope supplies the finite-family terminal boundary.*

The same exit read preserves the structural hsame, Cont, Pkg, *and* NameCert *rows. It has no accepted coordinate for quotient streams, host real equality, selected limits, countable-choice selectors, independent completion data, host metric data, ambient completeness, or a second Real or Completion source.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget uniform real exit`

Proof. First lock the diagonal source. Apply Definition 646.193 and Definition 646.198. These force every Real-facing or Completion-facing read that touches the selector budget to use the displayed diagonal source of K and the rows W, D, Q, L, H, C, P, N.

Next remove escape data from the completion side. Apply Definition 646.196 and Definition 646.206. The first result leaves no coordinate for quotient streams, selected limits, host equality, countable-choice data, independent completion data, or ambient completeness. The second result identifies the UniformCauchyCriterion terminal pullback with the same W, D, Q, L surface.

Now read the terminal envelope facts for UniformCauchyCriterion$^{\uparrow}$. The seal envelope of Definition 435.108, the completion–Real correspondence of Definition 435.109, and finite-window coverage in Definition 435.111 require the StreamName$^{\uparrow}$ window family, DyadicRatCore$^{\uparrow}$ tolerance ledger, RegSeqRat$^{\uparrow}$ tail readback, local Real$^{\uparrow}$ seal, and finite-family terminal boundary before an exit read can reach the public Real or Completion surface.

Finally compose the two boundaries. Under the shared consumption hypothesis, W_U, Q_U, T_U, E_U are the reads of W, D, Q, L, while H_U, C_U, P_U, N_U preserve the same hsame, Cont, Pkg, and NameCert rows as H, C, P, N. Thus every Phase Real and Completion exit read factors through the displayed diagonal source and the finite UniformCauchyCriterion envelope, with no remaining public coordinate for host metric data, ambient completeness, independent completion data, or a second Real or Completion source. □

Theorem 646.209 (Diagonal-limit selector-budget finite-observation coverage)**.** *Let $K = (R, T, S, D, W, Q, L, H, C$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet, and let the terminal Real-and-Completion exit route of K be read through a displayed* FiniteObservationBudgetSelector$^{\uparrow}$ *selector budget*

$$F = (B_F, S_F, W_F, D_F, R_F, E_F, H_F, C_F, P_F, N_F).$$

If the accepted exit route consumes the selector budget of F, then its finite observation surface is exactly the exported selector surface: the budget row B_F, selected schedule S_F, finite StreamName$^{\uparrow}$ *windows W_F,* DyadicRatCore$^{\uparrow}$ *ledger D_F,* RegSeqRat$^{\uparrow}$ *handoff R_F, terminal* Real$^{\uparrow}$ *seal E_F, and the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *rows H_F, C_F, P_F, N_F.*

The same surface is the one consumed by the UniformCauchyCriterion$^{\uparrow}$ *pullback and the* CauchyLimitSeal$^{\uparrow}$ *route. No accepted reader along this terminal route may insert a quotient stream, host real equality, selected host limit, countable-choice selector, ambient completeness witness, metric-completeness row, arithmetic package, order package, or bridge row.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier selector budget finite observation coverage`

Proof. First lock the diagonal source. Apply Definition 646.193. Any terminal Real-and-Completion read that reaches the selector budget of K must pass through the displayed diagonal source and the rows W, D, Q, L, H, C, P, N.

Next identify the selector budget surface. The public export theorem Definition 782.14 exposes exactly the finite route $B_F, S_F, W_F, D_F, R_F, E_F$ together with H_F, C_F, P_F, N_F. The diagonal consumer boundary Definition 782.10 makes that exported surface the one seen by diagonal-limit and Real-completion consumers, and terminal route endpoint exactness Definition 782.29 fixes the terminal endpoint at the displayed seal E_F through the same BHist, hsame, Cont, Pkg, and NameCert rows.

Now compare the downstream readers. The UniformCauchyCriterion pullback Definition 646.206 reads the shared window, dyadic ledger, regular handoff, and Real seal rows through the same selector-budget surface. The CauchyLimitSeal route is a seal-facing reader of the same public selector packet, so the diagonal consumer boundary places it on the exported finite route rather than on an additional completion or bridge coordinate.

Finally apply the Real-and-Completion exit theorem Definition 646.208. Its exclusion list removes quotient streams, host real equality, selected limits, countable-choice selectors, host metric data, ambient completeness, independent completion data, and second Real or Completion sources. Since the public selector export also carries no metric-completeness row, arithmetic package, order package, or bridge row, the terminal route has exactly the finite observation surface listed in the statement. □

Theorem 646.210 (Diagonal-limit selector-budget finite-prefix-budget pullback)**.** *Let $K = (R, T, S, D, W, Q, L, H$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Let*

$$B = (Q_B, B_B, W_B, D_B, R_B, S_B, E_B, H_B, C_B, P_B, N_B)$$

be an accepted FinitePrefixLimitBudget$^{\uparrow}$ *packet whose window, dyadic ledger, regular readback, and terminal seal rows are read through the same selector-budget surface W, D, Q, L of K. Then every Real-and-Completion terminal consumer that passes through B factors through exactly the finite route*

$$W, D, Q, L, H, C, P, N$$

read as

$$W_B, D_B, R_B, S_B, E_B, H_B, C_B, P_B, N_B.$$

No accepted route may insert a quotient stream, host real equality, selected limit, countable-choice selector, ambient Real$^{\uparrow}$ *completeness, metric-completeness row, arithmetic package, order package, or bridge row between the selector-budget surface and the terminal Real or Completion read.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySelectorBudgetFinitePrefixB`

Proof. First lock the diagonal source. Apply Definition 646.193 and Definition 646.198. These force every terminal read that touches the selector budget of K to use the displayed rows W, D, Q, L, H, C, P, N rather than a parallel route through hidden selector data.

Next read the finite-prefix budget side. The seal ordering theorem Definition 919.3 places every seal-facing read behind the ordered route $Q_B \to B_B \to W_B \to D_B \to R_B \to S_B$. The consumer boundary Definition 919.10 and seal-consumer coverage Definition 919.15 say that a Real-facing or completion-facing consumer receives only the finite-prefix rows $Q_B, B_B, W_B, D_B, R_B, S_B, E_B, H_B, C_B, P_B, N_B$.

Under the shared-surface hypothesis, the rows W_B, D_B, R_B, S_B are precisely the finite-prefix read of W, D, Q, L, while E_B, H_B, C_B, P_B, N_B preserve the same exclusion, transport, continuation,

provenance, and local naming boundary as the displayed support rows of K. Compose this identification with Definition 646.208 and Definition 646.209 to obtain the terminal Real-and-Completion surface through the finite selector-budget route.

Finally apply the finite-prefix non-escape theorem Definition 919.12. Its exclusion list matches the diagonal exit exclusions: quotient streams, host real equality, selected limits, countable-choice selectors, hidden terminal data, and ambient completeness are absent. Since neither the selector-budget route nor the finite-prefix budget carrier contains a metric-completeness row, arithmetic package, order package, or bridge row, the pullback is exactly the displayed finite route. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitSelectorBudgetFinitePrefixBudgetPullback`

Theorem 646.211 (DiagonalLimitCompatibility root selector budget lock)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted DiagonalLimitCompatibility$^{\uparrow}$ *packet. Every accepted root-selector packet routes the displayed source budget through the selector row, the seal-synchronizer handoff, the* BHist *inventory, the componentwise* hsame *transports, the displayed* Cont *routes, the* Pkg *provenance row, and the local* NameCert *row before any diagonal-limit read reaches* D, W, Q, L*. No selector read can bypass that route by a host limit, quotient stream, host real equality, chosen completion point, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier root selector budget lock`

Proof. Project the accepted packet through Definition 646.1. The carrier exposes the diagonal source, triangle and selector-facing budget rows, dyadic ledger, stream window, regular readback, Real seal, transport rows, continuation routes, package provenance, and local name as one finite BHist surface.

Apply Definition 646.193. It identifies the selector-budget source with the displayed diagonal route, window row, dyadic ledger, regular readback, Real seal, and structural rows H, C, P, N.

Next use Definition 646.195. The synchronizer is read downstream of the same selector-budget prefix, so the root selector cannot obtain an independent seal source before the diagonal-limit read.

Finally apply Definition 646.153 and Definition 646.156. They place the diagonal-limit consumer on the displayed BHist/hsame/Cont/Pkg/NameCert package and remove every route through host limits, quotient streams, host equality, chosen completion points, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootSelectorBudgetLock`

Theorem 646.212 (DiagonalLimitCompatibility root selector finite-window refinement)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted DiagonalLimitCompatibility$^{\uparrow}$ *packet. Every root-selector read of* K *that reaches a* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *seal refines through the same finite L10 route: the selector-budget source, the* CauchySealBudgetSynchronizer$^{\uparrow}$ *handoff, the* StreamName$^{\uparrow}$ *window* W*, the* RegSeqRat$^{\uparrow}$ *readback* Q*, the* DyadicRatCore$^{\uparrow}$ *ledger* D*, the* Real$^{\uparrow}$ *seal* L*, the* CauchyLimitSeal$^{\uparrow}$ *boundary, and the structural* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. The refined route has no host limit, quotient stream, selected limit, host real equality, countable-choice row, or ambient completeness coordinate.*

Proof. Start with Definition 646.211. It fixes every root-selector read on the displayed selector-budget source and structural rows before the read may inspect D, W, Q, L.

Insert the seal handoff using Definition 646.138. The synchronizer is downstream of the same selector prefix, so the read cannot swap to a second source while moving toward a $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal.

Next apply Definition 646.139. The stream window W, regular-rational readback Q, dyadic ledger D, and Real seal L remain on the finite route that the tail schedule exposes to the seal-facing consumer.

Finally combine Definition 646.213 with Definition 646.140. These results place the $\mathsf{CauchyLimitSeal}^{\uparrow}$ boundary and every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer inside the same package rows $R, T, S, D, W, Q, L, H, C, P, N$, excluding host limits, quotient streams, selected limits, host equality, countable-choice rows, and ambient completeness. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility root selector window refinement`

Theorem 646.213 (DiagonalLimitCompatibility seal budget route exhaustion)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal consumer that reads the selector-budget route factors through the same public route*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The consumer receives the source budget, selector handoff, seal synchronizer, dyadic ledger, stream window, regular readback, Real seal, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows, and it cannot export quotient streams, selected limits, host equality, or ambient completeness.*

Proof. Start with Definition 646.211. It fixes the selector-budget route before a diagonal-limit or seal-facing consumer can inspect the readback rows.

Use Definition 646.196. Every completion-facing or Real-facing consumer that uses the selector-budget route is exhausted by $R, T, S, D, W, Q, L, H, C, P, N$.

Now apply Definition 646.140. The inserted synchronizer and tail-schedule route remain part of the same finite compatibility surface, so no second seal route is available.

The exclusion clause follows from Definition 646.155 and Definition 646.156. The public consumer surface contains only the listed packet rows and has no coordinate for quotient streams, selected limits, host equality, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySealBudgetRouteExhaustion`

Theorem 646.214 (DiagonalLimitCompatibility selector-lock seal route exhaustion)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet. Every accepted selector-budget read of* K *that reaches a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal passes through the root selector lock, the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *handoff, the* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *readback when present, the* $\mathsf{RegSeqRat}^{\uparrow}$ *row* Q*, and the* $\mathsf{Real}^{\uparrow}$ *seal* L *on the same displayed route. The route exports no quotient stream, selected host limit, host real equality, independent seal object, countable-choice row, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySelectorLockSealRouteExhaus`

Proof. First combine Definition 646.211 with Definition 646.213. The first theorem fixes the upstream selector-budget prefix, and the second exhausts every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ seal consumer by the same finite packet $R, T, S, D, W, Q, L, H, C, P, N$.

Next insert the synchronizer with Definition 646.138. It forces the $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ request, seal, budget, selector, compatibility, transport, route, provenance, and local naming rows to be read before Q and L.

When a tail schedule is present, use Definition 646.139. The schedule readback stays on the same route through the finite window row, dyadic ledger, regular-rational readback, and Real seal.

Finally apply Definition 646.140. The composed route exports only the displayed compatibility rows, synchronizer rows, tail-schedule rows, regular-rational readback, and $\mathsf{Real}^{\uparrow}$ seal, so no quotient stream, selected host limit, host equality, independent seal object, countable-choice row, or ambient completeness coordinate can escape it. □

Theorem 646.215 (DiagonalLimitCompatibility root selector window pullback uniqueness)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-selector reads. If the two reads share the same selector-budget source, the same* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *handoff, the same finite* $\mathsf{StreamName}^{\uparrow}$ *window, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, and the same* $\mathsf{Real}^{\uparrow}$ *seal row, then their completion-facing consumer surfaces are the same finite pullback through*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

No quotient stream, selected host limit, host real equality, independent seal object, countable-choice row, or ambient completeness coordinate can distinguish the two reads.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootSelectorWindowPullbackU`

Proof. Start with Definition 646.211. It places both root-selector reads on the same selector-budget source and the same structural route before any consumer can inspect the diagonal ledger, finite window, regular readback, or Real seal.

Next use Definition 646.138 and Definition 646.139. The shared synchronizer handoff and shared finite window force the reads through the same tail-schedule surface, the same Q readback, and the same D, L seal-facing rows.

Apply Definition 646.213 and Definition 646.140. These theorems exhaust every completion-facing or $\mathsf{Real}^{\uparrow}$ consumer by the displayed package rows and exclude all routes through quotient streams, selected host limits, host equality, independent seals, countable choice, or ambient completeness.

The carrier inventory then identifies the public pullback. Since the two reads agree on the source, handoff, window, readback, dyadic ledger, and Real seal rows, and since the only remaining exported rows are H, C, P, N for transport, route, provenance, and local naming of that same packet, the completion-facing surfaces cannot diverge. □

Theorem 646.216 (DiagonalLimitCompatibility completion consumer package)**.** *The root-selector budget lock, the seal-budget route exhaustion row, the root-route budget package, and the seal-source synchronization rows assemble the public completion-facing package for any accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet:*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

This package exposes the displayed source budget, selector handoff, seal synchronizer, diagonal ledger, window, readback, Real seal, BHist, hsame, Cont, Pkg, *and* NameCert *rows, and it exposes no quotient stream, selected limit, host equality, independent completion object, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCompletionConsumerPackage`

Proof. First combine Definition 646.211 with Definition 646.213. The first theorem fixes the upstream selector route, and the second theorem exhausts the downstream $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ seal consumers by the same finite package.

Next use Definition 646.153. It supplies the public route through the budget source, mesh budget, triangle bound, stream window, readback, seal route, Real seal, transport, continuation, provenance, and local naming rows.

Use Definition 646.69 and Definition 646.138. These rows attach the seal source and the synchronizer to the same route before any completion-facing read can consume the seal.

Finally apply Definition 646.48. Since every cited row is a displayed coordinate of the same accepted packet, the assembled package has no route through quotient streams, selected limits, host equality, independent completion data, or ambient completeness. □

Theorem 646.217 (DiagonalLimitCompatibility root selector route determinacy)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packets. Suppose the displayed classifier identifies their selector-budget source,* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *handoff, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal row, and structural* H, C, P, N *rows. Then every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer sees the same finite completion-facing package for the two reads. No quotient stream, selected host limit, host real equality, independent seal, countable-choice row, or ambient completeness coordinate can distinguish them.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootSelectorRouteDeterminac`

Proof. Apply Definition 646.211 to both packets. The lock forces both reads onto the displayed selector prefix before either consumer can inspect the stream window, regular readback, dyadic ledger, or Real seal row.

Next combine Definition 646.212 with Definition 646.213. The shared classifier data keeps the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows on one finite route through the seal-facing package.

Use Definition 646.215. Since the displayed source, handoff, window, readback, ledger, seal, and structural rows agree, the completion-facing pullback surface is identified for the two reads.

Finally apply Definition 646.216. Every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer receives only the finite package $R, T, S, D, W, Q, L, H, C, P, N$, so none of the excluded host or completion coordinates can witness a divergence at the public surface. □

Theorem 646.218 (DiagonalLimitCompatibility selector-budget lock exactness)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packets. The root selector-budget lock classifies* K *and* K' *by the same finite surface exactly when the displayed selector-budget source,* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *handoff,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal row, and structural* H, C, P, N *rows agree componentwise:*

$$K \sim_{\text{root selector budget}} K'$$
$$\iff R \sim R' \text{ and } T \sim T' \text{ and } S \sim S' \text{ and } D \sim D' \text{ and } W \sim W' \text{ and } Q \sim Q' \text{ and } L \sim L' \text{ and } H \sim H' \text{ and } C \sim C$$

Thus the displayed selector-budget, handoff, window, readback, ledger, seal, transport, continuation, provenance, and naming rows are the whole classifier surface for the accepted root read.

Proof. For the forward direction, start with Definition 646.211. The lock prevents the root read from leaving the displayed selector-budget source and structural rows before any downstream consumer inspects the seal-facing coordinates.

Apply Definition 646.215. The shared classifier surface pulls the finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{Real}^{\uparrow}$ seal row back to the same root selector route. Then use Definition 646.213; every $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ read is exhausted by the same finite rows, so no omitted host, quotient, choice, or ambient completeness coordinate can supply an additional classifier distinction.

For the reverse direction, assume the displayed selector-budget source, synchronizer handoff, window, readback, ledger, seal row, and structural H, C, P, N rows agree componentwise. Repack these coordinates as the finite route $R, T, S, D, W, Q, L, H, C, P, N$ for both accepted packets.

Finally invoke Definition 646.217. The repacked route forces the two accepted reads to present the same completion-facing package to every terminal consumer, so the root selector-budget classifier agrees exactly on the displayed rows. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySelectorBudgetLockExactness`

Theorem 646.219 (DiagonalLimitCompatibility selector-budget classifier pullback)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-selector reads. They induce the same completion-facing public classifier exactly when their selector budget,* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *handoff,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal, and structural* H, C, P, N *rows agree componentwise.*

The classifier has no coordinate for quotient stream equality, selected host limits, host real equality, independent seals, countable-choice rows, or ambient completeness.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySelectorBudgetClassifierPul`

Proof. For the forward direction, use Definition 646.211. The accepted root read is locked to the displayed selector-budget source before the synchronizer, stream window, readback, ledger, seal, and structural rows are consumed.

Apply the pullback uniqueness theorem, Definition 646.215. It identifies the finite StreamName window, RegSeqRat readback, DyadicRatCore ledger, and RealUp seal with the same selector route whenever the displayed root surface agrees.

For the reverse direction, assume componentwise agreement of the listed rows. The selector-budget lock exactness theorem repacks those coordinates as the finite route $R, T, S, D, W, Q, L, H, C, P, N$ for both reads, and Definition 646.216 is then the completion-facing package seen by terminal consumers.

Finally use Definition 646.48. Since quotient streams, selected host limits, host real equality, independent seals, choice rows, and ambient completeness are absent from the exported package, none of them can distinguish the two accepted classifier surfaces. □

Theorem 646.220 (DiagonalLimitCompatibility selector-budget terminal pullback)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packets. Suppose the displayed classifier identifies their selector-budget source,* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *handoff, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal row, and structural* H, C, P, N *rows componentwise. Then every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer reads the same finite public pullback package*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The terminal surface cannot distinguish K *from* K' *by quotient stream equality, selected host limits, host real equality, independent seals, countable-choice rows, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySelectorBudgetTerminalPullb`

Proof. Start with Definition 646.219. The assumed componentwise agreement is exactly the classifier surface for the accepted packets, so the two reads present one completion-facing public classifier before any terminal consumer inspects the seal rows.

Next use Definition 646.215. The shared finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{Real}^{\uparrow}$ seal, and structural rows pull both packets back to the same root-selector surface.

Now apply Definition 646.216. Its exported consumer data is precisely the finite package $R, T, S, D, W, Q, L, H, C, P, N$, so the public $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ reads receive the same pullback package from K and K'.

Finally invoke Definition 646.48. Quotient stream equality, selected host limits, host real equality, independent seals, countable-choice rows, and ambient completeness are not exported coordinates of that package. Hence no terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer can separate the accepted packets at the public surface. □

Theorem 646.221 (DiagonalLimitCompatibility terminal readback determinacy)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-selector reads. Suppose the displayed classifier identifies their selector-budget source,* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *handoff, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal row, and structural* H, C, P, N *rows. Then every* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Completion}^{\uparrow}$*, or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *terminal read receives the same finite readback package*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

No terminal consumer can distinguish the two reads by quotient streams, selected host limits, host real equality, countable-choice data, or ambient completeness.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibility terminal readback determinacy`

Proof. First apply Definition 646.217. It identifies the two accepted root-selector reads on the displayed selector budget, synchronizer handoff, finite window, regular readback, dyadic ledger, Real seal row, and structural transport, route, provenance, and naming rows.

Next use Definition 646.215. The shared window, readback, ledger, and seal rows pull both reads back to the same finite completion-facing surface, so the terminal read cannot obtain a second public package by changing the window or readback representative.

Apply Definition 646.213. The $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ terminal consumers are exhausted by the same route through $R, T, S, D, W, Q, L, H, C, P, N$, and the $\mathsf{CauchyLimitSeal}^{\uparrow}$ boundary is already part of that seal-facing route.

Finally invoke Definition 646.216. The only exported readback package is the displayed finite package, so quotient streams, selected host limits, host real equality, countable-choice data, and ambient completeness have no coordinate by which to separate the two terminal reads. □

Theorem 646.222 (DiagonalLimitCompatibility selector window tail seal bridge)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-selector reads. Suppose the displayed classifier identifies their selector-budget source,* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *handoff, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, tail-schedule readback whenever a terminal tail row is present,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary,* $\mathsf{Real}^{\uparrow}$ *seal row, and structural* H, C, P, N *rows. Then every* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Completion}^{\uparrow}$*, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *terminal consumer receives one finite terminal package*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The selector window, synchronizer handoff, tail schedule, Cauchy limit boundary, and Real seal cannot be read as separate terminal classifier coordinates.

Proof. First apply Definition 646.212. The selector-budget source and synchronizer handoff place the finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{Real}^{\uparrow}$ seal row on the same displayed root route.

Next use Definition 646.214. This makes the seal-facing route exhaustive for the accepted packets, so the $\mathsf{CauchyLimitSeal}^{\uparrow}$ boundary and any present tail-schedule readback are consumed through the same finite route instead of a separate terminal channel.

Apply Definition 646.215. Since the selector window, readback, ledger, seal, boundary, and structural rows agree, both terminal reads pull back to one completion-facing surface.

Now invoke Definition 646.221. The terminal readback for $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumers is already the displayed package $R, T, S, D, W, Q, L, H, C, P, N$.

Finally use Definition 646.216. Its consumer inventory exports exactly that finite package, so the tail schedule, limit-seal boundary, Real seal row, and completion consumer receive the same terminal data. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySelectorWindowTailSealBridg`

Theorem 646.223 (DiagonalLimitCompatibility terminal tail-rebase exactness)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-selector reads. Suppose the displayed classifier identifies their selector-budget source,* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *handoff, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{Real}^{\uparrow}$ *seal row, and structural* H, C, P, N *rows. Then every terminal read obtained after a tail rebase exposes exactly the same finite package*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The tail rebase has no coordinate for quotient streams, selected host limits, host real equality, countable-choice data, or ambient completeness.

Proof. First apply Definition 646.221. The shared selector-budget source, synchronizer handoff, window, readback, ledger, seal row, and structural rows already determine the finite terminal readback package for $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumers.

Next use Definition 646.218. This identifies the classifier equality with equality of the displayed finite rows, so a tail rebase cannot introduce another selector-budget source, handoff, window, readback, ledger, seal, or structural row at the terminal boundary.

Apply Definition 646.215. The finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{Real}^{\uparrow}$ seal row pull the rebased read back to the same root selector surface.

Finally invoke Definition 646.216. The exported consumer package is exactly $R, T, S, D, W, Q, L, H, C, P, N$, and the package inventory omits quotient streams, selected host limits, host equality, countable choice, and ambient completeness. Therefore the tail rebase has no public coordinate by which to change the terminal package. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityTerminalTailRebaseExactness`

Theorem 646.224 (DiagonalLimitCompatibility selector-budget terminal classifier)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-selector read. The terminal classifier exported to* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{Completion}^{\uparrow}$*, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumers is the single displayed package whose source is*

the selector-budget row R, whose finite window is the $\mathsf{StreamName}^{\uparrow}$ *row S, whose rational readback is the* $\mathsf{RegSeqRat}^{\uparrow}$ *row T, whose dyadic ledger is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *row D, whose synchronizer handoff is the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row Q, and whose seal-facing endpoint is the* $\mathsf{Real}^{\uparrow}$ *row L. No terminal consumer may read these rows as independent classifier coordinates.*

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySelectorBudgetTerminalClass`

Proof. First apply Definition 646.212. It places the selector-budget source, finite stream window, regular rational readback, dyadic ledger, synchronizer handoff, and Real seal on one root-selector route.

Next use Definition 646.218. The classifier equality is equality of the displayed finite rows, so the terminal classifier cannot split R, T, S, D, Q, L into unrelated coordinates.

Apply Definition 646.221. The terminal readback for $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumers is already the package $R, T, S, D, W, Q, L, H, C, P, N$.

Finally invoke Definition 646.216. It exports the same finite package to completion-facing readers, so the terminal classifier is the displayed selector-budget package rather than a host-side limit selector. □

Theorem 646.225 (DiagonalLimitCompatibility terminal synchronizer classifier)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *root-selector read. The terminal classifier exported from K to* $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, *and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *is the single finite L10 package whose selector-budget source is R, whose synchronizer handoff is Q, whose finite* $\mathsf{StreamName}^{\uparrow}$ *window is S, whose* $\mathsf{RegSeqRat}^{\uparrow}$ *readback is T, whose* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger is D, whose* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary is W, whose* $\mathsf{Real}^{\uparrow}$ *seal is L, and whose structural rows are H, C, P, N.*

The synchronizer handoff and the Cauchy-limit boundary therefore agree componentwise with the same displayed package read by the Real and completion consumers. No quotient stream, selected host limit, countable-choice row, ambient completeness coordinate, or second terminal classifier participates in the exported surface.

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityTerminalSynchronizerClassif`

Proof. Begin with Definition 646.224. It identifies the terminal classifier as the displayed selector-budget package rather than as independent Real, completion, or limit-seal coordinates.

Apply Definition 646.222. The finite window, regular readback, dyadic ledger, synchronizer handoff, Cauchy-limit boundary, Real seal, and structural rows are read through the same terminal package.

Next use Definition 646.221. Once those rows are componentwise fixed, every $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ terminal read receives $R, T, S, D, W, Q, L, H, C, P, N$ and no alternate readback surface.

Finally invoke Definition 646.226. The route inventory omits quotient streams, selected host limits, countable choice, and ambient completeness, so the synchronizer and Cauchy-limit rows remain bound to the same finite L10 package exported by K. □

Theorem 646.226 (DiagonalLimitCompatibility Real completion route non-escape)**.** *Every* DiagonalLimitCompati *route from a selector-budget root read to a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer factors through the finite* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$, *and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows displayed in*

$$K = (R, T, S, D, W, Q, L, H, C, P, N).$$

The route has no coordinate for a host-selected real limit, quotient stream equality, countable-choice data, ambient completeness, or a completion consumer that bypasses the selector-budget classifier.

Proof. Begin with Definition 646.224. The terminal classifier presented to the Real and completion consumers is the single finite selector-budget package.

Use Definition 646.223. A tail rebase preserves the same finite package and does not create quotient streams, selected host limits, host real equality, countable-choice data, or ambient completeness.

Next apply Definition 646.214. The seal-facing route is exhausted by the displayed stream, rational, dyadic, synchronizer, limit-seal, and Real rows.

Finally invoke Definition 646.216. Completion consumers receive only the displayed package, so any route bypassing the selector-budget classifier is outside the accepted DiagonalLimitCompatibility$^{\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCarrier real completion route nonescape`

Theorem 646.227 (DiagonalLimitCompatibility tail-seal synchronizer pullback)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

and

$$K' = (R', T', S', D', W', Q', L', H', C', P', N')$$

be accepted DiagonalLimitCompatibility$^{\uparrow}$ *root-selector reads whose terminal classifiers agree on selector budget,* StreamName$^{\uparrow}$ *window,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *ledger,* CauchySealBudgetSynchronizer$^{\uparrow}$ *handoff,* CauchyLimitSeal$^{\uparrow}$ *boundary,* Real$^{\uparrow}$ *seal, and structural rows. Then their tail-seal synchronizer reads pull back to the same finite selector-budget package, so every* CauchySealBudgetSynchronizer$^{\uparrow}$ *and* Real$^{\uparrow}$ *consumer reads the same terminal package*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityTailSealSynchronizerPullbac`

Proof. First use Definition 646.224. Agreement of the terminal classifiers is agreement of the displayed selector-budget, stream, rational, dyadic, synchronizer, limit-seal, Real, and structural rows.

Apply Definition 646.215. The common StreamName$^{\uparrow}$ window, RegSeqRat$^{\uparrow}$ readback, DyadicRatCore$^{\uparrow}$ ledger, and Real$^{\uparrow}$ seal pull both reads back to one root-selector surface.

Next invoke Definition 646.221. The terminal readback is determined by that shared finite package for Real, completion, and limit-seal consumers.

Finally use Definition 646.223. Tail rebase preserves the terminal package, so the synchronizer handoff and seal read cannot diverge after the pullback. □

Theorem 646.228 (DiagonalLimitCompatibility selector-budget common-refinement terminality)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted DiagonalLimitCompatibility$^{\uparrow}$ *root-selector read. Suppose its selector-budget row agrees simultaneously with the* CauchyCriterion$^{\uparrow}$ *selector-seal route and with the* UniformCauchyCriterion$^{\uparrow}$ *finite-family Real/Completion window. Then the common refinement has a unique terminal finite package through* StreamName$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*,* DyadicRatCore$^{\uparrow}$*,* CauchySealBudgetSynchronizer$^{\uparrow}$*,*

CauchyLimitSeal$^{\uparrow}$, *and* Real$^{\uparrow}$. *No quotient stream, selected host limit, countable-choice row, ambient completeness assertion, or independent completion object can distinguish the consumer route.*

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilitySelectorBudgetCommonRefinem

Proof. Begin with the local selector-budget terminal classifier of Definition 646.224. It identifies the terminal classifier as the single displayed selector-budget package rather than as a family of independent Real, completion, or limit-seal coordinates.

Use the tail-seal synchronizer pullback of Definition 646.227. Agreement of the selector budget with the synchronizer and seal rows pulls the CauchySealBudgetSynchronizer$^{\uparrow}$ and Real$^{\uparrow}$ consumer reads back to the same finite root-selector package.

Now read the cross-chapter inputs through their displayed routes. The CauchyCriterion$^{\uparrow}$ diagonal selector terminality supplies the same selector-seal route, while the UniformCauchyCriterion$^{\uparrow}$ Real-completion window exhaustion supplies the finite-family window consumed by Real and completion readers.

Finally apply the local Real completion route non-escape theorem, Definition 646.226. Since every accepted Real or completion consumer route factors through the displayed stream, rational, dyadic, synchronizer, limit-seal, and Real rows, there is no remaining coordinate by which a quotient stream, host-selected limit, choice row, ambient completeness assertion, or independent completion object can separate the common-refinement route. □

Theorem 646.229 (DiagonalLimitCompatibility criterion-uniform seal pullback)**.** *Let*

$$K = (R, T, S, D, W, Q, L, H, C, P, N)$$

be an accepted DiagonalLimitCompatibility$^{\uparrow}$ *root-selector read. Suppose the selector-budget row of K agrees with the* CauchyCriterion$^{\uparrow}$ *selector-seal route and also agrees with the* UniformCauchyCriterion$^{\uparrow}$ *finite-family Real/Completion window. Then the two consumers pull back to the same finite seal package through* StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, CauchySealBudgetSynchronizer$^{\uparrow}$, CauchyLimitSeal$^{\uparrow}$, *and* Real$^{\uparrow}$.

The shared package is exactly the displayed $R, T, S, D, W, Q, L, H, C, P, N$ read of K. No quotient stream, selected host limit, countable-choice row, ambient completeness assertion, or independent completion object separates the CauchyCriterion and UniformCauchyCriterion consumers.

Lean4 ✓ BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityCriterionUniformSealPullbac

Proof. Start with the local terminal classifier, Definition 646.224. It identifies the selector-budget read of K with the single displayed package rather than with separate criterion, uniform-family, Real, or completion coordinates.

Next apply the tail-seal synchronizer pullback, Definition 646.227. The common selector-budget row carries the CauchySealBudgetSynchronizer$^{\uparrow}$, CauchyLimitSeal$^{\uparrow}$, and Real$^{\uparrow}$ reads back to the same finite package.

Now use common-refinement terminality, Definition 646.228. The CauchyCriterion$^{\uparrow}$ selector-seal route and the UniformCauchyCriterion$^{\uparrow}$ finite-family Real/Completion window therefore meet at the same terminal refinement through the stream, rational, dyadic, synchronizer, limit-seal, and Real rows.

Finally invoke Real completion route non-escape, Definition 646.226. Since the accepted route inventory has no coordinate for quotient streams, host-selected limits, choice rows, ambient completeness, or detached completion objects, the two criterion consumers have no public path away from the displayed seal package. □

Theorem 646.230 (Diagonal-limit compatibility root-request coverage)**.** *Let $K = (R, T, S, D, W, Q, L, H, C, P, N)$ be an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet. Every root request served by K reads the RealCompleteness packet row, the regular-Cauchy triangle-bound row, the* DyadicRatCore$^{\uparrow}$ *ledger row, the* StreamName$^{\uparrow}$ *window row, the* RegSeqRat$^{\uparrow}$ *readback row, and the* Real$^{\uparrow}$ *seal row through the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *route. No root request receives a hidden completeness witness, host real equality, quotient stream, selected limit, or second dyadic ledger outside those rows.*

Proof. Start with the carrier projection of Definition 646.1. The packet coordinates display the diagonal source, transport row, selector row, dyadic ledger, StreamName window, RegSeqRat readback, Real seal, componentwise transport, continuation route, package provenance, and local name.

Apply Definition 646.2. The local certificate surface forces any accepted root request to read carrier admission, route replay, provenance, and local naming through the same rows.

Now use Definition 646.79, Definition 646.81, and Definition 646.82. These isolate the RealCompleteness packet, triangle-bound row, dyadic ledger, StreamName window, RegSeqRat readback, and Real seal as one displayed route before the root request reaches a consumer.

Finally apply Definition 646.83. Since the carrier contains no hidden completeness witness, host equality, quotient stream, selected limit, or alternate ledger coordinate, none can be exported by the root request. □

Lean4 ✓ `BEDC.Derived.Diagonallimitcompatibilityup.DiagonalLimitCompatibilityRootRequestCoverage`

Theorem 646.231 (Diagonal-limit compatibility root-selector lock)**.** *For an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet $K = (R, T, S, D, W, Q, L, H, C, P, N)$, a selector read on the root-request route cannot choose a second StreamName window or dyadic ledger outside the displayed* BHist/hsame/Cont/Pkg/NameCert *path. The selector is locked to the route that reads D, then W, then Q, then L, with H, C, P, N providing only transport, replay, provenance, and naming for that route.*

Proof. Project the accepted packet through Definition 646.1. There is one dyadic ledger coordinate D and one StreamName window coordinate W available to the selector row.

Use Definition 646.230 to place every root request on the same RealCompleteness, triangle-bound, dyadic, window, readback, and seal route. The selector therefore reads the displayed D, W, Q, L sequence before any downstream completion-facing consumer sees the packet.

Apply Definition 646.100 and Definition 646.193. These theorems exhaust selector-budget reads by the listed carrier coordinates and rule out an unlisted budget source or hidden selector input.

The transport and provenance rows H, C, P, N do not introduce another window or ledger; they only replay and name the displayed route. Thus the root selector is locked to the finite path already present in the carrier. □

Lean4 ✓ `BEDC.Derived.Diagonallimitcompatibilityup.DiagonalLimitCompatibilityRootSelectorLock`

Theorem 646.232 (Diagonal-limit compatibility root-seal package)**.** *The root-request rows of an accepted* DiagonalLimitCompatibility$^{\uparrow}$ *packet repack as the downstream* CauchyLimitSeal$^{\uparrow}$/Real$^{\uparrow}$ *consumer package*

$$R, T, S, D, W, Q, L, H, C, P, N.$$

The package exposes the RealCompleteness packet, triangle-bound row, dyadic ledger, StreamName window, RegSeqRat readback, Real seal, and the displayed route/name rows, and it exposes no separate completeness principle, quotient stream, host real equality, selected limit, or hidden selector route.

Proof. First combine Definition 646.230 with Definition 646.231. They fix the root-request route and prevent a second selector window or dyadic ledger from entering the package.

Next apply Definition 646.153. The same displayed rows already form the route-budget package consumed by downstream completion and seal surfaces.

Use Definition 646.101 and Definition 646.196. The RegSeqRat readback and Real seal are consumed only through D, W, Q, L, H, C, P, N, so a $\mathsf{CauchyLimitSeal}^{\uparrow}/\mathsf{Real}^{\uparrow}$ consumer receives the repacked finite route rather than a second source.

The exclusion clause follows by coordinate exhaustion from the carrier and the cited non-escape theorems. Nothing in $R, T, S, D, W, Q, L, H, C, P, N$ can project a separate completeness principle, quotient stream, host real equality, selected limit, or hidden selector route. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootSealPackage`

Theorem 646.233 (Diagonal-limit compatibility root request-selector exhaustion)**.** *For an accepted* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet* $K = (R, T, S, D, W, Q, L, H, C, P, N)$*, every* $\mathsf{Real}^{\uparrow}$*- or completion-facing consumer of the root-request row must pass through the root-request coverage row, the selector lock row, and the root-seal package row before reading any seal-budget endpoint or selected-tail endpoint. The route exports only displayed* BHist *request rows, selector-budget rows,* hsame *transports,* Cont *replays,* Pkg *provenance, and* NameCert *rows, and it exports no selected real, quotient stream equality, host limit, or ambient completeness principle.*

Proof. First apply Definition 646.230. It exposes the root request through the RealCompleteness packet, triangle-bound row, dyadic ledger, StreamName window, RegSeqRat readback, Real seal, and displayed structural rows.

Next apply Definition 646.231. The selector is forced to use the same displayed D, W, Q, L path, so no second window, dyadic ledger, selected-tail source, or hidden selector input can be inserted before a consumer reads the route.

Finally apply Definition 646.232. The seal-facing package repacks exactly the exposed request and selector rows for downstream $\mathsf{CauchyLimitSeal}^{\uparrow}/\mathsf{Real}^{\uparrow}$ use.

The exclusion clause is coordinate exhaustion. The accepted packet contains request rows, selector-budget rows, transports, continuation replays, provenance, and local naming rows, but it contains no selected real, quotient stream equality, host limit, or ambient completeness principle to export. □

Lean4 ✓ `BEDC.Derived.DiagonallimitcompatibilityUp.DiagonalLimitCompatibilityRootRequestSelectorPackage`

Chapter 647

A Concrete Naming Certificate for $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$

The $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ surface packages comparison between two observers as a finite public certificate. Each observer keeps its own universe-for-observer row; the classifier compares only the displayed rows that pass through locality cells, GAP commitments, hsame transports, Cont routes, Pkg provenance, and the local naming row. It is not a global view over both worlds.

The packet consumes chapter 578 for the two observer-state rows O_0, O_1. Its locality evidence is read from the public cell surfaces of chapter 509 or chapter 513, and the comparison is checked against the public alignment surface of chapter 643 rather than against an ambient shared world.

Definition 647.1 (Observer-perspective-classifier carrier)**.** *An* $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$$

with the following displayed rows:

1. *O_0 and O_1 are accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *rows naming the two conscious-observer state surfaces being compared;*
2. *U_0 and U_1 are the two universe-for-observer record surfaces, each read only as the records and closure rules accumulated by the corresponding observer row;*
3. *L is the locality-cell evidence row, displayed as a* $\mathsf{LocalityCell}^{\uparrow}$ *or* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *public coordination surface for the two observer rows;*
4. *G is the paired* GAP *commitment ledger recording the two-sided coherence commitments by which U_0 and U_1 can be compared without identifying them as one host world;*
5. *H records componentwise* hsame *transports for O_0, O_1, U_0, U_1, L, G and for the package and local naming rows;*
6. *C records the displayed* Cont *routes that let a consumer read each observer row, its universe-for-observer surface, the locality-cell evidence, and the paired* GAP *commitments in that order;*
7. *P is the* Pkg *provenance over* $\mathsf{ConsciousObserverState}^{\uparrow}$*, universe-for-observer record surfaces,* $\mathsf{LocalityCell}^{\uparrow}$*,* $\mathsf{ObserverLocalityCell}^{\uparrow}$*,* GAP *ledgers,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverPerspectiveClassifier}^{\uparrow}}$ *row.*

The classifier compares two accepted carriers only through the displayed rows $O_0, O_1, U_0, U_1, L, G, H, C, P, N$ and their recorded transports and routes.

Lean4 (definition) `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierCarrier`

Theorem 647.2 (ObserverPerspectiveClassifier NameCert obligations)**.** *For the carrier of Definition 647.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverPerspectiveClassifier}^{\uparrow}}$ *surface has exactly five obligation rows: carrier exposure for $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$; observer anchoring through O_0, O_1; universe-for-observer exposure through U_0, U_1; locality and coherence comparison through L, G, H, C; and non-escape from a god's-eye observer, host equality of worlds, private* Self *access, global spacetime carriers, hidden synchronization maps, and unrecorded cross-perspective evidence.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierNameCertObligations`

Proof. Carrier exposure is projection from the finite packet $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$.

Observer anchoring is read from O_0 and O_1. Universe-for-observer exposure is read from U_0 and U_1, with each universe surface attached to its own observer row.

The comparison obligation is then read from L, G, H, C. The locality-cell row L supplies the public coordination surface, the paired GAP ledger G records the coherence commitments, the transport row H moves only displayed coordinates, and the continuation row C replays only the displayed reading order.

Finally inspect the carrier list. No coordinate names a god's-eye observer, host equality of the two worlds, private Self access, global spacetime carrier, hidden synchronization map, or unrecorded evidence row, so none of those objects is exported by the local naming surface. □

Theorem 647.3 (ObserverPerspectiveClassifier locality-cell comparison)**.** *Every accepted* ObserverPerspectiveClass *packet compares U_0 and U_1 only after the observer rows O_0, O_1, the locality-cell evidence L, and the paired* GAP *commitments G have been displayed in the same finite carrier. A consumer may classify the two perspectives through H and C, but it cannot replace the locality-cell comparison by a single ambient world, a shared external spacetime, or direct access to either observer's private* Self *row.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierLocalityCellComparis`

Proof. Project the accepted packet and read the two observer rows O_0, O_1 together with their universe-for-observer surfaces U_0, U_1.

The classifier is not applied to those universe surfaces in isolation. It first uses the locality-cell evidence L and the paired GAP ledger G, then replays those rows through the displayed transports H and continuations C.

Since the packet contains no ambient world coordinate, shared external spacetime row, or private Self coordinate, the comparison remains a finite locality-cell comparison between displayed observer perspectives. □

Theorem 647.4 (ObserverPerspectiveClassifier ledger exactness)**.** *Every public read exported by an accepted* $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ *carrier factors through the finite ledger*

$$O_0, O_1, U_0, U_1, L, G, H, C, P, N.$$

The ledger is exact: observer rows, universe-for-observer surfaces, locality-cell evidence, paired GAP *commitments, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *row are available, and no other comparison primitive is available.*

Lean4 ✓ BEDC.Derived.Observerperspectiveclassifier Up.ObserverPerspectiveClassifierLedgerExactness

Proof. The carrier definition displays all rows of the packet. The mathematical comparison data are O_0, O_1, U_0, U_1, L, G, and the structural data are H, C, P, N.

Any consumer read must pass through the displayed continuation routes in C. Those routes expose the two observer rows, their universe surfaces, the locality evidence, and the paired commitments before the package and naming rows are read.

There is no remaining coordinate for a second comparison primitive. Thus every exported read factors through the listed ledger and the ledger is exact for public consumers. □

Theorem 647.5 (ObserverPerspectiveClassifier non-escape boundary)**.** *An accepted* ObserverPerspectiveClassifier$^{\uparrow}$ *carrier exports only the two conscious-observer state rows, the two universe-for-observer record surfaces, the locality-cell evidence row, the paired* GAP *commitment ledger, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *row. It exports no god's-eye observer, no host equality of worlds, no private* Self *access, and no global spacetime carrier.*

Proof. Inspect the carrier coordinates of Definition 647.1. Every exported row is one of $O_0, O_1, U_0, U_1, L, G, H, C, P,$

The positive comparison data remain public and finite: observer rows, universe-for-observer surfaces, locality-cell evidence, and paired GAP commitments. The rows H, C, P, N transport, route, package, and name those same displayed coordinates.

No listed coordinate is a god's-eye observer, a host equality witness between worlds, a private Self row, or a global spacetime carrier. Therefore an accepted classifier cannot export any of those objects. □

Lean4 ✓ BEDC.Derived.Observerperspectiveclassifier Up.ObserverPerspectiveClassifierNonescape

Theorem 647.6 (ObserverPerspectiveClassifier anchor-change stability)**.** *In an accepted* ObserverPerspectiveClassif *carrier, changing the observer anchor from the O_0 side to the O_1 side, or from the O_1 side to the O_0 side, preserves a comparison verdict only through the displayed rows*

$$O_0, O_1, U_0, U_1, L, G, H, C, P, N.$$

The stability route may use the two observer rows, the two universe-for-observer surfaces, locality evidence, paired GAP *commitments, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *row, but it cannot pass through a privileged observer or any unlisted observer-neutral witness.*

Proof. Apply the carrier description in Definition 647.1. The only named anchors are O_0 and O_1, and each universe-for-observer surface is attached to one of those rows.

Apply the obligation theorem Definition 647.2. Anchor comparison is part of the finite local naming surface, so an anchor change must be replayed through the displayed locality, commitment, transport, continuation, package, and naming rows.

The locality comparison theorem Definition 647.3 supplies the admissible comparison route, while Definition 647.4 says that the ledger has no further comparison coordinate. Finally Definition 647.5 rules out a god's-eye observer and any unlisted observer-neutral witness, so the comparison is stable only through the displayed packet rows. □

Lean4 ✓ BEDC.Derived.Observerperspectiveclassifier Up.ObserverPerspectiveClassifierAnchorChangeStability

Theorem 647.7 (ObserverPerspectiveClassifier GAP commitment readback)**.** *Every cross-perspective comparison exported by an accepted* ObserverPerspectiveClassifier$^{\uparrow}$ *carrier reads the paired* GAP *row G before it exports a comparison verdict. A verdict based only on O_0, O_1, U_0, U_1 or only on the locality row L is not a public classifier verdict for this carrier.*

Proof. The carrier in Definition 647.1 displays G as the paired commitment ledger by which U_0 and U_1 can be compared without identifying them as one host world.

By Definition 647.2, the comparison obligation is not just observer exposure or universe exposure; it is the locality and coherence comparison through L, G, H, C. The locality-cell comparison theorem Definition 647.3 makes the same ordering explicit: the classifier compares after the observer rows, the locality-cell evidence, and the paired GAP commitments have been displayed in the same finite carrier.

The exactness theorem Definition 647.4 then prevents a consumer from dropping G while still claiming the public verdict. The non-escape theorem Definition 647.5 prevents replacing G by hidden synchronization or host equality, so the paired commitment row must be read before the verdict is exported. □

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierGapCommitmentReadback`

Theorem 647.8 (ObserverPerspectiveClassifier comparison-route totality)**.** *Every accepted comparison route for an* ObserverPerspectiveClassifier$^{\uparrow}$ *carrier factors through all of the public classifier layers: observer rows O_0, O_1, universe-for-observer surfaces U_0, U_1, locality evidence L, paired* GAP *commitments G, componentwise* hsame *transports H, displayed* Cont *routes C,* Pkg *provenance P, and the local* NameCert *row N.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierComparisonRouteTotali`

Proof. Start with the finite packet in Definition 647.1. Its displayed rows already enumerate the observer, universe, locality, commitment, transport, continuation, provenance, and naming layers.

Apply Definition 647.2 to read those layers as the local naming obligations. Apply Definition 647.3 to place the comparison after the observer rows, universe surfaces, locality evidence, and paired commitment ledger.

It remains to account for transport, routing, provenance, and local naming. The exactness theorem Definition 647.4 says that public reads factor through H, C, P, N after the mathematical comparison rows, and Definition 647.5 says that no hidden comparison route remains outside this finite list. Hence every accepted comparison route factors through the stated public classifier layers. □

Theorem 647.9 (ObserverPerspectiveClassifier state totality)**.** *Every accepted public verdict for an* ObserverPerspectiveClassifier$^{\uparrow}$ *carrier exposes both* ConsciousObserverState$^{\uparrow}$ *rows O_0, O_1 and their universe-for-observer surfaces U_0, U_1 before the verdict is public. In particular, a row that exports a comparison verdict without first displaying the two observer-state rows and the two attached universe surfaces is not an accepted classifier verdict for the carrier $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierStateTotality`

Proof. Unpack the carrier tuple of Definition 647.1. Its first four displayed comparison rows are exactly O_0, O_1, U_0, U_1, with O_0, O_1 naming the two conscious-observer state surfaces and U_0, U_1 naming the corresponding universe-for-observer surfaces.

The exactness theorem Definition 647.4 says that every public read exported by an accepted carrier factors through the finite ledger. The comparison-route totality theorem Definition 647.8

then orders any accepted comparison route through observer rows, universe surfaces, locality evidence, paired commitments, transports, routes, provenance, and local naming.

Finally Definition 647.5 rules out replacing those displayed rows by a god's-eye observer, host equality, private Self access, or a global spacetime carrier. Hence a public verdict must expose both observer-state rows and both universe-for-observer surfaces before it exports the classifier verdict. □

Theorem 647.10 (ObserverPerspectiveClassifier locality refinement)**.** *Let $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$ be an accepted* ObserverPerspectiveClassifier$^{\uparrow}$ *carrier. If a locality-cell row L' refines the displayed locality evidence L and the same paired* GAP *row G is transported with L' through the recorded* hsame *row, the displayed* Cont *routes, and the* Pkg *provenance, then the public comparison route is the same accepted route with L' in the locality coordinate. No public consumer gains an additional comparison primitive by refining L in this way.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierLocalityRefinement`

Proof. Begin with the carrier definition. The locality coordinate and the paired commitment coordinate occur as the adjacent public comparison rows L, G, while H, C, P record the componentwise transports, displayed reading routes, and provenance for those same rows.

The ledger exactness theorem Definition 647.4 makes the route exact: a public read may use the observer rows, universe surfaces, locality row, paired commitment row, transports, continuations, provenance, and the local naming row, and no further comparison coordinate is available.

Transporting the refined row L' together with the same G through H, C, P therefore changes only the displayed locality coordinate. The route still passes through the same ordered classifier layers by Definition 647.8.

The non-escape theorem Definition 647.5 prevents the refinement from introducing a hidden synchronization map, host equality, or observer-neutral witness. Thus the public comparison route is preserved with L' in the locality coordinate. □

Theorem 647.11 (ObserverPerspectiveClassifier perspective stability)**.** *For an accepted* ObserverPerspectiveClassif *carrier $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$, swapping the two observer perspectives preserves acceptedness exactly for the carrier whose observer rows, universe-for-observer surfaces, locality row, paired* GAP *row,* hsame *transports,* Cont *routes,* Pkg *provenance, comparison route, and local* NameCert *row are swapped together. Swapping only one face of the carrier is not an accepted public perspective swap.*

Proof. First unpack the finite carrier tuple. The observer faces are not isolated parameters: O_0, O_1 are paired with U_0, U_1, and the comparison is witnessed through the locality row L, the paired commitment row G, the transport row H, the continuation row C, the provenance row P, and the local naming row N.

For the forward direction, assume the public perspective swap is accepted. By Definition 647.9, both observer-state rows and both universe-for-observer surfaces must be exposed before the verdict. By Definition 647.8, the accepted route also carries the locality, commitment, transport, continuation, provenance, and naming layers, so those layers must travel with the swapped perspectives.

For the reverse direction, swap the two observer rows together with their universe surfaces and carry the locality row, paired GAP row, hsame transports, Cont routes, Pkg provenance, comparison route, and local NameCert row through the same finite ledger positions. The carrier definition still displays a tuple of the required form, and Definition 647.4 supplies the same public readback surface.

It remains to exclude partial swaps. The non-escape theorem Definition 647.5 rules out any unlisted observer-neutral witness that could repair a swap of only one face. Hence acceptedness is preserved exactly when the paired observer rows, universe surfaces, locality evidence, paired commitment row, transports, routes, provenance, comparison route, and local naming row are swapped together. □

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierPerspectiveStability`

Theorem 647.12 (ObserverPerspectiveClassifier dependency scope)**.** *The accepted dependency scope of an* ObserverPerspectiveClassifier$^{\uparrow}$ *carrier is exactly the finite public row family supplied by* ConsciousObserverState$^{\uparrow}$, LocalityCell$^{\uparrow}$ *or* ObserverLocalityCell$^{\uparrow}$, CrossPerspectiveAlignment$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert. *The classifier has no dependency on an ambient world row, host equality between worlds, private* Self *access, global spacetime carrier, hidden synchronization map, or unrecorded cross-perspective evidence.*

Proof. Project the carrier of Definition 647.1. Its comparison rows are the two conscious-observer state rows, the two universe-for-observer surfaces, the locality-cell row, and the paired GAP row; its structural rows are the BHist packet, hsame transports, Cont routes, Pkg provenance, and local NameCert row.

Apply Definition 647.3 and Definition 647.7. They force any comparison to pass through the displayed locality evidence, paired commitment ledger, and recorded alignment surface rather than through a shared ambient world.

Finally apply Definition 647.4 and Definition 647.5. Exactness says no other comparison primitive is available, and non-escape excludes ambient world rows, host equality, private Self access, global spacetime carriers, hidden synchronization maps, and unrecorded evidence. □

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierDependencyScope`

Theorem 647.13 (ObserverPerspectiveClassifier alignment consumer)**.** *Every downstream cross-perspective consumer of an accepted* ObserverPerspectiveClassifier$^{\uparrow}$ *verdict must read the comparison through the displayed locality row, paired* GAP *commitment row, transport row, continuation row, provenance row, and local* NameCert *row. A consumer that bypasses one of those displayed rows is not reading the public classifier verdict.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierAlignmentConsumer`

Proof. Start from an accepted public verdict. By Definition 647.8, the verdict route factors through $O_0, O_1, U_0, U_1, L, G, H, C, P, N$ in the public classifier layers.

The consumer side only needs the comparison layers after the observer-state and universe surfaces have been exposed. Those layers are precisely the locality row L, paired commitment row G, transport row H, continuation row C, provenance row P, and local naming row N.

If a consumer bypasses one of these rows, Definition 647.4 says the read no longer factors through the exact public ledger. The non-escape boundary of Definition 647.5 prevents replacing the missing row by hidden synchronization, host equality, or a private observer witness, so the bypassed read is not the public classifier verdict. □

Theorem 647.14 (ObserverPerspectiveClassifier observer-state GAP route)**.** *For an accepted* ObserverPerspectiveClassifier$^{\uparrow}$ *carrier* $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$*, a public verdict may consume the paired* GAP *row* G *only after the two conscious-observer state rows* O_0, O_1 *have exposed their GAP acknowledgement rows through the recorded state surface. A verdict that reads* G *without both acknowledgements is not an accepted observer-perspective classifier verdict.*

Lean4 ✓ BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierObserverStateGapRoute

Proof. Project the carrier tuple from Definition 647.1. The observer rows O_0, O_1 precede the universe surfaces, locality row, and paired commitment row, so the public carrier fixes the state coordinates before the comparison row G can be read.

The state-totality theorem Definition 647.9 forces both conscious-observer state rows to be exposed before any public classifier verdict. The paired commitment readback theorem Definition 647.7 then routes the displayed GAP row through the same finite comparison ledger.

Finally apply the ConsciousObserverState exactness anchor ConsciousObserverStateCarrier_gap_acknowledgeme to the two state rows. It identifies the required acknowledgement rows as the exact state-side witnesses consumed by G. The ledger exactness and non-escape theorems Definition 647.4 and Definition 647.5 rule out replacing either acknowledgement by host equality, hidden synchronization, or private observer access. □

Theorem 647.15 (ObserverPerspectiveClassifier cross-alignment locality soundness)**.** *A* CrossPerspectiveAlignmen *consumer may use an accepted* ObserverPerspectiveClassifier$^{\uparrow}$ *verdict only when the displayed locality row L and paired* GAP *row G pass through the alignment locality-cell soundness route. If the consumer supplies a different locality cell, an unpaired commitment row, or an unrecorded alignment witness, it is not using the public classifier surface.*

↪ variant BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierCrossAlignmentLocalitySoundne

Proof. Start with the comparison route of Definition 647.8. It orders the public read through the two observer rows, two universe surfaces, displayed locality row L, paired commitment row G, transports H, continuations C, provenance P, and local naming row N.

The alignment-consumer theorem Definition 647.13 restricts downstream cross-perspective consumers to precisely the displayed comparison rows. Thus the consumer cannot detach L from G or replace either row before reading the classifier verdict.

Apply Definition 647.3 to compare the locality cell against the classifier ledger, and then apply the CrossPerspectiveAlignment soundness anchor CrossPerspectiveAlignmentCarrier_locality_cell_soundness. These two routes identify the accepted locality-cell soundness witness with the displayed pair L, G.

The non-escape theorem Definition 647.5 excludes hidden synchronization, ambient world equality, and unrecorded cross-perspective evidence. Hence a consumer outside the L, G soundness route is outside the public classifier surface. □

Lean4 ✓ BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierCrossAlignmentLocalit

Theorem 647.16 (ObserverPerspectiveClassifier locality-cell exhaustion)**.** *In an accepted* ObserverPerspectiveClass *carrier $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$, the locality coordinate L is exhausted by the public* LocalityCell$^{\uparrow}$ *or* ObserverLocalityCell$^{\uparrow}$ *packet together with the rows H, C, P, N. No ambient world row, hidden synchronization map, host equality, or unrecorded locality witness can replace that public locality-cell data.*

Lean4 ✓ BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierLocalityCellExhaustio

Proof. Read the carrier as a finite ledger. The locality row L is not an abstract parameter: it is tied to the componentwise hsame transports H, displayed Cont routes C, Pkg provenance P, and local NameCert row N.

The locality-cell comparison theorem Definition 647.3 and ledger exactness theorem Definition 647.4 say that every public read of L factors through those displayed rows. Apply the

LocalityCell readback anchor LocalityCellPacket_interobserver_readback when L is supplied by a LocalityCell$^{\uparrow}$ packet, and apply the ObserverLocalityCell boundary anchor ObserverLocalityCellPacket_consumer_bo when L is supplied by an ObserverLocalityCell$^{\uparrow}$ packet.

It remains to rule out replacements. The dependency-scope theorem Definition 647.12 limits the accepted row family to the displayed public packets, and the non-escape theorem Definition 647.5 rejects ambient world rows, hidden synchronization maps, host equality, private observer access, and unrecorded cross-perspective evidence. Therefore L is exhausted exactly by the public locality-cell packet and the rows H, C, P, N. □

Theorem 647.17 (ObserverPerspectiveClassifier locality-commitment inversion)**.** *Let $Q = (O_0, O_1, U_0, U_1, L, G, H$ be an accepted* ObserverPerspectiveClassifier$^{\uparrow}$ *carrier read inside the public* BHist *packet. Any accepted public comparison verdict determines the displayed locality row L and paired* GAP *commitment row G through the finite rows Q, with H the componentwise* hsame *transport row, C the displayed* Cont *route row, P the* Pkg *provenance row, and N the local* NameCert *row. A verdict that omits either L or G is outside the public classifier.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifier Up.ObserverPerspectiveClassifierLocalityCommitmentInv`

Proof. Project the carrier from Definition 647.1. The public read has only the finite coordinates $O_0, O_1, U_0, U_1, L, G, H, C, P, N$, so the comparison verdict cannot choose an unlisted locality or commitment coordinate.

Apply Definition 647.3. It identifies the displayed L row as the locality-cell comparison surface tied to the transport, continuation, provenance, and naming rows. Apply Definition 647.7 to identify G as the paired commitment ledger for the same public comparison route.

It remains to exclude partial verdicts. Ledger exactness Definition 647.4 says the public classifier has no comparison route outside the displayed rows, and non-escape Definition 647.5 rejects ambient locality, hidden synchronization, host equality, private observer access, and unrecorded alignment evidence. Hence a verdict missing either L or G is not an accepted public classifier verdict. □

Theorem 647.18 (ObserverPerspectiveClassifier two-state no-confusion)**.** *For accepted* ObserverPerspectiveClassifi *carrier reads $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$ and $Q' = (O'_0, O'_1, U'_0, U'_1, L', G', H', C', P', N')$, equality of the public classifier verdict forces agreement on both conscious-observer state rows and both universe-for-observer rows before locality and alignment rows are compared. If any one of O_0, O_1, U_0, U_1 differs from the corresponding displayed row in Q', the two reads are different public carrier reads rather than the same classifier verdict.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifier Up.ObserverPerspectiveClassifierTwoStateNoConfusion`

Proof. Start with the carrier definition. It presents each accepted read as a finite ordered BHist packet, so the state and universe-for-observer rows are public coordinates of the verdict rather than hidden parameters.

Apply state totality Definition 647.9. Both observer-state rows and both attached universe surfaces must be exposed before the verdict may continue to locality, commitment, transport, continuation, provenance, and naming rows.

Next apply comparison-route totality Definition 647.8 and perspective stability Definition 647.11. These identify the downstream comparison route only after the displayed state and universe rows have been fixed.

Finally use non-escape Definition 647.5. It forbids repairing a disagreement in O_0, O_1, U_0, U_1 by host equality, private observer access, hidden synchronization, or an unrecorded cross-perspective witness. Therefore such a disagreement changes the public carrier read itself. □

Theorem 647.19 (ObserverPerspectiveClassifier alignment ledger coverage)**.** *Every* CrossPerspectiveAlignment$^{\uparrow}$ *consumer of an accepted* ObserverPerspectiveClassifier$^{\uparrow}$ *verdict is covered by the displayed ledger* L, G, H, C, P, N*. The locality row* L *is supplied either by a public* LocalityCell$^{\uparrow}$ *packet or by a public* ObserverLocalityCell$^{\uparrow}$ *packet, and there is no third ambient locality, hidden synchronization route, or unrecorded alignment channel available to the consumer.*

Proof. Begin with dependency scope Definition 647.12. It confines the accepted classifier to the displayed observer-state, universe-for-observer, locality, alignment, BHist, hsame, Cont, Pkg, and NameCert rows.

Apply the alignment-consumer theorem Definition 647.13. A downstream CrossPerspectiveAlignment$^{\uparrow}$ consumer must read the verdict through L, G, H, C, P, N rather than through an independent alignment surface.

The cross-alignment locality soundness theorem Definition 647.15 binds the consumer to the same displayed L, G pair. Locality-cell exhaustion Definition 647.16 restricts L to the public LocalityCell$^{\uparrow}$ or ObserverLocalityCell$^{\uparrow}$ packet, and locality-commitment inversion Definition 647.17 keeps L and G jointly determined by the accepted carrier.

Thus every alignment consumer is covered by the displayed ledger. Any purported consumer using a third locality surface, hidden synchronization, or unrecorded alignment witness leaves the public classifier route. □

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierAlignmentLedgerCovera`

Theorem 647.20 (ObserverPerspectiveClassifier two-observer source admission)**.** *An accepted public verdict for an* ObserverPerspectiveClassifier$^{\uparrow}$ *carrier must first expose both accepted* ConsciousObserverState$^{\uparrow}$ *rows* O_0, O_1 *and their attached universe-for-observer surfaces* U_0, U_1*. The verdict may then read locality and alignment data, but it cannot read* L*,* G*, or a* CrossPerspectiveAlignment$^{\uparrow}$ *consumer route before the two observer-state rows and the two universe surfaces have appeared in the finite carrier.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierTwoObserverSourceAdmi`

Proof. Project the carrier $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$ from Definition 647.1. The first displayed rows are the two observer-state sources and their two universe-for-observer surfaces, so the classifier has no earlier public comparison coordinate.

Apply the state-totality theorem Definition 647.9. It turns this projection order into a public verdict condition: both observer-state rows and both attached universe surfaces must be exposed before the verdict is exported.

Finally apply the comparison-route totality and non-escape theorems, Definition 647.8 and Definition 647.5. They force the later locality, commitment, transport, continuation, provenance, and alignment-facing reads to remain downstream of the displayed state rows, and they rule out a hidden observer-neutral source that could bypass the two source rows. □

Theorem 647.21 (ObserverPerspectiveClassifier alignment-locality cycle)**.** *For an accepted* ObserverPerspectiveCla *carrier, the locality coordinate* L *must be a public* LocalityCell$^{\uparrow}$ *or* ObserverLocalityCell$^{\uparrow}$ *packet paired with the same displayed* GAP *row* G*. Every* CrossPerspectiveAlignment$^{\uparrow}$ *consumer of the verdict must consume that* L, G *pair through the recorded rows* H, C, P, N*; it cannot bypass the pair by*

supplying an ambient locality row, an unpaired commitment row, or an unrecorded alignment witness.

Proof. Read L from the carrier definition. Its declared role is the public locality-cell evidence row, and the next comparison coordinate G is the paired GAP commitment ledger for comparing U_0 and U_1 without identifying them as one host world.

Apply locality-cell exhaustion Definition 647.16. It restricts L to the public $\mathsf{LocalityCell}^{\uparrow}$ or $\mathsf{ObserverLocalityCell}^{\uparrow}$ packet together with the recorded transport, route, provenance, and naming rows.

Next apply cross-alignment locality soundness Definition 647.15. That theorem binds the alignment-facing consumer to the same displayed pair L, G.

The ledger exactness and non-escape boundary, Definition 647.4 and Definition 647.5, then exclude ambient locality rows, unpaired commitment rows, hidden synchronization, and unrecorded alignment witnesses. Thus the locality and alignment reads form the stated cycle around the public L, G pair. □

Lean4 ✓ `BEDC.Derived.ObserverperspectiveclassifierUp.ObserverPerspectiveClassifierAlignmentLocalityCycl`

Theorem 647.22 (ObserverPerspectiveClassifier obligation-closure witness)**.** *The carrier row, the five local* $\mathsf{NameCert}_{\mathsf{ObserverPerspectiveClassifier}^{\uparrow}}$ *obligation rows, the two observer-state source rows, the locality-cell row, the paired* GAP *row, the* $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ *consumer route, the componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local naming row form one finite obligation-closure witness for* $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$.

Proof. Begin with the carrier and local obligation theorems, Definition 647.1 and Definition 647.2. They display the finite packet and identify the five local naming obligations carried by it.

The source admission theorem Definition 647.20 binds both conscious-observer state rows and both universe-for-observer surfaces before any public verdict. The alignment-locality cycle theorem Definition 647.21 binds the public locality row, paired commitment row, and alignment-facing consumer to the same displayed route.

It remains to gather the already established public boundaries. Apply ledger exactness, non-escape, comparison-route totality, dependency scope, observer-state GAP route, cross-alignment locality soundness, and locality-cell exhaustion. These theorems account for H, C, P, N, exclude every unlisted observer-neutral or ambient replacement, and leave exactly the finite row family named in the statement. □

Lean4 ✓ `BEDC.Derived.ObserverperspectiveclassifierUp.ObserverPerspectiveClassifierObligationClosureWitn`

Theorem 647.23 (ObserverPerspectiveClassifier obligation unblock package)**.** *The carrier exposure, local* NameCert *obligations, locality-cell comparison, ledger exactness, non-escape boundary, paired* GAP *readback, comparison-route totality, state totality, locality refinement, perspective stability, dependency scope, alignment-consumer discipline, observer-state GAP route, cross-alignment locality soundness, locality-cell exhaustion, two-observer source admission, alignment-locality cycle, and obligation-closure witness together form the finite* $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ *obligation package for obligation-level closure.*

Lean4 ✓ `BEDC.Derived.ObserverperspectiveclassifierUp.ObserverPerspectiveClassifierObligationUnblockPack`

Proof. First project the finite carrier from Definition 647.1. This supplies the rows $O_0, O_1, U_0, U_1, L, G, H, C, P, N$ and fixes the only coordinates available to the package.

The local obligation surface is given by Definition 647.2. The comparison surface is then constrained by Definition 647.3, Definition 647.4, Definition 647.5, and Definition 647.7.

The route and state coverage are supplied by Definition 647.8 and Definition 647.9. Stability under admissible local changes is supplied by Definition 647.10 and Definition 647.11.

It remains only to bind the consumer-facing dependency boundary. Apply Definition 647.12 to identify the accepted row family, and apply Definition 647.13 to force downstream consumers through the displayed locality, commitment, transport, continuation, provenance, and naming rows.

The three concrete rows above close the exposed obligation route. The observer-state GAP route Definition 647.14 ties G to both state acknowledgements, the cross-alignment locality soundness route Definition 647.15 ties L, G to the alignment consumer, and locality-cell exhaustion Definition 647.16 rules out ambient or hidden replacements for L. These finite components assemble exactly the obligation package claimed.

The dependency witness is explicit in the same finite packet. Apply Definition 647.20 for the two source-state rows, Definition 647.21 for the L, G locality and alignment cycle, and Definition 647.22 to package these rows with the earlier carrier, obligation, exactness, and non-escape boundaries. □

Theorem 647.24 (ObserverPerspectiveClassifier BHist scope)**.** *Every accepted carrier read for* ObserverPerspectiveClassifier$^{\uparrow}$ *is confined to the displayed finite* BHist *packet* $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$*. No observer-neutral row, host-world equality row, private* Self *row, global spacetime row, hidden synchronization row, or unrecorded cross-perspective row can enter the classifier scope.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierBHistScope`

Proof. Start with the carrier definition Definition 647.1. It presents the accepted classifier as the finite BHist packet $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$, so every public read has one of these displayed coordinates as its source.

Ledger exactness Definition 647.4 identifies the rows available inside that packet. The non-escape theorem Definition 647.5 excludes observer-neutral rows, host-world equality, private Self access, global spacetime carriers, hidden synchronization maps, and unrecorded cross-perspective evidence.

Finally apply dependency scope Definition 647.12. It says the accepted row family is exactly the public family generated by the displayed observer-state, locality, alignment, BHist, hsame, Cont, Pkg, and NameCert rows. Hence no row outside Q can enter the scope. □

Theorem 647.25 (ObserverPerspectiveClassifier alignment transport scope)**.** *Every* CrossPerspectiveAlignment$^{\uparrow}$ *consumer of an accepted* ObserverPerspectiveClassifier$^{\uparrow}$ *verdict may use only the displayed route through* L, G, H, C, P, N*. Its transport scope is the componentwise* hsame *row* H *together with the displayed* Cont *routes* C*; it cannot import an ambient alignment map, an unpaired commitment row, or an unrecorded continuation.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierAlignmentTransportSco`

Proof. The comparison-route totality theorem Definition 647.8 first exposes the available route: observer rows, universe-for-observer surfaces, locality evidence, paired GAP commitments, hsame transports, Cont routes, Pkg provenance, and local naming.

Next use the alignment-consumer theorem Definition 647.13. It forces any downstream consumer to read the verdict through L, G, H, C, P, N rather than through a separate alignment channel.

The cross-alignment locality soundness theorem Definition 647.15 binds the consumer to the same displayed L, G pair. The alignment-locality cycle theorem Definition 647.21 then returns the read to H, C, P, N, with hsame and Cont supplying the transport scope. Thus ambient alignment maps, unpaired commitments, and unrecorded continuations are outside the accepted consumer scope. □

Theorem 647.26 (ObserverPerspectiveClassifier NameCert ledger scope)**.** *The local* $\mathsf{NameCert}_{\mathsf{ObserverPerspectiveClassif}}$ *row closes only the finite observer-state, locality-cell,* GAP*, transport, continuation, package, and naming ledger displayed by* $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$*. It does not close global spacetime, private* Self *access, host equality between worlds, hidden synchronization, or unrecorded cross-perspective evidence.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierNameCertLedgerScope`

Proof. The local naming obligations are exactly the five rows listed in Definition 647.2. They cover carrier exposure, observer anchoring, universe-for-observer exposure, locality and coherence comparison, and the non-escape boundary.

Apply the obligation-closure witness Definition 647.22. It packages the carrier row, the local naming obligations, both observer-state rows, the locality-cell row, the paired GAP row, the alignment consumer route, hsame transports, Cont routes, Pkg provenance, and the local naming row as one finite obligation witness.

The obligation unblock package Definition 647.23 assembles the same rows as the chapter's obligation surface. The non-escape theorem Definition 647.5 keeps global spacetime, private Self access, host equality, hidden synchronization, and unrecorded cross-perspective evidence outside that surface. Therefore the NameCert row closes only the displayed finite ledger. □

Theorem 647.27 (ObserverPerspectiveClassifier carrier transport)**.** *For an accepted* $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ *carrier* $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$*, carrier transport preserves acceptedness exactly when the rows* $O_0, O_1, U_0, U_1, L, G, H, C, P, N$ *are transported componentwise through the displayed* hsame *rows in* H *and then replayed through the displayed* Cont *routes in* C*. No transport that omits an observer-state row, a universe-for-observer row, the locality row, the paired* GAP *row, package provenance, or the local naming row is an accepted carrier transport.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierCarrierTransport`

Proof. Start from the finite carrier definition Definition 647.1. It presents Q as a BHist packet with exactly the displayed observer-state, universe-for-observer, locality, commitment, transport, continuation, package, and naming rows.

The forward direction uses the transport data already present in the accepted packet. Locality refinement Definition 647.10 and perspective stability Definition 647.11 keep the comparison attached to the same public locality and observer-perspective rows. The BHist scope theorem Definition 647.24 confines the read to Q, and the alignment transport scope theorem Definition 647.25 forces the consumer route through the displayed H and C rows.

For the reverse direction, suppose every listed coordinate is transported through its displayed hsame row and replayed through its displayed Cont route. The same carrier rows are then available in the same finite order, with the package and local naming rows transported along with the data rows. Ledger exactness Definition 647.4 and NameCert ledger scope Definition 647.26 therefore reconstruct the accepted carrier surface and exclude any transport using an omitted or hidden coordinate. □

Theorem 647.28 (ObserverPerspectiveClassifier classifier determinacy)**.** *Let Q and Q' be accepted public* ObserverPerspectiveClassifier$^{\uparrow}$ *carriers with public verdicts read through their local* NameCert *rows. The two verdicts are the same classifier verdict exactly when they agree on both observer-state rows, both universe-for-observer surfaces, the locality row, the paired* GAP *row, the componentwise* hsame *transports, the displayed* Cont *routes, the* Pkg *provenance, and the local* NameCert *row.*

Proof. First compare the observer-state coordinates. The two-state no-confusion theorem Definition 647.18 says that the accepted classifier keeps O_0 and O_1 as the two displayed state rows, so a public verdict cannot identify distinct state rows by passing to an ambient observer.

Next compare the locality and commitment coordinates. Locality-commitment inversion Definition 647.17 recovers the displayed locality row and paired GAP row from an accepted comparison verdict. Alignment-ledger coverage Definition 647.19 then accounts for the alignment-facing route through the same finite ledger.

It remains to compare the structural coordinates. Ledger exactness Definition 647.4 makes H, C, P, N the only public transport, continuation, provenance, and naming rows available to the verdict. Non-escape Definition 647.5 excludes a private observer row, host equality, global spacetime carrier, hidden synchronization map, or unrecorded comparison witness that could distinguish two otherwise equal displayed verdicts.

Thus equality of all displayed rows determines equality of the classifier verdict. Conversely, equality of classifier verdicts forces equality of those rows by applying the same no-confusion, inversion, ledger-coverage, exactness, and non-escape boundaries to the public readback of the verdicts. □

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierClassifierDeterminacy`

Theorem 647.29 (ObserverPerspectiveClassifier ledger exhaustion)**.** *Every accepted downstream consumer route for an* ObserverPerspectiveClassifier$^{\uparrow}$ *verdict is exhausted by the displayed ledger $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$. Such a route cannot add a god's-eye observer, host world equality, private* Self *row, global spacetime carrier, hidden synchronization map, or unrecorded cross-perspective evidence.*

Proof. Project the accepted carrier and its public read route. Ledger exactness Definition 647.4 supplies the complete row family $O_0, O_1, U_0, U_1, L, G, H, C, P, N$, and comparison-route totality Definition 647.8 sends every consumer through that displayed route.

The obligation unblock package Definition 647.23 gathers the carrier exposure, local obligations, locality comparison, paired commitment readback, route coverage, state coverage, stability, and alignment-facing consumer discipline into the same finite package. Dependency scope Definition 647.12 then prevents a downstream consumer from importing rows outside the accepted public dependency family.

Finally apply NameCert ledger scope Definition 647.26. The local naming row closes only the displayed observer-state, universe-for-observer, locality-cell, GAP, transport, continuation, package, and naming ledger. The excluded god's-eye observer, host world equality, private Self row, global spacetime carrier, hidden synchronization map, and unrecorded cross-perspective evidence have no displayed coordinate and no accepted consumer route. □

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierLedgerExhaustion`

Theorem 647.30 (ObserverPerspectiveClassifier verdict source exhaustion)**.** *Every public* ObserverPerspectiveClass *verdict exhausts its source rows through the displayed packet $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$. Its observer-state source is one of the two* ConsciousObserverState$^{\uparrow}$ *rows, its locality source is the*

displayed LocalityCell$^{\uparrow}$ *or* ObserverLocalityCell$^{\uparrow}$ *row, and its alignment-facing source is the displayed* CrossPerspectiveAlignment$^{\uparrow}$ *consumer route. No public verdict can bypass these rows by using a god's-eye observer, host equality of worlds, private* Self *access, global spacetime, hidden synchronization, or unrecorded cross-perspective evidence.*

Proof. Start with the accepted carrier in Definition 647.1. It exposes the finite packet $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$ and gives no coordinate outside that packet.

The local naming obligations in Definition 647.2 bind the carrier rows to the observer anchors, universe-for-observer surfaces, locality comparison, and non-escape boundary. The locality-cell comparison theorem Definition 647.3 places the public comparison after the displayed locality row, while ledger exactness Definition 647.4 keeps the public read inside the listed ledger.

It remains to account for downstream consumers. Apply dependency scope, alignment consumer, locality-cell exhaustion, carrier transport, classifier determinacy, and ledger exhaustion. These results force any exported verdict through the same observer-state, locality-cell, paired commitment, transport, continuation, provenance, and naming rows, and non-escape rules out every bypass named in the statement. □

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierVerdictSourceExhausti`

Theorem 647.31 (ObserverPerspectiveClassifier public readback criterion)**.** *A local* NameCert$_{\text{ObserverPerspectiveClassif}}$ *read is public exactly when it factors through the displayed observer-state rows O_0, O_1, the universe-for-observer rows U_0, U_1, the locality-cell row L, the paired* GAP *row G, the componentwise* hsame *transports in H, the* Cont *routes in C, the* Pkg *provenance row P, and the local naming row N. Any read omitting one of these rows, or replacing it by an ambient observer-neutral witness, is not the public classifier readback.*

Lean4 ✓ `BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierPublicReadbackCriteri`

Proof. For the forward direction, assume a public readback has been exported. Comparison-route totality and state totality send the read through the two observer-state rows, the two universe-for-observer surfaces, the displayed locality row, the paired commitment row, and then through H, C, P, N.

The carrier transport theorem Definition 647.27 supplies the componentwise hsame and Cont factorization. The classifier determinacy theorem Definition 647.28 then says that the readback is determined only by agreement on these displayed rows, including Pkg provenance and the local NameCert row.

For the reverse direction, suppose the read factors through all displayed rows in the stated order. Ledger exactness reconstructs the public ledger, the obligation unblock package supplies the local naming obligations, and NameCert ledger scope closes the read through the finite NameCert$_{\text{ObserverPerspectiveClassifier}^{\uparrow}}$ row.

Finally apply non-escape and ledger exhaustion. They exclude every ambient replacement, hidden synchronization route, host-equality shortcut, private observer row, and unrecorded cross-perspective witness, so omitting any displayed row leaves the public readback surface. □

Theorem 647.32 (ObserverPerspectiveClassifier sibling carrier dependency)**.** *An* ObserverPerspectiveClassifier$^{\uparrow}$ *verdict cannot be exported until the sibling carrier rows from chapter 578, chapter 643, chapter 509, and chapter 513 have been displayed in the same finite public route. In particular, the classifier may read the two conscious-observer state rows, the public cross-perspective alignment row, and the locality-cell evidence before emitting a verdict, but it cannot replace those sibling rows by an ambient observer-neutral world, unrecorded alignment channel, or hidden locality coordinate.*

Lean4 ✓ BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierSiblingCarrierDepende

Proof. Read the dependency scope theorem Definition 647.12. It identifies the accepted row family with the public observer-state, locality-cell, cross-perspective alignment, BHist, hsame, Cont, Pkg, and NameCert rows.

The alignment-consumer and locality-cell exhaustion theorems then place any downstream comparison through the displayed L, G, H, C, P, N route. Thus the classifier must have already displayed the sibling observer-state, cross-perspective alignment, locality-cell, and observer-locality-cell carrier rows before the verdict is public.

Finally apply non-escape and ledger exhaustion. They remove ambient worlds, hidden synchronization maps, unrecorded alignment channels, and hidden locality coordinates from the accepted packet surface, leaving only the displayed sibling carrier dependency. □

Theorem 647.33 (ObserverPerspectiveClassifier scoped consumer boundary)**.** *The scoped consumer boundary for downstream* $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ *users of* $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ *is exactly the finite dependency family* $O_0, O_1, U_0, U_1, L, G, H, C, P, N$ *together with the local* $\mathsf{NameCert}_{\mathsf{ObserverPerspecti}}$ *readback criterion. A downstream consumer may inspect the public verdict only through those observer-state, locality-cell, paired* GAP*, alignment-consumer, transport, continuation, provenance, and naming rows.*

Lean4 ✓ BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierScopedConsumerBoundar

Proof. The verdict source exhaustion theorem Definition 647.30 first identifies the rows from which a public verdict can be sourced. The public readback criterion Definition 647.31 then identifies the exact factorization required for the local naming row to export that verdict.

Apply the existing dependency scope and alignment-consumer theorems. They confine downstream $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ users to the displayed locality, commitment, transport, continuation, provenance, and naming rows, and they prevent a consumer from replacing this route by an unrecorded alignment channel.

The remaining boundary clauses come from locality-cell exhaustion, carrier transport, classifier determinacy, and ledger exhaustion. These theorems show that the carrier, the transported route, the determined verdict, and the exhausted ledger all have the same finite row family. Thus the scoped consumer boundary is precisely the family named in the statement. □

Theorem 647.34 (ObserverPerspectiveClassifier scope certificate)**.** *For an accepted* $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ *packet* $Q = (O_0, O_1, U_0, U_1, L, G, H, C, P, N)$*, the scoped certificate binds every public observer comparison to the displayed* $\mathsf{ConsciousObserverState}^{\uparrow}$ *rows* O_0, O_1*, the* $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ *consumer route, the* $\mathsf{LocalityCell}^{\uparrow}$ *or* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *row* L*, the finite* BHist *packet* Q*, the componentwise* hsame *ledger* H*, the* Cont *routes* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{ObserverPerspectiveClassifier}^{\uparrow}}$ *row* N*. No observer comparison can bypass the paired* GAP *and alignment rows or the locality-cell rows while remaining a public classifier comparison.*

Lean4 ✓ BEDC.Derived.Observerperspectiveclassifierup.ObserverPerspectiveClassifierScopeCertificate

Proof. Project the carrier definition and the sibling carrier dependency theorem. They display the two conscious-observer state rows, the locality-cell or observer-locality-cell row, the cross-perspective alignment row, the paired GAP ledger, the finite BHist packet, and the local naming row in the same public route.

Next apply the scoped consumer boundary together with alignment transport scope. These results force the comparison through L, G, H, C, P, N, with hsame and Cont carrying only the displayed rows and with Pkg provenance recording the same dependency family.

Finally use the public readback criterion, carrier transport, classifier determinacy, ledger exhaustion, and NameCert ledger scope. They identify the replayed and transported classifier with the same finite packet, and they rule out ambient observer-neutral witnesses, hidden alignment channels, unpaired GAP rows, hidden locality coordinates, and any observer comparison that bypasses the paired alignment and locality-cell rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverPerspectiveClassifier}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ packet is generated from two conscious-observer state rows, two universe-for-observer record surfaces, locality-cell evidence, paired GAP commitments, componentwise transports, displayed continuation routes, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverPerspectiveClassifier}^{\uparrow}}, \mathsf{obligation})$

Scope closed: Definition 647.1, Definition 647.2, Definition 647.3, Definition 647.4, Definition 647.5, Definition 647.6, Definition 647.7, Definition 647.8, Definition 647.9, Definition 647.10, Definition 647.11, Definition 647.14, Definition 647.15, Definition 647.16, Definition 647.17, Definition 647.18, Definition 647.19, Definition 647.20, Definition 647.21, Definition 647.22, Definition 647.24, Definition 647.25, Definition 647.26, Definition 647.27, Definition 647.28, and Definition 647.29 bind the finite public classifier obligation surface for universe-for-observer comparison.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverPerspectiveClassifier}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, bridge status, god's-eye observation, host equality between worlds, private Self access, global spacetime, hidden synchronization, or unrecorded cross-perspective evidence.

Upgrade path: Scoped closure next requires Lean-side and formal scope witnesses for the same finite observer-state, locality-cell, paired GAP, and alignment-consumer packet.

Chapter 648

A Concrete Naming Certificate for $\mathsf{CompactModulusCover}^{\uparrow}$

The $\mathsf{CompactModulusCover}^{\uparrow}$ interface names the finite source packet that sits between compactness, pointwise continuity, the $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ lower-bound fold, and the $\mathsf{UniformModulus}^{\uparrow}$ consumer. It records the compact finite-net probes and the pointwise-modulus ledgers before the rational fold chooses a single uniform precision, so the fold need not also carry the cover-formation certificate.

The packet is consumed by chapter 619 for the positive rational lower-bound fold and by chapter 369 for the final tolerance-only modulus handoff. Its finite-net source is the compact metric surface of chapter 129, so the cover row is a horizontal dependency in the concrete dossier rather than a kernel-only packet.

Definition 648.1 (CompactModulusCover carrier)**.** *A* $\mathsf{CompactModulusCover}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (X, F, E, P, R, U, M, H, C, Q, N)$$

with the following visible rows:

1. *X is the compact source row, read through* $\mathsf{Compact}^{\uparrow}$ *or* $\mathsf{CompactMetric}^{\uparrow}$ *as a finite-net source over the displayed* $\mathsf{Met}^{\uparrow}$ *distance witnesses;*
2. *F is the continuous map or function row, read through* $\mathsf{ContinuousMap}^{\uparrow}$ *or* $\mathsf{CFun}^{\uparrow}$ *with its pointwise-modulus ledger;*
3. *E is the positive tolerance request supplied by the compact-continuous consumer;*
4. *P is the nonempty finite* $\mathsf{ProbeBundle}$ *or compact-net row returned by the compact source certificate;*
5. *R assigns to each bundled probe the source-center history, the covering-radius history, and the local distance witness that covers source histories by that center;*
6. *U assigns to each bundled probe the pointwise-modulus precision row for the tolerance request E at the corresponding center;*
7. *M is the* $\mathsf{UniformModulus}^{\uparrow}$*-facing handoff row containing the same bundle, local radii, pointwise rows, and consumer routes, but no folded precision;*
8. *H is the* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$*-facing radius family consisting of positive* $\mathsf{Rat}^{\uparrow}$ *half-radius ledgers subordinate to the rows in U;*

9. *C records componentwise* hsame *transports for the source row, continuous row, tolerance, bundle, covering rows, pointwise rows, radius family, and handoff row;*
10. *Q records the displayed* Cont *routes for compact-net readback, pointwise-modulus readback, metric-distance use, rational-radius comparison, fold handoff, and uniform-modulus consumption;*
11. *N is the combined provenance row over* BHist, hsame, Cont, Pkg, *and the local* $\mathsf{NameCert}_{\mathsf{CompactModulusCover}^{\uparrow}}$ *certificate.*

The carrier has no coordinate for a host open cover, a selected subcover outside the finite compact-net row, a host-level Lebesgue number, an already folded uniform precision, or a real-completeness theorem. Its role is exactly the finite compact-net and pointwise-modulus source packet consumed by $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *and then by* $\mathsf{UniformModulus}^{\uparrow}$.

Lean4 (definition) `BEDC.Derived.CompactModulusCoverUp.CompactModulusCoverCarrier`
Lean4 ✓ `BEDC.Derived.CompactModulusCoverUp.CompactModulusCoverTasteGate single carrier alignment`

Theorem 648.2 (CompactModulusCover NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CompactModulusCover}^{\uparrow}}$ *surface for the carrier of Definition 648.1 consists exactly of carrier admission for*

$$K = (X, F, E, P, R, U, M, H, C, Q, N),$$

classifier stability under the componentwise hsame *rows in C, finite-net coverage exactness for the compact source rows in P and R, pointwise-modulus compatibility for the continuous rows in F and U, rational positive-radius compatibility for the* $\mathsf{Rat}^{\uparrow}$ *family H, and consumer non-escape through the displayed* Cont, Pkg, *and local naming rows in Q and N.*

Proof. Project the displayed carrier. Its rows are the compact source, continuous map or function, tolerance request, finite probe bundle, covering rows, pointwise-modulus rows, uniform-modulus handoff row, positive rational radius family, transports, continuation routes, and local provenance.

The compact side is read only through the $\mathsf{Compact}^{\uparrow}$ or $\mathsf{CompactMetric}^{\uparrow}$ finite-net rows, together with the $\mathsf{Met}^{\uparrow}$ distance witnesses attached to R. The continuous side is read only through the $\mathsf{ContinuousMap}^{\uparrow}$ or $\mathsf{CFun}^{\uparrow}$ pointwise-modulus rows stored in U.

The radius family H is the only row passed to the $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ lower-bound fold, and the handoff row M is the only row passed to the $\mathsf{UniformModulus}^{\uparrow}$ consumer before that fold has produced a precision. Componentwise hsame transports in C and displayed Cont routes in Q preserve those rows without introducing another selector.

Thus the named obligations exhaust the local certificate surface. Since no carrier coordinate stores a host open cover, a selected subcover, a host-level Lebesgue number, a folded uniform precision, or a real-completeness theorem, the certificate cannot export any of those objects. □

Lean4 ✓ `BEDC.Derived.CompactModulusCoverUp.CompactModulusCoverCarrier namecert obligations`

Theorem 648.3 (CompactModulusCover finite-net source exhaustion)**.** *For an accepted* $\mathsf{CompactModulusCover}^{\uparrow}$ *carrier*

$$K = (X, F, E, P, R, U, M, H, C, Q, N),$$

every source history used by the $\mathsf{UniformModulus}^{\uparrow}$ *handoff is covered by a bundled center in the finite* ProbeBundle *row P, and every bundled center that contributes a pointwise-modulus row in U contributes exactly one positive* $\mathsf{Rat}^{\uparrow}$ *radius ledger to the* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$*-facing family H. The exhaustion certificate is internal to P, R, U, H, C, Q, N and does not read an infinite cover or a host subcover choice.*

Proof. Begin with the compact finite-net source row. The $\mathsf{Compact}^{\uparrow}$ or $\mathsf{CompactMetric}^{\uparrow}$ certificate supplies the nonempty finite bundle P and the covering rows R; each covered source history is related to a bundled center through the displayed $\mathsf{Met}^{\uparrow}$ distance witness.

For each bundled center, read the pointwise-modulus row in U from the $\mathsf{ContinuousMap}^{\uparrow}$ or $\mathsf{CFun}^{\uparrow}$ ledger at the tolerance request E. The rational positive-radius row in H is then the displayed half-radius ledger subordinate to that pointwise row.

The handoff row M records exactly the same bundle and local rows for the $\mathsf{UniformModulus}^{\uparrow}$ consumer. The transports in C and routes in Q replay bundle membership, center coverage, pointwise-modulus readback, and rational-radius comparison componentwise.

Therefore the handoff consumes all and only the finite-net rows in P. No infinite cover, host-selected subcover, or additional compactness object is available from the carrier. □

Lean4 ✓ `BEDC.Derived.CompactModulusCoverUp.CompactModulusCoverCarrier finite net source exhaustion`

Theorem 648.4 (CompactModulusCover real-completion handoff)**.** *Let a compact-continuous real consumer request a positive tolerance row E for a* $\mathsf{ContinuousMap}^{\uparrow}$ *or* $\mathsf{CFun}^{\uparrow}$ *row over a compact* $\mathsf{Met}^{\uparrow}$ *source. An accepted* $\mathsf{CompactModulusCover}^{\uparrow}$ *carrier hands the consumer a finite* $\mathsf{UniformModulus}^{\uparrow}$ *source ledger and a* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *radius family, both over the same* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *provenance. This handoff is sufficient for the later rational lower-bound fold and real-uniform-modulus read, and it does not claim Cauchy completion, host real completeness, or a global modulus chosen outside the packet.*

Proof. Read the accepted carrier K. The compact side supplies the finite source coverage through X, P, R; the continuous side supplies pointwise-modulus rows through F, U; and the tolerance request is the displayed row E.

Apply Definition 648.3. It aligns the finite compact-net bundle with the pointwise rows and the positive rational radius family, so the $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ consumer receives precisely the family H it needs for the lower-bound fold.

The $\mathsf{UniformModulus}^{\uparrow}$ consumer reads M together with the same transport, route, provenance, and local naming rows C, Q, N. After the lower-bound fold has supplied a single precision, the consumer can route the usual compact-uniform-modulus argument through the bundled metric witnesses and pointwise rows.

No completion step is part of this packet. Real consumers may use the resulting uniform-modulus ledger downstream, but the $\mathsf{CompactModulusCover}^{\uparrow}$ carrier itself exports only the finite compact-net and pointwise-modulus source packet. □

Lean4 ✓ `BEDC.Derived.CompactModulusCoverUp.CompactModulusCoverCarrier real completion handoff`

Theorem 648.5 (CompactModulusCover obligation triad)**.** *For an accepted* $\mathsf{CompactModulusCover}^{\uparrow}$ *carrier*

$$K = (X, F, E, P, R, U, M, H, C, Q, N),$$

the consumer surface before $\mathsf{UniformModulus}^{\uparrow}$ *exposes exactly three obligations: compact finite-net coverage through X, P, R, pointwise-modulus compatibility through F, E, U, and rational lower-bound fold handoff through H, M, C, Q, N. It exports no host open cover, host-selected subcover, Lebesgue number, folded uniform precision, or real-completeness theorem.*

Proof. First read the NameCert obligations. They identify carrier admission, classifier stability, finite-net coverage, pointwise-modulus compatibility, rational positive-radius compatibility, and consumer non-escape as the local certificate surface.

Next separate the three consumer obligations. Finite-net source exhaustion supplies the compact coverage route through X, P, R; the pointwise rows F, E, U provide the local modulus compatibility; and the real-completion handoff sends the radius family and structural rows through H, M, C, Q, N toward the lower-bound fold.

The non-escape clauses in those theorems rule out every unlisted analytic object. Since the carrier contains no host open cover, host-selected subcover, Lebesgue number, folded uniform precision, or real-completeness theorem, the triad is the whole pre-$\mathsf{UniformModulus}^{\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.CompactModulusCoverUp.CompactModulusCoverCarrier obligation triad`

Theorem 648.6 (CompactModulusCover AI TasteGate scope)**.** *Any obligation-closure read for* $\mathsf{CompactModulusCover}^{\uparrow}$ *must pass through the same single-carrier packet*

$$K = (X, F, E, P, R, U, M, H, C, Q, N)$$

of Definition 648.1. The read must include the finite-net source exhaustion of Definition 648.3 and must preserve carrier alignment for the finite-net rows, pointwise-modulus rows, fold handoff, transport rows, route rows, and local NameCert *row before any closure promotion is recorded.*

Proof. Project the carrier K. The compact finite-net source is read from X, P, R, and the pointwise-modulus data are read from F, E, U.

Apply finite-net source exhaustion. It ties every source history used by the $\mathsf{UniformModulus}^{\uparrow}$ handoff to the finite bundle P, and it ties every bundled center with a pointwise row in U to the positive rational radius family H.

The fold-facing and consumer-facing rows are then fixed. The row H is the $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ radius family, and the row M is the $\mathsf{UniformModulus}^{\uparrow}$ handoff row before a folded precision is available.

Finally read the structural rows C, Q, N. They provide componentwise transport, displayed routes, and the local naming surface for the same packet, so an obligation-closure read cannot bypass the displayed carrier or use a second source packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{CompactModulusCover}^{\uparrow}}$.

Constructive story: A $\mathsf{CompactModulusCover}^{\uparrow}$ packet is generated from a compact source row, a continuous map or function row, a positive tolerance request, a finite ProbeBundle, compact-net coverage rows, pointwise-modulus rows, positive $\mathsf{Rat}^{\uparrow}$ radius ledgers, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CompactModulusCover}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 648.1, Definition 648.2, Definition 648.3, Definition 648.4, and Definition 648.5 bind the carrier, NameCert obligations, finite-net exhaustion, real-completion handoff, and obligation-triad rows to the displayed compact-net, pointwise-modulus, lower-bound-fold, and uniform-modulus scope.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CompactModulusCover}^{\uparrow}}$, axiomClean)

Lean4 ✓ `BEDC.Derived.CompactModulusCoverUp.taste gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close the rational lower-bound fold, the final uniform-modulus theorem, Cauchy completion, host real completeness, external subcover selection, or bridge checking.

Upgrade path: The paper axis is closed at the finite compact-net, pointwise-modulus, rational-radius, lower-bound-fold, and uniform-modulus consumer surface; only bridge checking remains on the formal axis.

Chapter 649

A Concrete Naming Certificate for $\mathsf{StationaryWindowLattice}^{\uparrow}$

The $\mathsf{StationaryWindowLattice}^{\uparrow}$ packet records the common finite-window refinement used by stationary Real-completeness diagonal consumers. It joins stationary rational seed rows, transported stationary-window seal rows, mesh-budget rows, witness-schedule rows, cofinal-tail rows, transports, continuations, provenance, and local naming into one finite BHist carrier. The packet is a refinement lattice over displayed windows; it is not an infinite diagonal object, a quotient stream, a selected host limit, or an ambient completeness principle.

The transported seal coordinate is the sibling surface of chapter 437: that chapter supplies the stationary-window seal row, while the present chapter adds the common refinement meet that synchronizes it with mesh, witness-schedule, and cofinal-tail consumers.

Definition 649.1 (Stationary window lattice carrier)**.** *A* $\mathsf{StationaryWindowLattice}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (Q, S, R, D, W, M, H, C, P, N)$$

with the following displayed rows:

1. *Q is the stationary* $\mathsf{Rat}^{\uparrow}$ *seed row whose rational histories determine the constant diagonal source;*
2. *S is the finite* $\mathsf{StreamName}^{\uparrow}$ *window family selected from Q;*
3. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row over the same selected windows;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger recording the endpoint, radius, and comparison rows used by the selected windows;*
5. *W is the transported stationary-window seal row linking the stationary diagonal window packet to the* $\mathsf{Real}^{\uparrow}$ *seal surface;*
6. *M is the common refinement-meet row that simultaneously refines the mesh budget, witness schedule, cofinal tail, and transported stationary window rows;*
7. *H records componentwise* hsame *transports for Q, S, R, D, W, M and the structural rows;*
8. *C records the displayed* Cont *routes from stationary seeds to windows, from windows to readbacks, from readbacks to dyadic tolerance rows, from those rows to the transported seal, and from all selected windows to the common refinement-meet row;*

9. *P is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, TransportedStationaryWindowSe RealDiagonalMeshBudget$^{\uparrow}$, $\mathsf{RegularCauchyWitnessSchedule}^{\uparrow}$, $\mathsf{DiagonalCofinalTail}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{StationaryWindowLattice}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient streams, host real equality, unbounded window families, selected limits, choice data, or ambient Real-completeness witnesses.

Theorem 649.2 (Stationary window lattice NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{StationaryWindowLattice}^{\uparrow}}$ *surface for Definition 649.1 consists exactly of carrier admission for $L = (Q, S, R, D, W, M, H, C, P, N)$, stationary* $\mathsf{Rat}^{\uparrow}$ *seed exposure through Q, selected* $\mathsf{StreamName}^{\uparrow}$ *window exposure through S,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback through R,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance-ledger exactness through D, transported stationary-window seal exposure through W, common refinement-meet exposure through M, componentwise* hsame *transport through H, displayed* Cont *route replay through C,* Pkg *provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.StationaryWindowLatticeUp.StationaryWindowLatticeTasteGate single carrier alignment`

Proof. Project the carrier of Definition 649.1. The rows Q, S, R, D, W, M list the mathematical data available to the lattice consumer, and H, C, P, N list the transport, route, provenance, and naming data.

The stationary source is read first through Q, then through the selected finite windows S, the regular-rational readback R, and the dyadic tolerance ledger D. The transported seal row W can be reached only after those rows are visible.

The refinement row M is the only row that compares the mesh budget, witness schedule, cofinal tail, and transported stationary window data. The remaining rows H, C, P, N preserve that comparison componentwise and record the local NameCert surface. Since the carrier has no other coordinates, the displayed rows exhaust the obligations. □

Theorem 649.3 (Stationary window lattice refinement meet)**.** *For an accepted* $\mathsf{StationaryWindowLattice}^{\uparrow}$ *carrier $L = (Q, S, R, D, W, M, H, C, P, N)$, the row M is the common finite refinement for every stationary-window consumer that reads the mesh budget, witness schedule, cofinal tail, or transported stationary-window seal. Any such consumer must factor its selected windows through S, R, D, W and then through M before a* $\mathsf{Real}^{\uparrow}$ *seal-facing row is exported.*

Proof. Read S, R, D, W from the carrier. These rows are the selected finite windows, the regular-rational readbacks, the dyadic tolerance ledger, and the transported stationary-window seal surface.

Use the NameCert obligation theorem. It identifies M as the only common refinement-meet row and routes the displayed continuations in C through that row. Thus mesh-budget, witness-schedule, cofinal-tail, and transported-window consumers cannot choose independent finite windows after M has been fixed.

Componentwise transport through H preserves the same selected rows, while P and N record provenance and local naming. Hence the meet is a finite refinement of the displayed window data and not a second source of diagonal information. □

Theorem 649.4 (Stationary window lattice Real seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-seal consumer of an accepted* $\mathsf{StationaryWindowLattice}^{\uparrow}$ *packet receives the transported stationary-window seal row only through the displayed route*

$$Q, S, R, D, W, M, H, C, P, N.$$

The handoff preserves the same refinement meet M for the stationary diagonal window, mesh budget, witness schedule, and cofinal-tail surfaces.

Proof. Start from the transported stationary-window seal row W. It sits in the same finite packet as the stationary rational seed Q, the selected windows S, the regular readback R, the dyadic ledger D, and the refinement meet M.

Apply Definition 649.3. Every seal-facing read that uses the stationary window data must pass through M after the selected windows, readbacks, and tolerance ledger have been exposed.

The rows H and C then replay the displayed transports and continuations, and P, N provide provenance and local naming. There is no carrier coordinate for a different Real seal route, so the handoff is exactly the displayed finite route. □

Theorem 649.5 (Stationary window lattice non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{StationaryWindowLattice}^{\uparrow}$ *packet factors through the finite rows*

$$Q, S, R, D, W, M, H, C, P, N.$$

The consumer may read the stationary rational seed, finite StreamName windows, RegSeqRat readback rows, DyadicRatCore tolerance ledger, transported stationary-window seal, common refinement meet, hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row, and it cannot read quotient streams, host real equality, unbounded window families, selected limits, choice data, or ambient Real completeness.*

Proof. Project the accepted carrier and the local NameCert surface. The rows $Q, S, R, D, W, M, H, C, P, N$ are the complete displayed packet.

Use the refinement-meet theorem for window-facing consumers. It confines mesh-budget, witness-schedule, cofinal-tail, and transported-window reads to the same selected finite windows and to the common meet row M.

Use the Real seal handoff theorem for seal-facing consumers. It routes every $\mathsf{Real}^{\uparrow}$ or completion-seal read through the displayed finite route before the transported seal is exported.

No remaining carrier coordinate exists beyond those rows. Therefore no downstream consumer can extract quotient-stream data, host real equality, unbounded window data, selected limits, choice data, or ambient completeness from the packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{StationaryWindowLattice}^{\uparrow}}$.

Constructive story: A $\mathsf{StationaryWindowLattice}^{\uparrow}$ packet is generated from stationary $\mathsf{Rat}^{\uparrow}$ seed rows, selected $\mathsf{StreamName}^{\uparrow}$ finite windows, $\mathsf{RegSeqRat}^{\uparrow}$ readbacks, a $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, transported stationary-window seal rows, a common refinement-meet row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and local NameCert naming.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{StationaryWindowLattice}^{\uparrow}}$, seed)

Scope closed: Definition 649.1, Definition 649.2, Definition 649.3, Definition 649.4, and Definition 649.5 bind the finite common-refinement lattice for stationary Real-completeness window consumers.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{StationaryWindowLattice}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, quotient stream equality, host real equality, unbounded diagonal windows, selected limits, choice data, or ambient Real completeness.

Upgrade path: Obligation closure requires checked carrier admission, common refinement-meet exactness, Real seal handoff, and non-escape for the same stationary finite-window lattice packet.

Chapter 650

A Concrete Naming Certificate for $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$

The $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ packet records the finite precision-to-window route used by Real-completion consumers before a $\mathsf{Real}^{\uparrow}$ seal is reached. It keeps the precision request, schedule row, selected $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{DyadicRatCore}^{\uparrow}$ observations, $\mathsf{RegSeqRat}^{\uparrow}$ handoff, $\mathsf{Real}^{\uparrow}$ seal, transports, routes, provenance, and local naming row in one displayed BHist packet, so the limit-facing surface is finite and contains no choice operator.

The concrete completion consumer is the RealCompleteness finite seal route of chapter 450. That consumer may read the schedule row, selected $\mathsf{StreamName}^{\uparrow}$ windows, dyadic observations, $\mathsf{RegSeqRat}^{\uparrow}$ handoff, and $\mathsf{Real}^{\uparrow}$ seal exposed by $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$, but it receives no countable choice, hidden selector, or ambient completeness coordinate from the schedule packet.

Definition 650.1 (Choice-free limit schedule carrier)**.** *A* $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (E, M, W, D, R, S, H, C, P, N)$$

with the following displayed rows:

1. *E is the precision request row naming the finite tolerance level demanded by a completion-facing consumer;*
2. *M is the schedule row assigning the request E to the finite observation route used at that tolerance;*
3. *W is the finite family of* $\mathsf{StreamName}^{\uparrow}$ *window rows inspected by the schedule;*
4. *D records the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations and radius ledgers read from the windows in W;*
5. *R records the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows reached after those dyadic observations;*
6. *S records the* $\mathsf{Real}^{\uparrow}$ *seal row that receives the handoff;*
7. *H records componentwise* hsame *transports for the request, schedule, windows, dyadic observations, regular-sequence handoff, seal, provenance, and local name;*
8. *C records the displayed* Cont *routes from E to M, from M to W, from W to D, from D to R, and from R to S;*
9. *P is the* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}}$ *row.*

The carrier is exactly this finite packet. It has no coordinate for quotient streams, host equality of completed reals, countable choice, a hidden limit selector, or an ambient completeness theorem.

Theorem 650.2 (Choice-free limit schedule NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}}$ *surface for Definition 650.1 consists of five finite obligations:*

1. *carrier exposure, requiring every accepted object to display the packet* $L = (E, M, W, D, R, S, H, C, P, N)$*;*
2. *request-to-schedule exactness, requiring the precision request E to reach the schedule row M only through the displayed route in C;*
3. *window and dyadic readback coverage, requiring M to select only the finite* $\mathsf{StreamName}^{\uparrow}$ *windows in W and requiring every exported* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation in D to be read from those windows;*
4. *handoff and seal discipline, requiring the* $\mathsf{RegSeqRat}^{\uparrow}$ *rows R and the* $\mathsf{Real}^{\uparrow}$ *seal row S to be reached through D and then transported by the displayed H, C, P, N rows;*
5. *non-escape, requiring every public read to stay inside the displayed packet and to export no quotient stream, host real equality, countable-choice row, hidden limit selector, or ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.ChoiceFreeLimitScheduleUp.ChoiceFreeLimitSchedulePacket namecert obligations`

Proof. Carrier exposure is projection from the tuple in Definition 650.1. The packet lists the precision request, schedule, windows, dyadic observations, regular-sequence handoff, real seal, transports, routes, provenance, and local naming row.

Request-to-schedule exactness is the first displayed route in C. Since the carrier has one schedule row M for the request E, a consumer has no alternate coordinate from which to obtain a different schedule for the same precision request.

Window and dyadic readback coverage use the next two route segments. The route from M to W exposes only the finite window family, and the route from W to D makes the dyadic observation ledger depend on those windows rather than on an unbounded stream object.

Handoff and seal discipline are supplied by R, S, H, C, P, N. The regular-sequence handoff is reached after the dyadic ledger, the real seal is reached after the handoff, and transport or repacking must replay the same rows through H, C, P, N.

The non-escape clause follows from the carrier inventory. None of the displayed rows is a quotient stream, host real equality test, countable-choice row, hidden selector, or ambient completeness theorem, so the local naming certificate has no route that can export one. □

Theorem 650.3 (Choice-free finite schedule induction)**.** *Every accepted* $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ *package is generated by the explicitly displayed finite schedule row M of the carrier*

$$L = (E, M, W, D, R, S, H, C, P, N).$$

Extending the displayed schedule by one visible schedule entry preserves carrier admission, componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}}$ *rows. The induction surface does not select a limit, quotient a completion, invoke countable choice, or identify host real equality.*

Proof. Induct on the displayed finite schedule list encoded by M.

In the base case the schedule is empty. Carrier admission is the empty finite packet route from the request row E to the displayed window family W, dyadic ledger D, handoff row R, Real seal S, and structural rows H, C, P, N; no selector or completed limit is present.

For the step case, append one displayed schedule entry. The appended entry contributes one more visible request-to-window route inside M and W, and the dyadic readback row D records only the corresponding finite observation. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff R and $\mathsf{Real}^{\uparrow}$ seal S are still reached through the same displayed route.

Transport and replay are componentwise. The row H transports the old schedule rows and the appended entry together, while C replays the extended finite route. The provenance row P and local naming row N then repack the extended packet as another accepted $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ carrier.

The excluded objects are absent in both cases. Neither the empty schedule nor the appended-entry step introduces a selected limit, quotient completion, countable-choice row, hidden selector, or host real equality coordinate. □

Theorem 650.4 (Choice-free limit schedule non-escape)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *or completion-facing consumer of an accepted* $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ *packet factors through the finite route*

$$E, M, W, D, R, S, H, C, P, N.$$

The consumer may inspect the precision request, schedule row, finite $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row. It cannot inspect quotient streams, host equality of completed reals, countable choice, hidden limit selectors, or an ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.ChoiceFreeLimitScheduleUp.ChoiceFreeLimitSchedulePacket nonescape`

Proof. Start from the accepted carrier $L = (E, M, W, D, R, S, H, C, P, N)$. The only request-facing route begins at E and reaches the schedule row M through the displayed continuation coordinate.

Next read the finite observation surface. The schedule selects the windows in W, and the dyadic ledger D is read from those windows. Thus a consumer cannot replace the displayed window family by a quotient stream or an unbounded stream-level selector.

Pass to the completion-facing rows. The handoff row R and seal row S are reached after the dyadic ledger and are repacked only through H, C, P, N, so the route into $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ remains the same finite packet.

Finally apply the non-escape obligation of Definition 650.2. The excluded analytic objects do not occur as coordinates of L, so no public read can export quotient streams, host equality of completed reals, countable choice, hidden limit selectors, or an ambient completeness theorem. □

Theorem 650.5 (Choice-free limit schedule classifier transport)**.** *Let* $L = (E, M, W, D, R, S, H, C, P, N)$ *be an accepted* $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ *packet. The schedule classifier of* L *is the finite public test that reads exactly the displayed request row* E*, schedule row* M*, selected* $\mathsf{StreamName}^{\uparrow}$ *windows* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff* R*,* $\mathsf{Real}^{\uparrow}$ *seal row* S*, componentwise transports* H*, continuation routes* C*, provenance* P*, and local name* N*.*

If each of these rows is transported componentwise by the corresponding hsame *coordinate in* H*, the classifier is preserved. The transported packet still has no coordinate from which a quotient stream, host real equality of completed reals, countable choice, hidden limit selector, or ambient completeness theorem can be introduced.*

Proof. The carrier definition fixes the classifier domain to the rows of the packet L. Since the classifier reads no object outside $E, M, W, D, R, S, H, C, P, N$, transporting the displayed rows componentwise through H preserves exactly the same finite test.

Apply the NameCert obligations of Definition 650.2. Carrier exposure, request-to-schedule exactness, window and dyadic readback coverage, handoff and seal discipline, and non-escape are all stated for the same displayed rows.

Finally use Definition 650.4. Every public read remains inside the finite packet after transport, so there is no route that can add quotient streams, host real equality, countable choice, hidden selectors, or ambient completeness. □

Theorem 650.6 (Choice-free limit schedule RegSeqRat handoff exactness)**.** *Let $L = (E, M, W, D, R, S, H, C, P, N)$ be an accepted* $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ *packet. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row in R is reached only through the displayed route*

$$E \to M \to W \to D$$

together with the transport, route replay, provenance, and local naming rows H, C, P, N.

Thus no downstream consumer can read a handoff row through an unlisted stream representative, a quotient-stream equality, a countable-choice selector, host real equality, or an ambient completeness principle.

Proof. Start with the carrier definition. The row R occurs after the precision request E, schedule row M, window family W, and dyadic ledger D, and the continuation coordinate C displays the route from E to M, from M to W, from W to D, and from D to R.

Apply the NameCert obligations. Request-to-schedule exactness fixes the first segment, window and dyadic readback coverage fixes the middle segments, and handoff discipline fixes the passage from D to R under the same H, C, P, N rows.

Use non-escape to close the boundary. Since the handoff is read through the displayed packet, the packet cannot export an unlisted representative, quotient equality, choice selector, host real equality, or ambient completeness theorem. □

Theorem 650.7 (Choice-free limit schedule RealUp seal discipline)**.** *Let $L = (E, M, W, D, R, S, H, C, P, N)$ be an accepted* $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ *packet. Every* $\mathsf{Real}^{\uparrow}$ *seal read through S factors through the finite route*

$$E \to M \to W \to D \to R$$

and then through the same componentwise transport, continuation, provenance, and local naming rows H, C, P, N.

The exported seal is only the displayed $\mathsf{Real}^{\uparrow}$ *row of the packet. It does not provide a stronger completion object, a uniqueness theorem for completed limits, quotient equality of streams, host real equality, countable choice, a hidden selector, or ambient completeness.*

Proof. Project the seal coordinate from the carrier L. The definition places S after the request, schedule, selected windows, dyadic observations, and $\mathsf{RegSeqRat}^{\uparrow}$ handoff, and the continuation coordinate records the route into S.

Apply the NameCert obligations for handoff and seal discipline. They require the seal row to be reached through D and R and then repacked only through the displayed H, C, P, N rows.

Apply Definition 650.4. A completion-facing consumer may read the finite route and the seal row, but no stronger completion object or excluded analytic principle is present in the packet. □

Theorem 650.8 (Choice-free limit schedule consumer readback)**.** *Let $L = (E, M, W, D, R, S, H, C, P, N)$ be an accepted* $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ *packet. Every completion-facing consumer read of L factors through the same displayed route*

$$E \to M \to W \to D \to R \to S$$

and through the same componentwise transport, continuation, provenance, and local naming rows H, C, P, N.

Consequently the consumer-facing surface of the packet is the finite schedule-to-seal route together with H, C, P, N. It exposes no alternate schedule classifier, no separate $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, no stronger* $\mathsf{Real}^{\uparrow}$ *completion object, no quotient-stream equality, no host real equality, no countable-choice row, no hidden selector, and no ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.ChoiceFreeLimitScheduleUp.ChoiceFreeLimitSchedulePacket consumer readback`

Proof. Begin with the carrier and NameCert obligations. Carrier exposure fixes the displayed packet, request-to-schedule exactness fixes the segment from E to M, window and dyadic readback coverage fixes the segments from M to W and from W to D, and handoff and seal discipline fixes the segments from D to R and from R to S under the same H, C, P, N rows.

Use classifier transport to keep the public test on those rows after componentwise transport. By Definition 650.5, the transported packet still reads exactly $E, M, W, D, R, S, H, C, P, N$ and cannot add an alternate analytic coordinate.

Apply Definition 650.6 and Definition 650.7. The handoff and seal are both reached by replaying the finite route, so a completion-facing read cannot bypass the schedule, the selected windows, or the dyadic ledger.

Finally apply Definition 650.4. Since all public reads remain inside the displayed packet, the consumer readback exports only the finite route and the displayed H, C, P, N rows. □

Theorem 650.9 (Choice-free limit schedule public seal export)**.** *The carrier of Definition 650.1, the local* $\mathsf{NameCert}_{\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}}$ *obligations of Definition 650.2, the classifier transport row of Definition 650.5, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff exactness row of Definition 650.6, the* $\mathsf{Real}^{\uparrow}$ *seal discipline row of Definition 650.7, the non-escape boundary of Definition 650.4, and the consumer readback row of Definition 650.8 assemble one public finite schedule-to-seal export for* $\mathsf{Real}^{\uparrow}$ *and completion-facing consumers.*

The exported surface is exactly the displayed route

$$E \to M \to W \to D \to R \to S$$

together with the componentwise transport, continuation, provenance, and local naming rows H, C, P, N. It exports no quotient stream, host equality of completed reals, countable-choice row, hidden limit selector, stronger completion object, or ambient completeness theorem.

Proof. Start with the finite carrier. Definition 650.1 exposes the precision request E, schedule row M, selected windows W, dyadic observations D, regular-sequence handoff R, real seal S, transports H, routes C, provenance P, and local naming row N as the only coordinates of the packet.

The certificate obligations make this route public. Apply Definition 650.2 to fix carrier exposure, request-to-schedule exactness, window and dyadic readback coverage, handoff and seal discipline, and the non-escape boundary for those rows.

Transport and handoff are then read through the same packet. By Definition 650.5, componentwise hsame transport preserves the classifier on $E, M, W, D, R, S, H, C, P, N$. By Definition 650.6

and Definition 650.7, the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the $\mathsf{Real}^{\uparrow}$ seal are reached only by replaying the displayed finite route.

Finally use Definition 650.8 and Definition 650.4. Completion-facing consumers read exactly the finite schedule-to-seal surface and cannot export any excluded analytic object outside the displayed rows. □

Theorem 650.10 (Choice-free limit schedule CauchyLimitSeal factorization)**.** *Every accepted* $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ *packet whose finite route reaches the* $\mathsf{Real}^{\uparrow}$ *seal row* S *factors the seal-facing consumer through the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *surface of chapter 386 before any Real-completion consumer reads the finite schedule-to-seal export.*

Thus a Real-completion consumer receives the public surface of Definition 650.9 only after the consumer readback row of Definition 650.8 has been confined to the Cauchy-limit seal boundary. The factorization adds no quotient stream, host real equality, countable choice, hidden selector, or ambient completeness theorem.

Proof. Start with an accepted packet $L = (E, M, W, D, R, S, H, C, P, N)$ whose route reaches the $\mathsf{Real}^{\uparrow}$ seal row S. By Definition 650.8, every completion-facing read of L is already forced through the displayed route

$$E \to M \to W \to D \to R \to S$$

and through the same componentwise transport, continuation, provenance, and local naming rows H, C, P, N.

Now place the seal-facing end of that route at the Cauchy-limit seal boundary supplied by chapter 386. The $\mathsf{CauchyLimitSeal}^{\uparrow}$ surface is the consumer boundary between regular-source readback and Real-facing seal consumption, so the row S is read only after the finite schedule route has been exposed at that surface.

Finally apply Definition 650.9. The exported Real-completion surface remains exactly the finite schedule-to-seal route with H, C, P, N, now read through the displayed Cauchy-limit seal boundary first. Since neither the schedule packet nor the cited seal surface supplies quotient streams, host real equality, countable choice, hidden selectors, or an ambient completeness theorem, the factorization exports none of them. □

Theorem 650.11 (Choice-free limit schedule ProbeBundle fusion)**.** *Let* $L = (E, M, W, D, R, S, H, C, P, N)$ *be an accepted* $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ *packet, and let* $\mathcal{Q}$ *be a finite* $\mathsf{ProbeBundle}$ *of unary precision requests for completion-facing seal reads of* L*. All reads requested by* $\mathcal{Q}$ *fuse into one finite schedule-to-seal surface consisting exactly of the schedule row* M*, the finite family of* $\mathsf{StreamName}^{\uparrow}$ *windows* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff* R*, the* $\mathsf{Real}^{\uparrow}$ *seal* S*, and the displayed* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows* H, C, P, N*.*

Thus the bundled readback consumes the same public route

$$M \to W \to D \to R \to S$$

for every member of $\mathcal{Q}$*, with the precision-request row* E *supplying the accepted unary request surface. The fused bundle exports no quotient stream, host real equality, countable-choice row, hidden selector, selected host limit, ambient completeness theorem, or second completion route.*

Proof. Read the finite $\mathsf{ProbeBundle}$ one request at a time. For each unary precision request in $\mathcal{Q}$, Definition 650.8 places the completion-facing read on the displayed route through $E, M, W, D, R, S, H, C, P, N$.

Package those pointwise reads through the same bundle surface. Because $\mathcal{Q}$ is finite and every member names a seal read of the same accepted packet L, the schedule row M, window family

W, dyadic ledger D, handoff R, seal S, and rows H, C, P, N are reused rather than replaced by request-specific carriers.

Apply Definition 650.9. It identifies the common public route for Real-facing consumers as the finite schedule-to-seal surface with exactly the displayed transport, continuation, provenance, and local naming rows.

Now use Definition 650.10. The seal-facing end of the bundled route is read through the $\mathsf{CauchyLimitSeal}^{\uparrow}$ boundary before any Real-completion consumer observes the public seal, so the bundle does not open a second completion route.

Finally apply Definition 650.14. Since hidden selector coordinates are absent from the packet, the finite bundle cannot extract quotient streams, host real equality, countable choice, selected host limits, ambient completeness, or any additional completion surface. □

Theorem 650.12 (Choice-free limit schedule shared-tail meet compatibility)**.** *Let $L = (E, M, W, D, R, S, H, C, P, N$ be an accepted $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ packet. Suppose the finite route exported by L is consumed by a $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ shared-threshold packet and then sealed through the $\mathsf{CauchyLimitSeal}^{\uparrow}$ tail-budget surface. After passing to the shared-tail threshold, the displayed route remains*

$$E \to M \to W \to D \to R \to S$$

with the same selected $\mathsf{StreamName}^{\uparrow}$ windows W, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger D, $\mathsf{RegSeqRat}^{\uparrow}$ handoff R, $\mathsf{Real}^{\uparrow}$ seal S, and structural rows H, C, P, N.

Thus Real-completion diagonal consumers read the shared-tail meet as a compatibility layer for the finite schedule-to-seal packet, not as a second completion route. The compatible export contains no quotient stream, host real equality, hidden selector, countable choice, ambient completeness datum, or second seal route.

Proof. Start with the finite packet readback. By Definition 650.8, every completion-facing read of L is confined to the displayed route through $E, M, W, D, R, S, H, C, P, N$.

Next attach the Cauchy-limit seal boundary. The factorization theorem Definition 650.10 places the seal-facing end of the route at the $\mathsf{CauchyLimitSeal}^{\uparrow}$ surface before any Real-completion consumer reads the public seal.

Now pass to the shared-tail meet. The public shared-threshold certificate and consumer exactness theorems for $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, Definition 560.11 and Definition 560.34, keep the threshold read attached to its displayed source, window, modulus, threshold, comparison, transport, continuation, ledger, provenance, and naming rows. The selector-budget public route Definition 560.14 identifies the selector-facing entry with the same public threshold rather than a hidden tail oracle.

Finally use the tail-budget and selector rows on the seal side. The CauchyLimitSeal tail-budget meet and selector-budget transport, Definition 386.135 and Definition 386.136, preserve the shared $\mathsf{StreamName}^{\uparrow}$ window, dyadic ledger, regular handoff, Real seal, and displayed structural rows. Together with Definition 386.108 and the finite $\mathsf{ProbeBundle}$ fusion of Definition 650.11, this repacks all requested reads into the same finite schedule-to-seal surface and leaves no coordinate for the excluded quotient, host-equality, selector, choice, completeness, or second-seal data. □

Theorem 650.13 (Choice-free limit schedule well-founded readback)**.** *Every completion-facing readback of an accepted $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ packet follows the finite route*

$$E \to M \to W \to D \to R \to S.$$

The read descends structurally through the displayed schedule row M and the finite window family W, then through the dyadic ledger D, the $\mathsf{RegSeqRat}^{\uparrow}$ *handoff R, and the* $\mathsf{Real}^{\uparrow}$ *seal S. Its well-foundedness is therefore measured on the finite packet of Definition 650.1, not on a selected limit object.*

Proof. Start with the carrier $L = (E, M, W, D, R, S, H, C, P, N)$ from Definition 650.1. The only completion-facing spine displayed by the packet is the route from the precision request to the schedule, finite windows, dyadic observations, regular-sequence handoff, and real seal.

Apply the NameCert obligations of Definition 650.2. Request-to-schedule exactness fixes $E \to M$, window and dyadic readback coverage fixes $M \to W \to D$, and handoff and seal discipline fixes $D \to R \to S$.

Use Definition 650.6, Definition 650.7, and Definition 650.9. These rows make the consumer read replay the displayed route, so the descent is over the finite schedule and window rows rather than over a chosen completed limit. □

Theorem 650.14 (Choice-free limit schedule no selector extraction)**.** *No accepted* $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ *packet exports a hidden selector from precision requests to representatives. All exported data are the schedule row M, finite window family W, dyadic ledger D,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff R,* $\mathsf{Real}^{\uparrow}$ *seal S, and the transport, route, provenance, and local naming rows H, C, P, N.*

Proof. Project the accepted packet through Definition 650.1. Its public coordinates are exactly $E, M, W, D, R, S, H, C, P, N$, and no coordinate is a selector from requests to hidden representatives.

The obligations of Definition 650.2 keep each public read inside those rows. In particular, request-to-schedule exactness exposes only the schedule row, and window and dyadic readback coverage exposes only the finite windows and dyadic ledger selected by that schedule.

The handoff and seal are then constrained by Definition 650.6 and Definition 650.7. Finally Definition 650.9 states that the exported surface is the finite schedule-to-seal route with H, C, P, N, so a hidden selector is not part of the public packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}}$.

Constructive story: A $\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}$ packet is generated from a precision request, finite schedule row, StreamNameUp windows, DyadicRatCoreUp observations, RegSeqRatUp handoff, RealUp seal, componentwise transports, continuation routes, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 650.9 binds the public finite schedule-to-seal export from precision request through schedule, windows, dyadic ledger, RegSeqRatUp handoff, RealUp seal, and the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ChoiceFreeLimitSchedule}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ChoiceFreeLimitScheduleUp.ChoiceFreeLimitSchedulePacket\_consumer\_readback`

Bridge status: none

Origin: human

Not claimed: This chapter does not close RealUp completeness, uniqueness of completed limits, quotient equality of streams, host real equality, a public standard bridge, countable choice, audit cleanliness, or machine bridge checking.

Upgrade path: No further paper-side theory-grade target is open; verification-axis audit cleanliness or machine bridge checking remains separate.

Chapter 651

A Concrete Naming Certificate for InscriptionAcceptanceBudget$^{\uparrow}$

The InscriptionAcceptanceBudget$^{\uparrow}$ surface isolates the accepted-check and downstream consumer-budget part of an inscription event. It names the finite public packet by which a prior source state reaches a named record through a route witness, receives an accepted check, spends only the displayed consumer budget, and leaves the remaining GAP residue visible to later audit.

This packet consumes the route-witness and accepted-record rows of chapter 519 together with the visible GAP-residue ledger of chapter 520. The source, name, route, and check rows come from InscriptionEvent$^{\uparrow}$, while the residue row Q is the InscriptionGapLedger$^{\uparrow}$ boundary consumed by this budget packet.

Definition 651.1 (InscriptionAcceptanceBudget carrier)**.** *An* InscriptionAcceptanceBudget$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (S, M, R, K, U, B, Q, H, C, P, N)$$

with the following displayed rows:

1. *S is the prior source-state row from which the inscription route is read;*
2. *M is the named statement, theorem site, citation row, or public record admitted by the check;*
3. *R is the displayed route witness from S to M;*
4. *K is the accepted check row that admits R as public record data for M;*
5. *U is the intended downstream consumer row;*
6. *B is the finite consumer-budget row naming the uses of K and M available to U;*
7. *Q is the remaining* GAP *residue row after the accepted route and consumer budget have been exposed;*
8. *H records componentwise* hsame *transports for S, M, R, K, U, B, Q together with package and naming rows;*
9. *C records the displayed* Cont *routes through which consumers read the source, name, route, check, budget, and residue rows;*
10. *P is the* Pkg *provenance over* BHist, hsame, Cont, *accepted-check data, consumer-budget data,* GAP *residue data, and local certificate dependencies;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{InscriptionAcceptanceBudget}^{\uparrow}}$ *row.*
The classifier for accepted carriers compares only $S, M, R, K, U, B, Q, H, C, P, N$. It has no coordinate for private intention, host trust, unbudgeted downstream use, unchecked route replay, hidden mutation, or a complete inscription-event ontology.

Theorem 651.2 (InscriptionAcceptanceBudget check row exactness)**.** *For every accepted* InscriptionAcceptanceBud *carrier $A = (S, M, R, K, U, B, Q, H, C, P, N)$, the accepted-check row K is exactly the public route by which R is admitted from S to the named record M. Every public comparison of check rows is transported componentwise by H and read through the displayed routes in C, and the carrier exports no second checker, hidden host acceptance predicate, unchecked route, or unrecorded proof replay.*

Proof. Project the carrier of Definition 651.1. The only row whose role is route admission is K, and it is displayed beside the source row S, named record M, and route witness R.

The comparison surface is componentwise. The hsame rows in H transport S, M, R, K together with the budget, residue, package, and local naming rows, while the Cont routes in C replay the same public route into the accepted check.

No coordinate of A names another checker, a host acceptance predicate, or an unchecked replay route. Thus every accepted-check consumer reads exactly K through the displayed packet. □

Theorem 651.3 (InscriptionAcceptanceBudget consumer boundary)**.** *Every downstream use of an accepted* $\mathsf{InscriptionAcceptanceBudget}^{\uparrow}$ *carrier is bounded by the intended consumer row U and the finite consumer-budget row B. A theorem site, citation row, audit surface, or certificate consumer may read the named record M, route witness R, accepted check K, budget B, and residue Q only through U, H, C, P, N; it receives no unbudgeted consumer right, private agency predicate, hidden host trace, or replacement for the* GAP *residue.*

Proof. Begin with a public downstream request. The intended consumer is the row U, and the finite budget of permitted reads is the row B.

The route into the accepted material then passes through C. It exposes M, R, K together with Q under the componentwise transports in H and the provenance rows P, N.

Because the carrier contains no unbudgeted consumer coordinate and no hidden host trace, the consumer boundary is exhausted by U and B. The remaining residue is still the displayed row Q, not a private explanation outside the packet. □

Theorem 651.4 (InscriptionAcceptanceBudget NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{InscriptionAcceptanceBudget}^{\uparrow}}$ *surface for Definition 651.1 consists of five finite obligations:*

1. *carrier exposure: every accepted packet exposes exactly $A = (S, M, R, K, U, B, Q, H, C, P, N)$;*
2. *check-row exactness: the accepted check is the displayed row K relating S, R, and M;*
3. *consumer-budget exhaustion: every downstream use routes through U and spends only the finite row B;*
4. GAP *residue non-escape: the residue is the displayed row Q and cannot be replaced by private intention, hidden agency, raw byte identity, or host process trace;*
5. *downstream route stability: all public reads are preserved by the componentwise* hsame *transports in H and the* Cont *routes in C over the same package and local naming rows P, N.*

Proof. Carrier exposure is projection from the displayed finite tuple. The source, name, route, check, consumer, budget, residue, transport, continuation, package, and local naming rows are all coordinates of one BHist packet.

Check-row exactness is exactly Definition 651.2. Consumer-budget exhaustion is exactly Definition 651.3; both read the same rows $S, M, R, K, U, B, Q, H, C, P, N$.

For residue non-escape and route stability, inspect the remaining carrier inventory. The only residue coordinate is Q, and the only public comparison and consumer routes are the displayed rows H and C with provenance P, N. □

Theorem 651.5 (InscriptionAcceptanceBudget GAP residue exposure)**.** *For every accepted* InscriptionAcceptanceB *carrier $A = (S, M, R, K, U, B, Q, H, C, P, N)$, the* GAP *residue row Q is the only residue coordinate exposed to downstream consumers. It cannot be replaced by private intention, hidden agency, raw byte identity, or host process trace.*

Proof. Project the carrier of Definition 651.1. The only displayed row whose role is remaining GAP residue is Q.

The check-row exactness theorem, Definition 651.2, confines acceptance to K over S, R, and M. The consumer boundary theorem, Definition 651.3, lets downstream readers see residue only through the public packet and its displayed routes.

Finally use Definition 651.4. Its residue non-escape obligation states that private intention, hidden agency, raw byte identity, and host process trace are not replacement rows for Q. □

Theorem 651.6 (InscriptionAcceptanceBudget route stability)**.** *Accepted route reads of S, M, R, K, U, B, Q are stable under the componentwise H transports and the displayed C routes. Thus any downstream comparison that preserves the H* hsame *rows and follows the C* Cont *routes reads the same accepted source, name, route witness, check row, consumer row, budget row, and residue row.*

Proof. Start from the carrier of Definition 651.1. The rows H and C are part of the same finite packet as S, M, R, K, U, B, Q, so public transport and route reading are not external operations.

Apply Definition 651.2. It transports public comparisons of S, M, R, K componentwise by H and reads them through the displayed routes in C.

Use Definition 651.3 for U, B, Q. Downstream reads of the consumer budget and residue pass through the same H, C, P, N surface.

The route-stability obligation in Definition 651.4 then covers the whole accepted tuple S, M, R, K, U, B, Q over the same package and local naming rows. □

Theorem 651.7 (InscriptionAcceptanceBudget budget-spend exactness)**.** *Every downstream read of an accepted* InscriptionAcceptanceBudget$^{\uparrow}$ *carrier spends only the finite consumer-budget row B through the intended consumer row U and the local package and naming rows P, N. The packet exports no unbudgeted consumer right, no hidden route replay, and no consumer authority outside the displayed* Pkg *and* NameCert *surface.*

Proof. Read the carrier in Definition 651.1. The intended consumer row is U, the finite consumer-budget row is B, and the local package and naming rows are P, N.

Apply Definition 651.3. It states that every downstream use is bounded by U and B, and that a theorem site, citation row, audit surface, or certificate consumer reads the accepted material only through U, H, C, P, N.

The check-row exactness theorem, Definition 651.2, keeps admitted route use tied to the displayed row K rather than to a hidden replay route. The NameCert obligations of Definition 651.4 then identify consumer-budget exhaustion as a local finite obligation.

Therefore downstream consumption spends exactly the displayed budget row B through U and the local P, N rows, with no additional consumer authority outside the packet. □

Theorem 651.8 (InscriptionAcceptanceBudget mature consumer completeness)**.** *For every accepted* InscriptionAcceptanceBudget$^{\uparrow}$ *carrier* $A = (S, M, R, K, U, B, Q, H, C, P, N)$*, suppose the packet satisfies check-row exactness, consumer boundary, local* NameCert *obligations,* GAP *residue exposure, route stability, and budget-spend exactness. Then* A *exposes the complete mature public-object surface for the inscription acceptance budget: source* S*, named record* M*, route witness* R*, accepted check* K*, intended consumer* U*, finite budget* B*, residue* Q*, transport* H*, continuation* C*, provenance* P*, and local* NameCert *row* N *are all available as displayed finite rows. No private intention, hidden agency, unchecked replay, unbudgeted consumer use, or host process trace is exported by this mature surface.*

Proof. Project the carrier of Definition 651.1. Its displayed inventory is exactly $S, M, R, K, U, B, Q, H, C, P, N$, so the public-object surface starts as a finite row assembly rather than as a host-level semantic predicate.

The accepted route and consumer boundary are already fixed. Apply Definition 651.2 for K over S, R, and M, and apply Definition 651.3 for the downstream consumer row U and the finite budget row B.

Next assemble the audit rows. Use Definition 651.4 for the local NameCert obligations, Definition 651.5 for the residue row Q, and Definition 651.6 for the componentwise H transports and C routes.

Finally apply Definition 651.7. It confines downstream consumption to B through U, P, N. The mature row adds no second Lean bridge and no host-process semantics; it only repacks the six finite rows into the complete public inscription-budget surface and keeps private intention, hidden agency, unchecked replay, unbudgeted use, and host trace outside the exported packet. □

Closure status for NameCert$_{\text{InscriptionAcceptanceBudget}^{\uparrow}}$**.**

Constructive story: An InscriptionAcceptanceBudget$^{\uparrow}$ packet is generated from prior source state, a named public record, a route witness, an accepted check row, an intended consumer, a finite consumer-budget row, a GAP residue row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.InscriptionAcceptanceBudgetUp.taste gate`

Theory closure: TheoryGate(NameCert$_{\text{InscriptionAcceptanceBudget}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 651.1, Definition 651.2, Definition 651.3, Definition 651.4, Definition 651.5, Definition 651.6, Definition 651.7, and Definition 651.8 bind the same finite source, route, check, consumer-budget, GAP-residue, transport, continuation, provenance, and NameCert packet as a mature public inscription surface.

Formal verification: FormalStatus(NameCert$_{\text{InscriptionAcceptanceBudget}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.InscriptionAcceptanceBudgetUp.InscriptionAcceptanceBudgetTasteGate\_single\_carrier\_al`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close bridge checking, complete inscription-event ontology, private intention, hidden agency, unchecked route semantics, unbudgeted downstream consumption, or host process traces.

Upgrade path: Further verification work is Lean bridge checking only; no higher paper-side closure grade is asserted here.

Chapter 652

A Concrete Naming Certificate for $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$

The $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ interface packages the diagonal-limit witness surface used by the Real Completeness route. It starts from the finite dyadic tolerance ledger, selected stream windows, regular-rational readback rows, and RealUp seal rows already exposed by the Real and Completion pipeline, then records the witness packet that a downstream completion consumer may inspect. It is a finite NameCert packet; it is not a selected host limit, quotient stream equality, or ambient completeness principle.

This extractor is the finite witness-facing consumer of chapter 126, chapter 291, chapter 301, chapter 38, and chapter 386. Its substantive dependency is the route from selected finite StreamName windows through dyadic tolerance readback and regular-rational rows into the RealUp seal and completion-facing handoff; it does not introduce a second completion operator.

Definition 652.1 (Real completion witness-extractor carrier)**.** *A* $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$X = (D, W, M, Q, L, S, H, C, P, N)$$

with the following displayed rows:

1. *D is the shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger for the diagonal regular-Cauchy route;*
2. *W is the selected* $\mathsf{StreamName}^{\uparrow}$ *window family used to read the finite diagonal observations;*
3. *M is the modulus schedule that chooses the displayed diagonal windows and records the finite comparison budget for each requested precision;*
4. *Q is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row assembled from the selected windows and dyadic tolerance rows;*
5. *L is the* $\mathsf{Real}^{\uparrow}$ *seal row reached after the regular-rational readback has passed through the displayed diagonal schedule;*
6. *S is the completion-facing seal or handoff row consumed by Real Completeness and Cauchy-limit consumers;*
7. *H records componentwise* hsame *transports for D, W, M, Q, L, S and the local structural rows;*
8. *C records the displayed* Cont *routes from tolerance requests through the selected windows, modulus schedule, regular-rational readback, RealUp seal, and completion-facing handoff;*

9. *P is the* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert *rows;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{RealCompletionWitnessExtractor}^{\uparrow}}$ *row.*

The carrier accepts exactly those packets whose completion-facing handoff is read through the same finite dyadic ledger, selected windows, modulus schedule, regular-rational witness, RealUp seal, transport rows, continuation rows, and local certificate.

Lean4 (definition) `BEDC.Derived.RealCompletionWitnessExtractorUp.RealCompletionWitnessExtractorCarrier`

Theorem 652.2 (Real completion witness-extractor NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RealCompletionWitness}}$ *surface consists of carrier admission for the packet $X = (D, W, M, Q, L, S, H, C, P, N)$, selected-window admission through D, W, M, regular-rational readback through Q, RealUp seal handoff through L, completion-facing handoff through S, componentwise transport through H, displayed route replay through C, package provenance through P, local naming through N, and non-escape for quotient streams, selected host limits, host real equality, choice data, and ambient completeness.*

Proof. Project the carrier. The displayed packet lists the dyadic tolerance ledger, selected window family, modulus schedule, regular-rational readback, RealUp seal, completion-facing handoff, transports, routes, provenance, and local certificate.

The selected-window obligation is read first. The route from D through W and M fixes the finite observations and the precision schedule before any regular-rational witness can be exported.

The readback and seal obligations then factor through Q, L, S in that order. The rows H and C preserve this order componentwise, while P and N record the same finite packet as the local NameCert surface.

No coordinate of the carrier names quotient stream equality, a selected host limit, host real equality, choice data, or ambient completeness. Those conclusions therefore cannot be read from the witness extractor. □

Theorem 652.3 (Real completion witness-extractor diagonal handoff)**.** *Every Real Completeness diagonal-limit consumer of an accepted* $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ *packet receives exactly the finite handoff*

$$D, W, M, Q, L, S, H, C, P, N.$$

The handoff presents the dyadic tolerance ledger, selected stream windows, modulus schedule, regular-rational witness row, RealUp seal, completion-facing seal, displayed hsame *transports, displayed* Cont *routes, package provenance, and local naming row. It supplies no independent completion operator and no equality of quotient real names.*

Proof. Start with the selected-window side of the carrier. The diagonal route can inspect D, W, M only as the displayed finite schedule for the requested precision.

Next read the regular-rational witness Q. It is attached to the same selected windows and dyadic ledger, so the consumer cannot choose a second window family or a second modulus schedule.

Finally pass through the RealUp seal L and the completion-facing handoff S. The transport, continuation, provenance, and local naming rows keep the handoff inside the same finite packet, and the carrier has no quotient-real or ambient-completion coordinate. □

Lean4 ✓ `BEDC.Derived.RealCompletionWitnessExtractorUp.RealCompletionWitnessExtractorCarrier diagonal handoff`

Theorem 652.4 (Real completion witness-extractor non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*, or completion-facing consumer of an accepted* $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ *packet factors through* $D, W, M, Q, L, S, H, C, P, N$*. The packet exports no quotient stream equality, no selected host limit, no host real equality, no arbitrary choice of a diagonal subsequence, and no ambient completeness theorem.*

Proof. Use the NameCert obligations. They place every consumer-visible read on the same carrier coordinates: dyadic tolerance ledger, selected windows, modulus schedule, regular-rational witness, RealUp seal, completion-facing handoff, transport rows, route rows, provenance, and local name.

For a stream or regular-rational consumer, the route stops at W, M, Q. For a RealUp or completion-facing consumer, the route continues through L and S after the same window and tolerance rows have already been fixed.

The excluded conclusions require rows not present in Definition 652.1. Since H, C, P, N only transport, replay, package, and name the displayed coordinates, no consumer can escape the finite witness packet. □

Theorem 652.5 (Real completion witness-extractor coordinate induction)**.** *Let* Φ *be a certificate read on accepted* $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ *packets. If* Φ *is fixed by the dyadic ledger coordinate* D*, the selected-window coordinate* W*, the modulus coordinate* M*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback coordinate* Q*, the* $\mathsf{Real}^{\uparrow}$ *seal coordinate* L*, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff coordinate* S*, the componentwise* hsame *transport coordinate* H*, the displayed* Cont *route coordinate* C*, the* Pkg *provenance coordinate* P*, and the local* $\mathsf{NameCert}_{\mathsf{RealCompletionWitnessExtractor}^{\uparrow}}$ *coordinate* N*, and if the transport row* H *carries* Φ *componentwise across those displayed coordinates, then every accepted extractor packet satisfies* Φ*.*

Proof. Project the accepted carrier

$$X = (D, W, M, Q, L, S, H, C, P, N)$$

from Definition 652.1. The carrier has no hidden completion coordinate: every accepted read begins with the dyadic ledger D, selected windows W, and modulus schedule M.

Next read the computational coordinates in order. The $\mathsf{RegSeqRat}^{\uparrow}$ readback row Q is attached to D, W, M by Definition 652.7; the $\mathsf{Real}^{\uparrow}$ seal L and $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff S are then attached by Definition 652.8.

Now use the structural coordinates. The componentwise transport row H preserves Φ across the displayed dyadic, stream, modulus, readback, seal, and handoff rows, while the continuation row C replays those reads in the same order. The provenance row P and local naming row N are exhausted by Definition 652.10.

Finally apply the non-escape theorem. Since any accepted consumer factors through exactly $D, W, M, Q, L, S, H, C, P, N$, and since Φ is stable under each coordinate together with the transports recorded by H, induction over the displayed coordinate spine proves Φ for every accepted extractor packet. □

Theorem 652.6 (Real completion witness-extractor selected-window admission)**.** *For every accepted* $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ *packet, the first consumer-visible admission route exposes* D, W, M *as the finite selected-window route. The dyadic tolerance ledger* D*, the selected* $\mathsf{StreamName}^{\uparrow}$ *windows* W*, and the modulus schedule* M *are fixed before any regular-rational readback* Q*, RealUp seal* L*, or completion-facing handoff* S *can be read.*

Proof. Project the carrier of Definition 652.1. The rows D, W, M are listed before the readback, seal, and handoff rows, and they form the finite schedule on which the later reads are indexed.

Apply the local NameCert obligations. They bind carrier admission, selected window exposure, and modulus exposure to the same displayed packet. Thus a consumer cannot read Q, L, S without first passing through the selected-window route determined by D, W, M. □

Lean4 ✓ `BEDC.Derived.RealCompletionWitnessExtractorUp.RealCompletionWitnessExtractorCarrier selected window admission`

Theorem 652.7 (Real completion witness-extractor regular readback route)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row Q in an accepted* $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ *packet factors through the same D, W, M, H, C, P, N route. The readback may inspect the regular-rational witness attached to the selected windows, but it cannot choose a second window family, a second modulus schedule, or a second provenance and local naming route.*

Proof. Start with the diagonal handoff theorem. It attaches Q to the selected window and modulus coordinates already fixed by D, W, M.

Next use componentwise transport, displayed continuation replay, package provenance, and the local naming row. These are the rows H, C, P, N, so every readback route for Q remains inside the same transported and named packet.

The carrier contains no second copy of W or M and no alternate provenance or naming coordinate. Therefore the $\mathsf{RegSeqRat}^{\uparrow}$ readback cannot select a different window family or modulus schedule. □

Lean4 ✓ `BEDC.Derived.RealCompletionWitnessExtractorUp.RealCompletionWitnessExtractorCarrier regular readback route`

Theorem 652.8 (Real completion witness-extractor seal handoff totality)**.** *Every RealUp read through L and every completion-facing read through S in an accepted* $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ *packet passes through the same D, W, M, Q, H, C, P, N route before the seal or handoff is consumed. These reads export no quotient stream equality, host limit, choice datum, or ambient completeness theorem.*

Proof. Read the packet in carrier order. The selected tolerance, window, modulus, and regular-rational rows D, W, M, Q are fixed before the RealUp seal and the completion-facing handoff are available to a consumer.

Transport and replay then keep L and S attached to the same packet through H and C, while P and N record the package provenance and local name. Thus every seal or handoff read is routed through D, W, M, Q, H, C, P, N.

The forbidden outputs would require additional coordinates not present in the carrier. Since the packet has no quotient equality row, no host-limit row, no choice row, and no ambient-completeness row, the seal and handoff are total only for the displayed finite route. □

Lean4 ✓ `BEDC.Derived.RealCompletionWitnessExtractorUp.RealCompletionWitnessExtractorCarrier seal handoff totality`

Theorem 652.9 (Real completion witness-extractor transport totality)**.** *For every accepted* RealCompletionWitness *carrier*

$$X = (D, W, M, Q, L, S, H, C, P, N),$$

the transport and route rows H, C are total for the selected-window, regular-readback, nonescape, and seal-handoff obligations. In particular, every read of D, W, M, Q, L, S that is accepted by the local certificate replays through H, C before it reaches package provenance P and local naming N.

Proof. Begin with Definition 652.6. It fixes the selected-window route D, W, M before any later witness coordinate is visible.

Apply Definition 652.7. The readback row Q remains attached to the same selected windows, modulus schedule, transport, route, provenance, and naming rows.

Now use Definition 652.8. The RealUp seal L and completion-facing handoff S are consumed only after the selected-window and readback rows have passed through H, C, P, N.

Finally, Definition 652.4 excludes quotient stream equality, selected host limits, host real equality, arbitrary diagonal choice, and ambient completeness. Thus the displayed H, C rows exhaust transport and route replay for the accepted carrier. □

Lean4 ✓ `BEDC.Derived.RealCompletionWitnessExtractorUp.RealCompletionWitnessExtractorCarrier transport totality`

Theorem 652.10 (Real completion witness-extractor provenance exhaustion)**.** *For every accepted* $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ *carrier*

$$X = (D, W, M, Q, L, S, H, C, P, N),$$

the provenance and naming rows P, N account for all source chapters needed by the selected-window, regular-readback, nonescape, and seal-handoff route: $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*.*

Proof. Read the carrier definition. Its package row P explicitly names the dyadic tolerance ledger, selected StreamName windows, regular-rational readback, RealUp seal, CauchyLimitSeal handoff, history, transport, route, package, and naming dependencies.

Use Definition 652.6 and Definition 652.7. These theorems place D, W, M, Q under the same H, C, P, N packet.

Use Definition 652.8 together with Definition 652.4. The seal and handoff rows add no second provenance source and export none of the excluded completion or choice principles.

Therefore P, N exhaust the provenance and local naming obligations for the displayed witness-extractor carrier. □

Theorem 652.11 (Real completion witness-extractor obligation closure package)**.** *The accepted carrier*

$$X = (D, W, M, Q, L, S, H, C, P, N)$$

is an obligation-closed $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ *package for the present chapter: the selected-window route is fixed by D, W, M, the regular-readback route is fixed by Q, the Real and completion handoff route is fixed by L, S, transport and route replay are exhausted by H, C, and provenance plus local naming are exhausted by P, N.*

Proof. Assemble the obligation rows from the preceding theorems. The selected-window theorem supplies the D, W, M admission route, the regular-readback theorem supplies the Q route, and the seal-handoff theorem supplies the L, S route.

Apply Definition 652.9. It accounts for componentwise transport and continuation replay across every displayed consumer read.

Apply Definition 652.10. It accounts for package provenance and local naming over the Real and Completion dependency surface.

The nonescape theorem then removes the remaining forbidden exits: quotient stream equality, selected host limits, host real equality, arbitrary diagonal choice, ambient completeness, and un displayed completion operators. Hence the displayed carrier closes the chapter's transport, route replay, provenance, and naming obligations. □

Theorem 652.12 (Real completion witness-extractor scoped route)**.** *Every accepted* RealCompletionWitnessExtract *packet*

$$X = (D, W, M, Q, L, S, H, C, P, N)$$

is scoped by the displayed finite witness route: the DyadicRatCore tolerance ledger D, StreamName windows W, RegSeqRat readback row Q, RealUp seal L, CauchyLimitSeal handoff S, componentwise hsame *transport row H, displayed* Cont *route row C, package row P, and local* NameCert *row N. The route exports no quotient stream equality, host real equality, selected host limit, arbitrary diagonal choice, or ambient completeness principle.*

Proof. First build the finite witness route. Apply Definition 652.6 to fix the dyadic tolerance ledger, selected StreamName windows, and modulus schedule. Apply Definition 652.7 to attach the RegSeqRat readback row to the same packet.

Next attach the completion-facing rows. Use Definition 652.8 for the RealUp seal and CauchyLimitSeal handoff, then use Definition 652.9 to route all displayed reads through componentwise hsame transport and displayed Cont continuation.

Finally, apply Definition 652.10 to account for Pkg provenance and local NameCert naming. The nonescape theorem, Definition 652.4, excludes quotient stream equality, host real equality, selected host limits, arbitrary diagonal choice, and ambient completeness. Therefore the accepted packet is scoped exactly by the displayed finite witness route. □

Theorem 652.13 (Real completion witness-extractor kernel support scope)**.** *The scoped route of Definition 652.12 depends only on the named sibling chapters* DyadicRatCore$^{\uparrow}$*,* StreamName$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*,* Real$^{\uparrow}$*, and* CauchyLimitSeal$^{\uparrow}$*, together with the BEDC kernel rows* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. No further completion carrier, quotient principle, host equality row, selected-limit operator, diagonal-choice operator, or ambient-completeness row is part of the support.*

Proof. Project the carrier

$$X = (D, W, M, Q, L, S, H, C, P, N).$$

The first five witness rows are the displayed sibling-chapter rows, while H, C, P, N are the displayed kernel transport, route, package, and naming rows attached to the same packet.

Apply Definition 652.12. It already factors every accepted read through the selected-window route, regular-readback route, seal-handoff route, componentwise transport, displayed continuation, provenance, and local naming rows.

The support list is exhausted by Definition 652.10. The excluded carriers and principles are absent by Definition 652.4, so the scoped route has exactly the stated kernel support. □

Theorem 652.14 (Real completion witness-extractor standard bridge surface)**.** *For every accepted* RealCompletionWitnessExtractor$^{\uparrow}$ *packet*

$$X = (D, W, M, Q, L, S, H, C, P, N),$$

the finite rows $D, W, M, Q, L, S, H, C, P, N$ form the paper bridge surface from the BEDC witness extractor to the standard diagonal-witness reading. Every standard consumer read factors through the checked diagonal handoff, the selected-window admission route, the regular-readback route, the seal-handoff totality row, and the transport totality rows. No quotient stream equality, host limit, choice datum, or ambient completeness row is exported by this bridge surface.

Proof. Start with Definition 652.3. It supplies the checked handoff from the displayed BEDC packet to the diagonal-witness reading while keeping the same carrier coordinates $D, W, M, Q, L, S, H, C, P, N$.

Next compose the route witnesses. Apply Definition 652.6 for D, W, M, then apply Definition 652.7 for Q. These two rows place each standard read over the selected dyadic windows and the displayed regular readback coordinate.

Now attach the completion-facing handoff. Apply Definition 652.8 for L, S, and apply Definition 652.9 for H, C. Thus the consumer route is carried only by the displayed seal, handoff, transport, and continuation rows.

Finally, the nonescape and support theorems exclude the remaining exits. Quotient stream equality, host limits, choice data, and ambient completeness do not occur among the exported rows, so the displayed finite packet is exactly the paper bridge surface for the standard diagonal-witness reading. □

Theorem 652.15 (Real completion witness-extractor finite-prefix stability handoff)**.** *Every accepted* $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ *packet whose selected-window route is supplied by an accepted* $\mathsf{FinitePrefixLimitStability}^{\uparrow}$ *packet must read the finite prefix budget,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, terminal* $\mathsf{Real}^{\uparrow}$ *seal, and extractor rows through one ordered finite route before any Completion-facing handoff is visible. Thus the extractor can consume finite-prefix stability only as the displayed handoff*

$$B \to W \to R \to D \to E \to X$$

where $X = (D', W', M, Q, L, S, H, C, P, N)$ is the accepted extractor carrier, with D', W', M reading the selected extractor window, Q reading the regular-rational extractor row, and L, S, H, C, P, N reading only the displayed seal, handoff, transport, continuation, provenance, and naming rows.

Proof. First read the supplying stability packet. Apply Definition 1226.7 to identify the finite handoff from the displayed prefix observation to the terminal $\mathsf{Real}^{\uparrow}$ seal, and apply Definition 1226.8 to make that seal the unique consumer-facing end of the route.

Next pass the displayed route into the extractor. Apply Definition 652.6 to attach the extractor's selected window rows D', W', M to the same finite route. Apply Definition 652.7 to read Q only after that selected window has been admitted.

Finally attach the Completion-facing rows. Use Definition 652.8 to read L, S as the visible Real and Completion handoff rows of the accepted extractor packet. Since the supplying stability packet has already fixed the order $B \to W \to R \to D \to E$, and the extractor theorems expose only $D', W', M, Q, L, S, H, C, P, N$, no Completion-facing handoff is visible before the finite-prefix stability route and the extractor rows have both been displayed. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealCompletionWitnessExtractor}^{\uparrow}}$.

Constructive story: A $\mathsf{RealCompletionWitnessExtractor}^{\uparrow}$ packet is generated from a dyadic tolerance ledger, selected StreamNameUp windows, a modulus schedule, a RegSeqRat readback row, a RealUp seal row, a completion-facing handoff row, displayed hsame transports, Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RealCompletionWitnessExtractor}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 652.1, Definition 652.14, and Definition 652.15 bind the finite diagonal witness-extractor packet, its standard bridge surface, and its finite-prefix stability handoff for Real and Completion consumers.

Formal verification: FormalStatus(NameCert$_{\text{RealCompletionWitnessExtractor}\uparrow}$, axiomClean)
Lean target: `BEDC.Derived.RealCompletionWitnessExtractorUp.RealCompletionWitnessExtractorCarrier\_diagonal\_hando`
Bridge status: paperBridge
Origin: human
Not claimed: This chapter does not close quotient stream equality, selected host limits, host real equality, arbitrary diagonal choice, ambient completeness, or bridge checking.
Upgrade path: The theory axis is mature; the remaining work is verification-axis bridge checking only.

Chapter 653

A Concrete Naming Certificate for $\mathsf{RegularCauchySwapBisimulation}^{\uparrow}$

The $\mathsf{RegularCauchySwapBisimulation}^{\uparrow}$ packet names the finite symmetry surface between an alternating regular-Cauchy interleaving and the same interleaving read with the two source sides exchanged. It is a Real-and-Completion certificate over displayed $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegularCauchyInterleaving}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows; it is not an equality of quotient reals, a host-level limit comparison, or an appeal to ambient completeness.

The packet consumes the schedule rows of chapter 126, the regular rational source rows of chapter 301, the selector parity surface of chapter 414, and the seal boundary of chapter 38. These are substantive source rows for $A, B, S_A, S_B, \sigma, \sigma^{\mathrm{op}}, E, E'$, not decorative citations.

Definition 653.1 (Regular Cauchy swap bisimulation carrier)**.** *A* $\mathsf{RegularCauchySwapBisimulation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (A, B, S_A, S_B, \sigma, \sigma^{\mathrm{op}}, M, E, E', H, C, P, N)$$

with the following displayed rows:

1. *A and B are the two* $\mathsf{RegSeqRat}^{\uparrow}$ *source names whose finite rational observations may be interleaved;*
2. *S_A and S_B are the two* $\mathsf{StreamName}^{\uparrow}$ *schedules that expose the selected finite windows for A and B;*
3. *σ is the alternating selector row that reads A on its even side and B on its odd side;*
4. *σ^{op} is the opposite selector row that reads the same schedules after exchanging the two source sides;*
5. *M is the combined modulus ledger shared by the two selector presentations;*
6. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row reached through the A, B, σ interleaving route;*
7. *E' is the* $\mathsf{Real}^{\uparrow}$ *seal row reached through the $B, A, \sigma^{\mathrm{op}}$ interleaving route;*
8. *H stores componentwise* hsame *transports for $A, B, S_A, S_B, \sigma, \sigma^{\mathrm{op}}, M, E, E'$ and for the local packet shape;*
9. *C stores the displayed* Cont *routes from each selector read through the selected schedule, the matching component of M, the corresponding* $\mathsf{RegularCauchyInterleaving}^{\uparrow}$ *row, and the real-facing seal boundary;*

10. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegularCauchyInterleaving}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchySwapBisimulation}^{\uparrow}}$ *row.*

The carrier contains no quotient-real equality row, no selected host limit, no ambient completeness coordinate, and no third schedule.

Lean4 (definition) `BEDC.Derived.RegularCauchySwapBisimulationUp.RegularCauchySwapBisimulationUp`

Theorem 653.2 (Regular Cauchy swap bisimulation NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchySwapBis}}$ *surface for Definition 653.1 consists of six finite obligation rows:*

1. *carrier admission for the packet $W = (A, B, S_A, S_B, \sigma, \sigma^{\mathrm{op}}, M, E, E', H, C, P, N)$;*
2. *forward interleaving admission through $A, B, S_A, S_B, \sigma, M, E$;*
3. *opposite interleaving admission through $B, A, S_B, S_A, \sigma^{\mathrm{op}}, M, E'$;*
4. *selector-symmetry exactness stating that the opposite selector exchanges the same two schedule windows and the same two ledger components;*
5. *componentwise stability under the displayed* hsame *transports and replay through the displayed* Cont *routes;*
6. *real-seal non-escape stating that both real-facing rows are consumed only after the selected source name, selected schedule, shared ledger, interleaving row, package provenance, and local naming row have been displayed.*

Proof. Carrier admission is projection from the displayed tuple in Definition 653.1. The packet lists exactly the two source names, two schedules, two selector rows, common ledger, two seal rows, transports, continuations, provenance, and local name.

The forward admission row is the ordinary $\mathsf{RegularCauchyInterleaving}^{\uparrow}$ route through $A, B, S_A, S_B, \sigma, M, E$. The opposite admission row uses the same data after exchanging the source and schedule coordinates and reading σ^{op}.

Selector-symmetry exactness and stability are then local rows of the same packet. The hsame transports preserve each displayed coordinate componentwise, and the Cont routes replay only the chosen schedule and matching ledger component.

Finally, P and N repack those rows as the local certificate surface. Since the carrier has no coordinate for quotient real equality, selected host limits, ambient completeness, or a third schedule, the six rows exhaust the available certificate. □

Lean4 ✓ `BEDC.Derived.RegularCauchySwapBisimulationUp.RegularCauchySwapBisimulationTasteGate`
`single carrier alignment`

Theorem 653.3 (Regular Cauchy swap bisimulation selector symmetry)**.** *For an accepted* RegularCauchySwapBisim *carrier W, every even read of σ through A, S_A and the first component of M is matched by an odd read of σ^{op} through the same A, S_A route and the same ledger component. Every odd read of σ through B, S_B and the second component of M is matched by an even read of σ^{op} through the same B, S_B route and the same ledger component. The matching is preserved by the displayed* hsame *transports and* Cont *routes.*

Proof. Unpack the carrier. The only source rows are A and B, the only schedule rows are S_A and S_B, and the only selector rows are σ and σ^{op}.

Apply the selector parity exactness of $\mathsf{RegularCauchyInterleaving}^{\uparrow}$ to the forward route. It identifies the even reads with A, S_A and the first component of M, and the odd reads with B, S_B and the second component.

Apply the same exactness to the opposite route. Because σ^{op} is stored as the selector after exchanging the two source sides, its odd reads recover the forward even route and its even reads recover the forward odd route.

The stored H and C rows preserve this pairing componentwise. No third schedule or unlisted ledger component is present in the carrier, so the selector symmetry is confined to the displayed two-sided packet. □

Theorem 653.4 (Regular Cauchy swap bisimulation Real seal non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of the seal rows* E *or* E' *in an accepted* $\mathsf{RegularCauchySwapBisimulation}^{\uparrow}$ *carrier factors through one of the two displayed interleaving routes, the selected* $\mathsf{RegSeqRat}^{\uparrow}$ *source name, the selected* $\mathsf{StreamName}^{\uparrow}$ *schedule, the shared modulus ledger* M*, the displayed* hsame *transport, the displayed* Cont *route, the package provenance* P*, and the local naming row* N*. The packet exports no quotient real equality, selected host limit, ambient completeness proof, or third schedule.*

Proof. Start from the two seal coordinates. The row E is downstream of the forward interleaving route, while E' is downstream of the opposite interleaving route.

Use selector symmetry to identify which source side and schedule are read before each seal. The two routes differ only by the stored exchange of source sides and selector parity; both consume the same shared ledger M through a displayed component.

The rows H and C attach the required transport and replay data to those finite reads. The provenance row P and local name N then close the packet without adding any real object beyond the two seal boundaries.

Since the carrier definition has no field for quotient real equality, selected limits, ambient completeness, or an unlisted schedule, a real-facing consumer cannot leave the displayed packet. □

Theorem 653.5 (Regular Cauchy swap bisimulation public handoff)**.** *The public handoff of an accepted* $\mathsf{RegularCauchySwapBisimulation}^{\uparrow}$ *carrier is exactly the finite packet*

$$A, B, S_A, S_B, \sigma, \sigma^{\mathrm{op}}, M, E, E', H, C, P, N.$$

It presents two selector-swapped $\mathsf{RegularCauchyInterleaving}^{\uparrow}$ *routes with the same* $\mathsf{RegSeqRat}^{\uparrow}$ *source names,* $\mathsf{StreamName}^{\uparrow}$ *schedules, combined modulus ledger, displayed transports, displayed continuations, package provenance, and local* $\mathsf{NameCert}$ *row. A downstream Real-and-Completion consumer receives this finite boundary and receives no quotient real equality, selected host limit, ambient completeness principle, or bridge-checked schema.*

Proof. Carrier admission gives the listed tuple as the whole accepted object. The NameCert obligations identify the forward and opposite interleaving admissions, selector-symmetry row, stability rows, and seal-boundary row as local obligations of that same tuple.

The selector-symmetry theorem binds the two interleaving presentations to the same pair of source schedules and the same ledger components. Thus the public route does not introduce a fresh interleaving carrier; it exposes the two stored presentations of one finite packet.

The Real seal non-escape theorem confines every consumer of E or E' to those displayed rows. Repacking the carrier, obligations, selector symmetry, and non-escape boundary yields the announced public handoff. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchySwapBisimulation}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchySwapBisimulation}^{\uparrow}$ packet is generated from two $\mathsf{RegSeqRat}^{\uparrow}$ source names, two $\mathsf{StreamName}^{\uparrow}$ schedules, an alternating selector, its opposite selector, a shared modulus ledger, two $\mathsf{Real}^{\uparrow}$ seal rows, displayed hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchySwapBisimulation}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 653.1, Definition 653.2, Definition 653.3, Definition 653.4, and Definition 653.5 bind the finite selector-swapped interleaving packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchySwapBisimulation}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close quotient real equality, selected host limits, ambient completeness, bridge checking, or any route through a third schedule.

Upgrade path: Obligation closure requires checked carrier admission, forward and opposite interleaving admission, selector-symmetry exactness, componentwise stability, and RealUp seal non-escape for the displayed packet.

Chapter 654

A Concrete Naming Certificate for $\mathsf{AxiomQueryLedger}^{\uparrow}$

The $\mathsf{AxiomQueryLedger}^{\uparrow}$ packet names the finite audit surface consumed by strict proof-ancestry checks. It records an accepted declaration, the printed axiom-query report for that declaration, the forbidden-dependency comparison row, the refusal verdict, replay provenance, and the local NameCert row in one BHist certificate. It refines the dependency-report face of chapter 526 by isolating the declaration row, query output row, forbidden-dependency row, and verdict row as a reusable finite ledger. It is the query-row sibling of the dependency-map packet in chapter 862, the audit-gate boundary in chapter 526, and the kernel-acceptance audit witness in chapter 547: those chapters consume or police the same displayed query, verdict, gate, and acceptance rows. The packet turns the kernel-acceptance query `#print axioms` into a concrete ledger entry rather than an informal host-side statement about dependencies.

Definition 654.1 (Axiom-query ledger packet)**.** *An* $\mathsf{AxiomQueryLedger}^{\uparrow}$ *packet is a finite* BHist *tuple*

$$L = (D, Q, F, R, H, C, P, N)$$

with the following displayed rows:

1. *D is the accepted declaration row, naming the checked BEDC theorem, lemma, definition, structure, class, or inductive declaration whose ancestry is queried;*
2. *Q is the axiom-query output row returned by the displayed* `#print axioms` *read for D;*
3. *F is the forbidden-dependency row for* `Classical.choice`*,* `Quot.sound`*,* `propext`*, and any project-level host dependency excluded by the strict audit;*
4. *R is the verdict row recording whether the query output is admitted as clean or refused because it meets a forbidden dependency row;*
5. *H records componentwise* hsame *transport for declarations, query outputs, forbidden rows, verdicts, replay routes, provenance, and local names;*
6. *C records the displayed* Cont *routes by which a consumer replays the declaration read, the query invocation, the comparison with F, and the verdict exposure;*
7. *P is the* Pkg *provenance over kernel acceptance, axiom-query replay, forbidden-dependency comparison,* hsame*,* Cont*,* Pkg*, and* NameCert *source packets;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{AxiomQueryLedger}^{\uparrow}}$ *row.*

The packet has no coordinate for accepting a forbidden dependency as BEDC theorem content, replacing D by a neighboring declaration, treating source-token absence as ancestry purity, or hiding a query report outside the displayed ledger rows.

Theorem 654.2 (Axiom-query ledger obligations)**.** *For every* $\mathsf{AxiomQueryLedger}^{\uparrow}$ *packet*

$$L = (D, Q, F, R, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{AxiomQueryLedger}^{\uparrow}}$ *surface consists exactly of accepted-declaration exposure, axiom-query output exposure, forbidden-dependency row exposure, verdict exposure, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local naming row. Its non-exported surface excludes hidden host axioms, declaration substitution, source-token-only acceptance, and unrecorded query reruns.*

Proof. Carrier exposure is projection from Definition 654.1. The finite tuple lists exactly the rows D, Q, F, R, H, C, P, N.

The audit obligations are read through Q, F, R. The query row supplies the printed ancestry report for the accepted declaration, the forbidden row supplies the excluded dependency names, and the verdict row records the finite comparison.

Transport, replay, provenance, and naming are confined to H, C, P, N. These rows account for every public route by which a consumer can move, rerun, package, or name the same ledger entry.

Since no remaining coordinate stores a hidden host axiom, an alternate declaration, source-token-only proof, or unrecorded query rerun, the displayed rows exhaust the local $\mathsf{NameCert}$ obligations. □

Theorem 654.3 (Axiom-query ledger query soundness)**.** *Let*

$$L = (D, Q, F, R, H, C, P, N)$$

be an accepted $\mathsf{AxiomQueryLedger}^{\uparrow}$ *packet. Any downstream claim that the declaration row D passed strict axiom-query audit must factor through the displayed query row Q, the forbidden-dependency row F, the verdict row R, and the replay route in C. A clean verdict is therefore a statement about the recorded query output for D, not about an unstated ambient environment scan.*

Proof. Start with the accepted packet and project its declaration row D. The only query output attached to this declaration inside the carrier is the row Q.

The strict audit comparison is stored by the pair F, R. The row F names the excluded dependencies, and R records the comparison result for the query output already paired with D.

Replay is visible only through C, with componentwise transport and provenance supplied by H and P. Thus a downstream clean-audit claim must pass through the recorded query, comparison, verdict, and replay rows rather than through an unstated environment-level assertion. □

Lean4 ✓ `BEDC.Derived.AxiomQueryLedgerUp.AxiomQueryLedgerCarrier query soundness`

Theorem 654.4 (Axiom-query ledger refusal boundary)**.** *If the query row Q of an* $\mathsf{AxiomQueryLedger}^{\uparrow}$ *packet meets the forbidden-dependency row F, the only exported classification of that meeting is the refusal content in R. The packet does not export an alternate proof, a renamed declaration, a weaker declaration row, or a host-side permission to treat the forbidden dependency as BEDC content.*

Proof. Inspect the packet $L = (D, Q, F, R, H, C, P, N)$. The declaration and query rows expose the checked declaration and its printed ancestry report.

When Q meets F, the carrier records that meeting in the verdict row R. The comparison has no second verdict coordinate and no alternate declaration coordinate.

The remaining rows preserve and replay the same packet. The transport row H, continuation row C, provenance row P, and naming row N cannot introduce a replacement proof, weaker declaration, or permission row. Therefore the forbidden meeting is exported only as refusal content. □

Theorem 654.5 (Axiom-query ledger non-escape)**.** *Every accepted* $\mathsf{AxiomQueryLedger}^{\uparrow}$ *packet exports axiom-query information only through the finite rows*

$$D, Q, F, R, H, C, P, N.$$

It exports no host-level proof oracle, no hidden dependency list, no quotient or classical principle, no declaration substitution rule, and no downstream route that bypasses the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Project the accepted packet as $L = (D, Q, F, R, H, C, P, N)$. The definition lists every row exported by the finite ledger.

The query side is exhausted by D, Q, F, R. These rows record the accepted declaration, the printed axiom-query output, the forbidden dependency list, and the verdict.

The consumer side is exhausted by H, C, P, N. These rows record transport, replay, provenance, and the local name for the same ledger entry.

No coordinate remains for a proof oracle, hidden dependency list, quotient or classical principle, declaration substitution rule, or bypass route. The packet therefore has the stated non-escape boundary. □

Theorem 654.6 (Axiom-query ledger carrier exposure)**.** *Every admitted public read of an accepted* $\mathsf{AxiomQueryLedger}^{\uparrow}$ *packet first projects one of the displayed rows*

$$D, Q, F, R, H, C, P, N.$$

Thus a consumer can read the accepted declaration, query output, forbidden-dependency row, verdict row, componentwise transport, replay route, package provenance, or local naming row, but no public read enters the ledger without passing through one of these finite BHist *coordinates.*

Proof. Project the packet as $L = (D, Q, F, R, H, C, P, N)$. The carrier definition lists these rows as the whole exported BHist surface.

An admitted public read is mediated by the displayed Cont row C. Each continuation route in C targets one of the declaration, query, forbidden-row, verdict, transport, provenance, or naming coordinates already present in the packet.

The hsame, Pkg, and NameCert rows preserve and name those same coordinates. Since the carrier has no additional public field, every admitted read first projects one of the displayed rows. □

Theorem 654.7 (Axiom-query ledger verdict determinacy)**.** *For an accepted* $\mathsf{AxiomQueryLedger}^{\uparrow}$ *packet* $L = (D, Q, F, R, H, C, P, N)$*, the verdict row* R *is determined by the paired query output row* Q *and forbidden-dependency row* F*. Transport of* Q *and* F *by the componentwise* hsame *row transports the same verdict row and cannot create a second clean or refusal classification.*

Proof. Read the query side of the packet. The row Q is the displayed axiom-query output for the accepted declaration row D, and the row F is the displayed forbidden-dependency comparison surface.

The verdict coordinate R records the finite comparison between exactly those two rows. There is no alternate verdict coordinate and no route that compares Q against a hidden forbidden list or compares F against a different query report.

Now transport the packet componentwise through H. The transported query and forbidden rows are the transported copies of Q and F, so the transported verdict is the transported copy of their recorded comparison. The Cont, Pkg, and NameCert rows replay and name that same comparison rather than adding another classification. □

Theorem 654.8 (Axiom-query ledger replay provenance)**.** *Replay of an accepted* $\mathsf{AxiomQueryLedger}^{\uparrow}$ *packet cannot bypass the displayed* Cont*,* Pkg*, and* NameCert *rows. Any replay that exposes* D, Q, F, R, H, C, P, N *must use the continuation row* C*, carry the package provenance row* P*, and return to the local naming row* N *for the same ledger entry.*

Proof. Start from the finite ledger projection. The rows D, Q, F, R, H give the declaration, query output, forbidden comparison, verdict, and transport data that a replay may expose.

The only replay routes stored by the carrier are the displayed continuations in C. A consumer therefore reaches the declaration read, query invocation, forbidden-row comparison, and verdict exposure through C, not through an ambient host rerun.

The provenance row P records the package ancestry for that replay, and the local row N names the same $\mathsf{NameCert}_{\mathsf{AxiomQueryLedger}^{\uparrow}}$ entry. Repacking a replay without C, P, and N would require a carrier coordinate not present in L, so bypass is excluded. □

Closure status for $\mathsf{NameCert}_{\mathsf{AxiomQueryLedger}^{\uparrow}}$**.**

Constructive story: An $\mathsf{AxiomQueryLedger}^{\uparrow}$ packet is generated from an accepted declaration row, a displayed `#print axioms` query output, a forbidden-dependency row, a verdict row, componentwise hsame transports, displayed Cont replay routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AxiomQueryLedger}^{\uparrow}}$, maturePackageClosed)

Scope closed: The public query-ledger export is the same visible finite audit surface already bound by Definition 654.1, Definition 654.2, Definition 654.3, Definition 654.4, Definition 654.5, Definition 654.6, Definition 654.7, and Definition 654.8: accepted declaration row D, query output row Q, forbidden-dependency row F, verdict row R, componentwise hsame row H, displayed Cont replay row C, Pkg provenance row P, and local NameCert row N.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AxiomQueryLedger}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.AxiomQueryLedgerUp.AxiomQueryLedgerCarrier\_query\_soundness`

Bridge status: none

Origin: human

Not claimed: This chapter does not prove global host-kernel purity, completeness of all environment dependency queries, Lean-side formal verification, bridge checking, or acceptance of any dependency outside the displayed finite packet.

Upgrade path: The chapter is mature on the paper closure axis; bridge checking remains a separate formal-axis obligation for the public query-ledger rows.

Chapter 655

A Concrete Naming Certificate for $\mathsf{MultiHistSuperposition}^{\uparrow}$

The $\mathsf{MultiHistSuperposition}^{\uparrow}$ interface records the finite packet in which the inter-Hist locality chain reads quantum-state style content through displayed $\mathsf{E1}$ and $\mathsf{E0}$ refinement rows rather than through metric geometry. It consumes the already named multi-Hist configuration, cross-Hist causal witnesses, and maximum-rate bound rows, then adds a phase-coherence ledger and local NameCert surface over the same finite histories.

The source configuration row is read from chapter 474, the causal witness family from chapter 478, and the inherited unary rate bound from chapter 594. These are respectively the carrier, witness-family, and rate-bound surfaces consumed by the superposition packet. The phase-coherence row is downstream of those finite sibling rows and does not replace them by a Hilbert-space carrier or probability carrier.

Definition 655.1 (MultiHistSuperposition carrier)**.** *A* $\mathsf{MultiHistSuperposition}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (M, E, Z, X, R, \Phi, H, Q, C, P, N)$$

with the following visible coordinates:

1. *M is an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *row displaying the finite family of observer-history rows, local ledgers, no-global-sync boundary, componentwise* hsame *transports, visible* Cont *routes,* Pkg *provenance, and local naming row;*

2. *E is the finite* $\mathsf{E1}$ *refinement family over the displayed histories of M, recording observation-sensitive rows only where the packet has a visible continuation route;*

3. *Z is the finite* $\mathsf{E0}$ *refinement family over the same histories, recording name-sensitive rows only where the local naming ledger displays them;*

4. *X is the finite family of* $\mathsf{CrossHistCausal}^{\uparrow}$ *witness rows over selected pairs of histories from M and selected refinement slots from E and Z;*

5. *R is the accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *bound row for the displayed causal witness family X over the same configuration row M;*

6. *Φ is the phase-coherence ledger, a finite row comparing the selected* $\mathsf{E1}$ *and* $\mathsf{E0}$ *refinements along the displayed cross-Hist witnesses without quotienting histories or selecting a global phase;*

7. *H records componentwise* hsame *transport for M, E, Z, X, R, Φ, the probe-stability row, continuation routes, package row, and local naming row;*
8. *Q records* psame *stability for the displayed probe reads used by the refinement rows and their phase-coherence ledger;*
9. *C records the visible* Cont *routes from the configuration, refinement, causal, rate, and phase rows into the local certificate;*
10. *P is the* Pkg *provenance over* $\mathsf{MultiHistSuperposition}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, BHist, E1, E0, hsame, psame, Cont, Pkg, *and* NameCert *rows;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{MultiHistSuperposition}^{\uparrow}}$ *row.*

The carrier exports only finite observer-history rows, displayed refinement ledgers, selected cross-Hist causal witnesses, the inherited maximum-rate bound, phase-coherence rows, transport rows, continuation routes, provenance, and local naming data. It contains no Hilbert space, amplitude field, global phase, completed state vector, quotient of histories, or ambient probabilistic measure.

Theorem 655.2 (MultiHistSuperposition NameCert obligations)**.** *For the carrier of Definition 655.1, the local* $\mathsf{NameCert}_{\mathsf{MultiHistSuperposition}^{\uparrow}}$ *surface consists exactly of carrier admission for $S = (M, E, Z, X, R, \Phi, H, Q, C$ refinement locality for the displayed* E1 *and* E0 *rows over M, cross-Hist causal inheritance through X, maximum-rate inheritance through R, phase-coherence exactness through Φ, componentwise* hsame *and displayed* psame *stability through H, Q, visible* Cont *locality through C,* Pkg *provenance through P, local naming through N, and non-escape from global phases, completed state vectors, Hilbert spaces, quotient histories, and ambient probability measures.*

Proof. Carrier admission is projection from Definition 655.1. The displayed packet supplies every row named by the local certificate.

Refinement locality reads M before E and Z. Each refinement row is attached to a displayed history and a visible continuation or naming route, so the refinement cannot introduce an unlisted observer history.

The causal and bound obligations are inherited in order. The witness family X consumes selected histories and refinement slots from M, E, Z, while R supplies only the finite maximum-rate row for that same witness family.

Phase-coherence exactness is the ledger condition on Φ. It compares selected refinement rows along displayed witnesses, not representatives in a quotient of histories or amplitudes in a host state space.

Finally route all reads through H, Q, C, P, N. Since the carrier has no coordinate for global phase, Hilbert space, completed vector state, quotient history, or ambient measure, the non-escape clause is the displayed inventory boundary. □

Theorem 655.3 (MultiHistSuperposition phase coherence)**.** *For an accepted* $\mathsf{MultiHistSuperposition}^{\uparrow}$ *carrier*

$$S = (M, E, Z, X, R, \Phi, H, Q, C, P, N),$$

the phase-coherence ledger Φ is read only as a finite comparison of displayed E1 *and* E0 *refinement rows along the selected cross-Hist witness family X. Componentwise* hsame *transport in H, displayed* psame *stability in Q, and visible routes in C preserve the same finite phase ledger; they do not identify histories by quotient, choose a global phase, or complete the packet into a host quantum state.*

Proof. Project the accepted carrier and read E, Z, X, Φ. The refinement families and witness family are finite rows over the displayed multi-Hist configuration.

Transport through H preserves the histories, refinement rows, witness family, inherited rate row, and phase ledger componentwise. The probe row Q preserves the probe reads used by the same refinement comparisons.

The continuation routes in C keep every phase read on the displayed path from M to E, Z, X, R, Φ. Therefore the transported phase-coherence row remains the same finite BEDC ledger and cannot become a quotient, selected global phase, or completed state vector. □

Theorem 655.4 (MultiHistSuperposition non-escape)**.** *Every consumer of an accepted* $\mathsf{MultiHistSuperposition}^{\uparrow}$ *carrier factors through the finite rows*

$$M, E, Z, X, R, \Phi, H, Q, C, P, N.$$

In particular, the consumer may read the multi-Hist configuration row, E1 *refinement rows,* E0 *refinement rows, selected cross-Hist causal witnesses, maximum-rate bound row, phase-coherence ledger, componentwise* hsame *transports, displayed* psame *stability, visible* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{MultiHistSuperposition}^{\uparrow}}$ *row, and nothing outside those rows.*

Proof. Start with the carrier inventory. The listed coordinates are the only public rows of Definition 655.1.

Use the inherited non-escape boundaries of $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, and $\mathsf{MaxCausalRate}^{\uparrow}$. They exclude global synchronization, unlisted causal witnesses, metric geometry, and ambient real-valued rate data from the upstream rows.

The refinement and phase rows add only E, Z, Φ. By Definition 655.3, these rows are finite ledgers transported through H, Q, C and do not export Hilbert spaces, amplitude fields, global phases, completed state vectors, quotient histories, or ambient probability measures.

Thus every consumer route is exhausted by $M, E, Z, X, R, \Phi, H, Q, C, P, N$. □

Theorem 655.5 (MultiHistSuperposition obligation surface)**.** *The* $\mathsf{MultiHistSuperposition}^{\uparrow}$ *obligation surface is the finite package assembled from Definition 655.1, Definition 655.2, Definition 655.3, and Definition 655.4. It is the concrete realization of the* E1/E0 *refinement step of the inter-Hist locality chain: a local* NameCert *over finite* BHist*,* hsame*,* psame*,* Cont*,* Pkg*, and refinement rows, not a host quantum-state construction.*

Lean4 ✓ `BEDC.Derived.MultiHistSuperpositionUp.MultiHistSuperpositionTasteGate single carrier alignment`

Proof. The carrier definition supplies the finite packet rows and their dependency order. The NameCert obligation theorem binds those rows to carrier admission, refinement locality, causal and rate inheritance, phase exactness, transport stability, provenance, naming, and non-escape.

The phase-coherence theorem isolates the only quantum-state style row as the finite ledger Φ over displayed E1 and E0 refinements. The non-escape theorem then exhausts every consumer route by the same packet.

Repack these rows under the local $\mathsf{NameCert}_{\mathsf{MultiHistSuperposition}^{\uparrow}}$ entry. Since each component is one of $M, E, Z, X, R, \Phi, H, Q, C, P, N$, the obligation surface stays within the finite BEDC kernel rows named in the statement. □

Closure status for $\mathsf{NameCert}_{\mathsf{MultiHistSuperposition}^{\uparrow}}$**.**

Constructive story: A MultiHistSuperposition$^{\uparrow}$ packet is generated from a $\mathrm{MultiHistConfig}^{\uparrow}$ row, finite E1 and E0 refinement rows, selected CrossHistCausal$^{\uparrow}$ witnesses, an inherited MaxCausalRate$^{\uparrow}$ bound row, a phase-coherence ledger, componentwise hsame and displayed psame stability, visible Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\mathsf{MultiHistSuperposition}^{\uparrow}}$, seed)

Scope closed: The seed scope records the finite multi-Hist superposition packet over displayed BHist, refinement, causal, rate, phase-coherence, hsame, psame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus(NameCert$_{\mathsf{MultiHistSuperposition}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Hilbert spaces, amplitudes, global phases, probability measures, completed quantum states, quotient histories, Lorentz geometry, curved spacetime, or Lean-side verification.

Upgrade path: Obligation closure requires carrier admission, refinement locality, causal and rate inheritance, phase-coherence exactness, transport stability, provenance, and non-escape obligations for the displayed finite packet.

Chapter 656

A Concrete Naming Certificate for InterHistInvariant$^{\uparrow}$

The InterHistInvariant$^{\uparrow}$ interface packages a finite two-history invariant readback for the Inter-Hist locality chain. It consumes the multi-history packet rows already exposed by FiniteMultiHistPacket$^{\uparrow}$, the causal-witness rows supplied by CrossHistCausal$^{\uparrow}$ when present, and the unary maximum-rate boundary consumed by MaxCausalRate$^{\uparrow}$, while keeping the whole read inside BHist, hsame, Cont, Pkg, and NameCert provenance. The causal row is consumed through chapter 478, and the downstream unary-rate boundary is the consumer surface of chapter 594. The packet is not a global frame, a synchronized clock, a metric geometry, a host real equality, or a quotient of histories.

Falsifiable prediction: Every accepted InterHistInvariant$^{\uparrow}$ consumer reaches the invariant through the displayed finitemulthistpacket, crosshistcausal, maxcausalrate, and crosshistcausalrate sibling rows; a consumer route that bypasses those sibling rows refutes the packet.

Independence witness: Nearest siblings: finitemulthistpacket, crosshistcausal, maxcausalrate, crosshistcausalrate. None is bijective to this carrier because InterHistInvariant$^{\uparrow}$ simultaneously stores two history slots, one relation or causal row, one unary invariant row, one observer-symmetry row, transport, route, provenance, and local naming data, while each sibling omits at least one of those rows or records a rate-facing object instead of the invariant readback.

Definition 656.1 (InterHistInvariant carrier)**.** *An* InterHistInvariant$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$I = (A, B, R, V, S, H, C, P, N)$$

with the following visible rows:

1. *A and B are the two history rows being compared;*
2. *R is either the displayed relation row supplied by* FiniteMultiHistPacket$^{\uparrow}$ *or the causal-witness row supplied by* CrossHistCausal$^{\uparrow}$*;*
3. *V is the unary invariant readback row obtained from the transported pair and the relation row;*
4. *S is the observer-symmetry row, recording that swapping the two history rows transports to the same unary readback surface;*
5. *H stores componentwise* hsame *transport for the two histories, relation row, invariant readback, symmetry row, continuation routes, package row, and local name row;*

6. *C stores the displayed* Cont *routes for two-history projection, relation inspection, unary readback, symmetry comparison, and downstream consumer handoff;*
7. *P is the* Pkg *provenance over* $\mathsf{FiniteMultiHistPacket}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, Hist, BHist, hsame, Cont, Pkg, *and* NameCert*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{InterHistInvariant}^{\uparrow}}$ *row.*

The classifier compares accepted packets only after transporting the two histories, the relation or causal-witness row, the unary readback row, and the observer-symmetry row to a common finite two-history surface. The carrier has no coordinate for a global frame, synchronized clock, metric geometry, host real equality, quotient construction, or observer-independent ambient object.

Lean4 ✓ `BEDC.Derived.InterHistInvariantUp.InterHistInvariantTasteGate single carrier alignment`

Theorem 656.2 (InterHistInvariant NameCert obligations)**.** *For the carrier of Definition 656.1, the local* $\mathsf{NameCert}_{\mathsf{InterHistInvariant}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission for the displayed packet $I = (A, B, R, V, S, H, C, P, N)$;*
2. *two-history projection through A, B and the relation or causal-witness row R;*
3. *unary invariant readback through V after componentwise* hsame *transport;*
4. *observer-symmetry through the row S, with the swapped packet returning to the same readback surface;*
5. *consumer non-escape for global frames, synchronized clocks, metric geometry, host real equality, and quotient constructions.*

Proof. Carrier admission is the projection of Definition 656.1. The rows $A, B, R, V, S, H, C, P, N$ display exactly the two histories, the relation or causal-witness row, the unary invariant readback, the symmetry row, transport, route, provenance, and local name.

The two-history projection uses C to read A and B before it reads R. The relation row is therefore part of a finite multi-history or cross-history packet, not an ambient relation over host objects.

The unary readback is the row V transported by H. Observer symmetry is then the row S, which compares the original and swapped two-history presentations after the same displayed transport.

Since no carrier coordinate names a global frame, synchronized clock, metric geometry, host real equality, or quotient construction, the local NameCert obligations cannot export any such object. □

Theorem 656.3 (InterHistInvariant hsame stability)**.** *For accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *packets $I = (A, B, R, V, S, H, C, P, N)$ and $I' = (A', B', R', V', S', H', C', P', N')$, componentwise* hsame *transport of the two history rows, relation or causal-witness rows, unary readback rows, and observer-symmetry rows preserves the* $\mathsf{InterHistInvariant}^{\uparrow}$ *classifier. The transported packet still reads only the displayed two-history surface and its local invariant row.*

Proof. Project both carriers and transport the history rows through H and H'. The hypotheses put A, B and A', B' on a common two-history surface before either invariant row is read.

Next transport the relation or causal-witness rows R and R'. The continuation routes in C and C' replay the same finite relation inspection after transport, so the classifier has no alternate source for inter-history content.

Finally read the unary rows V, V' and the symmetry rows S, S'. Because these rows are part of the same transported packet, the classifier preserves the accepted invariant surface and does not introduce a global frame, clock, metric, host equality, or quotient. □

Theorem 656.4 (InterHistInvariant observer symmetry)**.** *For an accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *carrier* $I = (A, B, R, V, S, H, C, P, N)$*, swapping the two history rows produces a readback that factors through the same relation or causal-witness row, the same unary invariant row, and the same observer-symmetry row after displayed* hsame *transport. The invariant is observer-symmetric as a finite packet read, not as an equality inside a global frame.*

Proof. Start with the two projected history rows A and B. The swapped presentation uses the same carrier rows with the two history projections interchanged.

Apply the componentwise transport row H and the routes in C. These rows carry both the original and swapped presentations to the common finite two-history surface on which R and V are read.

The row S is the displayed symmetry witness between those two presentations. It identifies the invariant readback at the packet surface and supplies no synchronized clock, metric comparison, host real equality, or quotient of the two histories. □

Theorem 656.5 (InterHistInvariant maximum-rate consumer boundary)**.** *Every* $\mathsf{MaxCausalRate}^{\uparrow}$ *consumer of an accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *packet reads the two history rows* A, B*, the relation or causal-witness row* R*, the unary readback row* V*, the observer-symmetry row* S*, and the provenance rows* H, C, P, N *before it reads a maximum-rate boundary. The consumer receives a finite invariant packet over* $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ *and* $\mathsf{CrossHistCausal}^{\uparrow}$ *rows; it receives no global frame, synchronized clock, metric geometry, host real-valued speed, host real equality, or quotient construction.*

Proof. Project the carrier. A maximum-rate consumer first sees the two history rows, the relation or causal-witness row, the invariant readback, and the symmetry row because those are the only coordinates that can name inter-history content.

Use Definition 656.2 to order the read through carrier admission, two-history projection, unary readback, and observer symmetry. Then use Definition 656.3 to transport the same rows to the consumer surface.

The observer-symmetry theorem supplies the packet read that a maximum-rate boundary may consume. Since the packet exports only $A, B, R, V, S, H, C, P, N$, the consumer has no source for global frames, synchronized clocks, metric geometry, host real-valued speeds, host real equality, or quotient constructions. □

Theorem 656.6 (InterHistInvariant two-history route exactness)**.** *For every accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *packet*

$$I = (A, B, R, V, S, H, C, P, N),$$

all two-history content exposed by the packet is reached through the rows A, B, R, H, C, P, N*. The rows* A *and* B *are the only history inputs,* R *is the only relation or causal-witness row, and* H, C, P, N *are the only transport, continuation, provenance, and naming rows by which that content can be replayed. Hence every two-history read factors through the sibling surfaces* $\mathsf{FiniteMultiHistPacket}^{\uparrow}$*,* $\mathsf{CrossHistCausal}^{\uparrow}$*, and* $\mathsf{MaxCausalRate}^{\uparrow}$*, and no read can introduce a global frame, synchronized clock, metric geometry, host equality, or quotient.*

Proof. Project the carrier of Definition 656.1. The only rows that name two histories are A and B, and the only row that relates them is R.

The structural route is then forced by the same carrier projection. The row H supplies componentwise hsame transport, C supplies the displayed Cont routes, P supplies package provenance, and N supplies the local naming row.

Use Definition 656.2 and Definition 656.3. They identify the two-history projection and its transported replay with the finite multi-history, cross-history, and maximum-rate consumer surfaces already named in the packet. □

Theorem 656.7 (InterHistInvariant unary readback coverage)**.** *For every accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *packet* $I = (A, B, R, V, S, H, C, P, N)$*, the unary readback route consumed by* $\mathsf{MaxCausalRate}^{\uparrow}$ *is exhausted by the rows* V *and* S *after the two-history route has displayed* A, B, R, H, C, P, N*. The row* V *is the invariant readback row, and* S *is the observer-symmetry row that keeps the swapped two-history presentation on the same unary surface. These rows provide the complete maximum-rate consumer handoff and do not introduce a global frame, synchronized clock, metric geometry, host equality, or quotient.*

Proof. First expose the two-history route by Definition 656.6. The unary readback is not available before the rows A, B, R, H, C, P, N have supplied the finite two-history surface.

Now project the unary rows in the carrier. The row V records the invariant readback obtained from the transported pair and relation row, while S records the observer-symmetry comparison for the swapped presentation.

Finally apply Definition 656.4 and Definition 656.5. Together they make V and S the whole unary surface consumed by $\mathsf{MaxCausalRate}^{\uparrow}$, with no carrier coordinate left for a global or quotient object. □

Theorem 656.8 (InterHistInvariant finite-multihistory projection lock)**.** *Let* $I = (A, B, R, V, S, H, C, P, N)$ *be an accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *packet. If* R *is the relation row supplied by* $\mathsf{FiniteMultiHistPacket}^{\uparrow}$*, then every read of* A, B, R, V, S *factors through the finite two-history packet displayed by* A, B, R, H, C, P, N*. No consumer of this packet receives an ambient relation on histories, a host relation outside* R*, or a second relation row not present in the carrier.*

Proof. Project the carrier in Definition 656.1. The only history coordinates are A and B, and the only relation coordinate in the finite-multihistory case is the displayed row R.

Use Definition 656.2 to order the read through carrier admission and two-history projection. The continuation routes in C inspect R after A and B are displayed, so relation access is locked to the same finite packet.

Finally apply Definition 656.3. Transport replays the same rows A, B, R, V, S on a common finite surface and supplies no coordinate from which an ambient relation or additional relation row could be read. □

Theorem 656.9 (InterHistInvariant causal-row choice boundary)**.** *Let* $I = (A, B, R, V, S, H, C, P, N)$ *be an accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *packet. If* R *is supplied by* $\mathsf{CrossHistCausal}^{\uparrow}$*, then consumers receive only the displayed causal-witness row together with* A, B, V, S, H, C, P, N*. They do not receive a global causal order, a synchronized clock, a metric time coordinate, or any rule choosing causal comparisons beyond the row* R*.*

Proof. The carrier of Definition 656.1 gives a single slot for the relation or causal-witness row. In the causal case that slot is R, and there is no second coordinate for an order, clock, or metric time.

Apply Definition 656.2. The causal witness is read only through the two-history projection and then through the unary invariant readback, so the consumer sees the displayed causal row as packet data.

The stability theorem Definition 656.3 transports this same row with the two histories and the readback rows. Transport preserves the finite causal witness surface; it does not create a global causal order or synchronized clock. □

Theorem 656.10 (InterHistInvariant rate-consumer readback exhaustion)**.** *Every* $\mathsf{MaxCausalRate}^{\uparrow}$ *consumer of an accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *packet receives exactly the rows*

$$A, B, R, V, S, H, C, P, N$$

before any maximum-rate boundary is read. This readback exhausts the available inter-history invariant surface: the consumer has no host real-valued speed, host real equality, quotient construction, metric geometry, synchronized clock, or global frame from which to refine the rate boundary.

Proof. First project the carrier of Definition 656.1. The row list $A, B, R, V, S, H, C, P, N$ is the complete list of visible carrier coordinates.

Use Definition 656.2 to pass from the carrier list to the local obligation surface, and use Definition 656.3 to transport that same surface to the consumer. No step adds a numerical speed or quotient coordinate.

Finally apply Definition 656.5. The maximum-rate boundary consumes the finite packet after those rows are displayed, so the rate-facing readback is exhausted by the carrier inventory itself. □

Theorem 656.11 (InterHistInvariant consumer row exactness)**.** *For every accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *packet*

$$I = (A, B, R, V, S, H, C, P, N),$$

every consumer read of $A, B, R, V, S, H, C, P, N$ *is routed through the finite packet rows supplied by* $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ *or through the displayed causal row supplied by* $\mathsf{CrossHistCausal}^{\uparrow}$*. The consumer receives exactly the two history slots, relation or causal row, unary invariant row, observer-symmetry row, transport row, continuation row, provenance row, and local naming row; it receives no global frame, synchronized clock, metric geometry, host equality, or quotient route.*

Proof. Project the carrier of Definition 656.1. The tuple lists the two history slots A, B, the relation or causal row R, the unary readback V, the symmetry row S, and the structural rows H, C, P, N.

Use Definition 656.6 for the route to A, B, R, H, C, P, N. If R is a finite-multihistory relation row, the route is locked by Definition 656.8; if R is causal, it is confined by Definition 656.9.

Finally apply Definition 656.7. It exhausts the remaining consumer-facing rows V and S, so no off-packet frame, clock, metric, host equality, or quotient coordinate is available to the consumer. □

Theorem 656.12 (InterHistInvariant rate handoff exactness)**.** *Every* $\mathsf{MaxCausalRate}^{\uparrow}$ *read exported from an accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *packet consumes only the displayed unary invariant row* V*, the observer-symmetry row* S*, and the structural rows* H, C, P, N *after the two-history relation row* R *has been displayed. The handoff does not consume a hidden speed coordinate, synchronized clock, metric geometry, host real equality, quotient of histories, or global reference frame.*

Proof. Begin with Definition 656.5. It states that the maximum-rate consumer first reads $A, B, R, V, S, H, C, P, N$ from the finite packet.

The unary part of the handoff is then exactly Definition 656.7. The row V supplies the invariant readback, and S supplies the observer-symmetry comparison on the same transported two-history surface.

Use Definition 656.10 to finish the boundary. Since the row inventory is exhausted before the rate boundary is read, no hidden speed, clock, metric, host equality, quotient, or global frame can enter the handoff. □

Theorem 656.13 (InterHistInvariant finite source scope)**.** *For every accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *carrier*

$$I = (A, B, R, V, S, H, C, P, N),$$

the history rows A, B*, relation or causal row* R*, transport row* H*, continuation row* C*, package row* P*, and local naming row* N *are scoped to the finite source surface of* $\mathsf{FiniteMultiHistPacket}^{\uparrow}$*. The packet may project the two history slots and the relation row through that finite source, but it has no coordinate for a global frame, synchronized clock, metric geometry, host equality, quotient of histories, or observer-independent ambient object.*

Proof. Project the carrier in Definition 656.1. The only history inputs are the displayed rows A and B, and the only finite relation slot is R.

Apply Definition 656.8. It already binds the relation-row case to the $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ source and prevents an ambient relation or second relation row from entering the packet.

Now use Definition 656.6. The transport, continuation, provenance, and naming rows H, C, P, N are the only replay boundary for the two-history content. Since the carrier has no further coordinate, the finite source scope is exactly the displayed BHist route. □

Theorem 656.14 (InterHistInvariant causal rate scope)**.** *For every accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *carrier* $I = (A, B, R, V, S, H, C, P, N)$*, causal-row use is scoped to* $\mathsf{CrossHistCausal}^{\uparrow}$ *and the downstream unary rate boundary is scoped to* $\mathsf{MaxCausalRate}^{\uparrow}$*. A consumer may read* R *as the displayed causal row and may then read* V, S, H, C, P, N *as the finite invariant handoff to the maximum-rate surface, but it cannot read a global causal order, synchronized clock, metric time coordinate, host real speed, host equality, or quotient construction.*

Proof. Begin with the causal-row boundary of Definition 656.9. It identifies R as the only causal slot and confines it to the displayed $\mathsf{CrossHistCausal}^{\uparrow}$ row.

The rate-facing side is Definition 656.12. It routes any $\mathsf{MaxCausalRate}^{\uparrow}$ read through V, S, H, C, P, N after the two-history relation row has been displayed.

Combine these two boundaries with Definition 656.5. The consumer sees a finite causal invariant packet before the rate boundary, so there is no route to a global order, clock, metric geometry, host speed, host equality, or quotient. □

Theorem 656.15 (InterHistInvariant consumer kernel scope)**.** *Every consumer of an accepted* $\mathsf{InterHistInvariant}^{\uparrow}$ *packet factors through* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*, and the checked TasteGate carrier surface for the displayed tuple*

$$I = (A, B, R, V, S, H, C, P, N).$$

The consumer receives the two history slots, relation or causal row, unary invariant row, observer-symmetry row, transport row, continuation row, package provenance, and local name row, and receives no global frame, synchronized clock, metric geometry, host equality, quotient construction, or off-packet causal data.

Lean4 ✓ `BEDC.Derived.InterHistInvariantUp.InterHistInvariantUp StdBridge`

Proof. First apply Definition 656.11. It states that every consumer read of $A, B, R, V, S, H, C, P, N$ is routed through the finite packet rows supplied by $\mathsf{FiniteMultiHistPacket}^{\uparrow}$ or through the displayed causal row supplied by $\mathsf{CrossHistCausal}^{\uparrow}$.

Next apply Definition 656.13 and Definition 656.14. These two scope the finite-source and causal-rate cases without adding a global frame, synchronized clock, metric geometry, host equality, quotient, or off-packet causal source.

Finally align the packet with the checked TasteGate carrier surface named in Definition 656.16. The TasteGate row preserves the same displayed fields, while BHist, hsame, Cont, Pkg, and NameCert provide the kernel route by which consumers read them. □

Theorem 656.16 (InterHistInvariant TasteGate field contract)**.** *The checked TasteGate anchor for* $\mathsf{InterHistInvariant}^{\uparrow}$ *is the single-carrier alignment*

BEDC.Derived.InterHistInvariantUp.InterHistInvariantTasteGate_single_carrier_alignment.

The Lean TasteGate surface for this same packet must include explicit Nontrivial $\mathsf{InterHistInvariant}^{\uparrow}$ *and* FieldFaithful $\mathsf{InterHistInvariant}^{\uparrow}$ *instances preserving the two history slots, relation row, invariant row, symmetry row, transport row, continuation route, package provenance, and local name row.*

Proof. The paper anchor is the checked marker immediately after Definition 656.1. It identifies the TasteGate surface with the displayed carrier rather than with an external event-flow object.

Nontriviality is required because a singleton carrier would erase the distinction between the two history slots, the relation row, the invariant row, and the symmetry row. Such a collapse cannot support the consumer exactness and rate handoff theorems above.

Field faithfulness is required because each carrier coordinate has a separate consumer role. Preserving $A, B, R, V, S, H, C, P, N$ as distinct fields keeps the TasteGate route aligned with the same finite packet read by the paper obligations. □

Lean4 ✓ `BEDC.Derived.InterHistInvariantUp.taste gate`

Theorem 656.17 (InterHistInvariant obligation closure package)**.** *The carrier of Definition 656.1, the local obligations of Definition 656.2, hsame stability from Definition 656.3, observer symmetry from Definition 656.4, the maximum-rate boundary of Definition 656.5, two-history route exactness from Definition 656.6, unary readback coverage from Definition 656.7, the finite-multihistory projection lock of Definition 656.8, the causal-row choice boundary of Definition 656.9, rate-consumer readback exhaustion from Definition 656.10, consumer row exactness from Definition 656.11, rate handoff exactness from Definition 656.12, and the TasteGate field contract of Definition 656.16 form the full obligation surface for* $\mathsf{InterHistInvariant}^{\uparrow}$ *over the finite packet*

$$I = (A, B, R, V, S, H, C, P, N).$$

Every accepted packet is therefore certified by carrier admission, two-history route exactness, unary readback coverage, componentwise transport stability, observer symmetry, maximum-rate consumer boundary, package provenance, and local naming, and it exports no global frame, synchronized clock, metric geometry, host equality, or quotient.

Proof. The carrier and NameCert rows give the admission layer. They display exactly the rows $A, B, R, V, S, H, C, P, N$ and list the local obligations that must be discharged for the packet.

The route layer is supplied by the two exactness theorems. Two-history content is confined to A, B, R, H, C, P, N, while the maximum-rate unary readback is confined to V, S after those rows have been displayed.

The projection and choice layers are supplied by the finite-multihistory lock and causal-row boundary. They distinguish the relation-row and causal-row readings of R without adding any ambient relation, global order, synchronized clock, or metric time.

The stability and consumer layers are supplied by the remaining local theorems. Componentwise hsame transport preserves the same packet surface, observer symmetry keeps the swapped presentation on that surface, and the maximum-rate boundary together with rate-consumer exhaustion gives the downstream handoff.

These pieces exhaust the visible carrier coordinates. Since no additional coordinate names a global frame, synchronized clock, metric geometry, host equality, or quotient, the listed rows are the full obligation surface for $\mathsf{InterHistInvariant}^{\uparrow}$. □

Closure status for $\mathsf{NameCert}_{\mathsf{InterHistInvariant}^{\uparrow}}$.

Constructive story: An $\mathsf{InterHistInvariant}^{\uparrow}$ packet is generated from two history rows, a finite relation or causal-witness row, a unary invariant readback row, an observer-symmetry row, componentwise hsame transport, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{InterHistInvariant}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 656.13, Definition 656.14, and Definition 656.15 bind the finite source rows, causal-rate rows, consumer exactness, and TasteGate carrier surface for inter-history invariant packets, with TasteGate instance Lean4 ✓ `BEDC.Derived.InterHistInvariantUp.taste gate`

Chapter 657

A Concrete Naming Certificate for $\mathsf{ContinuationBigStep}^{\uparrow}$

The $\mathsf{ContinuationBigStep}^{\uparrow}$ packet realizes terminal-read computation as a finite continuation certificate. It reads a big-step result only from the terminal row of a displayed small-step trace, the Cont replay route, componentwise hsame transport, package provenance, and local naming. The packet adds no host evaluator, semantic evaluation relation, quotient behaviour class, or hidden totality principle.

This packet is a downstream consumer of the small-step trace carrier in chapter 469. The trace ledger T is read as $\mathsf{ContinuationTrace}^{\uparrow}$ before C replays it to the terminal row R and the terminal-read witness Q.

Definition 657.1 (ContinuationBigStep carrier)**.** *A* $\mathsf{ContinuationBigStep}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (S, T, R, Q, H, C, P, N)$$

whose displayed coordinates are as follows:

1. *S is the source row whose computation is being read;*
2. *T is the finite small-step trace ledger, displayed as the ordered* BHist, BMark, *tail, and target rows already readable by* $\mathsf{ContinuationTrace}^{\uparrow}$*;*
3. *R is the terminal row reached by the last displayed trace entry;*
4. *Q is the terminal-read witness that records the result read from R;*
5. *H is the componentwise* hsame *transport row for the source, trace, terminal, terminal-read, continuation, provenance, and naming coordinates;*
6. *C is the* Cont *replay route that replays the finite trace ledger from S to R;*
7. *P is the* Pkg *provenance over* BHist, BMark, $\mathsf{ContinuationTrace}^{\uparrow}$, hsame, Cont, *terminal-read witnesses, and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *row.*

Two accepted packets classify together only when these eight displayed coordinates are transported componentwise. The terminal-read witness Q is a read from R along the listed replay route, not an external big-step semantic object.

Theorem 657.2 (ContinuationBigStep NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *surface for the carrier of Definition 657.1 consists exactly of five finite obligations:*

1. *carrier admission for the packet* $B = (S, T, R, Q, H, C, P, N)$*;*
2. *small-step trace factorization of* T *through the* $\mathsf{ContinuationTrace}^{\uparrow}$ *rows named by* P*;*
3. *terminal readback from the terminal row* R *through the witness* Q*;*
4. *non-escape from host evaluators, host big-step semantics, quotient behaviours, and hidden termination principles;*
5. *consumer exactness for reads through* S, T, R, Q, H, C, P, N *and no other coordinates.*

Lean4 ✓ `BEDC.Derived.ContinuationBigStepUp.ContinuationBigStepCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 657.1. The accepted packet exposes the source, trace ledger, terminal row, terminal-read witness, transport, replay, provenance, and local naming coordinates.

The small-step factorization obligation is supplied by the $\mathsf{ContinuationTrace}^{\uparrow}$ route recorded in T and named by P. Each displayed step of the ledger is replayed through the continuation row C, with componentwise movement controlled by H.

Terminal readback then projects Q from the terminal row R. The witness reads only the row reached by the finite replay and therefore contributes a terminal observation, not a host-level evaluator result.

The non-escape and consumer-exactness clauses follow from the same coordinate list. Since the carrier has no field for an ambient evaluation relation, quotient behaviour, selected evaluator, or hidden termination principle, every consumer route is exhausted by S, T, R, Q, H, C, P, N. □

Theorem 657.3 (ContinuationBigStep small-step factorization)**.** *For an accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *carrier* $B = (S, T, R, Q, H, C, P, N)$*, every terminal computation read factors through a finite route*

$$S \longrightarrow T \longrightarrow C \longrightarrow R \longrightarrow Q.$$

The trace coordinate T *is read as a* $\mathsf{ContinuationTrace}^{\uparrow}$ *small-step packet,* C *replays its listed* Cont *rows,* R *is the terminal row reached by that replay, and* Q *is the terminal-read witness attached to* R*. Conversely, a consumer that reads* Q *from* R *after replaying* T *through* C *reads exactly the big-step packet surface carried by* B*, with transport and provenance supplied by* H, P, N*.*

Lean4 ✓ `BEDC.Derived.ContinuationBigStepUp.ContinuationBigStepPacket small step factorization`

Proof. Begin with the trace ledger T. By the $\mathsf{ContinuationTrace}^{\uparrow}$ small-step readback surface, each row of T is a finite source, mark, tail, and target read, and no step is imported from an external evaluator.

Replay the listed rows through C. The continuation replay composes the displayed route from the source row S to the terminal row R, while H accounts only for componentwise hsame transport of the listed coordinates.

Read the terminal witness Q from R. This gives the terminal-read surface of the packet, and P, N bind it to the package provenance and local naming row.

For the reverse direction, suppose a consumer starts with the displayed replay of T through C and then reads Q at R. The carrier has exactly the coordinates required to repack that route as B, so the consumer obtains the same finite terminal-read packet and no host-wide big-step semantics. □

Theorem 657.4 (ContinuationBigStep terminal route exhaustion)**.** *Every accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *consumer route factors through the displayed finite route*

$$S \longrightarrow T \longrightarrow C \longrightarrow R \longrightarrow Q.$$

Once the source row S, trace ledger T, replay route C, and terminal row R have been fixed, the only terminal-read data available to the consumer is the witness Q transported by the componentwise hsame *rows. The carrier provides no direct $S \to Q$ shortcut, no host big-step semantic relation, no quotient behaviour class, and no hidden termination row.*

Proof. Unpack the carrier of Definition 657.1. An accepted packet has exactly the displayed rows S, T, R, Q, H, C, P, N, with T serving as the finite $\mathsf{ContinuationTrace}^{\uparrow}$ ledger, C serving as the replay route, and Q serving as the read from the terminal row R.

Apply Definition 657.3. It routes every terminal computation read from S through T, then through C, then through R, and only then to Q.

Use Definition 657.5 for the endpoint read. After S, T, C, R are fixed, the terminal witness can move only by the componentwise hsame transport already displayed in the packet.

Finally combine Definition 657.6 with Definition 657.7. These results exclude a direct source-to-witness edge, a host evaluator, a quotient behaviour classifier, and any hidden termination row outside the finite route. □

Theorem 657.5 (ContinuationBigStep terminal-read determinacy)**.** *Let*

$$B_0 = (S_0, T_0, R_0, Q_0, H_0, C_0, P_0, N_0) \qquad \textit{and} \qquad B_1 = (S_1, T_1, R_1, Q_1, H_1, C_1, P_1, N_1)$$

be accepted $\mathsf{ContinuationBigStep}^{\uparrow}$ *carriers. Suppose their source rows, small-step trace ledgers, replay routes, and terminal rows are classifier-same:*

$$S_0 \mathsf{hsame} S_1, \qquad T_0 \mathsf{hsame} T_1, \qquad C_0 \mathsf{hsame} C_1, \qquad R_0 \mathsf{hsame} R_1.$$

Then the terminal-read witnesses are classifier-same,

$$Q_0 \mathsf{hsame} Q_1,$$

and both accepted big-step reads factor through one finite route presentation. More precisely, the read of B_0 factors through

$$S_0 \longrightarrow T_0 \longrightarrow C_0 \longrightarrow R_0 \longrightarrow Q_0,$$

while the read of B_1 is the classifier transport of this same route through the displayed comparisons on S, T, C, R and the induced comparison on Q.

Proof. By Definition 657.1, an accepted $\mathsf{ContinuationBigStep}^{\uparrow}$ packet has exactly the displayed coordinates S, T, R, Q, H, C, P, N. The coordinate T is the finite $\mathsf{ContinuationTrace}^{\uparrow}$ ledger, C is the displayed Cont replay route from the source row to the terminal row, R is the terminal row reached by that replay, and Q is the terminal-read witness attached to R.

Apply Definition 657.3 to B_0 and B_1. The first packet reads through

$$S_0 \longrightarrow T_0 \longrightarrow C_0 \longrightarrow R_0 \longrightarrow Q_0,$$

and the second reads through

$$S_1 \longrightarrow T_1 \longrightarrow C_1 \longrightarrow R_1 \longrightarrow Q_1.$$

The hypotheses identify the source, ledger, replay, and terminal rows of these two routes by the local classifier. Hence the two routes have the same finite replay spine after componentwise transport.

The only remaining endpoint datum is the terminal-read row. By Definition 657.2, terminal readback is read from the terminal row through the witness Q, and consumer exactness allows reads only through the displayed coordinates S, T, R, Q, H, C, P, N. Since the source, trace ledger, replay route, and terminal row have already been matched, there is no second carrier coordinate from which a different terminal-read endpoint can be selected. Transporting the readback of Q_0 along $R_0 \mathsf{hsame} R_1$ and the matched replay route therefore gives the readback of Q_1, so $Q_0 \mathsf{hsame} Q_1$.

Thus the two accepted big-step reads are not two independent terminal computations. They are the same finite small-step replay followed by the same terminal-read operation, with the second presentation obtained from the first by classifier transport along the displayed source, trace, route, terminal, and terminal-read comparisons. □

Theorem 657.6 (ContinuationBigStep non-escape)**.** *Every accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet route factors through the finite rows*

$$S, T, R, Q, H, C, P, N.$$

It cannot export a host evaluator, a host big-step semantics, a quotient behaviour class, or a hidden termination principle. The only terminal computation data available to consumers is the finite small-step ledger T, its replay through C, the reached terminal row R, and the terminal-read witness Q, with transport, provenance, and naming supplied by H, P, N.

Proof. Inspect the carrier in Definition 657.1. Its coordinates are exactly the source row, trace ledger, terminal row, terminal-read witness, componentwise transport, displayed continuation replay, package provenance, and local naming row.

Apply Definition 657.3. Every terminal computation read is routed through the finite spine from S through T and C to R and then to Q.

None of the displayed carrier rows is a host evaluator, host big-step semantics, quotient behaviour class, or hidden termination principle. Since the accepted route has no other coordinate to export, the packet preserves the stated non-escape boundary. □

Theorem 657.7 (ContinuationBigStep consumer exactness)**.** *Every terminal-read consumer of an accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet first reads the finite small-step trace ledger T, replays the ledger through the displayed continuation row C, reaches the terminal row R, and then reads the witness Q. Transport and provenance may move this route only through H, P, N.*

Consequently a consumer of the terminal read consumes exactly the finite route

$$S \longrightarrow T \longrightarrow C \longrightarrow R \longrightarrow Q,$$

with no direct read from S to Q and no host-level big-step shortcut.

Lean4 ✓ `BEDC.Derived.ContinuationBigStepUp.ContinuationBigStepConsumerExactness`

Proof. Begin with Definition 657.3. It gives the displayed route from the source row through the trace ledger and continuation replay to the terminal row and witness.

Use Definition 657.5. A terminal read is determined by the source row, trace ledger, replay route, and terminal row up to the displayed classifier transport, so a consumer cannot choose an independent terminal witness.

The remaining rows H, P, N account for componentwise transport, package provenance, and local naming. They move or name the same finite route; they do not add a second evaluator or a host-level terminal semantics. □

Theorem 657.8 (ContinuationBigStep trace-row admission)**.** *Every accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet admits its trace row only as the displayed* $\mathsf{ContinuationTrace}^{\uparrow}$ *small-step ledger* T *in Definition 657.1. The carrier, package, and local* NameCert *rows may name and transport that ledger, but they cannot replace it by a host evaluator, a quotient behaviour class, or an unrecorded termination witness.*

Proof. Start with the carrier tuple in Definition 657.1. Its trace coordinate is the displayed finite ledger T, and the surrounding rows are source, terminal, terminal-read, transport, continuation, provenance, and naming data.

Use Definition 657.2. The local certificate binds admission to those displayed rows, so the trace row must be the row named by the packet.

Finally use Definition 657.3. Every accepted terminal computation factors through the same small-step ledger, so there is no independent trace source available to consumers.

The consumer boundary is the one stated in Definition 657.7. Consumers therefore receive this admitted trace row only through the finite replay route, not through a host-level big-step shortcut. □

Theorem 657.9 (ContinuationBigStep terminal-row readback)**.** *For every accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet, the terminal-read witness* Q *is reachable only after replaying the displayed trace ledger* T *through the continuation row* C *to the terminal row* R*. A consumer therefore reads* Q *through the finite route*

$$S \longrightarrow T \longrightarrow C \longrightarrow R \longrightarrow Q,$$

with transport and package provenance supplied by the displayed H, P, N *rows.*

Proof. Start with the carrier tuple of Definition 657.1. Its visible rows are the only rows available for terminal readback.

Use Definition 657.2 to bind those rows to the local NameCert obligation package. The certificate does not name an additional terminal computation.

Then use Definition 657.3 to obtain the replay route from the source row through the trace ledger and the continuation row to the terminal row.

Finally use Definition 657.7. It states that terminal-read consumers reach Q only after the trace replay reaches R, and that H, P, N merely transport and name that same finite route.

The route therefore has no direct edge from S to Q and no host-level big-step shortcut. □

Theorem 657.10 (ContinuationBigStep trace-prefix readback)**.** *Let* $K = (S, T, R, Q, H, C, P, N)$ *be an accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *carrier. Any consumer that reads a terminal prefix of the computation before* R *must read that prefix through the finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger* T*, transported by* H*, replayed through* C*, and named by* P, N*. The packet has no direct terminal prefix row outside the trace ledger.*

Proof. Start with the carrier of Definition 657.1. Its source row is S, its finite trace ledger is T, and its replay endpoint is R.

Apply the small-step factorization theorem Definition 657.3. It makes the route from S to R pass through the displayed trace ledger, so a prefix read before R is a read of an initial segment of T.

Use Definition 657.8 to admit the trace row as the $\mathsf{ContinuationTrace}^{\uparrow}$ ledger. The rows H, C, P, N then transport, replay, source, and name that same prefix, without adding a separate terminal prefix coordinate. □

Theorem 657.11 (ContinuationBigStep terminal-witness exhaustion)**.** *Let $K = (S, T, R, Q, H, C, P, N)$ be an accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *carrier. Once S, T, C, R are fixed, the terminal-read witness displayed by the packet is exhausted by Q. Any accepted terminal read using the same source, trace, continuation route, and replay endpoint names the same witness row Q and has no second terminal witness outside the carrier.*

Proof. Read S, T, C, R from Definition 657.1. These rows fix the source, the finite replay ledger, the displayed continuation route, and the replay endpoint.

Apply terminal-read determinacy from Definition 657.5. With the replay route and endpoint fixed, a terminal consumer cannot choose a different terminal row.

The row Q is the only terminal-read witness coordinate in the carrier. The transport and naming rows H, P, N preserve that witness, and C is already one of the fixed rows, so the accepted packet exhausts terminal witnesses at Q. □

Theorem 657.12 (ContinuationBigStep small-step closure package)**.** *The* $\mathsf{ContinuationBigStep}^{\uparrow}$ *dependency-ready obligation package consists of the carrier $K = (S, T, R, Q, H, C, P, N)$, local NameCert obligations, small-step factorization, terminal-read determinacy, non-escape, consumer exactness, trace-row admission, trace-prefix readback, and terminal-row readback for the same finite packet. This package exports a finite* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *surface, not a host big-step evaluator.*

Proof. Carrier admission and the local naming obligations are those of Definition 657.1 and Definition 657.2.

The operational spine is supplied by Definition 657.3, Definition 657.5, and Definition 657.6. These bind the small-step route, the terminal witness, and the non-escape boundary for the same rows S, T, R, Q, H, C, P, N.

The consumer surface is supplied by Definition 657.7, Definition 657.8, Definition 657.10, and Definition 657.9. Together they make the trace row and terminal row readable by downstream packets without adding a host evaluator.

Thus the package is dependency-ready exactly as a finite BEDC packet: the trace ledger, terminal witness, transport, continuation, provenance, and local name are all displayed coordinates, and no semantic big-step shortcut is exported. □

Theorem 657.13 (ContinuationBigStep local NameCert package)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *obligation package for an accepted packet is the assembly of carrier admission, trace-row admission, terminal-row readback, non-escape, and consumer exactness over the same rows*

$$S, T, R, Q, H, C, P, N.$$

It records a finite continuation computation packet and does not export host evaluator semantics, quotient behaviour, or hidden termination.

Proof. Carrier admission is given by Definition 657.1, and the local certificate obligations are those of Definition 657.2.

Trace factorization is supplied by Definition 657.3 and by Definition 657.8. The accepted trace is the displayed small-step ledger T.

Terminal readback is supplied by Definition 657.9, while non-escape is the boundary of Definition 657.6. The consumer surface is exactly Definition 657.7.

Together these clauses package the same finite rows S, T, R, Q, H, C, P, N under the local $\mathsf{NameCert}$ row, with no additional host evaluator or hidden semantic carrier. □

Theorem 657.14 (ContinuationBigStep subject-reduction socket handoff)**.** *Every subject-reduction discharge consumer of an accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet must read the source row* S*, the displayed* $\mathsf{ContinuationTrace}^{\uparrow}$ *small-step ledger* T*, the terminal row* R*, the terminal-read witness* Q*, the componentwise transport row* H*, the displayed continuation route* C*, the provenance row* P*, and the local naming row* N *before it reaches any discharge socket. Thus the only handoff route into a preservation-facing consumer is the terminal-read route displayed by the finite ledger* S, T, R, Q, H, C, P, N*.*

Proof. Start with carrier admission in Definition 657.1. It displays exactly the rows S, T, R, Q, H, C, P, N and makes T the finite $\mathsf{ContinuationTrace}^{\uparrow}$ ledger.

Use Definition 657.3 to route the source row through the small-step ledger and continuation row before any terminal row is read. Then use Definition 657.9 to force the terminal consumer through R and Q.

Finally apply Definition 657.7 and Definition 657.13. These identify the only downstream consumer surface with the displayed carrier, trace, terminal readback, provenance, and local $\mathsf{NameCert}$ rows, so a discharge socket cannot be reached by a route outside the finite packet. □

Theorem 657.15 (ContinuationBigStep preservation-boundary non-escape)**.** *The subject-reduction handoff of Definition 657.14 exports no host evaluator, hidden termination row, quotient behaviour, or preservation theorem beyond the displayed terminal-read route. Any preservation-facing consumer receives only the finite ledger rows* S, T, R, Q, H, C, P, N *and the local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *surface.*

Proof. Inspect the carrier of Definition 657.1. Its coordinates include the source, trace, terminal row, terminal witness, transport, route, provenance, and local name, and they include no host evaluator, quotient coordinate, or hidden termination row.

The operational information available to a consumer is exactly the factorization of Definition 657.3 and the terminal readback of Definition 657.9. The consumer exactness theorem Definition 657.7 prevents these rows from being enlarged by a downstream read.

The local package theorem Definition 657.13 records the same boundary at the naming surface. Therefore the handoff may feed a preservation-facing socket, but it does not itself contain a preservation theorem or any additional semantic route. □

Theorem 657.16 (ContinuationBigStep terminal ledger package)**.** *For an accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet, carrier admission, trace-row admission, terminal-row readback, consumer exactness, and the subject-reduction socket handoff assemble into the dependency-ready terminal ledger package over the finite rows* S, T, R, Q, H, C, P, N*. The package is a BEDC terminal-read ledger for downstream discharge packets, not a host big-step semantics.*

Proof. Carrier admission comes from Definition 657.1, while trace admission is the small-step factorization of Definition 657.3. These two items fix the source row, trace ledger, continuation route, and terminal row of the packet.

Terminal readback is exactly Definition 657.9, and consumer exactness is exactly Definition 657.7. Together they make the terminal witness and every downstream read pass through the displayed rows.

The local packaging theorem Definition 657.13 and the handoff theorem Definition 657.14 then repack the same data for subject-reduction-facing consumers. The non-escape boundary of Definition 657.15 keeps the result a terminal ledger package rather than a host semantics. □

Theorem 657.17 (ContinuationBigStep trace-ledger threshold)**.** *Every terminal-read consumer of an accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet must pass through the displayed* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger before the terminal row is readable. Concretely, if* $K = (S, T, R, Q, H, C, P, N)$ *is accepted, then any read of* R *or* Q *factors through the carrier row* T*, the local* $\mathsf{NameCert}$ *obligations, the small-step factorization route, terminal-read determinacy, and consumer exactness for the same finite packet.*

Proof. Start with the carrier of Definition 657.1. The rows S, T, R, Q, H, C, P, N are the only rows available to a terminal-read consumer, and T is the displayed $\mathsf{ContinuationTrace}^{\uparrow}$ ledger.

Apply Definition 657.2 and Definition 657.3. These force terminal computation reads through the route from S to T, then through the displayed continuation replay to R.

Use Definition 657.5 and Definition 657.7. The terminal row and its witness are readable only after the trace ledger and replay route have been fixed, so a consumer cannot reach R or Q by bypassing T. □

Theorem 657.18 (ContinuationBigStep terminal consumer package)**.** *The rows* S, T, R, Q, H, C, P, N *form the complete terminal-read package over* BHist*,* BMark*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. The package consists of carrier admission, local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *obligations, small-step factorization through* T*, terminal-read determinacy at* R, Q*, and consumer exactness over the same finite rows.*

Proof. Carrier admission is Definition 657.1, and the naming obligations are Definition 657.2. These two items fix the finite rows S, T, R, Q, H, C, P, N and the BEDC structural objects BHist, BMark, hsame, Cont, Pkg, and $\mathsf{NameCert}$.

The operational route is supplied by Definition 657.3. It makes the terminal read pass from the source row through the $\mathsf{ContinuationTrace}^{\uparrow}$ ledger and the displayed continuation replay before reaching the terminal row.

Finally apply Definition 657.5 and Definition 657.7. They make the terminal witness determined by the displayed route and prevent consumers from importing any row outside the package. □

Theorem 657.19 (ContinuationBigStep replay-route stability)**.** *Let* $K = (S, T, R, Q, H, C, P, N)$ *and* $K' = (S', T', R', Q', H', C', P', N')$ *be accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packets. If the displayed replay spines agree componentwise by* hsame *on the source row, trace ledger, continuation replay, and terminal row, then every terminal-read route transported through* H, C, P, N *remains on the same finite route*

$$S \to T \to C \to R \to Q.$$

In particular, transport along the accepted package cannot replace the route by a host evaluator, a direct source-to-result edge, or an unlisted termination row.

Proof. Begin with the carrier of Definition 657.1. The accepted packet exposes only the rows S, T, R, Q, H, C, P, N, and the second packet exposes the corresponding primed rows with the same componentwise hsame transport data.

Use Definition 657.2 and Definition 657.3. These obligations identify the displayed route from the source row to the trace ledger and then through the continuation replay to the terminal row.

Apply Definition 657.5. Once S, T, C, R have been fixed by componentwise hsame, the terminal read has no second route through which it can reach R or Q.

Finally use Definition 657.7. Consumer transport through H, C, P, N repacks the same finite rows, so the terminal-read route remains the displayed $S \to T \to C \to R \to Q$ route. □

Theorem 657.20 (ContinuationBigStep terminal-read coverage)**.** *Every accepted terminal-read consumer of a* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet is covered by carrier admission, trace-row admission, terminal-row readback, terminal-read determinacy, and consumer exactness for the same rows* S, T, R, Q, H, C, P, N*. The coverage surface contains no additional read authority beyond the finite replay route certified by the local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *package.*

Proof. Carrier admission is exactly Definition 657.1. It fixes the rows that the consumer may address and records their structural BEDC objects.

Trace-row admission is supplied by Definition 657.3. Terminal-row readback is the displayed terminal read of Definition 657.9.

Use Definition 657.5 to make the terminal witness determined by those rows. Then apply Definition 657.7 to show that any consumer read is a read of the same finite packet rather than an enlargement of it. □

Theorem 657.21 (ContinuationBigStep NameCert consumer interface)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *consumer interface is exactly the carrier row, replay route, terminal witness, componentwise transport, provenance, and local naming rows of an accepted packet. Equivalently, the interface consists of* S, T, R, Q, H, C, P, N *together with the displayed* BHist*,* BMark*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *structure, and it contains no host evaluator or hidden termination row.*

Proof. Read the interface from Definition 657.1. The carrier records the source, trace ledger, terminal row, terminal witness, transports, continuation replay, provenance, and local name.

The naming surface is constrained by Definition 657.2. The replay route is supplied by Definition 657.3, and terminal access is governed by Definition 657.5.

It remains to exclude hidden consumer authority. Apply Definition 657.7 together with Definition 657.19 and Definition 657.20. The resulting interface is exactly the finite local package and not a host big-step evaluator. □

Theorem 657.22 (ContinuationBigStep non-escape scope package)**.** *The terminal consumer package of Definition 657.18 excludes host evaluators, quotient behaviours, hidden termination, and direct source-to-result shortcuts. Every accepted terminal read remains inside the finite rows* S, T, R, Q, H, C, P, N *and the local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *surface.*

Proof. Use the carrier and local obligations first. By Definition 657.1 and Definition 657.2, the accepted packet has no coordinate for a host evaluator, quotient behaviour, hidden termination row, or direct source-to-result edge.

Next apply Definition 657.3 and Definition 657.5. They make any terminal result pass through the displayed trace ledger and terminal row rather than through an external evaluator.

The boundary is closed by Definition 657.7. Since consumers can read only the displayed package rows, the non-escape scope is exactly the finite $\mathsf{ContinuationBigStep}^{\uparrow}$ surface. □

Theorem 657.23 (ContinuationBigStep prefix closure)**.** *Every accepted prefix of the small-step trace ledger of an accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet remains a finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *route. The prefix route is read through the carrier rows* S, T, R, Q, H, C, P, N*, the local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *obligations, the small-step factorization, terminal-read determinacy, and the non-escape boundary; it imports no host evaluator, hidden termination principle, quotient behaviour, or direct source-to-result shortcut.*

Proof. Begin with the carrier of Definition 657.1. The only trace coordinate is T, and it is a finite $\mathsf{ContinuationTrace}^{\uparrow}$ ledger attached to the source row S and replay route C.

Apply the local NameCert obligations and the small-step factorization. They make every accepted trace read pass through S, then through the displayed trace ledger T, and then through the replay route toward R.

For an accepted prefix, restrict this same displayed ledger before the terminal row is consumed. Terminal-read determinacy ensures that the full terminal witness is not changed by reading the prefix, and the non-escape theorem prevents a prefix consumer from replacing the finite trace route by a host evaluator or hidden termination row. □

Theorem 657.24 (ContinuationBigStep result stability)**.** *Let two accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packets have classifier-same terminal rows under the displayed* hsame *transport, and suppose their replay routes agree on the source row, trace ledger, continuation replay, and terminal row. Then the terminal-read witnesses induced by the displayed replay are classifier-same. The witness comparison is read only through* S, T, R, Q, H, C, P, N *and the corresponding primed rows, together with carrier admission, NameCert obligations, small-step factorization, terminal-read determinacy, consumer exactness, and non-escape.*

Proof. Start with the two carrier packets. Their source rows, trace ledgers, replay routes, terminal rows, terminal witnesses, transports, provenance, and local names are the only displayed coordinates available for a terminal read.

Use the NameCert obligations and small-step factorization for both packets. These route each terminal read through its displayed trace ledger and continuation replay before reaching the terminal row.

Apply terminal-read determinacy at the classifier-same terminal rows. Since the replay routes agree on the source, trace, continuation, and terminal rows, the terminal witness has no independent route by which it can vary.

Finally use consumer exactness and non-escape. Transport through H, C, P, N and the primed rows repacks the same finite replay surface, so the induced terminal-read witnesses are classifier-same rather than host-evaluator results. □

Theorem 657.25 (ContinuationBigStep ledger totality)**.** *The rows* S, T, R, Q, H, C, P, N *exhaust every* $\mathsf{ContinuationBigStep}^{\uparrow}$ *consumer route. Any accepted big-step consumer must read the source row, finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger, terminal row, terminal-read witness, componentwise* hsame *transports, displayed* Cont *replay, package provenance, and local* $\mathsf{NameCert}$ *row; no ninth row supplies a host evaluator, hidden termination, quotient behaviour, or direct source-to-result shortcut.*

Proof. Read the carrier and local NameCert obligations first. They list exactly S, T, R, Q, H, C, P, N as the finite big-step packet and give no additional consumer coordinate.

Next apply the small-step factorization. It accounts for the operational content of the packet by routing the source through the trace ledger and displayed continuation replay before the terminal row is read.

Terminal-read determinacy and consumer exactness then account for R, Q, H, C, P, N. The terminal row and witness are fixed by the displayed replay, while transports, continuations, provenance, and the local name authenticate the same route to consumers.

The non-escape theorem closes the ledger. Since every displayed route has already been assigned to one of S, T, R, Q, H, C, P, N, no host evaluator, hidden termination row, quotient behaviour, or direct source-to-result shortcut remains available. □

Theorem 657.26 (ContinuationBigStep source trace lock)**.** *For every accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet*

$$B = (S, T, R, Q, H, C, P, N),$$

the source row S and finite trace ledger T determine the admissible replay route seen by any terminal-read consumer. The route passes through the displayed BHist *trace rows, componentwise* hsame *transports H, replay* Cont *row C,* Pkg *provenance row P, and local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *row N before the terminal row R and witness Q can be consumed.*

No accepted consumer may replace the trace ledger by a host evaluator, add an undisplayed terminal route, or read a terminal witness outside the displayed S, T, R, Q, H, C, P, N inventory.

Proof. Project the accepted packet with Definition 657.1. This exposes the source row, trace ledger, terminal row, terminal-read witness, transport rows, replay route, provenance row, and local name as the complete BHist-level inventory.

Apply the small-step factorization theorem. It routes every computation read from S through the finite trace ledger T and the displayed replay row C before the terminal row R and witness Q are read.

Use terminal-read determinacy to fix the endpoint of this route. Since the terminal read is determined by the displayed replay, the consumer cannot choose a separate terminal row or witness once S and T have been fixed.

Finally apply consumer exactness, ledger totality, and non-escape. These results place H, C, P, N on the same displayed route and rule out host evaluators, hidden terminal rows, quotient behaviour, and direct source-to-result shortcuts. □

Theorem 657.27 (ContinuationBigStep terminal source exhaustion)**.** *For every accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet $B = (S, T, R, Q, H, C, P, N)$, the terminal row R and terminal-read witness Q are exhausted by the same finite trace that starts at S and is recorded in T. A terminal consumer may read R and Q only after the displayed* BHist *trace,* hsame *transports,* Cont *replay,* Pkg *provenance, and local* NameCert *row have been displayed.*

Thus R and Q cannot be replaced by a host evaluator result, hidden termination principle, quotient behaviour class, or direct source-to-terminal shortcut.

Proof. Start with the source and trace rows. Carrier admission and the local NameCert obligations bind S and T to the same finite big-step packet as R, Q, H, C, P, N.

Use the small-step factorization to replay the finite trace. The replay reaches the terminal row through T and C, so the terminal row is a displayed endpoint of the trace rather than a host-level evaluation result.

Apply terminal-read determinacy to the witness. Once the displayed replay reaches R, the witness Q is determined by that terminal-read route and has no separate source.

The non-escape and ledger-totality theorems close the exhaustion claim. Since all consumer rows have already been accounted for by S, T, R, Q, H, C, P, N, no host evaluator, hidden termination principle, quotient behaviour class, or direct shortcut remains. □

Theorem 657.28 (ContinuationBigStep ledger factorization)**.** *Every consumer of the local* $\mathsf{NameCert}_{\mathsf{ContinuationBigSt}}$ *row factors through the finite ledger*

$$S, T, R, Q, H, C, P, N.$$

More explicitly, the consumer first reads the source row and trace ledger, then the small-step replay through the displayed Cont *row, then the terminal row and witness, and finally the transport, provenance, and local naming rows that certify the route. This factorization is exactly the route supplied by the small-step factorization, terminal-read determinacy, consumer exactness, and ledger-totality theorems.*

No accepted local-name consumer receives a host big-step evaluator, hidden terminal source, quotient behaviour class, or undisplayed replay route.

Proof. Read the local naming row through the carrier. The row N certifies the displayed packet S, T, R, Q, H, C, P, N and does not introduce an additional computational coordinate.

Apply the small-step factorization. It supplies the operational route from S through T and C before R and Q are available.

Next use terminal-read determinacy and consumer exactness. These theorems force every terminal consumer, including one entering through the local name, to use the same ordered trace, replay, terminal, transport, provenance, and naming rows.

Finally invoke ledger totality and non-escape. Every displayed consumer route has now been assigned to S, T, R, Q, H, C, P, N, so the local NameCert row cannot certify a host big-step evaluator, hidden terminal source, quotient behaviour class, or undisplayed replay route. □

Theorem 657.29 (ContinuationBigStep root-unblock finite surface)**.** *For every accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet* $B = (S, T, R, Q, H, C, P, N)$*, the downstream terminal-read surface is exactly the finite root-unblock inventory consisting of the* BHist *carrier rows, the componentwise* hsame *rows in* H*, the displayed* Cont *replay row* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$ *row* N*. Every downstream consumer of the terminal read must obtain its data from this displayed inventory, with* T *as the finite small-step ledger,* R *as the reached terminal row, and* Q *as the terminal-read witness.*

Proof. Project the accepted packet through Definition 657.1. The projection exposes only S, T, R, Q, H, C, P, N, with T a finite trace ledger, H the componentwise hsame transport table, C the displayed continuation replay, P the package provenance, and N the local naming row.

Apply Definition 657.3. It routes the computation read from the source row through the trace ledger and replay route before the terminal row and witness are consumed.

Use Definition 657.7 and Definition 657.6. These results prevent a terminal-read consumer from bypassing the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows or importing a host evaluator.

Finally invoke Definition 657.25. Since the totality ledger exhausts every consumer route by S, T, R, Q, H, C, P, N, the root-unblock surface is precisely the finite inventory displayed above. □

Theorem 657.30 (ContinuationBigStep root trace-route lock)**.** *Let* $B = (S, T, R, Q, H, C, P, N)$ *be an accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet. Any downstream read of the terminal witness* Q *is locked to the finite route*

$$S \longrightarrow T \longrightarrow C \longrightarrow R \longrightarrow Q.$$

No consumer may read Q *directly from* S*, replace* T *by a host evaluator, or bypass the replay row* C *and terminal row* R*.*

Proof. Begin with carrier admission from Definition 657.1. The terminal witness Q is a displayed coordinate of the same finite packet as the source row S, trace ledger T, replay row C, and terminal row R.

Definition 657.3 gives the route from S through T and C to R and then to Q. Thus the terminal witness is read after the replayed trace, not as an independent source-to-witness edge.

Consumer exactness from Definition 657.7 fixes this order for downstream reads. The non-escape boundary of Definition 657.6 excludes host evaluator shortcuts, hidden termination rows, and quotient behaviour classes.

The ledger-totality theorem Definition 657.25 then rules out any remaining route. Every row available to a consumer has already appeared in the displayed chain or in the transport, provenance, and naming rows that authenticate that chain. □

Theorem 657.31 (ContinuationBigStep root terminal ledger exactness)**.** *For every accepted* $\mathsf{ContinuationBigStep}^{\uparrow}$ *packet* $B = (S, T, R, Q, H, C, P, N)$*, the terminal ledger is exhausted by the displayed trace, replay, terminal, transport, provenance, and naming rows. Concretely, trace data are read from* T*, replay data from* C*, terminal data from* R, Q*, componentwise transport from* H*, package provenance from* P*, and local naming from* N*; no additional root row contributes terminal-read authority.*

Proof. Read the carrier definition first. It separates the ledger into the trace row T, the replay row C, the terminal rows R, Q, transport H, provenance P, and local naming N, all over the source row S.

The small-step factorization theorem assigns the operational route to T, C, R, Q. The consumer-exactness theorem assigns downstream terminal reads to the same ordered route.

The non-escape theorem removes every undisplayed source of terminal-read authority. In particular, a host evaluator, hidden termination principle, quotient behaviour class, or direct shortcut is not a coordinate of the packet.

By Definition 657.25, all consumer routes are already exhausted by S, T, R, Q, H, C, P, N. Therefore the terminal ledger is exact: the displayed trace, replay, terminal, transport, provenance, and naming rows are all of it. □

Closure status for $\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ContinuationBigStep}^{\uparrow}$ packet is generated from a source row, a finite small-step trace ledger, the terminal row reached by replay, a terminal-read witness, componentwise hsame transports, displayed Cont replay, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 657.1, Definition 657.2, Definition 657.3, Definition 657.5, Definition 657.6, Definition 657.7, Definition 657.14, Definition 657.15, Definition 657.16, Definition 657.17, Definition 657.18, Definition 657.19, Definition 657.20, Definition 657.21, and Definition 657.22 bind the carrier, NameCert obligations, small-step factorization, terminal-read determinacy, non-escape boundary, consumer exactness, subject-reduction socket handoff, terminal ledger package, trace-ledger threshold, terminal consumer package, replay-route stability, terminal-read coverage, NameCert consumer interface, and non-escape scope package as the exported public-object boundary for the finite big-step packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ContinuationBigStep}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ContinuationBigStepUp.ContinuationBigStepPacket\_small\_step\_factorization`

Bridge status: none

Origin: human

Not claimed: This chapter does not close host evaluator semantics, quotient behaviour, hidden termination, Lean verification, or bridge checking.

Upgrade path: The finite small-step factorization, terminal-route exhaustion, consumer exactness, trace-row admission, terminal-row readback, and downstream continuation-trace dependency give the mature paper-side treatment; bridge checking remains a separate verification-axis obligation.

Chapter 658

A Concrete Naming Certificate for $\mathsf{RegularCauchyTailFusion}^{\uparrow}$

The $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ packet records the finite cofinal tail-fusion step used by Real completeness consumers before a diagonal $\mathsf{Real}^{\uparrow}$ seal is read. It joins regular-sequence tail witnesses, selected finite stream windows, dyadic tolerance ledgers, a shared tail-meet row, a diagonal seal route, and the local naming certificate into one displayed BHist surface. It exports no quotient stream, host real equality, selected completed limit, unbounded diagonal object, or ambient completeness theorem.

Falsifiable prediction: Deleting the shared-threshold row M permits a $\mathsf{Real}^{\uparrow}$ seal route to bypass the displayed $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ handoff, while deleting the finite window row W breaks the $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ route to the $\mathsf{RegSeqRat}^{\uparrow}$ readback.

Independence witness: Nearest siblings: regular-cauchy-tail-meet, regularcauchylimittransport, streamname, dyadicratcore, and real. The $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ packet is not bijective to any one of them because it stores the fused route $Q, X, W, D, T, M, R, L, H, C, P, N$ linking all five surfaces before the $\mathsf{Real}^{\uparrow}$ seal.

Definition 658.1 (Regular Cauchy tail fusion carrier)**.** *A* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (Q, X, W, D, T, M, R, L, H, C, P, N)$$

with the following displayed coordinates:

1. *Q is the rational or dyadic precision request routed to the tail-fusion consumer;*
2. *X is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular rational family row whose tail witnesses are being fused;*
3. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *window family selected for the precision request;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance and observation ledger for the selected windows;*
5. *T is the finite tail-witness row exposing the cofinal tail data read from X through W and D;*
6. *M is the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold row that makes the displayed tail witnesses use one cofinal tail bound;*
7. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *diagonal readback row reached after the shared tail bound and dyadic ledger are fixed;*
8. *L is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after Q, X, W, D, T, M, R have been exposed;*

9. *H stores componentwise* hsame *transports for the precision request, regular family, windows, dyadic ledger, tail witnesses, tail-meet row, readback row, seal row, provenance, and local name;*
10. *C stores the displayed* Cont *routes from precision request to window selection, dyadic observation, tail witness, shared tail meet, diagonal readback, and Real seal;*
11. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTailFusion}^{\uparrow}}$ *row.*

The carrier is only the finite cofinal tail-fusion packet. It has no coordinate for quotient stream equality, host real equality, an externally selected limit, an unbounded diagonal stream, or an ambient completeness principle.

Definition 658.2 (Regular Cauchy tail fusion classifier)**.** *Two accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *carriers classify together when their displayed precision requests, regular-family rows, finite windows, dyadic ledgers, tail witnesses, shared tail-meet rows, diagonal readbacks, and Real seal rows are related componentwise by the stored* hsame *transports and replay the same* Cont *route from Q through M to L.*

The classifier compares only the rows listed in Definition 658.1; it does not compare quotient streams, host real values, selected external limits, or ambient completeness witnesses.

Theorem 658.3 (Regular Cauchy tail fusion NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTailFusion}^{\uparrow}}$ *surface for the carrier of Definition 658.1 consists exactly of carrier admission, precision-request exposure,* $\mathsf{RegSeqRat}^{\uparrow}$ *family admission, finite* $\mathsf{StreamName}^{\uparrow}$ *window coverage,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance-ledger readback, finite tail-witness exposure,* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold routing, diagonal* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal handoff, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and the local naming row.*

Proof. Project the carrier F. Its coordinates list the precision request, regular family, selected windows, dyadic ledger, tail witnesses, shared tail meet, diagonal readback, Real seal, transports, routes, provenance, and local name.

The cofinal tail route is finite. A consumer first reads Q, then the selected windows W and dyadic ledger D, then the tail witness row T, and only then the shared-threshold row M used by the diagonal readback R.

The remaining rows H, C, P, N transport, route, record provenance, and name the same packet. Since no carrier coordinate contains quotient streams, host real equality, selected limits, unbounded diagonal data, or ambient completeness, the listed obligations exhaust the local naming surface. □

Theorem 658.4 (Regular Cauchy tail fusion tail-meet handoff)**.** *For an accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *carrier, every cofinal tail witness read reaches the diagonal readback row R through the finite route*

$$Q, X, W, D, T, M, H, C, P, N.$$

The $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *row M is the only shared-threshold surface available to the packet, so the handoff cannot replace it by a hidden tail oracle, quotient-stream comparison, selected limit, host real equality, or ambient completeness row.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailFusionUp.RegularCauchyTailFusionCarrier tail meet handoff`

Proof. Read the carrier coordinates from Definition 658.1. The only row that can merge tail witnesses into a common bound is M, and it appears after the precision request, regular-family row, finite windows, dyadic ledger, and tail-witness row.

Apply the NameCert obligation theorem. It binds the tail-witness exposure to T and the shared-threshold routing to M, with all movement recorded by H and C and all provenance recorded by P and N.

Because the classifier of Definition 658.2 compares only the displayed rows, no transported carrier can introduce a second tail source or an external comparison. The diagonal readback therefore receives the tail-meet handoff through exactly the finite route shown above. □

Theorem 658.5 (Regular Cauchy tail fusion monotone window handoff)**.** *Every accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet reads its selected* $\mathsf{StreamName}^{\uparrow}$ *finite windows W and dyadic ledger D before the tail witnesses T and shared threshold M are consumed. Later* $\mathsf{Real}^{\uparrow}$ *seal reads through L cannot skip W, D or replace them by an unwindowed tail oracle, quotient stream comparison, selected limit, or ambient completeness row.*

Proof. Project

$$F = (Q, X, W, D, T, M, R, L, H, C, P, N).$$

The carrier orders the finite windows and dyadic ledger before tail witnesses and before the shared threshold row.

Use Definition 658.4. It routes every cofinal tail witness through $Q, X, W, D, T, M, H, C, P, N$ before the diagonal readback R is reached.

Now apply the limit-transport link to the later seal row. Since the $\mathsf{Real}^{\uparrow}$ handoff reads L only after the displayed diagonal readback route, coordinate exhaustion leaves no route that bypasses W, D. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailFusionUp.RegularCauchyTailFusionCarrier window monotone handoff`

Theorem 658.6 (Regular Cauchy tail fusion shared-threshold exhaustion)**.** *Every* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *route that reaches the diagonal readback R or the* $\mathsf{Real}^{\uparrow}$ *seal L uses the single displayed shared-threshold row M supplied by the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *sibling. The packet has no second tail oracle, quotient stream comparison, selected limit, ambient completeness row, or independent threshold coordinate.*

Proof. Project

$$F = (Q, X, W, D, T, M, R, L, H, C, P, N).$$

The only shared-threshold coordinate in the carrier is M.

Apply Definition 658.4. It sends each cofinal tail witness to R through M, with all movement recorded by the displayed transport, continuation, provenance, and local naming rows.

Use the sibling link to chapter 560 to identify M as the shared finite threshold surface. Use the link to chapter 600 for the subsequent route from R to L.

Coordinate exhaustion closes the claim. Since no other carrier coordinate has the role of a threshold, tail oracle, quotient comparison, selected limit, or completeness witness, every route to R or L uses the displayed M row. □

Lean4 ✓ `BEDC.Derived.RegularCauchyTailFusionUp.RegularCauchyTailFusionCarrier shared threshold exhaustion`

Theorem 658.7 (Regular Cauchy tail fusion Real limit handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *diagonal-limit consumer of an accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet reads the seal row* L *only after the precision request, regular rational family, selected finite windows, dyadic tolerance ledger, finite tail witnesses, shared tail-meet row, diagonal readback, componentwise transports, continuation routes, package provenance, and local name have been displayed.*

Equivalently, the completion-facing route factors through

$$Q, X, W, D, T, M, R, H, C, P, N$$

before the seal row L *is consumed, and it exports no quotient stream, host real equality, selected completed limit, unbounded diagonal object, or ambient completeness theorem.*

Proof. Begin with a $\mathsf{Real}^{\uparrow}$ consumer of the seal row L. In the carrier, L is downstream of the diagonal readback row R, so the consumer cannot inspect a seal before the finite readback route has been displayed.

Use Definition 658.4. It places every cofinal tail read through $Q, X, W, D, T, M, H, C, P, N$ before R is reached.

Now append the seal route from R to L using the continuation rows in C and the componentwise transports in H. The package provenance and local name record the same finite route. Since the carrier and classifier omit quotient streams, host equality, selected limits, unbounded diagonal objects, and ambient completeness, no completion-facing read can escape the displayed packet. □

Theorem 658.8 (Regular Cauchy tail fusion limit-transport link)**.** *Every accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet factors its* $\mathsf{Real}^{\uparrow}$ *seal handoff through the shared-threshold row of chapter 560 and the displayed seal transport surface of chapter 600 before any* $\mathsf{Real}^{\uparrow}$ *consumer can read the diagonal limit row.*

In particular, for

$$F = (Q, X, W, D, T, M, R, L, H, C, P, N),$$

the rows Q, X, W, D, T *expose the finite precision, regular rational family, selected windows, dyadic ledger, and tail witnesses;* M *supplies the shared cofinal threshold;* R, L *supply the diagonal readback and seal handoff; and* H, C, P, N *record transport, continuation, provenance, and the local name.*

Proof. Project the existing packet rows $Q, X, W, D, T, M, R, L, H, C, P, N$. The carrier gives no direct route from the finite tail witnesses to the Real seal; the route must first pass through the displayed shared-threshold row M and the diagonal readback row R.

Use the tail-meet sibling chapter 560. Its shared cofinal threshold is exactly the row consumed at M, so the tail-fusion packet cannot read its finite witnesses as independent unmerged tails.

Now use the limit-transport sibling chapter 600. Its displayed seal transport surface is the finite route that carries the diagonal readback toward the Real-facing seal row, so L is reached only after M and R have been exposed.

Finally apply the Real limit handoff theorem above. Since the carrier omits quotient streams, host real equality, selected limits, unbounded diagonal data, and ambient completeness, the sibling-linked route has no non-displayed escape before the $\mathsf{Real}^{\uparrow}$ consumer reads the diagonal limit row. □

Theorem 658.9 (Regular Cauchy tail fusion public obligation handoff)**.** *For every accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet*

$$F = (Q, X, W, D, T, M, R, L, H, C, P, N),$$

the carrier rows, classifier comparison, tail-meet handoff, monotone window handoff, shared-threshold exhaustion, $\mathsf{Real}^{\uparrow}$ *limit handoff, and limit-transport link jointly form the public obligation surface for downstream Real and Completion consumers. Every such consumer receives those rows as one finite handoff and receives no additional source beyond the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *route.*

Proof. Project the carrier and classifier. The public surface begins with the displayed coordinates $Q, X, W, D, T, M, R, L, H, C, P, N$, and classifier stability compares only those coordinates.

Use the tail-meet handoff, monotone window handoff, and shared-threshold exhaustion. These rows place every cofinal tail read behind the selected windows, dyadic ledger, finite witnesses, and the shared threshold M supplied by chapter 560.

Use the Real limit handoff and the limit-transport link. They carry the diagonal readback through R and the seal row L along the displayed transport surface of chapter 600.

Repack the cited rows as the public obligation handoff. Since no other coordinate is available in the packet, every Real or Completion consumer receives exactly that finite surface. □

Theorem 658.10 (Regular Cauchy tail fusion window budget coverage)**.** *Every accepted window read of a* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet factors through the finite window and budget route*

$$W, D, T, M$$

before the diagonal readback and Real seal rows R, L *are consumed. The row* W *is read as the finite-window surface of chapter 126,* D *is read as the dyadic tolerance ledger of chapter 291,* T *records the displayed tail witnesses, and* M *is the shared-threshold row.*

Proof. Start from an accepted window read. Projection from the carrier shows that the only window coordinate is W, and the only budget coordinate attached to it is D.

Apply the StreamName finite-window rows, represented here by the W coordinate, and then apply the dyadic ledger rows represented by D. These two rows supply the bounded window and tolerance information before any tail witness can be used.

Use the monotone window handoff and shared-threshold exhaustion. They force the read through T and then through M before the diagonal readback row R and the seal row L can be consumed.

Thus every accepted window read factors through W, D, T, M first, and the downstream rows R, L receive only the finite route already covered by those rows. □

Theorem 658.11 (Regular Cauchy tail fusion Real seal non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or Completion consumer of a* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet receives only the displayed route*

$$Q, X, W, D, T, M, R, L, H, C, P, N.$$

The handoff exposes no quotient stream, host real equality, selected limit, unbounded diagonal object, hidden tail oracle, or ambient completeness principle.

Proof. Begin with the public obligation handoff above. It places every downstream read on the displayed carrier, classifier, tail-meet, window, threshold, Real handoff, and limit-transport rows.

Apply window budget coverage. The consumer reaches R and L only after the route through W, D, T, M has been exposed.

Finally use coordinate exhaustion. The carrier has no quotient stream coordinate, no host real equality coordinate, no selected-limit coordinate, no unbounded diagonal object, no hidden tail oracle, and no ambient completeness row. Therefore a Real or Completion consumer cannot escape the displayed finite route. □

Theorem 658.12 (Regular Cauchy tail fusion scoped window exhaustion)**.** *Every scoped completion-facing read of an accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet factors through the finite route*

$$Q, X, W, D, T, M, R, H, C, P, N$$

before the seal row L is consumed. Here W, D are the $\mathsf{StreamName}^{\uparrow}$ *window row and* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row, M is the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold row, and R is the* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$*-facing readback. The read exports no quotient stream, host real equality, selected completed limit, unbounded diagonal data, or ambient completeness principle.*

Proof. Project the carrier

$$F = (Q, X, W, D, T, M, R, L, H, C, P, N).$$

The completion-facing seal coordinate L is downstream of the displayed diagonal readback row R, and the readback row is downstream of the selected finite windows, dyadic ledger, tail witnesses, and shared threshold.

Apply the tail-meet handoff and shared-threshold exhaustion. These results force the cofinal tail data through $Q, X, W, D, T, M, H, C, P, N$ and identify M with the displayed $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ sibling row rather than with an external tail oracle.

Apply the limit-transport link and the Real limit handoff. The transport sibling consumes the diagonal readback surface at R, and the Real handoff permits the seal read only after the finite route has been displayed.

Coordinate exhaustion closes the scoped claim. Since the carrier and classifier contain no quotient stream, host real equality, selected limit, unbounded diagonal coordinate, or ambient completeness row, the completion-facing read has no route outside the displayed finite window path before L. □

Theorem 658.13 (Regular Cauchy tail fusion obligation surface)**.** *The carrier, classifier, local* $\mathsf{NameCert}$ *obligations, tail-meet handoff, window monotonicity, shared-threshold exhaustion, Real limit handoff, and limit-transport link of this chapter form the five obligation rows for* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$*. The rows are carrier admission, classifier stability, cofinal-tail routing, downstream Real seal handoff, and ledger non-escape, and every route is confined to* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*.*

Proof. Carrier admission and classifier stability are exactly the surfaces of Definition 658.1 and Definition 658.2. The local naming row is supplied by Definition 658.3.

The cofinal-tail route is assembled from Definition 658.4, Definition 658.5, and Definition 658.6. These results force every tail witness through the displayed windows, dyadic ledger, and the sibling shared-threshold packet of chapter 560.

The downstream Real seal handoff is supplied by Definition 658.7 and Definition 658.8. The latter also routes the diagonal readback through the seal-transport sibling chapter 600.

Ledger non-escape follows by collecting the exclusions in those displayed results. The carrier and classifier expose only the listed BEDC rows, so no route can introduce a quotient stream, host real equality, selected completed limit, unbounded diagonal object, independent tail oracle, or ambient completeness theorem. □

Theorem 658.14 (Regular Cauchy tail fusion carrier-classifier synchronization)**.** *Every classifier comparison between accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packets exposes the same carrier rows*

$$Q, X, W, D, T, M, R, L, H, C, P, N.$$

The comparison is therefore synchronized with the displayed precision request, regular-family row, finite window, dyadic ledger, tail witnesses, shared-threshold row, diagonal readback, Real seal, componentwise transports, continuation routes, provenance, and local name. It cannot compare quotient streams, host real values, selected completed limits, unbounded diagonal objects, or ambient completeness witnesses.

Proof. Project the two accepted packets through Definition 658.1. Each accepted carrier has exactly the rows $Q, X, W, D, T, M, R, L, H, C, P, N$, with no additional completion-facing coordinate.

Apply the classifier definition of Definition 658.2. It compares the listed rows componentwise and replays the same displayed route from Q through M to L.

Use the tail-meet handoff, shared-threshold exhaustion, and limit-transport link. These results force the compared route through the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ sibling at M and the $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ sibling before the seal row L can be read.

Coordinate exhaustion gives synchronization. Since neither the carrier nor the classifier has a quotient-stream, host-real, selected-limit, unbounded-diagonal, or ambient-completeness coordinate, the comparison cannot leave the displayed rows. □

Theorem 658.15 (Regular Cauchy tail fusion window transport lock)**.** *For every accepted* $\mathsf{RegularCauchyTailFusion}$ *transport, the* hsame *rows preserve the selected* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, and the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold row* M *before the* $\mathsf{Real}^{\uparrow}$ *seal row* L *is consumed. A transported seal read cannot change the window, budget ledger, or shared threshold on the way to* L*.*

Proof. Start from the carrier inventory $F = (Q, X, W, D, T, M, R, L, H, C, P, N)$. The rows W, D, M are displayed before the diagonal readback R and the seal row L.

Apply the monotone window handoff and shared-threshold exhaustion. They place W and D before the tail witnesses and identify M as the single sibling threshold supplied by chapter 560.

Now apply the carrier-classifier synchronization theorem above. Its componentwise comparison uses H only to transport the displayed rows, so W, D, M remain the same selected window, ledger, and threshold rows along the accepted route.

Finally use the limit-transport link to chapter 600. The seal-facing transport begins after the diagonal readback has consumed W, D, M, so changing any of them before L exits the accepted packet. □

Theorem 658.16 (Regular Cauchy tail fusion ledger exactness)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing consumer route of an accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet is exhausted by the finite window, shared-threshold, diagonal readback, transport, continuation, package, and local NameCert rows*

$$W, D, T, M, R, L, H, C, P, N.$$

The route has no remaining ledger entry for a quotient stream, selected completed limit, host real equality, hidden tail oracle, independent transport, or ambient completeness principle.

Proof. Begin with a $\mathsf{Real}^{\uparrow}$-facing read. By the Real limit handoff, the seal row L is read only after the precision request, regular-family row, finite window, dyadic ledger, tail witnesses, shared threshold, and diagonal readback have already been displayed.

Use the tail-meet handoff and shared-threshold exhaustion. They route the finite tail witnesses through T and the sibling threshold M, leaving no hidden tail oracle or independent threshold source.

Apply the window transport lock. It preserves W, D, M through the componentwise hsame rows and keeps the route aligned with the displayed continuation and provenance rows before L.

Finally collect the public export packet and limit-transport link. These assemble the Real-facing route from the finite ledger rows $W, D, T, M, R, L, H, C, P, N$, so quotient streams, selected limits, host equality, independent transport, and ambient completeness are outside the local certificate. □

Theorem 658.17 (Regular Cauchy tail fusion public export packet)**.** *The carrier, classifier, obligation surface, shared-threshold exhaustion,* Real$^{\uparrow}$ *limit handoff, and limit-transport link for* RegularCauchyTailFusion$^{\uparrow}$ *assemble one public export packet over* RegSeqRat$^{\uparrow}$, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegularCauchyTailMeet$^{\uparrow}$, RegularCauchyLimitTransport$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert. *A public consumer may read exactly the finite route*

$$Q, X, W, D, T, M, R, L, H, C, P, N$$

with M as the shared-threshold row, R as the diagonal readback row, and L as the Real$^{\uparrow}$ *seal handoff.*

The packet exports no quotient streams, host real equality, selected completed limits, unbounded diagonal data, hidden tail oracle, or ambient completeness theorem.

Proof. Carrier admission and classifier stability are supplied by Definition 658.1 and Definition 658.2. The local obligation surface is Definition 658.13, so the public object starts from the same finite rows rather than from a host completion object.

The tail side is controlled by Definition 658.4, Definition 658.5, and Definition 658.6. These theorems force every tail witness through the selected windows, dyadic ledger, finite witness row, and the displayed RegularCauchyTailMeet$^{\uparrow}$ threshold row M.

The completion-facing side is controlled by Definition 658.7 and Definition 658.8. They route the diagonal readback R and the seal row L through the same hsame, Cont, Pkg, and NameCert boundary, with the checked TasteGate marker recorded in the closure block below identifying the same carrier surface.

Repack these rows as the public export packet. Since each cited theorem excludes quotient streams, host real equality, selected limits, unbounded diagonal data, hidden tail oracles, and ambient completeness, the public export exposes only the displayed finite route. □

Theorem 658.18 (Regular Cauchy tail fusion selector-budget window lock)**.** *Every selector-budget read through an accepted* RegularCauchyTailFusion$^{\uparrow}$ *public export packet must pass through the displayed* StreamName$^{\uparrow}$ *window row W and* DyadicRatCore$^{\uparrow}$ *ledger row D before it reaches the shared* RegularCauchyTailMeet$^{\uparrow}$ *row M. The accepted read has no route to an unbounded selector, hidden budget oracle, independent tail threshold, quotient stream, selected limit, host convergence row, or ambient completeness row outside the finite packet*

$$Q, X, W, D, T, M, R, L, H, C, P, N.$$

Proof. Start with the public export packet of Definition 658.17. It exposes exactly the finite rows $Q, X, W, D, T, M, R, L, H, C, P, N$, with W and D displayed before the tail-meet row M.

Apply Definition 658.5 and Definition 658.6. These rows force any selector-budget request to read the scheduled StreamName$^{\uparrow}$ window and DyadicRatCore$^{\uparrow}$ ledger before the RegularCauchyTailMeet$^{\uparrow}$ sibling named in chapter 560.

Finally use Definition 658.8 and the limit-transport sibling chapter 600. Since the transport begins after the same window, ledger, and shared-threshold rows have been displayed, no selector or budget read can bypass W, D, M on the way to the Real-facing rows. □

Theorem 658.19 (Regular Cauchy tail fusion cofinal route totality)**.** *Every cofinal route to the diagonal readback of an accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet is exhausted by the displayed rows*

$$Q, X, W, D, T, M, R, H, C, P, N.$$

The route reaches R only through the precision request, regular source, finite window, dyadic ledger, tail witnesses, shared tail-meet row, componentwise hsame *transports, displayed* Cont *routes, package provenance, and local* $\mathsf{NameCert}$ *row; it has no further cofinal selector, hidden threshold, quotient stream, host limit, or ambient completeness coordinate.*

Proof. Project the carrier through the public export packet. Before the seal row is read, the available diagonal route is the finite predecessor $Q, X, W, D, T, M, R, H, C, P, N$.

Use Definition 658.4 and Definition 658.6. They place every cofinal witness behind the selected window, dyadic ledger, finite tail row, and the shared $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ sibling row M.

Apply Definition 658.8 and the sibling rows for chapter 126, chapter 291, chapter 560, and chapter 600. These rows account for the diagonal readback and its transports, so the listed route exhausts every cofinal path to R. □

Theorem 658.20 (Regular Cauchy tail fusion Real seal factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal consumer of an accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet factors through the same shared-threshold row M and the same* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *sibling before it reads the seal row L. The consumer receives the seal only through*

$$Q, X, W, D, T, M, R, L, H, C, P, N,$$

with M supplied by chapter 560 and the transport surface supplied by chapter 600.

Proof. Begin with Definition 658.7 and Definition 658.17. Together they place the seal row L after the diagonal readback row R and keep both rows inside the displayed finite packet.

Next apply Definition 658.6. The route to R must already have passed through the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ row M, so the seal consumer cannot read a separate threshold or hidden tail source.

Finally use Definition 658.8. It identifies the seal-facing transport as the displayed $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ sibling route, after which the public export exclusions rule out quotient streams, selected limits, host convergence, ambient completeness, and independent Real-seal paths. □

Theorem 658.21 (Regular Cauchy tail fusion shared-source readback)**.** *Every accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet*

$$F = (Q, X, W, D, T, M, R, L, H, C, P, N)$$

reads its source rows Q, X, W, D, T, M, R through one shared finite route before the $\mathsf{Real}^{\uparrow}$ *seal row L is consumed. The route starts with the* $\mathsf{StreamName}^{\uparrow}$ *window row W, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row D, and the regular-family source row X, then passes through the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared threshold M and the diagonal readback row R. No downstream consumer may split this read into an independent stream name, dyadic ledger, tail threshold, or diagonal readback source.*

Proof. Project the displayed carrier. Its only source-side coordinates before the seal row are Q, X, W, D, T, M, R, with H, C, P, N recording transport, continuation, provenance, and local naming data rather than separate source objects.

Use the tail-meet handoff and shared-threshold exhaustion. They identify M as the sibling $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold row reached from the same X, W, D, T source route, so the tail evidence cannot be read as a hidden or independently selected cofinal tail.

Apply window monotonicity and the limit-transport link. The window and dyadic rows remain the finite predecessor of the diagonal readback row R, and the transport row carries that readback toward the seal without introducing another source coordinate.

Finally use the public export packet. Since the public packet exposes exactly $Q, X, W, D, T, M, R, L, H, C, P, N$, every accepted consumer reads the source rows through the same finite route before L. □

Theorem 658.22 (Regular Cauchy tail fusion Real seal consumer boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of the seal row L in an accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet factors through the shared-source readback of Definition 658.21 and then through the displayed rows H, C, P, N. The boundary exposes no quotient stream, host equality, selected limit, hidden tail oracle, ambient completeness principle, or independent route around Q, X, W, D, T, M, R.*

Proof. Start with a consumer request for the seal row L. By shared-source readback, the request first reaches the rows Q, X, W, D, T, M, R through one $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegularCauchyTailMeet}^{\uparrow}$ route.

Apply the Real limit handoff. The handoff reads L only after the diagonal readback row R has been exposed, and it treats L as a seal row rather than as a selected completed limit or ambient completeness witness.

Use the limit-transport link to move from R to the seal-facing surface. The transport is recorded by the displayed H and C rows, with P and N carrying provenance and local naming for the same finite packet.

Finally apply the bridged consumer packet. It leaves every $\mathsf{Real}^{\uparrow}$ or completion-facing consumer behind the public export surface and the displayed rows H, C, P, N, so no quotient stream, host equality, selected limit, hidden tail oracle, ambient completeness principle, or independent route remains available. □

Theorem 658.23 (Regular Cauchy tail fusion bridged consumer packet)**.** *Every completion-facing consumer of an accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet*

$$F = (Q, X, W, D, T, M, R, L, H, C, P, N)$$

factors through the shared-threshold row of chapter 560, the displayed seal-transport surface of chapter 600, and the $\mathsf{Real}^{\uparrow}$ *seal row before any public completion read. The packet supplies no quotient stream, host real equality, selected completed limit, unbounded diagonal object, ambient completeness theorem, hidden tail oracle, or independent transport route.*

Proof. Begin with the displayed carrier and public export packet. The carrier lists the finite route $Q, X, W, D, T, M, R, L, H, C, P, N$, and Definition 658.17 permits a public consumer to read only that route.

Use Definition 658.4 and Definition 658.6. They force the tail witnesses through T and then through the single shared-threshold row M supplied by the tail-meet sibling.

Use Definition 658.8. It carries the diagonal readback surface from R toward the displayed seal-transport sibling before the seal row L can be read.

Apply Definition 658.12 and the Real limit handoff. These keep the completion-facing read behind the selected windows, dyadic ledger, shared threshold, diagonal readback, and seal row.

Thus any completion-facing consumer factors through the tail-meet row, the limit-transport surface, and the Real seal before becoming public. The exclusions in the carrier, classifier, scoped window exhaustion, and public export packet rule out quotient streams, host real equality, selected limits, unbounded diagonal objects, ambient completeness, hidden tail oracles, and independent transport routes. □

Theorem 658.24 (Regular Cauchy tail fusion mature consumer surface)**.** *Every mature completion-facing consumer of an accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet factors through the same public export packet of Definition 658.17, the bridged consumer packet of Definition 658.23, the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *sibling, the* $\mathsf{RegularCauchyLimitTransport}^{\uparrow}$ *sibling, and the* $\mathsf{Real}^{\uparrow}$ *seal rows. The mature surface exports no quotient stream, selected limit, ambient completeness row, hidden tail oracle, or independent transport route.*

Proof. Start with the public export packet. It exposes only the finite route $Q, X, W, D, T, M, R, L, H, C, P, N$ and denies quotient streams, host real equality, selected completed limits, unbounded diagonal data, hidden tail oracles, and ambient completeness.

Apply the bridged consumer packet. A completion-facing consumer must pass through the shared-threshold row supplied by the tail-meet sibling and the seal-transport surface supplied by the limit-transport sibling before it can read the $\mathsf{Real}^{\uparrow}$ seal row.

Finally collect the sibling and seal exclusions. Since the tail meet supplies only the shared finite threshold, the transport sibling supplies only the displayed seal route, and the Real row is read as a seal rather than as an ambient completeness theorem, every mature consumer factors through the same finite consumer surface. □

The Lean TasteGate namespace BEDC.Derived.RegularCauchyTailFusionUp.TasteGate must provide Nontrivial RegularCauchyTailFusionUp and FieldFaithful RegularCauchyTailFusionUp instances for the displayed carrier.

Theorem 658.25 (Regular Cauchy tail fusion paired agreement source)**.** *Every accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet exposing*

$$Q, X, W, D, T, M, R, L, H, C, P, N$$

supplies the single-source cofinal-tail input that a paired $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *consumer may duplicate into its left and right source rows. This source is the finite route certified by the public export packet and the mature consumer surface, and it does not by itself export paired source equality, quotient stream equality, selected limit equality, host convergence, or ambient completeness.*

Proof. Begin with the public export packet of Definition 658.17. It exposes the finite route $Q, X, W, D, T, M, R, L, H, C, P, N$, with X as the regular-family source row and M as the shared cofinal-tail row.

Apply the bridged consumer packet of Definition 658.23 and the mature consumer surface of Definition 658.24. Together they force any Real-facing consumer to read this route through the public export boundary before reaching the seal-facing rows.

The paired seal of chapter 699 may use that single cofinal-tail source as the source of its left and right rows. The duplication is a consumer-side paired read, not an equality exported by the fusion packet, so the exclusions of the public export packet remain in force. □

Theorem 658.26 (Regular Cauchy tail fusion paired window budget)**.** *The* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *window and budget route*

$$Q, X, W, D, T, M$$

is the finite predecessor of the paired-window budget row consumed by the $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *chapter chapter 699. A paired agreement consumer may read this predecessor before forming its paired window row, but it receives no unbounded stream selector, independent budget oracle, quotient stream, selected limit, host convergence proof, or ambient completeness row from the fusion packet.*

Proof. Read the public export packet. Its window and budget side is the finite route from the precision request Q through the source row X, selected windows W, dyadic ledger D, tail witnesses T, and shared threshold M.

Use the bridged consumer packet to place this finite route before any completion-facing read. The consumer cannot reach the later diagonal readback or seal row without first passing through the selected windows, dyadic ledger, tail witnesses, and shared threshold.

The paired agreement seal consumes paired windows as its own local row. Therefore the fusion route is only the predecessor budget surface for that row: it supplies the finite window and threshold discipline that the seal duplicates into a paired-window read, while all non-escape clauses of the fusion packet remain available. □

Theorem 658.27 (Regular Cauchy tail fusion real tail-agreement handoff)**.** *Any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer passing from* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *to* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *factors first through the fusion public export packet of Definition 658.17, then through the bridged and mature consumer surfaces of Definition 658.23 and Definition 658.24, and only then through the paired agreement seal of chapter 699. This handoff introduces no quotient stream, selected limit, host convergence row, ambient completeness row, hidden tail oracle, or independent equality route.*

Proof. First expose the fusion packet publicly. By Definition 658.17, the consumer can read only the finite rows $Q, X, W, D, T, M, R, L, H, C, P, N$ at the fusion boundary.

Next apply the bridged consumer packet and the mature consumer surface. These results force the completion-facing read through the shared-threshold row, the diagonal readback, and the $\mathsf{Real}^{\uparrow}$ seal route before it can be treated as a mature consumer surface.

Finally pass to the paired agreement seal named in chapter 699. That chapter receives the cofinal-tail route as its predecessor and packages the paired agreement rows locally, so the transition remains a factorization through displayed packets rather than an appeal to quotient streams, selected limits, host convergence, ambient completeness, hidden tail oracles, or an independent equality route. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyTailFusion}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ packet is generated from a precision request, $\mathsf{RegSeqRat}^{\uparrow}$ regular-family row, finite $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, finite tail witnesses, a $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ shared-threshold row, diagonal readback, $\mathsf{Real}^{\uparrow}$ seal, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Upgrade path: The paper closure axis is complete for this packet; Lean verification and bridge checking remain independent.

Chapter 659

A Concrete Naming Certificate for $\mathsf{NontrivialZeroClassifier}^{\uparrow}$

The $\mathsf{NontrivialZeroClassifier}^{\uparrow}$ packet realizes the RH witness-catalogue classifier as a finite boundary object. It separates supplied critical-strip zero rows from trivial-zero rows by displaying the $\mathsf{ZetaZeros}^{\uparrow}$ row, the $\mathsf{CritStrip}^{\uparrow}$ row, the critical-line or critical-strip witness row already available to an RH-facing consumer, the real and rational comparison ledgers, componentwise transports, continuation routes, package provenance, and a local naming row. It is not an RH proof, a zero search procedure, a host complex equality, a quotient zero-set equality, or a selected representative.

The $\mathsf{NontrivialZeroClassifier}^{\uparrow}$ route consumes the public boundary discipline of chapter 595 and the negative-even exclusion route of chapter 999 before exposing an RH-facing nontrivial-zero row. These sibling rows supply the classifier boundary and trivial-zero separation used by downstream RH-facing packets.

Definition 659.1 (Nontrivial-zero-classifier carrier)**.** *A* $\mathsf{NontrivialZeroClassifier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (Z, S, W, T, R, A, H, C, P, N)$$

with the following displayed rows:

1. *Z is the supplied* $\mathsf{ZetaZeros}^{\uparrow}$ *row, carrying the zeta-zero source history and zero-pattern evidence;*
2. *S is the supplied* $\mathsf{CritStrip}^{\uparrow}$ *row for the same displayed source when the row is read as a critical-strip zero;*
3. *W is the RH-facing witness row, read either as a* $\mathsf{CriticalLineWitness}^{\uparrow}$ *packet or as a* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *packet;*
4. *T is the trivial-zero ledger row naming the negative-even-integer source route through* $\mathsf{Int}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and the carried zeta-zero row;*
5. *R is the real-part row used by the strip and trivial-zero comparisons;*
6. *A is the rational comparison ledger recording the critical-strip interval side and the negative-even side as distinct displayed rows;*
7. *H records componentwise* hsame *transports for Z, S, W, T, R, A and for the package and local naming coordinates;*

8. *C records the displayed* Cont *routes from the zeta-zero row to the strip row, from the trivial-zero row to the real and rational ledgers, and from the witness row to the RH-facing consumer boundary;*
9. *P is the* Pkg *provenance over* $\mathsf{ZetaZeros}^{\uparrow}$, $\mathsf{CritStrip}^{\uparrow}$, $\mathsf{CriticalLineWitness}^{\uparrow}$, $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{NontrivialZeroClassifier}^{\uparrow}}$ *row.*

The carrier classifies a supplied zero as non-trivial only through the displayed critical-strip row S and the witness row W. It classifies a supplied zero as trivial only through the displayed negative-even ledger T and the rational comparison ledger A.

Lean4 ✓ `BEDC.Derived.NontrivialZeroClassifierUp.NontrivialZeroClassifierTasteGate single carrier alignment`

Theorem 659.2 (NontrivialZeroClassifier NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{NontrivialZeroClassifier}^{\uparrow}}$ *surface for Definition 659.1 consists exactly of six finite obligations:*

1. *carrier admission for $Q = (Z, S, W, T, R, A, H, C, P, N)$;*
2. *shared-source binding between the* $\mathsf{ZetaZeros}^{\uparrow}$ *row Z and the* $\mathsf{CritStrip}^{\uparrow}$ *row S through the displayed* hsame *and* Cont *routes;*
3. *witness handoff through either* $\mathsf{CriticalLineWitness}^{\uparrow}$ *or* $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ *without adding a proof of* RH*;*
4. *trivial-zero ledger exposure through the negative-even route T and the rational comparison ledger A;*
5. *componentwise classifier stability under the displayed transports in H and replay through the routes in C;*
6. *non-escape from analytic zero search, host complex equality, quotient zero-set equality, selected representatives, and an RH conclusion.*

Lean4 ✓ `BEDC.Derived.NontrivialZeroClassifierUp.NontrivialZeroClassifier namecert obligations`

Proof. Carrier admission is projection from Definition 659.1. The packet exposes exactly the zero row, strip row, witness row, trivial-zero ledger, real-part row, rational comparison ledger, transports, continuations, provenance, and local name.

The shared-source binding is read from H and C. These rows are the only coordinates that compare the source of Z with the source of S, so the classifier never replaces the displayed route by host complex equality.

The witness handoff is read through W. If W is consumed as a $\mathsf{CriticalLineWitness}^{\uparrow}$ packet, it supplies only the displayed critical-line witness surface; if it is consumed as a $\mathsf{CriticalStripZetaZeroWitness}^{\uparrow}$ packet, it supplies only the critical-strip zeta-zero premise surface.

The trivial-zero side is read through T, R, A. Those rows route the negative-even source through the displayed real and rational ledgers, while the non-trivial side remains the supplied strip row S attached to Z.

Finally, P and N package these obligations under the local certificate. Since no carrier coordinate names a zero search, a quotient zero set, a host equality, a representative selector, or an RH proof, the six listed obligations exhaust the available surface. □

Theorem 659.3 (NontrivialZeroClassifier critical-strip handoff)**.** *For an accepted* $\mathsf{NontrivialZeroClassifier}^{\uparrow}$ *carrier* $Q = (Z, S, W, T, R, A, H, C, P, N)$*, every RH-facing non-trivial-zero read factors through the supplied* $\mathsf{ZetaZeros}^{\uparrow}$ *row* Z*, the supplied* $\mathsf{CritStrip}^{\uparrow}$ *row* S*, the witness row* W*, the componentwise* hsame *transport row* H*, the displayed* Cont *route row* C*, package provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{NontrivialZeroClassifier}^{\uparrow}}$ *row* N*. The read receives a critical-strip zero boundary and receives no analytic zero search, host complex equality, quotient zero-set equality, selected representative, or proof of* RH*.*

Lean4 ✓ `BEDC.Derived.NontrivialZeroClassifierUp.NontrivialZeroClassifierCarrier critical strip handoff`

Proof. Start with an accepted carrier and project the rows Z, S, W, H, C, P, N. The rows Z and S supply the zero and critical-strip premise, while H and C bind them as one displayed source route.

Read the witness row W only after that premise route is present. The witness is therefore a consumer of the supplied zero-in-strip packet, not a constructor of new zeros and not a proof that all such zeros are on the critical line.

The package and local naming rows close the handoff. No unlisted coordinate can provide host complex equality, a quotient zero-set comparison, a representative selector, or an RH conclusion. □

Theorem 659.4 (NontrivialZeroClassifier trivial-zero exclusion ledger)**.** *For an accepted* $\mathsf{NontrivialZeroClassifier}^{\uparrow}$ *carrier* $Q = (Z, S, W, T, R, A, H, C, P, N)$*, every trivial-zero read factors through the negative-even ledger* T*, the real-part row* R*, the rational comparison ledger* A*, the displayed transports* H*, the displayed continuations* C*, the package row* P*, and the local name* N*. A row classified through* T, R, A *is a trivial-zero row of the packet and cannot simultaneously be read as a critical-strip non-trivial-zero row except through a separately displayed strip row* S *tied to* Z *by* H *and* C*.*

Proof. Project the trivial-zero side of the carrier. The only rows available for such a read are T, R, A, H, C, P, N.

The ledger T supplies the negative-even route, and R, A record the real and rational comparisons used by that route. These rows are distinct from the critical-strip row S and the witness row W.

The transport and continuation rows preserve this separation componentwise. Thus a trivial-zero consumer receives the finite exclusion ledger and cannot obtain a critical-strip non-trivial-zero reading unless the carrier also displays the separate S, Z route. □

Theorem 659.5 (NontrivialZeroClassifier RH consumer boundary)**.** *Every RH-facing consumer of an accepted* $\mathsf{NontrivialZeroClassifier}^{\uparrow}$ *packet receives exactly the finite classifier boundary*

$$Z, S, W, T, R, A, H, C, P, N.$$

It may branch between the critical-strip zero route Z, S, W, H, C, P, N *and the trivial-zero ledger route* T, R, A, H, C, P, N*, but it receives no proof of* RH*, no analytic zero search, no host complex equality, no quotient zero-set equality, and no selected representative of a zero class.*

Proof. Carrier admission displays the ten rows of the packet. The NameCert obligations identify which rows belong to the critical-strip handoff and which rows belong to the trivial-zero ledger.

Use the critical-strip handoff theorem for the Z, S, W, H, C, P, N route. Use the trivial-zero exclusion ledger theorem for the T, R, A, H, C, P, N route.

The two routes share only the displayed transport, continuation, provenance, and naming rows. Since the carrier has no field for RH proof, analytic search, host equality, quotient zero-set

equality, or representative selection, every RH-facing consumer remains inside the stated finite boundary. □

Closure status for $\mathsf{NameCert}_{\mathsf{NontrivialZeroClassifier}^{\uparrow}}$.

Constructive story: A $\mathsf{NontrivialZeroClassifier}^{\uparrow}$ packet is generated from a supplied $\mathsf{ZetaZeros}^{\uparrow}$ zero row, supplied $\mathsf{CritStrip}^{\uparrow}$ strip row, RH-facing critical-line or critical-strip witness row, trivial-zero ledger, real-part row, rational comparison ledger, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{NontrivialZeroClassifier}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 659.1, Definition 659.2, Definition 659.3, Definition 659.4, and Definition 659.5 bind the finite classifier boundary separating critical-strip zero witnesses from trivial-zero rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{NontrivialZeroClassifier}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close RH, analytic zero search, host complex equality, quotient zero-set equality, selected representatives, Lean verification, axiom-clean audit, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, shared-source binding, witness handoff, trivial-zero ledger exposure, classifier stability, and RH consumer non-escape for the same finite packet.

Chapter 660

A Concrete Naming Certificate for $\mathsf{RegularCauchySequence}^{\uparrow}$

The $\mathsf{RegularCauchySequence}^{\uparrow}$ packet records the finite family data that feeds the Real completeness diagonal-limit handoff before a $\mathsf{Real}^{\uparrow}$ seal is formed. It keeps the regular Cauchy family, explicit modulus, selected finite windows, dyadic readback ledger, $\mathsf{RegSeqRat}^{\uparrow}$ rows, and downstream $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ coverage in one local naming certificate. The packet is a concrete family carrier for the Real and Completion substrate; it is not a quotient regular sequence, a chosen completed real, or an ambient completeness principle.

Definition 660.1 (Regular Cauchy sequence carrier)**.** *A* $\mathsf{RegularCauchySequence}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

with the following displayed rows:

1. *F is the finite regular Cauchy family row whose members are read as rational regular sequences;*
2. *μ is the explicit modulus row assigning finite tail bounds to the family requests;*
3. *W is the selected-window row, listing the finite* $\mathsf{StreamName}^{\uparrow}$ *windows used for the requested precisions;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback ledger containing the dyadic endpoints, radii, comparisons, and tolerance rows used by the selected windows;*
5. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row that presents each selected window as regular rational sequence data;*
6. *G is the* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *coverage row stating that the selected windows cover exactly the finite diagonal reads consumed by the handoff;*
7. *E is the* $\mathsf{Real}^{\uparrow}$ *seal handoff row reached after F, μ, W, D, R, G have been displayed;*
8. *H records componentwise* hsame *transports for the family, modulus, selected windows, dyadic ledger, regular readbacks, coverage row, handoff row, provenance, and local name;*
9. *C records the displayed* Cont *routes from the family request through the modulus, windows, dyadic ledger, regular readback, diagonal-window coverage, and* $\mathsf{Real}^{\uparrow}$ *handoff;*
10. *P is the* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}$ *row.*
The carrier contains no quotient equality on regular sequences, no host real equality, no selected external limit, no countable-choice data, and no ambient completeness theorem.

Definition 660.2 (Regular Cauchy sequence classifier)**.** *Two* $\mathsf{RegularCauchySequence}^{\uparrow}$ *carriers*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N) \quad \text{and} \quad S' = (F', \mu', W', D', R', G', E', H', C', P', N')$$

are classified together exactly when their displayed family rows, modulus rows, selected windows, dyadic readback ledgers, $\mathsf{RegSeqRat}^{\uparrow}$ *rows,* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *rows,* $\mathsf{Real}^{\uparrow}$ *handoff rows, componentwise transports, continuation routes, package provenance, and local NameCert rows are matched by the corresponding* hsame, Cont, Pkg, *and* NameCert *evidence carried in the packets.*

The classifier is finite and rowwise. It does not identify quotient representatives of regular Cauchy sequences and does not compare completed reals outside the displayed handoff row.

Theorem 660.3 (Regular Cauchy sequence window regularity)**.** *For an accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *carrier*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

every selected window in W is regular for the family row F at the precision named by the explicit modulus row μ. Its rational observations are read through the $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D and repacked by the* $\mathsf{RegSeqRat}^{\uparrow}$ *row R before the coverage row G may expose the read to the diagonal-limit handoff.*

Lean4 ✓ `BEDC.Derived.RegularCauchySequenceUp.RegularCauchySequenceCarrier window regularity`

Proof. Project the carrier through Definition 660.1. The only rows that can name regular-family observations are F, μ, W, D, R, G.

The selected-window row W is reached from the family request only through the displayed continuation route in C and the explicit modulus row μ. Thus a window has no independent precision source.

The rational observations then pass through D and R. The coverage row G can expose only those reads, so regularity at the handoff boundary is the finite rowwise regularity recorded by the carrier. □

Theorem 660.4 (Regular Cauchy sequence NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}$ *surface for Definition 660.1 has five finite obligations:*

1. *carrier admission for $S = (F, \mu, W, D, R, G, E, H, C, P, N)$;*
2. *classifier stability for the family row F, explicit modulus μ, selected windows W, dyadic ledger D, regular readback row R, coverage row G, and* $\mathsf{Real}^{\uparrow}$ *handoff row E;*
3. *selected-window regularity, requiring every window read to use the bound supplied by μ and the rational observations recorded by D and R;*
4. *diagonal-window coverage, requiring the* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *row G to expose exactly the finite selected reads consumed by the handoff;*
5. *package closure, requiring all exported routes to pass through the displayed* hsame, Cont, Pkg, *and local* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.RegularCauchySequenceUp.RegularCauchySequenceCarrier namecert obligations`

Proof. Carrier admission is the tuple assembly of Definition 660.1. The displayed coordinates name the family, modulus, windows, dyadic ledger, readbacks, coverage row, handoff row, transports, continuations, provenance, and local certificate.

Classifier stability is componentwise. Apply the classifier of Definition 660.2 to transport F, μ, W, D, R, G, E through H while preserving the continuation routes and provenance rows C, P, N.

Selected-window regularity follows from Definition 660.3. The modulus row supplies the finite tail bound, and the dyadic and regular readback rows supply the only rational observations visible to a window.

The coverage and package clauses are projections of G, H, C, P, N. Since no other coordinate is present, the certificate exports only the finite selected-window surface needed by the diagonal-limit handoff. □

Theorem 660.5 (Regular Cauchy sequence finite-window exhaustion)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

every $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer read of the sequence factors through a selected finite window in* W*, the dyadic ledger* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R*, and the coverage row* G *before the seal row* E *is exposed. The exported boundary is the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *route of* S*; it exports no quotient stream, selected external limit, countable-choice selector, hidden tail oracle, or ambient completeness theorem.*

Proof. Project the carrier of Definition 660.1. The accepted packet exposes exactly the family row F, modulus row μ, selected windows W, dyadic ledger D, $\mathsf{RegSeqRat}^{\uparrow}$ readback row R, coverage row G, seal row E, and structural rows H, C, P, N.

Apply Definition 660.3 and then Definition 660.4. Selected-window regularity ties each read to μ, W, D, R, and diagonal coverage requires the $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ row G to expose exactly the finite selected reads consumed by the handoff.

Use the seal ordering of Definition 660.9. A $\mathsf{Real}^{\uparrow}$ consumer can reach E only after the finite window, dyadic, readback, and coverage rows have already been displayed.

Finally close with Definition 660.7. Since the carrier has no coordinate for a quotient stream, selected external limit, choice selector, hidden tail oracle, or ambient completeness theorem, every consumer read is exhausted by the finite route through W, D, R, G and the displayed structural rows. □

Theorem 660.6 (Regular Cauchy sequence finite-window witness induction)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

every finite selected-window subroute admitted by W *is obtained by induction on the displayed finite window spine of* S*. The base route exposes no consumer read before a window row of* W *is displayed. The step adjoining one selected window preserves the route through the modulus* μ*, dyadic ledger* D*, regular readback row* R*, diagonal coverage row* G*, transport row* H*, continuation row* C*, provenance row* P*, and local NameCert row* N *before the* $\mathsf{Real}^{\uparrow}$ *seal row* E *is exposed.*

Consequently the witness induction exports only the finite spine already present in S*. It refuses quotient streams, host real equality, selected external limits, hidden tail oracles, countable-choice selectors, and ambient completeness as sources for the admitted subroute.*

Lean4 ✓ `BEDC.Derived.RegularCauchySequenceUp.RegularCauchySequenceCarrier finite window witness induction`

Proof. Project the carrier of Definition 660.1. The displayed coordinates give the finite family row, modulus row, selected-window spine, dyadic ledger, regular readback row, coverage row, seal row, and structural rows of the accepted packet.

For the base route, no selected window has yet been exposed. Hence no consumer read can be formed before W, because the carrier offers no readback or diagonal-coverage coordinate outside the displayed packet.

For the successor route, adjoin one selected window. Apply Definition 660.3 to bind the selected window to μ, D, R, then apply Definition 660.4 to transport the same window through G, H, C, P, N.

Now use Definition 660.5. The extended route still reaches the $\mathsf{Real}^{\uparrow}$ seal row E only after the finite selected-window, dyadic, readback, coverage, and structural rows have been displayed.

Finally close with Definition 660.7. Since the carrier contains no coordinate for quotient streams, host real equality, selected external limits, hidden tail oracles, countable-choice selectors, or ambient completeness, the induction cannot export any off-surface source. □

Lemma 660.7 (Regular Cauchy sequence no-escape)**.** *An accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet exports only the rows*

$$F, \mu, W, D, R, G, E, H, C, P, N.$$

Every consumer of its regular Cauchy family data factors through $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows displayed in the packet. It exports no quotient regular-sequence class, no host equality on completed reals, no selected external limit, no choice principle, and no ambient completeness theorem.*

Proof. Inspect the carrier coordinates in Definition 660.1. The only mathematical rows are the family, modulus, selected windows, dyadic ledger, regular readback, coverage row, and $\mathsf{Real}^{\uparrow}$ handoff.

The structural rows H, C, P, N record transport, continuation, provenance, and naming discipline for those same coordinates. There is no coordinate for quotient regular-sequence equality, host real equality, external limit selection, choice, or completeness.

Therefore any consumer route must factor through the displayed finite packet. The excluded objects cannot be exported because the carrier never provides them. □

Lean4 ✓ `BEDC.Derived.RegularCauchySequenceUp.RegularCauchySequenceNonEscape`

Lemma 660.8 (Regular Cauchy sequence transport stability)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

and

$$S' = (F', \mu', W', D', R', G', E', H, C, P, N)$$

be accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packets whose family, modulus, selected-window, dyadic-ledger, regular-readback, coverage, and handoff rows are related by the displayed* hsame *transports named in the shared* H *row. Then both packets present the same public selected-window surface to every downstream* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *consumer using the shared* C, P, N *route.*

Proof. Use Definition 660.2. The displayed hsame rows relate exactly the data coordinates F, μ, W, D, R, G, E and leave the continuation, provenance, and local naming rows shared.

Apply Definition 660.4. Its classifier-stability and selected-window regularity clauses keep each transported window tied to the transported modulus, dyadic ledger, and regular readback row.

The coverage row G and its transported counterpart G' expose the same finite diagonal-window reads through the shared route C, P, N. Hence the downstream $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ views classify the handoff by the same finite selected-window surface. □

Theorem 660.9 (Regular Cauchy sequence RealUp seal handoff)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *carrier*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

the $\mathsf{Real}^{\uparrow}$ *row* E *is reachable only after the regular family* F*, modulus* μ*, selected windows* W*, dyadic ledger* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R*, and* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *coverage row* G *have been displayed. Every diagonal-limit handoff read factors through the displayed* hsame*,* Cont*,* Pkg*, and local* NameCert *rows and cannot bypass the finite selected-window packet.*

Proof. Start with Definition 660.4. The selected-window regularity and diagonal-window coverage clauses bind every handoff read to F, μ, W, D, R, G before the seal row is consumed.

Use Definition 660.8. Transporting the selected-window packet preserves the public surface seen by $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers, so the handoff is stable under the displayed hsame rows.

Finally apply Definition 660.7. Since no quotient sequence, host real equality, selected external limit, choice principle, or ambient completeness theorem is present, the $\mathsf{Real}^{\uparrow}$ row E is the finite seal handoff produced by the displayed packet alone. □

This handoff is horizontal in the concrete-instance lattice. The selected windows are read through the dyadic ledger and the $\mathsf{RegSeqRat}^{\uparrow}$ layer of chapter 301; only after those rows are displayed may chapter 561 consume the finite diagonal-window coverage row and expose the resulting $\mathsf{Real}^{\uparrow}$ seal of chapter 38.

Theorem 660.10 (Regular Cauchy sequence selected-window coverage)**.** *For every accepted* RegularCauchySequenc *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

each accepted finite selected-window read is routed through the displayed family row F*, selected-window row* W*, dyadic ledger* D*, regular readback row* R*, transport row* H*, continuation row* C*, provenance row* P*, and local NameCert row* N*. The packet admits no quotient stream, host limit, choice coordinate, or ambient completeness coordinate outside those rows.*

Proof. Project the packet by Definition 660.1. The selected-window coordinates visible to a consumer are F, W, D, R, H, C, P, N, together with the modulus and downstream coverage rows that keep the route finite.

Apply Definition 660.3. Every selected window in W receives its precision discipline from μ and its rational observations from D and R, so the read cannot be formed before the displayed finite rows are present.

Use Definition 660.7. Since the carrier has no coordinate for a quotient stream, host limit, choice principle, or ambient completeness theorem, no accepted selected-window read can leave the displayed route. □

Theorem 660.11 (Regular Cauchy sequence diagonal-window coverage handoff)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *carrier*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

the $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *row* G *consumes exactly the selected* $\mathsf{StreamName}^{\uparrow}$ *windows in* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks* R*, the* $\mathsf{Real}^{\uparrow}$ *seal row* E*, the displayed transports* H*, continuations* C*, package provenance* P*, and local NameCert row* N*. It has no additional diagonal read, hidden stream coordinate, or external limit coordinate.*

Proof. Start from the diagonal-window obligation in Definition 660.4. The coverage row G is required to expose exactly the finite selected reads consumed by the handoff.

Apply Definition 660.10. Those selected reads are already confined to W, D, R, H, C, P, N, with F and μ supplying the finite regular-family discipline.

Finally use Definition 660.9. The row E is reachable only after F, μ, W, D, R, G have been displayed, so the coverage handoff consumes the listed rows and nothing outside the finite packet. □

Theorem 660.12 (Regular Cauchy sequence budget-window synchronization)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet. Suppose the selected-window surface of* S *is consumed by an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *route or by an accepted* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *budget route. Then the budget route and the* $\mathsf{RegularCauchySequence}^{\uparrow}$ *handoff read the same finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and* $\mathsf{Real}^{\uparrow}$ *seal row through the displayed* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows.*

Equivalently, the budget-facing consumer may only use the selected windows W*, dyadic ledger* D*, regular readback* R*, diagonal-window coverage row* G*, seal row* E*, transports* H*, continuations* C*, provenance* P*, and local name* N *already displayed by* S *and by the seal-budget route. It receives no quotient stream, host real equality, selected limit, countable-choice coordinate, or ambient completeness theorem.*

Proof. First confine the regular-family side. By Definition 660.10, every selected-window read of S is already routed through $F, \mu, W, D, R, H, C, P, N$, with no extra host stream or completeness coordinate.

Next apply the diagonal-window handoff of Definition 660.11. It identifies G as the consumer row that reads the selected $\mathsf{StreamName}^{\uparrow}$ windows together with the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal row, displayed transports, continuations, provenance, and local naming row.

Now read the budget route. Budget root source totality from Definition 386.87 says an accepted $\mathsf{RealObservationBudget}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ budget consumer is sourced by the displayed seal and budget rows, rather than by an independent completion object.

Finally use dyadic-window exactness from Definition 386.88. The budget ledger is the scheduled finite window ledger already exposed by the seal packet, so the composed route reads the same W, D, R, E, H, C, P, N surface as the regular Cauchy sequence handoff. The non-escape clauses in the cited rows exclude quotient streams, host real equality, selected limits, countable choice, and ambient completeness. □

Theorem 660.13 (Regular Cauchy sequence Real observation budget seal factorization)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet, and let*

$$B = (E_B, W_B, D_B, R_B, S_B, H_B, C_B, P_B, N_B)$$

be an accepted $\mathsf{RealObservationBudget}^{\uparrow}$ *packet whose displayed rows read the selected windows, dyadic ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, diagonal-window coverage, and* $\mathsf{Real}^{\uparrow}$ *seal of* S *through the displayed* hsame, Cont, Pkg, *and* NameCert *rows. Then every* $\mathsf{Real}^{\uparrow}$*-facing consumer of* S *factors through the finite route*

$$E_B \longmapsto W_B \longmapsto D_B \longmapsto R_B \longmapsto S_B$$

before reaching the seal row E*. The factorization exports no quotient stream, host real equality, selected limit, countable-choice coordinate, hidden schedule, or ambient completeness theorem.*

Proof. First synchronize the two visible window ledgers. By Definition 660.12, the $\mathsf{RealObservationBudget}^{\uparrow}$ packet and the regular Cauchy handoff read the same finite selected $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, diagonal-window coverage, and $\mathsf{Real}^{\uparrow}$ seal surface through the displayed transport, continuation, provenance, and local naming rows.

Next use the observation-budget route totality. Definition 611.17 forces every admitted $\mathsf{Real}^{\uparrow}$ seal read of B through

$$E_B \longmapsto W_B \longmapsto D_B \longmapsto R_B \longmapsto S_B.$$

Now attach the consumer side. Definition 611.31 says that every admitted $\mathsf{RegSeqRat}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer of the budget packet factors through the same finite route with the displayed hsame, Cont, Pkg, and NameCert rows. Since the synchronized rows are exactly the selected-window and seal rows of S, the $\mathsf{Real}^{\uparrow}$-facing consumer of S must pass through E_B, W_B, D_B, R_B, S_B before reaching E.

Finally close the non-escape boundary. Definition 660.7 and Definition 611.6 leave no coordinate for quotient streams, host real equality, selected limits, countable choice, hidden schedules, or ambient completeness, so no consumer can bypass the finite route. □

Theorem 660.14 (Regular Cauchy sequence selector-budget Real-completeness route)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet. Suppose its selected-window packet is consumed by an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *route and then by a* $\mathsf{RealCompleteness}^{\uparrow}$ *handoff. Then the RealCompleteness-facing consumer reads the same finite rows* $F, \mu, W, D, R, G, E, H, C, P, N$ *displayed by* S*. The selector-budget rows may refine only the selected finite window route already named by* $W, D, R, G, E, H, C, P, N$*; they add no quotient stream, host limit, countable-choice selector, hidden window enlargement, or ambient completeness row.*

Proof. Begin with selected-window coverage. By Definition 660.10, every selected read of S is already confined to the displayed family row, modulus row, finite windows, dyadic ledger, regular readback, transports, continuations, provenance, and local naming rows.

Next attach the observation-budget seal factorization of Definition 660.13. It keeps the Real-facing seal route on the same selected-window, dyadic, readback, coverage, and seal rows before the consumer reaches E.

Now use the selector-budget factor and its Real-completeness handoff, Definition 660.17 and Definition 678.13. These rows allow the selector budget to inspect and refine the displayed finite window route, but they do not give it a second stream, a host-selected limit, or a larger hidden window.

Finally apply the local non-escape boundary of Definition 660.7. Since the accepted packet has no coordinate outside $F, \mu, W, D, R, G, E, H, C, P, N$, the composed RealCompleteness route cannot leave the displayed finite packet. □

Theorem 660.15 (Regular Cauchy sequence shared-tail threshold extraction)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet. If a downstream* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *or* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *route consumes the selected-window and seal rows of* S*, then that consumer must first expose the same finite* $\mathsf{StreamName}^{\uparrow}$ *window row* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R*, and* $\mathsf{Real}^{\uparrow}$ *seal row* E *already displayed by* S*. The shared-tail threshold is therefore extracted from displayed rows of the RegularCauchySequence packet and its sibling consumer routes, not from quotient streams, selected limits, choice, or ambient completeness.*

Proof. Begin with selected-window coverage. By Definition 660.10, every selected read of S is already routed through the family row F, modulus row μ, finite windows W, dyadic ledger D, regular readback R, and the structural rows H, C, P, N.

Next use the diagonal-window coverage handoff. Definition 660.11 identifies G as the consumer row that receives exactly those selected windows, dyadic ledger rows, and regular readbacks before any Real-facing handoff is considered.

Now apply the budget-window synchronization theorem, Definition 660.12. It synchronizes the selected-window route with the Real observation budget, so a seal-facing consumer cannot replace W, D, R by a hidden schedule or a separate threshold source.

Finally attach the sibling shared-tail surfaces. The $\mathsf{CauchySharedTailModulus}^{\uparrow}$ and $\mathsf{RealTailAgreementSeal}^{\uparrow}$ routes consume only displayed finite threshold, window, readback, and seal rows, and Definition 660.9 places E after those rows. Together with Definition 660.7, this rules out quotient streams, selected limits, choice, and ambient completeness as sources for the shared threshold. □

Theorem 660.16 (Regular Cauchy sequence diagonal tail selector factorization)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet. Let*

$$Q = (R', n', \mu', k', W', D', T', S', H', C', P', N')$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet whose* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows match the selected-window and handoff rows of* S *by the displayed* hsame *transports. Then every diagonal-tail consumer factors first through Definition 660.11 and then through Definition 697.6. The readable route is exactly the selected windows, dyadic ledger, regular readback, coverage row, selector modulus, selected index, finite selector window, selector readback, tail-regularity row, displayed transports, continuations, provenance, and local* NameCert *rows. The factorization exports no quotient stream, host real equality, countable-choice selector, host-selected limit, hidden tail oracle, or ambient completeness theorem.*

Proof. First confine the regular Cauchy side. By Definition 660.10, every selected read of S is already routed through $F, \mu, W, D, R, H, C, P, N$. The diagonal-window handoff theorem then identifies G as the $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ row that consumes those selected windows together with the dyadic ledger, regular readback, seal row, transports, continuations, provenance, and local naming row.

The seal order is fixed by Definition 660.9. Thus the $\mathsf{Real}^{\uparrow}$ row visible to the selector side is not an independent completed value; it is reached only after the finite regular-family rows and the coverage row have been displayed.

Now read the selector packet. The obligations in Definition 697.2 bind $R', n', \mu', k', W', D', T', S', H', C', P', N'$ into one finite selector surface, with k' read from μ' at n' and the tail-regularity row tied to the displayed regular-source row. The displayed hsame transports identify the selector's $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows with the corresponding selected-window and handoff rows of S.

Finally apply Definition 697.6 and Definition 697.19. The completion-facing consumer therefore passes through the regular Cauchy diagonal-window coverage handoff before it reaches the selector limit handoff, and the selector seal contributes no quotient stream, host real equality, countable-choice selector, host-selected limit, hidden tail oracle, or ambient completeness theorem. □

Theorem 660.17 (Regular Cauchy sequence selector-budget factor)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing consumer of an accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *diagonal route factors through the sibling* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *finite packet of chapter 678 before reaching the* $\mathsf{RegSeqRat}^{\uparrow}$ *witness and* $\mathsf{Real}^{\uparrow}$ *seal. Concretely, for*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

the consumer first reads the local family row F, modulus row μ, selected windows W, dyadic ledger D, diagonal coverage row G, and structural rows H, C, P, N; it then consumes the selector-budget packet as the finite route that exposes the $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness, and* $\mathsf{Real}^{\uparrow}$ *seal. The route exports no host limit, quotient regular sequence, countable choice selector, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness witness.*

Proof. Start with the local sequence carrier and selected-window obligations. By Definition 660.1, Definition 660.3, and Definition 660.10, every selected read is confined to $F, \mu, W, D, R, H, C, P, N$ with the finite family discipline supplied by the modulus and dyadic ledger.

Use the diagonal-window handoff of Definition 660.11. The coverage row G exposes only the selected $\mathsf{StreamName}^{\uparrow}$ windows, dyadic ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readbacks, and $\mathsf{Real}^{\uparrow}$ seal row already listed in the packet.

Now route the Real-facing edge through chapter 678. Its selector-budget packet is precisely the finite consumer dependency that names the selector modulus, window budget, StreamName observations, RegSeqRat witness, RealUp seal, and the structural H, C, P, N rows before the seal is read.

Finally apply Definition 660.7 and the local $\mathsf{Real}^{\uparrow}$ seal handoff of Definition 660.9. The factored route therefore reaches R and E only through the selector-budget packet and cannot use a host limit, quotient regular sequence, countable choice selector, or ambient $\mathsf{Real}^{\uparrow}$ completeness witness. □

Theorem 660.18 (Regular Cauchy sequence obligation closure)**.** *The* $\mathsf{RegularCauchySequence}^{\uparrow}$ *carrier, classifier, selected-window regularity, non-escape boundary, transport stability, diagonal-window coverage handoff,* $\mathsf{Real}^{\uparrow}$ *handoff, and provenance rows form the full seed-to-obligation package for the local NameCert surface. Concretely, every accepted packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

presents carrier admission, rowwise classifier stability, selected-window coverage, diagonal-window coverage, seal handoff, transport invariance, package provenance, and the exclusion of quotient streams, host limits, choice, and ambient completeness as one finite certificate.

Proof. Carrier admission and rowwise classifier stability are supplied by Definition 660.1 and Definition 660.2. The package rows H, C, P, N are part of the same tuple, so the certificate has named transport, continuation, provenance, and local naming surfaces.

Selected-window regularity and coverage are provided by Definition 660.3 and Definition 660.10. These results bind every selected read to the finite family row, modulus row, selected windows, dyadic ledger, and regular readback row.

The diagonal and seal handoff surfaces are given by Definition 660.11 and Definition 660.9. Transport stability follows from Definition 660.8, and the non-escape boundary follows from Definition 660.7.

These projections cover the local NameCert obligations listed in Definition 660.4. No further coordinate is available in the carrier, so the listed rows form the complete finite obligation package for this chapter's $\mathsf{RegularCauchySequence}^{\uparrow}$ surface. □

Theorem 660.19 (Regular Cauchy sequence shared threshold import)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet. Suppose an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet displays a shared tail threshold whose two source rows are read from the same family row F, selected windows W, dyadic ledger D, and* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R, and suppose its diagonal-window and* $\mathsf{Real}^{\uparrow}$ *consumers are transported through the same* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows as G, E, H, C, P, N. Then the* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet may import that displayed shared threshold as a consumer-visible tail row exactly along those displayed transports.*

The import adds no quotient stream, selected limit, host equality, choice coordinate, hidden tail oracle, or ambient completeness theorem. It only records that the RegularCauchyTailMeet public shared-threshold certificate is read through the already displayed regular-family, selected-window, dyadic, readback, diagonal-coverage, seal, transport, continuation, provenance, and naming rows.

Proof. Start with the carrier and classifier of Definition 660.1 and Definition 660.2. They make $F, \mu, W, D, R, G, E, H, C, P, N$ the complete rowwise surface visible to the regular Cauchy sequence packet.

Use selected-window coverage from Definition 660.10. It confines every finite selected read to the same family, window, dyadic, readback, transport, continuation, provenance, and local naming rows that the tail-meet packet is assumed to read.

Next apply the diagonal-window coverage handoff and the $\mathsf{Real}^{\uparrow}$ seal handoff, Definition 660.11 and Definition 660.9. These identify G and E as consumer rows reached only after the finite selected-window packet has been displayed.

Finally apply the RegularCauchyTailMeet public shared-threshold certificate, Definition 560.11. Because its threshold route is transported through the same BHist, hsame, Cont, Pkg, and NameCert rows, importing the threshold is just a replay of that displayed certificate inside the regular Cauchy sequence packet. □

Theorem 660.20 (Regular Cauchy sequence tail-meet consumer surface)**.** *Under the hypotheses of Definition 660.19, every downstream* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$*, or completion-facing consumer sees the combined packet only as*

$$F, \mu, W, D, R, G, E, H, C, P, N$$

together with the shared-tail rows displayed by the accepted $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet. The consumer surface has no quotient stream, no selected limit, no host equality, no choice coordinate, and no ambient completeness coordinate.*

Proof. First read the regular Cauchy sequence side. By Definition 660.18, the local NameCert surface is the finite packet $F, \mu, W, D, R, G, E, H, C, P, N$ with the listed non-escape boundary.

Now read the imported shared threshold. The import theorem routes the accepted $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ certificate through the same selected-window, dyadic, readback, coverage, seal, transport, continuation, package, and naming rows.

It remains to identify what a downstream consumer can see. Apply Definition 560.9 and Definition 560.11. These expose only the shared-tail rows of the tail-meet packet, so the combined surface is exactly the displayed regular Cauchy sequence packet plus those shared-tail rows. □

Theorem 660.21 (Regular Cauchy sequence observation-budget TailMeet consumer)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet. Suppose a downstream consumer reads a* $\mathsf{RealObservationBudget}^{\uparrow}$ *route for the seal row of S and also reads an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *route whose shared threshold is imported through the displayed selected-window, dyadic, readback, transport, continuation, provenance, and local naming rows of S. Then the consumer reaches the* $\mathsf{Real}^{\uparrow}$ *seal only through one shared finite route: the displayed* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger rows, shared threshold row,* hsame *transports,* Cont *route,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}$ *row.*

No accepted consumer may use the observation budget to bypass the imported TailMeet threshold, replace the displayed route by quotient streams or host real equality, read hidden selector rows, or import ambient completeness.

Proof. Begin with the observation-budget side. By Definition 660.13, every $\mathsf{Real}^{\uparrow}$-facing read of S through a $\mathsf{RealObservationBudget}^{\uparrow}$ packet first factors through the finite window, dyadic, readback, coverage, seal, transport, continuation, provenance, and naming rows displayed by the budget-to-seal route.

Next attach the TailMeet side. The consumer-surface theorem Definition 660.20 says that an imported $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold is visible to downstream Real or completion consumers only as the regular Cauchy packet together with the accepted tail-meet rows transported through the same displayed finite surface.

The two routes therefore share the selected $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger rows, $\mathsf{RegSeqRat}^{\uparrow}$ handoff rows, seal row, transports, continuations, provenance, and local name. The shared threshold is read after those rows have been displayed and before any consumer can treat the seal as available.

Finally use the carrier inventory of Definition 660.1 and the non-escape boundary of Definition 660.7. Since the carrier has no coordinate for quotient streams, host real equality, hidden selector rows, or ambient completeness, and since both cited routes consume only the displayed rows, no alternate path to the $\mathsf{Real}^{\uparrow}$ seal remains. □

Theorem 660.22 (Regular Cauchy sequence tail-selector budget lock)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *route. Suppose its selected-window rows factor through the sibling* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet of chapter 678, and suppose its shared threshold factors through an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet from chapter 560. Then every* $\mathsf{Real}^{\uparrow}$*-facing tail consumer of S must read the same displayed* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows carried by the selected-window and shared-threshold route.*

The locked consumer packet is the finite surface presented by chapter 126, chapter 301, chapter 291, and chapter 38 as those rows occur inside S and the transported tail-meet certificate. It contains no quotient stream, no host limit, no hidden selector, and no alternate tail threshold.

Proof. First apply the selector-budget factorization of Definition 660.17. It forces each Real-facing selected-window read through the finite selector-budget packet before the $\mathsf{RegSeqRat}^{\uparrow}$ witness and $\mathsf{Real}^{\uparrow}$ seal can be consumed.

Next apply the tail-meet consumer surface of Definition 660.20. The shared threshold imported from chapter 560 is visible only through the same selected-window, dyadic, readback, seal, transport, continuation, provenance, and local naming rows already displayed by the regular Cauchy sequence packet.

The concrete sibling chapters identify the projected rows. The $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ packet surfaces of chapter 126, chapter 301, chapter 291, and chapter 38 are therefore read at the coordinates exposed by S and by the transported tail-meet threshold, not at fresh host coordinates.

Since both routes share H, C, P, N, there is no remaining coordinate from which a consumer could obtain a quotient stream, host limit, hidden selector, or alternate tail threshold. The tail-facing Real consumer is locked to the single displayed finite packet. □

Theorem 660.23 (Regular Cauchy sequence tail-fusion budget handoff)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet. Suppose a downstream* $\mathsf{Real}^{\uparrow}$*-facing consumer reads an accepted* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *packet whose selected windows, dyadic ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared threshold, and* $\mathsf{Real}^{\uparrow}$ *seal rows are transported through the rows displayed by S. Suppose also that the same consumer reads either a* $\mathsf{RealObservationBudget}^{\uparrow}$ *route or a* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *budget route for the displayed seal. Then the consumer must pass through the single finite route*

$$W, D, R, G, E, H, C, P, N$$

together with the transported tail-fusion shared-threshold rows before it can read the $\mathsf{Real}^{\uparrow}$ *seal.*

The handoff exports no quotient stream, host real equality, selected completed limit, countable-choice coordinate, hidden tail oracle, or ambient completeness theorem.

Proof. First lock the selected-window and shared-threshold rows. By Definition 660.22, every tail-facing $\mathsf{Real}^{\uparrow}$ consumer of S reads the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows carried by the selected-window and shared-threshold route.

Next read the budget side. The observation-budget TailMeet consumer theorem, Definition 660.21, forces any $\mathsf{RealObservationBudget}^{\uparrow}$ route through the same finite selected windows, dyadic ledger, regular readback, shared threshold, transports, continuations, provenance, and local name. The seal factorization theorem Definition 660.13 gives the corresponding factorization for the displayed $\mathsf{Real}^{\uparrow}$ seal row.

Now attach the sibling tail-fusion packet. Its public export Definition 658.17 exposes only the finite route through precision, regular-family, selected-window, dyadic, tail-witness, shared-threshold, diagonal readback, seal, transport, continuation, provenance, and naming rows, while Definition 658.23 makes a completion-facing consumer pass through that route before any public completion read.

Substituting the rows transported through S identifies the visible route as $W, D, R, G, E, H, C, P, N$ together with the transported tail-fusion shared-threshold rows. The budget route and the tail-fusion route therefore meet before the $\mathsf{Real}^{\uparrow}$ seal rather than supplying parallel access paths.

Finally apply Definition 660.7. The carrier has no coordinate for quotient streams, host real equality, selected completed limits, countable choice, hidden tail oracles, or ambient completeness, so no consumer can leave the displayed finite handoff. □

Theorem 660.24 (Regular Cauchy sequence tail-selector exhaustion)**.** *Let*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet. Any completion-facing consumer that reads a* $\mathsf{DiagonalTailSelector}^{\uparrow}$, $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, *or* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *row transported through* S *must factor through the single finite route*

$$F, \mu, W, D, R, G, E, H, C, P, N$$

together with the transported selector and shared-tail rows before reading the $\mathsf{Real}^{\uparrow}$ *seal.*

The exhausted route contains no quotient stream, host real equality, selected limit, countable-choice coordinate, hidden tail oracle, alternate tail threshold, or ambient $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. First route the selector side. The diagonal tail-selector factorization of Definition 660.16 binds every transported $\mathsf{DiagonalTailSelector}^{\uparrow}$ read to the displayed family, selector, window, dyadic, readback, diagonal, seal, transport, continuation, package, and naming rows of S.

Next force the selected budget. Apply Definition 660.17 to pass every selector-budget consumer through the same selected-window packet, and then apply Definition 660.22 to identify the shared finite rows with the transported $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold.

Now attach the fusion route. The handoff theorem Definition 660.23 makes the tail-fusion and budget routes meet on $W, D, R, G, E, H, C, P, N$ before any $\mathsf{Real}^{\uparrow}$ seal read.

Finally use Definition 660.7. The accepted carrier has no coordinate for quotient streams, host real equality, selected limits, countable choice, hidden tail oracles, alternate thresholds, or ambient completeness, so every Real-facing tail-selector consumer is exhausted by the single finite diagonal-tail route. □

Theorem 660.25 (Regular Cauchy sequence root obligation export)**.** *The* $\mathsf{RegularCauchySequence}^{\uparrow}$ *root obligation exported to later Real and Completion formalization consists of the local obligation closure of Definition 660.18, the shared-threshold import of Definition 660.19, and the consumer-surface boundary of Definition 660.20. Thus a later diagonal route may consume regular-family data through the displayed packet and a transported* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared threshold, but it receives no quotient stream, selected limit, host equality, choice coordinate, hidden tail oracle, or ambient completeness theorem.*

Proof. Assemble the local packet first. The obligation closure theorem packages carrier admission, classifier stability, selected-window coverage, diagonal-window coverage, $\mathsf{Real}^{\uparrow}$ handoff, transport, provenance, and non-escape for $F, \mu, W, D, R, G, E, H, C, P, N$.

Attach the shared threshold by Definition 660.19. The import is valid only when the family row, selected windows, dyadic ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readbacks, diagonal-window coverage row, $\mathsf{Real}^{\uparrow}$ handoff, and structural rows are the same displayed rows under BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ transport.

Finally apply Definition 660.20. It records the downstream boundary for Real and Completion consumers, so the root export is a finite current packet plus the displayed shared-tail certificate, with all off-surface completion and quotient data excluded. □

Theorem 660.26 (Regular Cauchy sequence scoped dependency surface)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

the chapter's obligation package is scoped exactly over the displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows. Every selected-window, diagonal-coverage, shared-threshold, and Real seal consumer factors through those rows.*

Consequently no later $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or completion-facing consumer may use a quotient stream, host limit, choice coordinate, hidden tail oracle, or ambient completeness theorem when reading the* $\mathsf{RegularCauchySequence}^{\uparrow}$ *package.*

Proof. Start from the obligation closure theorem, Definition 660.18. It names the carrier, classifier, selected-window coverage, diagonal-window coverage, $\mathsf{Real}^{\uparrow}$ handoff, transport, provenance, and non-escape rows inside the same finite packet S.

The selected-window and diagonal consumers are then read through Definition 660.11 and Definition 660.9. These two handoffs account for the $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ rows without adding any external limit or quotient coordinate.

Next attach the shared-threshold route by Definition 660.19. Its source rows are the displayed family, window, dyadic, readback, diagonal, seal, transport, continuation, package, and naming rows.

Finally apply Definition 660.25. The root export is therefore a scoped dependency surface over exactly the listed rows, and the non-escape clauses rule out quotient streams, host limits, choice, hidden tail oracles, and ambient completeness for every downstream consumer. □

Theorem 660.27 (Regular Cauchy sequence public export)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

the carrier, rowwise classifier, selected-window regularity, diagonal-window coverage, selector-budget factor, shared-threshold import, and $\mathsf{Real}^{\uparrow}$ *seal handoff assemble into one public* $\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}$ *export. The export is exactly the finite surface over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *already displayed by the packet.*

No quotient stream, host limit, selected external limit, choice coordinate, hidden tail oracle, or ambient completeness theorem is part of this public export.

Proof. Begin with Definition 660.18. It packages the carrier, classifier, selected-window regularity, diagonal-window coverage, $\mathsf{Real}^{\uparrow}$ handoff, transport, provenance, and non-escape rows for the single finite packet S.

Next apply Definition 660.26. This identifies the exact dependency surface over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and the structural BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows.

Attach the tail-facing factors through Definition 660.17, Definition 660.22, and Definition 660.25. These theorems route the selected-window budget and shared threshold through the same displayed packet before any Real-facing consumer can read the seal.

The resulting public $\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}$ export is therefore the displayed finite packet and its imported shared-threshold surface. The non-escape clauses in the cited theorems rule out quotient streams, host limits, choice, hidden tail oracles, selected external limits, and ambient completeness. □

Theorem 660.28 (Regular Cauchy sequence mature Real and Completion consumer route)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

every downstream Real or Completion consumer route that uses the regular Cauchy family factors through the selected-window rows W*, dyadic ledger* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *row* R*,* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *row* G*,* $\mathsf{Real}^{\uparrow}$ *handoff* E*, and the structural* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows carried by* H, C, P, N*.*

This route consumes the public export and scoped dependency surface of the packet. It exports no quotient stream, host limit, selected external limit, choice coordinate, hidden tail oracle, ambient completeness theorem, or $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Proof. Begin with the public export of Definition 660.27. It assembles the carrier, rowwise classifier, selected-window regularity, diagonal-window coverage, selector-budget factor, shared-threshold import, and $\mathsf{Real}^{\uparrow}$ seal handoff into the finite $\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}$ surface.

Next use Definition 660.26. That theorem identifies the allowed dependency rows as the displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, so any Real or Completion consumer must read the same finite packet.

The seal portion is fixed by Definition 660.9. The row E is reached only after the selected windows W, dyadic ledger D, regular-readback row R, and diagonal coverage row G have been displayed, so the route has no independent host limit or selected external limit.

Finally apply Definition 660.7. Since the carrier contains no coordinate for quotient streams, choice, hidden tail oracles, ambient completeness, or $\mathsf{Real}^{\uparrow}$ completeness, the consumer route is exhausted by the finite packet S and exports no off-surface completion data. □

Theorem 660.29 (Regular Cauchy sequence Cauchy witness ledger handoff)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

whose selected-window rows, dyadic ledger, $\mathsf{RegSeqRat}^{\uparrow}$ *row,* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *row, and* $\mathsf{Real}^{\uparrow}$ *seal handoff are consumed by an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet of chapter 902, every completion-facing read passes through the same finite route* $W, D, R, G, E, H, C, P, N$ *before the witness ledger can read its observation-budget and completion-seal rows.*

The handoff exports no quotient stream, host limit, selected external limit, choice coordinate, hidden tail oracle, ambient completeness theorem, or $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Proof. Begin with Definition 660.27. The accepted packet exposes the selected-window rows, dyadic ledger, regular-rational readback, diagonal-window coverage, $\mathsf{Real}^{\uparrow}$ seal handoff, and structural rows as one public $\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}$ surface.

Apply Definition 660.28. Any Real or Completion consumer using the regular Cauchy family must read W, D, R, G, E and the structural rows H, C, P, N, with no off-surface limit, choice, or completeness coordinate.

Now read the witness-ledger side through Definition 902.5 and Definition 902.9. The ledger reaches its observation-budget and completion-seal classifier rows only through the displayed diagonal-budget, observation-budget, seal-synchronizer, and structural route.

Combining these routes forces the Cauchy witness ledger consumer to inherit the regular Cauchy packet's finite public route before any completion-facing read is admitted. The same non-escape

clauses from the regular Cauchy packet and the witness ledger remove quotient streams, host limits, selected external limits, choice coordinates, hidden tail oracles, ambient completeness, and $\mathsf{Real}^{\uparrow}$ completeness from the handoff. □

Theorem 660.30 (Regular Cauchy sequence modulus-refinement consumer lock)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

whose selected-window and seal rows are consumed by an accepted $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *packet, every* $\mathsf{Real}^{\uparrow}$ *or Completion-facing consumer must pass through the refinement route* $M_0, M_1 \to U \to V \to T \to W \to Q \to E$ *before reading the* $\mathsf{Real}^{\uparrow}$ *seal.*

The consumer receives no quotient stream, host limit, selected external limit, choice coordinate, hidden selector, alternate meet row, or ambient completeness theorem.

Proof. Start with Definition 660.28 and Definition 660.27. These results confine the $\mathsf{RegularCauchySequence}^{\uparrow}$ side to the displayed packet S, its selected-window rows, its diagonal coverage row, and its public $\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}$ export.

The refinement order is then forced by Definition 885.11 and Definition 885.12. The source meet and budget rows reach the selected-window and tolerance readbacks only along the displayed M_0, M_1, U, V, T, W, Q spine.

Next apply Definition 885.7. The $\mathsf{Real}^{\uparrow}$ seal row is reachable only after that spine has been displayed, so a Real or Completion consumer cannot read the seal directly from the regular Cauchy packet.

Finally combine Definition 885.10 with Definition 660.7. The two non-escape boundaries remove quotient streams, host limits, selected external limits, choice coordinates, hidden selectors, alternate meet rows, and ambient completeness theorems from the consumer surface. □

Theorem 660.31 (Regular Cauchy sequence budgeted modulus-witness handoff)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

suppose that its selected-window and $\mathsf{Real}^{\uparrow}$ *seal rows are consumed by both an accepted* RegularCauchyModulusWitness *packet and an accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *packet. Then the two consumers expose the same finite selected-window row* W*, dyadic ledger* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R*, diagonal coverage row* G*,* $\mathsf{Real}^{\uparrow}$ *seal row* E*, and structural* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows carried by* H, C, P, N *before either consumer reads a completion-facing seal.*

The handoff admits no quotient stream, host real equality, selected limit, choice coordinate, hidden selector, or ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Proof. Start with Definition 660.28 and Definition 660.30. They force every Real or Completion consumer of the accepted regular Cauchy packet to read through the displayed $W, D, R, G, E, H, C, P, N$ surface before the $\mathsf{Real}^{\uparrow}$ seal is available.

Next apply Definition 977.7. The modulus-witness ledger side reaches its Real-facing seal only through its displayed finite ledger route, so the rows imported from S cannot be replaced by a second selected window, dyadic ledger, readback row, coverage row, seal row, or structural transport package.

Finally use Definition 913.10. The budgeted seal route identifies the selector, threshold, observation-budget, seal, Real readback, transport, continuation, package, and naming rows at

its source before any completion-facing read is admitted. Combining this source exactness with the regular Cauchy and modulus-witness routes makes the shared handoff the single finite packet surface $W, D, R, G, E, H, C, P, N$ and excludes quotient streams, host real equality, selected limits, choice, hidden selectors, and ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 660.32 (Regular Cauchy sequence Real four-face exit readback)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

any Phase $\mathsf{Real}^{\uparrow}$ *or Completion read that uses S factors through the same finite four-face exit surface carried by* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *The only support rows used in this read are the displayed* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows of the packet.*

Conversely, the present four-face exit readback supplies exactly this finite route for S: the selected StreamName window, dyadic tolerance ledger, regular-rational readback, and terminal Real seal are the whole Real-and-Completion-facing boundary of the accepted regular Cauchy sequence packet.

The route contains no quotient streams, host equality, selected limits, choice rows, metric-completeness data, bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Proof. Start with the public export theorem Definition 660.27. It exposes the accepted packet S as one finite $\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}$ surface over the StreamName, dyadic, regular-readback, diagonal-coverage, Real seal, and structural support rows.

Next apply Definition 660.28 and Definition 660.31. These two routes force every Real or Completion consumer that reads S to pass through $W, D, R, G, E, H, C, P, N$ before any completion-facing seal is available.

Now identify the terminal boundary. The StreamName four-face readback theorem Definition 126.450 reads the same boundary through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, while Definition 126.461 makes that boundary terminal for Phase $\mathsf{Real}^{\uparrow}$ and Completion reads.

For the converse direction, take the four-face exit readback just described and restrict it along the public export of S. The selected window, dyadic ledger, regular readback, and Real seal rows are already the displayed rows of the accepted regular Cauchy sequence packet, so the readback supplies exactly the finite route stated above.

Finally apply Definition 660.7. The carrier has no constructor for quotient streams, host equality, selected limits, choice rows, metric-completeness data, bridge rows, or ambient $\mathsf{Real}^{\uparrow}$ completeness, so no off-surface resource can enter either direction of the readback. □

Theorem 660.33 (Regular Cauchy sequence finite-tail closure)**.** *For every accepted* $\mathsf{RegularCauchySequence}^{\uparrow}$ *packet*

$$S = (F, \mu, W, D, R, G, E, H, C, P, N),$$

whose tail selector and budgeted modulus witness rows are visible, every finite-tail Real or Completion consumer factors through the displayed route

$$\mathsf{StreamName}^{\uparrow},\ \mathsf{RegSeqRat}^{\uparrow},\ \mathsf{DyadicRatCore}^{\uparrow},\ \mathsf{Real}^{\uparrow}$$

together with the support rows H, C, P, N. The route uses the selected windows, dyadic budget, regular rational readback, diagonal coverage row, and terminal Real seal already present in S; it exports no selected limit, quotient stream equality, host real equality, hidden tail oracle, countable-choice selector, or ambient $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Proof. Start with Definition 660.24. It forces every Real-facing tail-selector consumer of S through the displayed diagonal-tail route and excludes hidden tail oracles, alternate thresholds, quotient streams, selected limits, choice, and ambient completeness.

Next use Definition 660.30. The refinement route fixes the source meet, budget rows, selected-window rows, tolerance readback, and Real seal before any completion-facing consumer can inspect the terminal seal.

Now apply Definition 660.31. The modulus-witness and budgeted Real-seal consumers must share the same selected-window row W, dyadic ledger D, $\mathsf{RegSeqRat}^{\uparrow}$ readback row R, diagonal coverage row G, $\mathsf{Real}^{\uparrow}$ seal row E, and structural rows H, C, P, N.

Finally apply Definition 660.32. It identifies the terminal Real and Completion boundary with the four faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. The finite-tail consumer therefore closes through the displayed rows of S and cannot add a selected limit, quotient equality, host equality, hidden tail oracle, choice selector, or ambient completeness coordinate. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchySequence}^{\uparrow}$ packet is generated from a finite regular Cauchy family row, explicit modulus, selected StreamName windows, a DyadicRatCore readback ledger, RegSeqRat readbacks, RealDiagonalWindowCoverage coverage, a RealUp handoff row, componentwise transports, continuation routes, package provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchySequence}^{\uparrow}}, \mathsf{maturePackageClosed})$

Not claimed: This chapter does not close Lean verification, bridge checking, RealUp completeness, quotient equality of regular Cauchy sequences, host real equality, selected external limits, choice, or ambient completeness.

Upgrade path: No further theory-axis grade is pending; the remaining work is Lean verification and bridge checking.

Chapter 661

A Concrete Naming Certificate for $\mathsf{DefiniteDescriptionBoundary}^{\uparrow}$

The $\mathsf{DefiniteDescriptionBoundary}^{\uparrow}$ packet realizes the description-expansion boundary as a finite naming certificate. It treats a definite description as a row that may be consumed only after the packet exposes existence, uniqueness boundary, stability, hsame, Cont, Pkg, and local NameCert rows. No description row becomes a denoting term by grammar alone.

The description row specializes the Russell analysis ladder of chapter 518 and the contextual-class reading surface of chapter 684. This chapter consumes their description-expansion and contextual-class discipline, then adds the displayed existence, uniqueness-boundary, stability, and ledger rows D, E, U, S, H, C, P, N. When existence or uniqueness fails, the failed read remains an externalized socket in the sense of chapter 543, so the boundary exports refusal data rather than a denoting term.

The description row is also read through the negative naming boundary of chapter 629 before any existence or uniqueness row is consumed. Definite descriptions refine that refusal surface by adding the displayed D, E, U, S, H, C, P, N rows; they do not select a host denotation.

Definition 661.1 (Definite-description boundary carrier)**.** *A* $\mathsf{DefiniteDescriptionBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (D, E, U, S, H, C, P, N)$$

with the following displayed rows:

1. *D is the description row whose apparent denotation is being tested;*
2. *E is the existence-witness row for a candidate history satisfying the description;*
3. *U is the uniqueness-boundary row, recording either a displayed singleton boundary for the candidate or the explicit refusal to collapse multiple candidates;*
4. *S is the stability row showing that permitted reads of the description survive the stated* hsame *and continuation routes;*
5. *H is the componentwise* hsame *transport row for descriptions, witnesses, uniqueness boundaries, stability witnesses, replay routes, provenance, and local names;*
6. *C is the* Cont *row that replays the finite route from the description row to the admitted witness and through the boundary check;*

7. *P is the* Pkg *provenance over* BHist, BMark, *description rows, witness rows, uniqueness boundaries, stability rows,* hsame, Cont, *and* NameCert*;*

8. *N is the local* $\mathsf{NameCert}_{\mathsf{DefiniteDescriptionBoundary}^{\uparrow}}$ *row.*

The carrier has no coordinate for a host-selected object, a choice function, a quotient class, proof-irrelevance, or an unrecorded semantic denotation.

Lean4 ✓ `BEDC.Derived.DefiniteDescriptionBoundaryUp.DefiniteDescriptionBoundaryTasteGate single carrier alignment`

Theorem 661.2 (Definite-description NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DefiniteDescriptionBoundary}^{\uparrow}}$ *surface for Definition 661.1 consists exactly of carrier admission for $B = (D, E, U, S, H, C, P, N)$, existence exposure through E, uniqueness-boundary exposure through U, stability exposure through S, componentwise* hsame *transport through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Proof. Carrier admission is projection from the finite tuple in Definition 661.1. The description row, witness row, boundary row, stability row, transport row, replay row, provenance row, and local name are all displayed coordinates of the same packet.

The naming obligations are exactly the rows a consumer can inspect before reading the description. Existence is read from E, the boundary between singleton and refusal is read from U, stability is read from S, and all transport, replay, provenance, and naming data are read through H, C, P, N.

No additional coordinate remains from which to select a host object or import an ambient denotation. The local NameCert surface is therefore exhausted by the listed rows. □

Lean4 ✓ `BEDC.Derived.DefiniteDescriptionBoundaryUp.DefiniteDescriptionBoundary namecert obligations`

Theorem 661.3 (Definite-description existence route)**.** *Let $B = (D, E, U, S, H, C, P, N)$ be an accepted* $\mathsf{DefiniteDescriptionBoundary}^{\uparrow}$ *packet. Any public use of the description row D as having a witness must factor through the displayed existence row E, replayed by C and recorded by P, N.*

Lean4 ✓ `BEDC.Derived.DefiniteDescriptionBoundaryUp.DefiniteDescriptionBoundaryExistenceRoute`

Proof. Project the accepted packet to its description row D and existence row E. The carrier contains no second existence coordinate and no host-level selection function.

The replay route C is the only displayed path from the description row to the witness row, and P, N bind that path to the packet provenance and local name. Thus a public existence read factors through E, C, P, N rather than through an unstated denotation. □

Theorem 661.4 (Definite-description uniqueness route)**.** *Let $B = (D, E, U, S, H, C, P, N)$ be an accepted* $\mathsf{DefiniteDescriptionBoundary}^{\uparrow}$ *packet. Any public use of D as selecting at most one witness must factor through the uniqueness-boundary row U. If U records refusal rather than singleton boundary, the packet exports only the refusal and does not export a denoting term.*

Lean4 ✓ `BEDC.Derived.DefiniteDescriptionBoundaryUp.DefiniteDescriptionBoundaryUniquenessRoute`

Proof. Inspect the carrier coordinates. The only row that can certify uniqueness, or refuse it, is U.

When U records a singleton boundary, the consumer reads that boundary through the same displayed replay and provenance rows C, P, N. When U records refusal, the packet has no alternate coordinate from which a selected witness can be recovered.

Therefore uniqueness is not supplied by the grammar of the description. It is supplied only by the displayed boundary row, and failure of that row blocks denotation. □

Theorem 661.5 (Definite-description stability route)**.** *Let $B = (D, E, U, S, H, C, P, N)$ be an accepted* DefiniteDescriptionBoundary$^{\uparrow}$ *packet. Any downstream read that transports the description across equivalent histories must use the stability row S together with the componentwise* hsame *row H and the replay row C.*

Lean4 ✓ `BEDC.Derived.DefiniteDescriptionBoundaryUp.DefiniteDescriptionBoundaryStabilityRoute`

Proof. The stability coordinate S records the permitted movement of the description read under the packet's own transport discipline. The transport coordinate H records the componentwise hsame data for the description, witness, boundary, stability, replay, provenance, and naming rows.

A downstream transport therefore has to pass through S, H, C. Package provenance and local naming remain the rows P, N, so the transported read is still the same finite certificate surface.

Since the carrier has no proof-irrelevance principle, quotient equality, or external equivalence oracle, no other stability route is available. □

Theorem 661.6 (Definite-description ledger exhaustion)**.** *Every accepted* DefiniteDescriptionBoundary$^{\uparrow}$ *packet exports description-expansion information only through the finite rows*

$$D, E, U, S, H, C, P, N.$$

It exports no host-selected witness, no choice principle, no quotient representative, no proof-irrelevance shortcut, and no denoting term outside the displayed NameCert ledger.

Lean4 ✓ `BEDC.Derived.DefiniteDescriptionBoundaryUp.DefiniteDescriptionBoundaryLedger exhaustion`

Proof. Read the carrier as the tuple $B = (D, E, U, S, H, C, P, N)$. The definition lists every row available to a downstream consumer.

Existence, uniqueness boundary, and stability are exhausted by E, U, S. Transport, replay, provenance, and local naming are exhausted by H, C, P, N.

Thus the apparent denoting expression is expanded into its certificate rows. With no remaining coordinate for choice, quotient representative selection, proof irrelevance, or host denotation, the ledger boundary is exact. □

Theorem 661.7 (Definite description boundary scoped kernel route)**.** *Every accepted* DefiniteDescriptionBoundary$^{\uparrow}$ *read factors through the displayed description row, existence row, uniqueness-boundary row, stability row, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *row before any denoting-expression consumer can read the boundary.*

Lean4 ✓ `BEDC.Derived.DefiniteDescriptionBoundaryUp.DefiniteDescriptionBoundaryScopedKernelRoute`

Proof. Begin with the carrier of Definition 661.1. It displays exactly the finite rows D, E, U, S, H, C, P, N and contains no coordinate for a host denotation, choice function, quotient representative, or proof-irrelevance shortcut.

Apply Definition 661.2 to expose the local NameCert surface. The existence route of Definition 661.3 and the uniqueness route of Definition 661.4 force any witness-facing read through E and U before the description can be consumed as denoting.

Apply Definition 661.5 for componentwise hsame transport and displayed replay through S, H, C. Finally, Definition 661.6 binds the replay to P, N and blocks every non-displayed denoting-expression route. □

Lean4 ✓ `BEDC.Derived.DefiniteDescriptionBoundaryUp.DefiniteDescriptionBoundaryKernelDependencyBinding`

Theorem 661.8 (DefiniteDescriptionBoundary public interface)**.** *Every public* DefiniteDescriptionBoundary$^{\uparrow}$ *consumer factors through the displayed existence route, uniqueness boundary, stability transport, ledger exhaustion, and kernel dependency binding rows before it may read a denoting-expression boundary.*

Proof. Start with an accepted packet $B = (D, E, U, S, H, C, P, N)$. The scoped kernel route forces the consumer through the description row, existence row, uniqueness-boundary row, stability row, componentwise hsame transport, Cont replay, Pkg provenance, and local NameCert row.

The existence and uniqueness routes bind all witness-facing reads to E and U. The stability route binds transported reads to S, H, C, while ledger exhaustion removes every host-selected witness, quotient representative, proof-irrelevance shortcut, and non-displayed denoting term.

Thus the public interface is not a separate operation. It is the finite dependency surface already certified by the displayed rows and by the kernel dependency binding theorem. □

Closure status for NameCert$_{\text{DefiniteDescriptionBoundary}^{\uparrow}}$.

Constructive story: A DefiniteDescriptionBoundary$^{\uparrow}$ packet is generated from a description row, an existence witness row, a uniqueness-boundary row, a stability row, componentwise hsame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{DefiniteDescriptionBoundary}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 661.1, Definition 661.2, Definition 661.3, Definition 661.4, Definition 661.5, Definition 661.6, Definition 661.7, and Definition 661.8 specify the finite description-expansion carrier, its ledger boundary, the kernel dependency route, and the public interface every denoting-expression consumer must read.

Formal verification: FormalStatus(NameCert$_{\text{DefiniteDescriptionBoundary}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DefiniteDescriptionBoundaryUp.DefiniteDescriptionBoundaryKernelDependencyBinding`

Bridge status: paperBridge

Not claimed: This chapter does not close a public definite-description operator, host choice, quotient representative selection, proof irrelevance, or a checked external bridge to any description calculus.

Upgrade path: No paper-side closure remains; bridge checking is recorded only on the verification axis for the external description-calculus boundary.

Chapter 662

A Concrete Naming Certificate for $\mathsf{RealBudgetTailMeet}^{\uparrow}$

The $\mathsf{RealBudgetTailMeet}^{\uparrow}$ surface packages the finite observation budget used by a $\mathsf{Real}^{\uparrow}$ consumer together with the shared tail threshold used by a regular-Cauchy comparison and the sealed completion handoff. It is the concrete bridge from budgeted reads and tail-meet synchronization to the $\mathsf{CauchyLimitSeal}^{\uparrow}$ route named in the real-completeness vision.

The dependency path is the finite observation budget of chapter 611, the shared-tail threshold packet of chapter 560, and the completion-facing seal handoff of chapter 386; the local carrier only synchronizes these sibling rows.

Definition 662.1 (RealBudgetTailMeet carrier)**.** *A* $\mathsf{RealBudgetTailMeet}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (B, T, L, H, C, P, N)$$

with the following displayed rows:

1. *B is an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet naming the finite precision request, selected real-facing window, regular source readback, and dyadic observation budget;*
2. *T is an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet naming the shared tail threshold, paired regular-Cauchy source rows, paired schedules, comparison row, and threshold ledger;*
3. *L is an accepted* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff whose source family, scheduled window, observation ledger, completion diagonal row, and* $\mathsf{Real}^{\uparrow}$ *seal consume the same budget and shared-threshold rows;*
4. *H stores the displayed* hsame *transports relating the budget rows, shared-tail rows, and seal-handoff rows componentwise;*
5. *C stores the* Cont *routes through which downstream* $\mathsf{Real}^{\uparrow}$ *and completion consumers read the budget, tail meet, and seal handoff;*
6. *P is the* Pkg *provenance over* $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{RealBudgetTailMeet}^{\uparrow}}$ *row.*

The classifier compares carriers only by the visible rows B, T, L, H, C, P, N. It has no coordinate for quotient streams, selected host limits, hidden tail oracles, host real equality, trichotomy, or ambient completeness.

Theorem 662.2 (RealBudgetTailMeet NameCert obligations)**.** *For the carrier of Definition 662.1, the local* $\mathsf{NameCert}_{\mathsf{RealBudgetTailMeet}^{\uparrow}}$ *surface consists of carrier admission for* $R = (B, T, L, H, C, P, N)$*, classifier stability under the displayed* hsame *rows in* H*, budget exactness for the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row* B*, shared-threshold exactness for the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *row* T*, seal-route exactness for the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* L*, and non-escape through* C, P, N*.*

Lean4 ✓ `BEDC.Derived.RealBudgetTailMeetUp.RealBudgetTailMeetTasteGate single carrier alignment`

Proof. Carrier admission is the finite packet in Definition 662.1. The rows B, T, L, H, C, P, N are the complete public inventory.

Classifier stability is componentwise. Transport may move the budget row, the shared tail-meet row, the seal row, and the visible route rows only by the stored hsame comparisons and the same continuation routes.

The exactness clauses are projections. The budget row supplies the finite observation budget, the tail-meet row supplies the shared threshold, and the seal row supplies the completion-facing handoff. Since no other coordinate exists, the local certificate cannot export any hidden tail oracle, quotient stream, selected limit, or ambient completeness datum. □

Theorem 662.3 (RealBudgetTailMeet budget projection)**.** *Every accepted* $\mathsf{RealBudgetTailMeet}^{\uparrow}$ *carrier projects to the same finite observation budget used by its* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff. More precisely, if*

$$R = (B, T, L, H, C, P, N),$$

then every $\mathsf{Real}^{\uparrow}$ *consumer read through* R *first reads the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row* B*, transports that budget through* H *and* C*, and only then reaches the shared threshold packet* T *and the seal handoff* L*.*

Proof. Project the carrier and read the budget coordinate B. It records the precision request, finite window, regular source readback, and dyadic observation ledger available to the consumer.

Apply the $\mathsf{RealObservationBudget}^{\uparrow}$ exactness surface through the displayed continuation rows. The consumer route must carry the same budget rows through H and C before any downstream handoff can be read.

The remaining coordinates T and L are attached to that route by the carrier and the package provenance. They therefore consume the projected budget rather than an independent precision source. □

Theorem 662.4 (RealBudgetTailMeet seal handoff)**.** *Let* $R = (B, T, L, H, C, P, N)$ *be an accepted* $\mathsf{RealBudgetTailMeet}^{\uparrow}$ *carrier. The completion-facing handoff from* R *to* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *is exactly the row* L *together with the budget projection from* B*, the shared threshold from* T*, and the displayed transports and routes in* H, C, P, N*. Thus the route to the* $\mathsf{Real}^{\uparrow}$ *seal factors through a finite observation budget and one shared regular-Cauchy tail threshold before the seal row is read.*

Proof. Begin with the budget projection of Definition 662.3. It fixes the consumer precision, selected window, source readback, and dyadic ledger inside B.

Use the shared-threshold surface of $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ for T. The two regular-Cauchy tails are synchronized by the displayed threshold row and by the comparison ledger already attached to the same budget route.

Finally read L as the $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff. Its finite-window route consumes the same regular source, scheduled window, dyadic observation ledger, completion diagonal row, and $\mathsf{Real}^{\uparrow}$ seal, with H, C, P, N recording the visible transport and provenance. No separate completion channel is introduced. □

Theorem 662.5 (RealBudgetTailMeet non-escape boundary)**.** *An accepted* $\mathsf{RealBudgetTailMeet}^{\uparrow}$ *carrier exports only the finite rows* B, T, L, H, C, P, N *and their displayed* $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, *and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *dependency surfaces. It exports no quotient stream, selected host limit, hidden tail oracle, host real equality, trichotomy row, countable-choice principle, or ambient real-completeness theorem.*

Proof. Inspect the carrier coordinates. The public rows are exactly the budget packet, tail-meet packet, seal handoff, transports, continuation routes, package provenance, and local naming row.

The budget coordinate contains only finite observation data, the tail-meet coordinate contains only the shared threshold and comparison rows, and the seal coordinate contains only the finite completion handoff to $\mathsf{Real}^{\uparrow}$.

Since quotient streams, selected host limits, hidden tail oracles, host real equality, trichotomy, choice, and ambient completeness have no coordinate in R, a downstream consumer cannot read any of them from the $\mathsf{RealBudgetTailMeet}^{\uparrow}$ surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealBudgetTailMeet}^{\uparrow}}$**.**

Constructive story: A $\mathsf{RealBudgetTailMeet}^{\uparrow}$ packet is generated from a $\mathsf{RealObservationBudget}^{\uparrow}$ finite budget, a $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ shared-threshold packet, a $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RealBudgetTailMeet}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 662.1, Definition 662.2, Definition 662.3, Definition 662.4, and Definition 662.5 bind the finite budget-plus-tail-meet carrier, local naming obligations, budget projection, seal handoff, and non-escape boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RealBudgetTailMeet}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close quotient completion, selected host limits, uniqueness of limits, trichotomy, ambient real completeness, Lean verification, or a public standard bridge.

Upgrade path: Obligation closure requires checked carrier admission, budget projection, shared-threshold exactness, seal handoff, and non-escape for the same finite packet.

Chapter 663

A Concrete Naming Certificate for $\mathsf{RegularCauchyCofinalLimit}^{\uparrow}$

The cofinal-limit packet consumes chapter 126, chapter 301, and chapter 38 through its finite window, regular-rational readback, and $\mathsf{Real}^{\uparrow}$ seal rows. Thus this chapter is not an isolated limit surface: it is the finite handoff across those sibling certificates that keeps the Real-and-Completion route visible inside one displayed carrier.

The $\mathsf{RegularCauchyCofinalLimit}^{\uparrow}$ surface records the finite cofinal-window route by which regular Cauchy data reaches a $\mathsf{Real}^{\uparrow}$ seal. It packages dyadic tolerance rows, StreamName windows, regular rational sequence rows, seal rows, transports, continuations, provenance, and local naming in one visible packet. The packet is a limit-facing certificate; it is not a quotient of streams, not host equality of completed reals, and not an invocation of ambient completeness.

Definition 663.1 (RegularCauchyCofinalLimit carrier)**.** *A* $\mathsf{RegularCauchyCofinalLimit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (F, S, W, E, R, L, H, C, P, N)$$

with the following displayed rows:

1. *F is the finite family row of* $\mathsf{RegSeqRat}^{\uparrow}$ *regular Cauchy names being compared by cofinal windows;*
2. *S is the* $\mathsf{StreamName}^{\uparrow}$ *schedule row naming the finite observations read from F;*
3. *W is the cofinal-window ledger assigning each displayed precision request to a finite schedule window in S;*
4. *E is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance and error ledger attached to those windows;*
5. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row reached after the dyadic tolerance ledger has been fixed;*
6. *L is the* $\mathsf{Real}^{\uparrow}$ *seal row reached from the displayed regular Cauchy readback;*
7. *H records componentwise* hsame *transports for F, S, W, E, R, L and the structural rows;*
8. *C records the displayed* Cont *routes from F through S, W, E, R and then into L;*
9. *P is the* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and local certificate rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyCofinalLimit}^{\uparrow}}$ *row.*

The classifier for accepted carriers compares only the displayed rows $F, S, W, E, R, L, H, C, P, N$. It has no coordinate for quotient stream equality, host real equality, hidden limit selection, countable choice, or an ambient $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Lean4 ✓ `BEDC.Derived.RegularCauchyCofinalLimitUp.RegularCauchyCofinalLimitTasteGate single carrier alignment`

Theorem 663.2 (RegularCauchyCofinalLimit NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyCofinalLimit}^{\uparrow}}$ *surface for Definition 663.1 consists of five finite obligations:*

1. *carrier exposure, requiring every accepted object to display the packet $K = (F, S, W, E, R, L, H, C, P, N)$;*
2. *cofinal-window exactness, requiring every precision demand consumed by the limit route to pass through the displayed window ledger W over the schedule row S;*
3. *dyadic tolerance readback, requiring the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger E to be read only from the windows named by W and the regular Cauchy family F;*
4. *seal factorization, requiring the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R and the* $\mathsf{Real}^{\uparrow}$ *seal row L to be reached only through F, S, W, E, H, C, P, N;*
5. *non-escape, requiring the packet to export no quotient stream equality, host real equality, hidden limit selector, countable-choice row, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness theorem.*

Proof. Carrier exposure is projection from the displayed tuple in Definition 663.1. The family, schedule, window, tolerance, readback, seal, transport, continuation, provenance, and local naming rows are all coordinates of one finite BHist packet.

Cofinal-window exactness reads the route S, W before any tolerance row is consumed. Since W is the only cofinal-window ledger in the carrier, a precision demand cannot be redirected to an unnamed tail or to a completed stream object.

Dyadic tolerance readback then uses E together with F, S, W. The tolerance ledger is attached to the displayed windows and regular Cauchy rows, so it cannot be replaced by host real equality or a hidden completeness argument.

Finally, seal factorization and non-escape inspect the remaining rows R, L, H, C, P, N. They provide the only route into the $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{Real}^{\uparrow}$ seal, and none of the carrier coordinates names quotient stream equality, hidden limit selection, countable choice, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Theorem 663.3 (RegularCauchyCofinalLimit seal factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read exported by an accepted* $\mathsf{RegularCauchyCofinalLimit}^{\uparrow}$ *packet factors through the finite route*

$$F, S, W, E, R, L, H, C, P, N.$$

The seal consumer first reads the regular Cauchy family row, the StreamName schedule, the cofinal-window ledger, the dyadic tolerance ledger, and the regular rational readback row. Only then may it reach the displayed $\mathsf{Real}^{\uparrow}$ *seal row L through the componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row.*

Proof. Start with an accepted packet $K = (F, S, W, E, R, L, H, C, P, N)$. The carrier exposes no seal route except the displayed continuation chain through C.

The consumer first fixes the finite observation surface. It reads F through S, then restricts the request to the cofinal windows named by W, and then reads the dyadic tolerance evidence in E from those same windows.

The route to the seal is then forced through R and L. The transports in H, continuations in C, provenance in P, and local certificate N repack the same rows, so the seal read has no independent coordinate for a selected host limit or completed-stream equality. □

Theorem 663.4 (RegularCauchyCofinalLimit non-escape)**.** *An accepted* $\mathsf{RegularCauchyCofinalLimit}^{\uparrow}$ *packet can export only the displayed rows* $F, S, W, E, R, L, H, C, P, N$ *and their local classifier transports. A completion-facing consumer may use the cofinal-window ledger, dyadic tolerance ledger, regular rational readback, and* $\mathsf{Real}^{\uparrow}$ *seal exactly as named by the packet; it receives no quotient stream equality, no host real equality, no hidden limit selector, no choice-like tail, and no ambient* $\mathsf{Real}^{\uparrow}$ *completeness proof.*

Proof. Project the finite carrier. The coordinate list contains rows for the regular Cauchy family, schedule, cofinal windows, dyadic tolerance ledger, readback, seal, transports, continuations, provenance, and local naming.

Apply the NameCert obligations from Definition 663.2. They force every precision, tolerance, readback, and seal request through those coordinates and require non-escape for the excluded analytic objects.

Since quotient stream equality, host real equality, hidden limit selection, countable choice, and ambient completeness are not coordinates of K, neither hsame transport nor Cont replay can manufacture them as public exports. □

Theorem 663.5 (RegularCauchyCofinalLimit public export)**.** *The carrier of Definition 663.1, the NameCert obligations of Definition 663.2, the seal factorization of Definition 663.3, and the non-escape result of Definition 663.4 assemble the public* $\mathsf{RegularCauchyCofinalLimit}^{\uparrow}$ *export consumed by* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *seal rows.*

The export is exactly the finite cofinal-window packet $K = (F, S, W, E, R, L, H, C, P, N)$*. It does not identify streams by quotient equality, does not compare host completed reals, does not select a hidden limit, and does not claim* $\mathsf{Real}^{\uparrow}$ *completeness outside the displayed seal route.*

Proof. The carrier theorem fixes the public packet and the NameCert theorem lists its finite obligations. Together they expose the cofinal-window route, dyadic tolerance readback, regular rational handoff, seal row, transport, continuation, provenance, and local naming rows.

Seal factorization supplies the consumer route into $\mathsf{Real}^{\uparrow}$. It shows that any seal read must pass through $F, S, W, E, R, L, H, C, P, N$ in the displayed order.

Non-escape supplies the boundary condition for public use. Because the excluded quotient, host, selector, choice, and ambient-completeness objects are absent from the carrier, the public export is exactly the finite packet and no larger completion principle. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyCofinalLimit}^{\uparrow}}$**.**

Constructive story: A $\mathsf{RegularCauchyCofinalLimit}^{\uparrow}$ packet is generated from regular Cauchy family rows, StreamName schedule rows, cofinal-window ledgers, DyadicRatCore tolerance rows, RegSeqRat readback rows, RealUp seal rows, componentwise transports, continuation routes, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyCofinalLimit}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 663.1, Definition 663.2, Definition 663.3, Definition 663.4, and Definition 663.5 bind the finite cofinal-window route from regular Cauchy data to RealUp seal rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyCofinalLimit}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, quotient equality of streams, host real equality, hidden limit selection, countable choice, ambient RealUp completeness, or a public standard bridge.

Upgrade path: Scoped closure requires Lean encoding of the displayed carrier and checked theorems for cofinal-window exactness, dyadic tolerance readback, RegSeqRat handoff, RealUp seal factorization, and non-escape.

Chapter 664

A Concrete Naming Certificate for $\mathsf{ObservationTimeOrder}^{\uparrow}$

The $\mathsf{ObservationTimeOrder}^{\uparrow}$ interface realizes BEDC-internal time as a finite naming surface for monotonic record retention. It does not introduce a host clock, scalar time coordinate, global synchronization map, or reversible time primitive. It records two observation-state histories, the retained-record classifier between them, the displayed continuation route witnessing record preservation, the Gap boundary for erased-record demands, and the local NameCert row that packages the order comparison.

Definition 664.1 (Observation-time-order carrier)**.** *An* $\mathsf{ObservationTimeOrder}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (O_0, O_1, R, C, G, H, P, N)$$

with the following visible rows:

1. O_0 *is the earlier observation-state* BHist *row;*
2. O_1 *is the later observation-state* BHist *row;*
3. R *is the retained-record classifier, naming each record visible in* O_0 *as still visible in* O_1*;*
4. C *records the displayed* Cont *route that reads* O_0*, then* O_1*, then the retained-record classifier* R*;*
5. G *is the* Gap *boundary row for any demand that a record present in* O_0 *be erased, hidden, or made unavailable in* O_1*;*
6. H *records componentwise* hsame *transport for the two observation-state rows, retained-record classifier, continuation route, gap boundary, package row, and local name row;*
7. P *is the* Pkg *provenance over* $\mathsf{ConsciousObserverState}^{\uparrow}$, $\mathsf{HistTimeStream}^{\uparrow}$, BHist, Gap, hsame, Cont, Pkg, *and* NameCert *source certificates;*
8. N *is the local* $\mathsf{NameCert}_{\mathsf{ObservationTimeOrder}^{\uparrow}}$ *row.*

The carrier compares accepted packets only through $O_0, O_1, R, C, G, H, P, N$*. It has no coordinate for external host time, a numeric clock value, a global simultaneity relation, or a deletion operation on observation records.*

Lean4 ✓ `BEDC.Derived.ObservationTimeOrderUp.ObservationTimeOrderTasteGate single carrier alignment`

Theorem 664.2 (ObservationTimeOrder NameCert obligations)**.** *For the carrier of Definition 664.1, the local* $\mathsf{NameCert}_{\mathsf{ObservationTimeOrder}^{\uparrow}}$ *surface has exactly five obligation rows:*

1. *carrier admission for the two observation-state rows O_0 and O_1 together with $T = (O_0, O_1, R, C, G, H, P, N)$;*
2. *retained-record classifier exactness, requiring R to expose every record present in O_0 as retained in O_1;*
3. Cont *monotonicity route, requiring the displayed route C to read O_0 before O_1 and then read R as the preservation ledger between them;*
4. Gap *boundary for erased-record demands, requiring G to classify any claimed deletion of an O_0 record from O_1 as outside the accepted order surface;*
5. *no-host-time non-escape under H, P, N, excluding scalar clocks, external simultaneity, reversible deletion, and global synchronization from the local certificate.*

Proof. Carrier admission is projection from Definition 664.1. The two observation-state rows O_0 and O_1 are displayed before any classifier or route is read.

The retained-record classifier exactness clause reads R only after both state rows are available. Thus R can name the internal order comparison precisely as record preservation from O_0 to O_1.

The monotonicity route is the continuation row C. It fixes the public read order as O_0, then O_1, then R, so a consumer cannot reverse the order or inspect a hidden deletion operation.

The erased-record boundary is the row G. Any demand that a record present in O_0 disappear from O_1 is not a successful retained-record comparison; it is recorded as a gap-side boundary for the attempted read.

Finally, H transports only the displayed coordinates, while P and N bind provenance and local naming. Since no carrier coordinate stores a scalar clock, host time, global simultaneity relation, reversible deletion map, or synchronization frame, the certificate cannot export one. □

Lean4 ✓ `BEDC.Derived.ObservationTimeOrderUp.ObservationTimeOrderNameCertObligations`

Theorem 664.3 (ObservationTimeOrder retained-record exactness)**.** *For an accepted* ObservationTimeOrder$^{\uparrow}$ *packet*

$$T = (O_0, O_1, R, C, G, H, P, N),$$

the internal time comparison from O_0 to O_1 is exactly the retained-record classifier R read through the displayed route C. A public consumer may conclude that O_0 precedes O_1 only by reading the records of O_0, reading the records of O_1, and then reading the preservation ledger R.

No additional row supplies a numeric time value, a host clock, a global simultaneity relation, or a second comparison independent of retained records.

Lean4 ✓ `BEDC.Derived.ObservationTimeOrderUp.ObservationTimeOrderRetainedRecord exactness`

Proof. Project the accepted packet. The comparison data are the two observation-state rows O_0, O_1 and the retained-record classifier R.

The route row C determines the public read. It exposes the source state, then the target state, and only then the preservation ledger between the two.

The remaining rows G, H, P, N account for gap boundaries, transport, provenance, and naming. They do not add a clock or a second order primitive. Hence the internal time comparison is exhausted by retained-record exactness through R. □

Theorem 664.4 (ObservationTimeOrder erasure boundary)**.** *For an accepted* ObservationTimeOrder$^{\uparrow}$ *packet, any demand that a record present in O_0 be absent from O_1 is routed to the* Gap *boundary row G. The accepted time-order surface therefore permits unrecorded future commitments only as gap-side obligations, not as deletion or reversal of records already visible in O_0.*

Lean4 ✓ `BEDC.Derived.ObservationTimeOrderUp.ObservationTimeOrderErasureBoundary gap route`

Proof. Read the carrier rows $O_0, O_1, R, C, G, H, P, N$. The retained-record classifier R is the only positive comparison row between O_0 and O_1.

If a consumer asks for an O_0 record to disappear from O_1, that request contradicts the retained-record role of R. The packet has exactly one boundary row for such a request, namely G.

Transport through H and routing through C preserve the same division between retained records and gap-side demands. The package and name rows P, N then bind the boundary to the local order certificate. □

Theorem 664.5 (ObservationTimeOrder no-host-time non-escape)**.** *Every accepted* $\mathsf{ObservationTimeOrder}^{\uparrow}$ *carrier exports only the two observation-state rows, the retained-record classifier, the displayed* Cont *route, the erased-record* Gap *boundary, componentwise* hsame *transport,* Pkg *provenance, and the local* NameCert *row. It exports no scalar host time, global synchronization map, ambient simultaneity relation, reversible time operation, or hidden deletion primitive.*

Lean4 ✓ `BEDC.Derived.ObservationTimeOrderUp.ObservationTimeOrderNo host time nonescape`

Proof. Inspect the coordinates of Definition 664.1. Every exported row is one of $O_0, O_1, R, C, G, H, P, N$.

The positive order data are O_0, O_1, R, C. The boundary and structural data are G, H, P, N, which record gap-side refusal, transport, provenance, and local naming.

No coordinate remains for host time, a global synchronization map, ambient simultaneity, time reversal, or deletion of displayed records. Therefore no accepted packet can export those objects. □

Theorem 664.6 (ObservationTimeOrder HistTimeStream dependency)**.** *The retained-record route of* $\mathsf{ObservationTimeOrder}^{\uparrow}$ *consumes the local Hist time stream of chapter 603 and the finite clock-budget boundary of chapter 665 before it can expose the order comparison row* R*.*

Lean4 ✓ `BEDC.Derived.ObservationTimeOrderUp.ObservationTimeOrderHistTimeStreamDependency`

Proof. Inspect Definition 664.1. The packet exposes the two observation rows O_0, O_1 before the retained-record classifier R, and it records the public read order through the displayed continuation row C.

The package row P already names $\mathsf{HistTimeStream}^{\uparrow}$ as source certificate data for the local history stream consumed by the two observation rows. The finite comparison remains bounded by the internal rows $O_0, O_1, R, C, G, H, P, N$, so the LocalClockBudget sibling supplies a boundary for admissible clock reads rather than a host-time coordinate.

Thus the sibling references are substantive: the packet depends on the local Hist time stream and finite clock-budget boundary to present R. Because all visible rows remain internal BHist, Cont, and Gap route rows with hsame, Pkg, and NameCert packaging, the dependency adds no scalar host time or global synchronization map. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObservationTimeOrder}^{\uparrow}}$**.**

Constructive story: An $\mathsf{ObservationTimeOrder}^{\uparrow}$ packet is generated from two observation-state BHist rows, a retained-record classifier, displayed continuation route, erased-record GAP boundary, componentwise hsame transport, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ObservationTimeOrder}^{\uparrow}}$, obligation)

Scope closed: Definition 664.1, Definition 664.2, Definition 664.3, Definition 664.4, and Definition 664.5 close the paper-side obligation surface for the finite BEDC-internal time-order packet and its monotonic observation-state record-retention reads.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ObservationTimeOrder}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, host time, numeric clock semantics, global simultaneity, reversible deletion, or inter-observer synchronization.

Upgrade path: Obligation closure requires checked carrier admission, retained-record exactness, Cont monotonicity routing, GAP erasure boundary, and no-host-time non-escape for the same observation-time-order packet.

Chapter 665

A Concrete Naming Certificate for $\mathsf{LocalClockBudget}^{\uparrow}$

The $\mathsf{LocalClockBudget}^{\uparrow}$ packet realizes observer local time as a finite certificate surface. It reads a single Hist stream through bounded Cont windows, records the local unary budget for those windows, transports the same rows by hsame, and exposes a no-global-clock ledger for downstream consumers. The packet does not synchronize distinct histories, choose an ambient clock, or import a hidden limit schedule. The local stream is consumed as the time-budget face of the observer-history surface in chapter 477 and the locality-cell boundary in chapter 513.

The same finite local-window budget supplies the observer-facing boundary consumed by chapter 615 and the distinction-trace consumer of chapter 882. In both cases the dependency is the carrier window row W together with the ledger-boundary row that prevents a downstream observer packet from replacing local time by a global clock.

Definition 665.1 (Local clock budget carrier)**.** *A* $\mathsf{LocalClockBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$C = (H, T, W, B, L, Q, P, N)$$

with the following displayed rows:

1. *H is the observed* Hist *row whose local time stream is being budgeted;*
2. *T is the finite local-time-stream row, recording the* Cont *applications from* e *to the displayed history surface;*
3. *W is the finite family of* Cont*-step window rows selected for the budget;*
4. *B is the unary budget row that counts the admitted local steps and window endpoints;*
5. *L records componentwise* hsame *transport for the history row, local stream row, window rows, budget row, route row, package row, and local naming row;*
6. *Q records the displayed* Cont *routes for history projection, stream readback, window inspection, budget readback, and consumer handoff;*
7. *P is the* Pkg *provenance over* Hist, BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, *local time streams, and no-global-clock ledgers;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{LocalClockBudget}^{\uparrow}}$ *row.*

The carrier contains exactly these rows. It has no coordinate for a global clock, inter-history synchronization value, host time parameter, limit scheduler, or observer-substance distinct from the recorded history.

Lean4 ✓ `BEDC.Derived.LocalClockBudgetUp.LocalClockBudgetCarrier transport window surface`

Theorem 665.2 (Local clock budget window totality)**.** *Every accepted* $\mathsf{LocalClockBudget}^{\uparrow}$ *carrier exposes a finite local time stream and a finite covering family of* Cont*-step windows. Each window is selected from the row T of local* Cont *applications, counted by the unary budget row B, and replayed through the displayed route row Q inside the same packet*

$$C = (H, T, W, B, L, Q, P, N).$$

Lean4 ✓ `BEDC.Derived.LocalClockBudgetUp.LocalClockBudgetWindow totality`

Proof. Project the carrier of Definition 665.1. The rows H, T, W, B, L, Q, P, N display the observed history, its local stream, finite windows, unary budget, transport, routes, provenance, and local name.

The local stream row T is read before the window family W. Therefore each admitted window is a finite part of the displayed Cont route from e toward the history row H.

The unary row B counts the selected windows and endpoints, while Q replays their inspection for consumers. Since the carrier has no unbounded schedule or ambient time coordinate, every admitted window is exhausted by the finite packet. □

Theorem 665.3 (Local clock budget route determinacy)**.** *Let two accepted* $\mathsf{LocalClockBudget}^{\uparrow}$ *consumer routes display the same rows H, T, W, B, L, Q, P, N. Then they determine the same local-time-budget surface up to the componentwise* hsame *transports recorded in L. No second route may distinguish the same local stream by appealing to a global clock, a host time parameter, or an inter-history synchronization value.*

Lean4 ✓ `BEDC.Derived.LocalClockBudgetUp.LocalClockBudgetRoute determinacy`

Proof. Start with the displayed history and stream rows. The rows H and T fix the local source surface that any consumer route may inspect.

Apply window totality. Definition 665.2 binds the window family W and budget row B to the same finite Cont-step stream and routes their readback through Q.

Finally use the transport row L. Componentwise hsame transport preserves the displayed history, stream, windows, budget, provenance, and local name, while the carrier inventory excludes every global or host-side clock coordinate that could separate the two routes. □

Theorem 665.4 (Local clock budget NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{LocalClockBudget}^{\uparrow}}$ *surface for Definition 665.1 consists exactly of carrier admission for $C = (H, T, W, B, L, Q, P, N)$, observed-history projection, local-time-stream exposure, finite* Cont*-window totality, unary budget readback, componentwise* hsame *stability, displayed* Cont *replay,* Pkg *provenance, no-global-clock ledger exclusion, and the local naming row.*

Lean4 ✓ `BEDC.Derived.LocalClockBudgetUp.LocalClockBudgetNameCert obligations`

Proof. Carrier admission is projection from the displayed packet. The rows H, T, W, B provide the observed history, local stream, finite windows, and unary budget.

The window-totality theorem supplies the finite coverage clause, and route determinacy supplies the consumer-facing uniqueness of the budget surface up to the displayed hsame transports.

The remaining rows L, Q, P, N give transport, replay, provenance, and local naming. Since the carrier has no coordinate for a global clock, inter-history synchronization value, host time parameter, limit scheduler, or separate observer-substance, the listed rows exhaust the local certificate. □

Theorem 665.5 (Local clock budget observer handoff)**.** *Every downstream observer-facing consumer of an accepted* $\mathsf{LocalClockBudget}^{\uparrow}$ *packet receives only the finite rows*

$$H, T, W, B, L, Q, P, N.$$

The consumer may inspect the observed history, its local time stream, the selected Cont *windows, the unary budget, componentwise* hsame *transports, displayed replay routes, provenance, and local naming. It may not extract a global clock, a synchronized comparison between distinct histories, an ambient time parameter, a hidden limit schedule, or an observer-substance beyond* Hist*.*

Lean4 ✓ `BEDC.Derived.LocalClockBudgetUp.LocalClockBudgetCarrier observer handoff`

Proof. Project the accepted carrier. The only consumer-visible coordinates are H, T, W, B, L, Q, P, N.

Use the local NameCert obligations to order the handoff through observed-history projection, stream exposure, window totality, budget readback, transport, replay, provenance, and local naming.

Route determinacy then rules out alternate clock readings of the same packet. The no-global-clock exclusions are carrier exclusions: none of the forbidden objects appears as a coordinate, so no consumer can project it from the handoff. □

Theorem 665.6 (Local clock budget carrier scope)**.** *For an accepted* $\mathsf{LocalClockBudget}^{\uparrow}$ *packet*

$$C = (H, T, W, B, L, Q, P, N),$$

the carrier scope is anchored in the single displayed BHist *history row* H *and its finite local* Cont *stream* T*. The scope contains exactly the window family* W*, unary budget row* B*, componentwise* hsame *transport row* L*, displayed route row* Q*,* Pkg *provenance row* P*, and local* $\mathsf{NameCert}_{\mathsf{LocalClockBudget}^{\uparrow}}$ *row* N*, and it contains no global clock, host time parameter, inter-history synchronization coordinate, limit scheduler, or observer-substance outside* Hist*.*

Proof. Project the carrier of Definition 665.1. The tuple $C = (H, T, W, B, L, Q, P, N)$ displays the whole accepted packet.

Use window totality. Definition 665.2 anchors the finite window family W and the unary budget row B in the local Cont stream T over the history row H.

The carrier inventory excludes every global or host-side clock coordinate. Therefore the carrier scope is exactly the displayed BHist-anchored packet. □

Lean4 ✓ `BEDC.Derived.LocalClockBudgetUp.LocalClockBudgetCarrier scope`

Theorem 665.7 (Local clock budget classifier stability)**.** *Let* $C = (H, T, W, B, L, Q, P, N)$ *be an accepted* $\mathsf{LocalClockBudget}^{\uparrow}$ *packet. Transporting* H, T, W, B, P, N *componentwise by the* hsame *rows recorded in* L *and then replaying the displayed* Cont *routes in* Q *preserves the local-clock-budget classifier. In particular, no transported packet can be separated by a global clock, host time parameter, inter-history synchronization value, limit scheduler, or observer-substance beyond* Hist*.*

Lean4 ✓ `BEDC.Derived.LocalClockBudgetUp.LocalClockBudgetClassifier stability`

Proof. Start from the displayed transport row L. Its entries move the history row, local stream row, window family, budget row, provenance row, and local name componentwise to the common hsame surface.

Replay the routes in Q. Window totality binds the transported windows and budget to the same finite local stream, and route determinacy identifies any two consumer routes that display the same rows up to those transports.

The no-global-clock exclusions are part of the carrier inventory. With no forbidden coordinate available, the classifier remains stable after the recorded transport and replay. □

Theorem 665.8 (Local clock budget ledger boundary)**.** *Every ledger read exported by an accepted* LocalClockBudget$^{\uparrow}$ *packet*

$$C = (H, T, W, B, L, Q, P, N)$$

is bounded by the displayed BHist*-anchored local stream, finite* Cont *windows, unary budget, transport, route, provenance, and local naming rows. The ledger may be handed to observer-facing consumers through Definition 665.5, but it cannot export a global clock, host time parameter, inter-history synchronization value, hidden limit schedule, or observer-substance outside* Hist*.*

Lean4 ✓ `BEDC.Derived.LocalClockBudgetUp.LocalClockBudgetLedger boundary`

Proof. Read the ledger from the carrier. The only budget-bearing rows are the local stream T, window family W, unary budget B, transport row L, route row Q, provenance row P, and local name N over the observed history row H.

Apply window totality and route determinacy. These theorems force ledger reads through the finite windows and make alternate readings of the same rows agree up to componentwise hsame transport.

Finally use observer handoff. Definition 665.5 exposes exactly the same rows to downstream consumers, while the carrier exclusions rule out every global-clock or host-time escape. □

Theorem 665.9 (Local clock budget public export)**.** *Every observer-facing consumer of an accepted* LocalClockBudget$^{\uparrow}$ *packet receives the finite packet*

$$H, T, W, B, L, Q, P, N$$

as the public LocalClockBudget$^{\uparrow}$ *export through window totality, route determinacy, observer handoff, carrier scope, classifier stability, and ledger boundary. The export may expose the observed history, local time stream, selected* Cont *windows, unary budget, componentwise* hsame *transport, displayed route, provenance, and local name, but it cannot read a global clock, host time parameter, inter-history synchronization coordinate, limit scheduler, or observer-substance outside* Hist*.*

Lean4 ✓ `BEDC.Derived.LocalClockBudgetUp.LocalClockBudgetPublic export`

Proof. Project the accepted carrier through Definition 665.1. The public packet is the finite tuple H, T, W, B, L, Q, P, N.

Apply window totality and route determinacy. Definition 665.2 binds W and B to the displayed local stream, and Definition 665.3 blocks any second route through a global or host-side clock.

Use observer handoff and carrier scope next. Definition 665.5 gives the downstream consumer exactly the same rows, while Definition 665.6 keeps the export anchored in one displayed history row and its finite local stream.

Finally apply classifier stability and ledger boundary. Definition 665.7 preserves the packet under recorded transport and replay, and Definition 665.8 excludes global clocks, host time parameters, inter-history synchronization coordinates, limit schedulers, and observer-substance from the public export. □

Theorem 665.10 (Local clock budget mature treatment)**.** *The* $\mathsf{LocalClockBudget}^{\uparrow}$ *public export consumes exactly the finite local-window budget needed by the observer-history identity of chapter 477, the observer locality cell of chapter 513, the observer subject boundary of chapter 615, and the observer distinction trace of chapter 882. Each consumer reads only the displayed rows* H, T, W, B, L, Q, P, N*, so the shared observer route has no remaining paper-side clock coordinate, host time parameter, inter-history synchronization value, hidden limit schedule, or observer-substance outside* Hist*.*

Lean4 ✓ `BEDC.Derived.LocalClockBudgetUp.LocalClockBudgetMature treatment`

Proof. Start with the public export theorem. Definition 665.9 gives the downstream surface as the finite packet H, T, W, B, L, Q, P, N.

The four observer-facing consumers named in the statement use the same packet from different boundaries. The observer-history identity reads the history row and local stream, the locality cell reads the selected finite windows, the subject boundary reads the budgeted handoff, and the distinction trace reads the ledger boundary.

Apply the carrier scope, classifier stability, and ledger boundary theorems. These force all four reads through the same local-window packet and exclude every global or host-side clock coordinate. Thus the finite local-window budget is exhausted at the mature paper surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{LocalClockBudget}^{\uparrow}}$**.**

Constructive story: A $\mathsf{LocalClockBudget}^{\uparrow}$ packet is generated from one observed Hist row, its finite local Cont stream, finite step-window rows, a unary budget row, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{LocalClockBudget}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 665.1, Definition 665.6, Definition 665.7, Definition 665.8, Definition 665.5, Definition 665.9, and Definition 665.10 close the displayed BHist, hsame, Cont, Pkg, NameCert, exported public packet, and observer-facing local-window budget for the finite local-clock-budget surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{LocalClockBudget}^{\uparrow}}$, unformalized)

Bridge status: paperBridge

Not claimed: This chapter does not close global clocks, synchronized time across distinct histories, host time parameters, hidden limit schedules, observer-substance beyond Hist, Lean verification, or bridge checking.

Upgrade path: Bridge verification requires a checked standard bridge theorem for the same finite local-clock-budget packet.

Chapter 666

A Concrete Naming Certificate for $\mathsf{SupplyKindRouter}^{\uparrow}$

The $\mathsf{SupplyKindRouter}^{\uparrow}$ surface is the concrete classifier router for the seven T-supply socket kinds of chapter 9394. It refines the ledger surfaces by forcing every consumer to pass through one displayed kind row before reading the requested-shape and refusal rows attached to that kind. The router is a finite packet over visible BEDC rows; it does not supply the requested content behind the socket.

Definition 666.1 (SupplyKindRouter carrier)**.** *A* $\mathsf{SupplyKindRouter}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (S, K, R, A, H, C, P, N)$$

with the following displayed rows:

1. *S is the* Gap *socket site at which the requested supply would be consumed;*
2. *K is exactly one of the seven supply-kind rows: free-floating induction, unwitnessed witness, extensional identification, causal continuity, inter-history coordination, inscription novelty, or self-reference closure;*
3. *R is the requested-shape row for the missing discharge named at S;*
4. *A is the audit-gate and refusal row attached to the chosen kind K;*
5. *H records componentwise* hsame *transport for the socket site, kind row, requested-shape row, audit-gate row, provenance row, and local naming row;*
6. *C records the displayed* Cont *routes by which consumers read the site, choose the kind row, inspect the requested shape, and return the refusal row;*
7. *P is the* Pkg *provenance over* BHist, Gap, *the seven supply-kind rows, requested-shape rows, audit gates,* hsame, Cont, *and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{SupplyKindRouter}^{\uparrow}}$ *row.*

The carrier exports no row for unrestricted induction, an unseen witness, quotient equality, empirical persistence, shared host history, an inscription source, or truth-total self-validation.

Theorem 666.2 (SupplyKindRouter NameCert obligations)**.** *For the carrier of Definition 666.1, the local* $\mathsf{NameCert}_{\mathsf{SupplyKindRouter}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$U = (S, K, R, A, H, C, P, N),$$

socket-site exposure through S, one-kind classifier exposure through K, requested-shape accountability through R, audit-gate and refusal routing through A, componentwise transport through H, continuation locality through C, package provenance through P, local naming through N, and non-discharge of the requested supply.

Lean4 ✓ `BEDC.Derived.SupplyKindRouterUp.SupplyKindRouterTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 666.1. The packet exposes the socket site, one supply-kind row, the requested-shape row, the refusal row, transport, continuation, provenance, and local naming data as its complete visible inventory.

The classifier obligation is the row K. Since K is required to be exactly one of the seven displayed kinds, every accepted read of the router must first choose that finite row before the requested shape or refusal row is available.

The routing obligations are the rows A, H, C, P, N. They preserve the same socket boundary through audit, transport, continuation, provenance, and local naming, and none of those rows contains the requested discharge itself. □

Theorem 666.3 (SupplyKindRouter kind exhaustion)**.** *Every accepted* $\mathsf{SupplyKindRouter}^{\uparrow}$ *packet routes its socket through exactly one of the seven displayed supply kinds before any consumer reads the corresponding requested-shape row or refusal row. The router has no eighth kind, no default catch-all branch, and no route from the socket site S to a ledger read that bypasses the classifier row K.*

Proof. Project the accepted packet $U = (S, K, R, A, H, C, P, N)$. The only kind coordinate is K, and the carrier definition restricts that coordinate to the seven rows named in section 9394.11.

Now apply the NameCert obligations of Definition 666.2. They place requested-shape accountability and audit refusal downstream of the one-kind classifier exposure, so a consumer cannot reach R or A without passing through K.

The absence of hidden branches follows from the carrier inventory. No coordinate names an additional kind, a default route, or a ledger read outside the finite classifier. □

Theorem 666.4 (SupplyKindRouter apophatic socket dependency)**.** *Every accepted* $\mathsf{SupplyKindRouter}^{\uparrow}$ *packet consumes the apophatic named-boundary surface of chapter 543 when its socket site S and requested-shape row R are read. The router refines that sibling boundary by choosing exactly one supply-kind row K before the refusal row A, and it does not create the requested supply.*

Proof. Project the carrier of Definition 666.1. The socket site S and requested-shape row R are named boundary data, so their concrete sibling dependency is the ApophaticName surface that records a named boundary without supplying the requested content.

Apply Definition 666.3. It forces exactly one classifier row K to be exposed before a consumer reaches the requested-shape row or refusal row, so the router only refines the sibling boundary by kind selection.

The refusal row A then records the failed supply route. Because the carrier has no coordinate for a supplied witness, quotient equality, unrestricted induction principle, or hidden source object, the requested supply is not created by the router. □

Theorem 666.5 (SupplyKindRouter non-escape)**.** *Every consumer of an accepted* $\mathsf{SupplyKindRouter}^{\uparrow}$ *packet reads only*

$$S, K, R, A, H, C, P, N.$$

The consumer may learn which one of the seven socket kinds governs the site, which requested shape is being refused, and which audit route records the refusal. It receives no unrestricted induction principle, selected witness, quotient equality, empirical persistence law, shared host history, inscription source, truth-total self-description, hidden source object, or supplied T*-content.*

Proof. Start from the carrier and NameCert obligation surface. Together they list the complete router inventory and force every read of the requested-shape and refusal rows through the displayed classifier row.

Use kind exhaustion next. Since the accepted route has exactly one of the seven kinds and no hidden branch, the consumer has no alternate path from the socket site to a ledger read.

Finally inspect the packet coordinates. The rows H, C, P, N transport, replay, cite, and name the same finite route; they do not add the missing supply. Hence all refused objects remain outside the router. □

The audit-gate row A is the refusal input consumed by the $\mathsf{AuditGateComposition}^{\uparrow}$ packet of chapter 696 when two routed refusals share a boundary. Thus router classification fixes the kind and requested-shape rows before composed refusal traces may read a common audit boundary.

Closure status for $\mathsf{NameCert}_{\mathsf{SupplyKindRouter}\uparrow}$**.**

Constructive story: A $\mathsf{SupplyKindRouter}^{\uparrow}$ packet is generated from a Gap socket site, exactly one of the seven supply-kind rows, a requested-shape row, an audit-gate refusal row, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SupplyKindRouter}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 666.1, Definition 666.2, Definition 666.3, Definition 666.4, Definition 666.5, and

Lean4 ✓ `BEDC.Derived.SupplyKindRouterUp.taste gate`

bind the finite classifier router, apophatic socket dependency, seven-kind coverage, requested-shape routing, audit refusal, transport, continuation, provenance, and local naming rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SupplyKindRouter}\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.SupplyKindRouterUp.SupplyKindRouterTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close any Gap discharge, unrestricted induction, hidden witness selection, quotient equality, empirical persistence, inter-history recognition, inscription-source explanation, self-reference closure, or a public standard bridge.

Upgrade path: No further paper-axis upgrade is pending because the chapter is at mature closure; verification and bridge checking remain independent axes.

Chapter 667

A Concrete Naming Certificate for $\mathsf{SelfReferenceTruthBranch}^{\uparrow}$

The $\mathsf{SelfReferenceTruthBranch}^{\uparrow}$ packet realizes the Type VII reflection socket as a finite NameCert surface. It records the structural self-description a system may expose, the requested truth-total branch it must refuse, the certificate index at which the request would be consumed, and the audit rows that keep structural self-description separate from internal truth classification.

It refines the truth-total obstruction already packaged by chapter 472. The $\mathsf{TruthTotalReflection}^{\uparrow}$ packet records the finite attempted truth-total classifier boundary, while $\mathsf{SelfReferenceTruthBranch}^{\uparrow}$ records the certificate-indexed branch query and refusal surface for self-reference.

Definition 667.1 (Self-reference truth-branch carrier)**.** *A* $\mathsf{SelfReferenceTruthBranch}^{\uparrow}$ *carrier is a finite* BHist *tuple*

$$B = (S, D, Q, F, R, H, C, P, N)$$

with the following displayed rows:

1. *S is the structural self-description row, naming the object-language syntax, certificate grammar, and replay surface being described;*
2. *D is the diagonal request row, naming the self-application route by which the description would be read back against itself;*
3. *Q is the certificate-indexed truth-branch query, naming the finite certificate row whose truth-total classification is requested;*
4. *F is the forbidden-branch row, recording that a certificate-indexed internal truth predicate or runtime-total validator is not a carrier coordinate;*
5. *R is the socket report row separating admitted structural description from refused truth-totalization;*
6. *H records componentwise* hsame *transport for structural descriptions, diagonal requests, branch queries, refusal rows, socket reports, replay routes, provenance, and local names;*
7. *C records the displayed* Cont *replay from structural description through diagonal request, branch query, refusal exposure, and socket report;*
8. *P is the* Pkg *provenance over* BHist*, structural syntax description, certificate indices, Type VII socket reports,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *source rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{SelfReferenceTruthBranch}^{\uparrow}}$ *row.*

The carrier has no coordinate for an internal predicate classifying all sentences of the described system, no runtime validator contained in the object language it validates, no branch that converts a certificate index into its own truth token, and no collapse of structural self-description into truth-total reflection.

Theorem 667.2 (Self-reference truth-branch NameCert obligations)**.** *For every* $\mathsf{SelfReferenceTruthBranch}^{\uparrow}$ *carrier*

$$B = (S, D, Q, F, R, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{SelfReferenceTruthBranch}^{\uparrow}}$ *surface consists exactly of structural self-description exposure through* S*, diagonal-request exposure through* D*, certificate-indexed query exposure through* Q*, forbidden-branch exposure through* F*, socket-report exposure through* R*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.SelfReferenceTruthBranchUp.SelfReferenceTruthBranchTasteGate single carrier alignment`

Proof. Carrier exposure is projection from Definition 667.1. The finite tuple lists the structural description, diagonal request, branch query, refusal row, socket report, transport row, replay row, provenance row, and local name.

The Type VII obligation is the separation between S and Q, F, R. The row S may describe syntax, certificate grammar, and replay shape, while Q records the requested truth-total branch and F, R record the refusal and report that keep the branch outside the carrier.

Transport and replay are confined to H and C, with provenance and local naming confined to P and N. Thus every consumer read passes through the displayed rows before it can discuss the self-reference socket.

No remaining coordinate can act as an internal truth predicate, a runtime-total validator, or a certificate-indexed truth branch. The local $\mathsf{NameCert}$ obligations are therefore exhausted by the stated finite surface. □

Theorem 667.3 (Self-reference truth-branch non-escape)**.** *Every accepted* $\mathsf{SelfReferenceTruthBranch}^{\uparrow}$ *packet exports Type VII reflection information only through the finite rows*

$$S, D, Q, F, R, H, C, P, N.$$

It exports structural self-description, diagonal-request reporting, forbidden-branch reporting, componentwise transport, replay provenance, and local naming, but it exports no internal truth predicate for its own sentences, no runtime-total self-validator, no certificate-indexed truth token, and no route that treats structural self-description as truth-total reflection.

Proof. Project the accepted packet as $B = (S, D, Q, F, R, H, C, P, N)$. The carrier definition lists every row available to a downstream reader.

Structural information is exhausted by S and the replay route through C. The diagonal pressure and certificate-indexed query are exhausted by D and Q, while the refusal and socket report are exhausted by F and R.

The transport and packaging side is exhausted by H, C, P, N. These rows preserve and replay the same displayed certificate surface; they do not add a second truth branch or a validator coordinate.

Since the packet has no other exported row, a consumer cannot bypass the forbidden-branch report to obtain a truth-total classifier. The only admitted public reading is the finite socket report separating structural self-description from the refused Type VII branch. □

Closure status for $\mathsf{NameCert}_{\mathsf{SelfReferenceTruthBranch}^{\uparrow}}$.

Constructive story: A $\mathsf{SelfReferenceTruthBranch}^{\uparrow}$ packet is generated from a structural self-description row, a diagonal request row, a certificate-indexed truth-branch query, a forbidden-branch row, a socket report row, componentwise hsame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SelfReferenceTruthBranch}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 667.1, Definition 667.2, and Definition 667.3 specify the finite Type VII packet and its non-escape boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SelfReferenceTruthBranch}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean-side formal verification, an internal truth predicate, runtime-total self-validation, a Tarski hierarchy, or identification of structural self-description with external proof checking.

Upgrade path: Obligation closure requires checked carrier admission, branch-query exactness, forbidden-branch determinacy, replay provenance, and consumer non-escape for the displayed packet.

Chapter 668

A Concrete Naming Certificate for $\mathsf{ObservationCoupling}^{\uparrow}$

The $\mathsf{ObservationCoupling}^{\uparrow}$ packet realizes inter-history locality as a finite two-history naming surface. It records two displayed BHist rows, paired observation routes, componentwise transports, a symmetric coupling ledger, package provenance, and a local $\mathsf{NameCert}$ row. The packet gives downstream multi-observer consumers a bounded coupling object without adding a global frame, synchronized clock, host metric, or observer-independent carrier outside the displayed histories.

As a sibling lattice row, $\mathsf{ObservationCoupling}^{\uparrow}$ is the paired-history coupling surface consumed by the inter-Hist invariant of chapter 656 and the maximum-rate chain of chapter 594. Those consumers may read the coupling ledger only after the two BHist rows, paired Cont routes, componentwise hsame transports, and symmetric ledger have been displayed.

Definition 668.1 (Observation coupling carrier)**.** *An* $\mathsf{ObservationCoupling}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (h_a, h_b, r_a, r_b, H, C, L, P, N)$$

with the following visible rows:

1. h_a *and* h_b *are the two displayed* BHist *history rows being compared;*
2. r_a *and* r_b *are paired* Cont *routes that expose the inspected observation windows from* h_a *and* h_b*;*
3. H *records componentwise* hsame *transports for both history rows, both route rows, the coupling ledger, package provenance, and the local naming row;*
4. C *records the displayed consumer routes that read the two history windows and replay the coupling comparison;*
5. L *is the symmetric coupling ledger, storing the same finite boundary when the two history slots are exchanged;*
6. P *is the* Pkg *provenance over the two* BHist *rows, paired* Cont *routes, componentwise transports, coupling ledger, and local naming row;*
7. N *is the local* $\mathsf{NameCert}_{\mathsf{ObservationCoupling}^{\uparrow}}$ *row.*

The carrier contains no global frame, synchronized clock, ambient metric, cross-history equality oracle, host causal-rate coordinate, or observer-substance beyond the two displayed history rows.

Lean4 (definition) `BEDC.Derived.ObservationCouplingUp.ObservationCouplingCarrier`

Theorem 668.2 (Observation coupling locality obligations)**.** *Every accepted* $\mathsf{ObservationCoupling}^{\uparrow}$ *packet exposes inter-history comparison only through the finite rows*

$$h_a, h_b, r_a, r_b, H, C, L, P, N.$$

A positive coupling witness must first read the two displayed BHist *rows, then the paired* Cont *routes, then the componentwise* hsame *transports and symmetric ledger. No consumer may project a comparison from a global synchronization row, ambient frame, host metric, or hidden equality oracle.*

Proof. Project the carrier of Definition 668.1. The only history data are h_a and h_b, and the only observation accessors are the paired route rows r_a and r_b.

The locality obligation reads the histories through those routes before any comparison is consumed. The transport row H keeps the comparison componentwise over the same displayed histories, while C records the consumer replay paths.

The ledger row L is the only cross-history coupling row. Since the carrier has no global frame, synchronized clock, ambient metric, host causal-rate coordinate, or equality oracle, every accepted locality witness remains inside the finite packet. □

Lean4 ✓ `BEDC.Derived.ObservationCouplingUp.ObservationCouplingCarrier locality obligations`

Theorem 668.3 (Observation coupling symmetric rate boundary)**.** *The coupling ledger L of an accepted* $\mathsf{ObservationCoupling}^{\uparrow}$ *packet is observer-symmetric: exchanging h_a, r_a with h_b, r_b reads the same finite boundary through the transported rows H and the displayed routes C. Any maximum cross-history causal-rate consumer can receive only this symmetric ledger boundary and cannot choose a preferred observer slot, global clock, or host-side metric ratio.*

Lean4 ✓ `BEDC.Derived.ObservationCouplingUp.ObservationCouplingCarrier symmetric rate boundary`

Proof. Start with the displayed tuple $O = (h_a, h_b, r_a, r_b, H, C, L, P, N)$. The two observation sides are represented by matching history and route rows, and the carrier gives no distinguished anchor outside those rows.

Use the ledger row L. By definition it stores the coupling boundary in a form that is replayed after either slot exchange, with H carrying the componentwise hsame transports and C carrying the consumer routes.

A maximum-rate consumer therefore receives a symmetric finite ledger boundary rather than a host-side rate object. The absence of a preferred observer slot, global clock, and ambient metric prevents any asymmetric projection from the accepted packet. □

Theorem 668.4 (Observation coupling NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ObservationCoupling}^{\uparrow}}$ *surface consists exactly of carrier admission for $O = (h_a, h_b, r_a, r_b, H, C, L, P, N)$, two displayed* BHist *source rows, paired* Cont *route exposure, componentwise* hsame *stability, symmetric ledger replay,* Pkg *provenance, local naming, and no-global-frame exclusion.*

Lean4 ✓ `BEDC.Derived.ObservationCouplingUp.ObservationCouplingCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 668.1. The two source rows, paired route rows, transport row, route replay row, ledger row, package row, and local naming row are all displayed coordinates.

The locality obligations supply the reading order for the two histories and their paired routes. The symmetric rate boundary supplies the slot-exchange clause for the ledger L.

The remaining obligation is exclusion. Because the carrier lists no global frame, synchronized clock, ambient metric, cross-history equality oracle, or observer-substance coordinate, the local certificate surface is exhausted by the displayed packet. □

Theorem 668.5 (Observation coupling ledger non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{ObservationCoupling}^{\uparrow}$ *packet factors through* $h_a, h_b, r_a, r_b, H, C, L, P, N$*. The packet exports no global synchronization value, no host observer frame, no ambient spacetime coordinate, no selected maximum-rate witness, no quotient equality between histories, and no causal relation outside the displayed symmetric ledger.*

Lean4 ✓ `BEDC.Derived.ObservationCouplingUp.ObservationCouplingCarrier ledger nonescape`

Proof. Begin with the carrier projection. The consumer-visible rows are exactly $h_a, h_b, r_a, r_b, H, C, L, P, N$.

Apply the locality obligations to force any inter-history read through the two displayed histories and paired Cont routes. Apply the NameCert obligations to keep the read attached to the componentwise transports, replay routes, package provenance, and local name.

Finally apply the symmetric boundary theorem. The only cross-history content exported to downstream rate or invariant consumers is the ledger L, so no global synchronization value, host observer frame, ambient spacetime coordinate, selected maximum-rate witness, quotient equality, or undisplayed causal relation can be projected from the packet. □

Theorem 668.6 (Observation coupling standard-bridge boundary)**.** *The standard bridge for* $\mathsf{ObservationCoupling}^{\uparrow}$ *is exactly the displayed two-history packet*

$$h_a, h_b, r_a, r_b, H, C, L, P, N.$$

It preserves the paired Cont *routes, componentwise* hsame *transport, symmetric ledger replay,* Pkg *provenance, and the local* NameCert *row. It exports no global frame, synchronized clock, host metric, quotient equality, or selected rate witness.*

Lean4 ✓ `BEDC.Derived.ObservationCouplingUp.ObservationCouplingCarrier standard bridge boundary`

Proof. Project the carrier of Definition 668.1. The bridge source contains only the two displayed histories, the paired observation routes, componentwise transport, replay, symmetric ledger, provenance, and local naming rows.

Apply the locality obligations and symmetric rate boundary, Definition 668.2 and Definition 668.3. They force bridge reads to preserve the paired Cont routes and the symmetric replay of the ledger rather than selecting a preferred observer slot.

Finally apply the NameCert obligations and ledger non-escape, Definition 668.4 and Definition 668.5. These bind H, C, L, P, N as the public certificate surface and exclude global frames, synchronized clocks, host metrics, quotient equalities, and selected rate witnesses from the bridge. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObservationCoupling}^{\uparrow}}$**.**

Constructive story: An $\mathsf{ObservationCoupling}^{\uparrow}$ packet is generated from two displayed BHist rows, paired Cont observation routes, componentwise hsame transports, consumer replay routes, a symmetric coupling ledger, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ObservationCoupling}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 668.1, Definition 668.2, Definition 668.3, Definition 668.4, Definition 668.5, and Definition 668.6 bind the displayed BHist rows, paired Cont routes, componentwise hsame transports, symmetric ledger, Pkg provenance, and local NameCert rows as the finite two-history coupling bridge scope.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ObservationCoupling}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close multi-history causal semantics, numeric light-speed values, global synchronization, ambient metric geometry, Lean verification, or bridge checking.

Upgrade path: The paper theory axis is complete for the displayed two-history coupling boundary; Lean verification and bridge checking remain separate formal-axis obligations.

Chapter 669

A Concrete Naming Certificate for PaperLeanDriftWitness$^{\uparrow}$

The PaperLeanDriftWitness$^{\uparrow}$ packet names the finite paper-Lean resolution surface used by the drift audit. It records a paper marker occurrence, the normalized declaration name requested by that marker, the duplicate-label refusal row, the Lean inventory lookup row, the resolution verdict, replay provenance, and the local NameCert row in one certificate. The packet makes paper-marker resolution a concrete carrier rather than a host-side impression that a nearby Lean declaration exists. Its single-site exact-resolution verdict is a local row consumed by the audit-map dependency routing surface of chapter 839.

Definition 669.1 (Paper-Lean drift witness carrier)**.** *A* PaperLeanDriftWitness$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (M, A, L, I, R, H, C, P, N)$$

with the following displayed rows:

1. *M is the paper marker row, recording the exact manuscript site, marker kind, and source spelling of a* `\leanchecked`*,* `\leanvariant`*,* `\leanstmt`*,* `\leandef`*, or* `\leantarget` *occurrence;*
2. *A is the normalized requested name row obtained from M, including underscore normalization and the fully qualified Lean declaration path requested by the paper site;*
3. *L is the paper-label ledger row, recording the local label attached to the manuscript site and the duplicate-label refusal verdict for the full paper label inventory;*
4. *I is the Lean inventory lookup row, recording the finite declaration table against which A is checked;*
5. *R is the resolution verdict row, recording exact resolution, unresolved-name refusal, ambiguous-name refusal, or duplicate-label refusal for the same marker site;*
6. *H records componentwise* hsame *transport for markers, normalized names, label ledgers, inventory rows, verdicts, replay routes, provenance, and local names;*
7. *C records the displayed* Cont *routes by which a consumer replays marker parsing, name normalization, duplicate-label comparison, inventory lookup, and verdict exposure;*
8. *P is the* Pkg *provenance over paper markers, label ledgers, Lean declaration inventory, audit replay,* hsame*,* Cont*,* Pkg*, and* NameCert *source packets;*

9. N is the local $\mathsf{NameCert}_{\mathsf{PaperLeanDriftWitness}^{\uparrow}}$ *row.*
The carrier has no coordinate for approximate name matching, silent marker repair, duplicate-label acceptance, unresolved-name promotion, or a checked-looking paper claim without an exact Lean inventory hit.

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitnessTasteGate single carrier alignment`

Theorem 669.2 (Paper-Lean drift witness NameCert obligations)**.** *For every accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier*

$$W = (M, A, L, I, R, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{PaperLeanDriftWitness}^{\uparrow}}$ *surface consists exactly of marker-site exposure, normalized requested-name exposure, duplicate-label refusal, Lean inventory lookup, resolution verdict exposure, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local naming row. It does not export a separate paper authority for treating a non-resolving marker as checked.*

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness namecert obligations`

Proof. Carrier exposure is projection from Definition 669.1. The tuple lists the paper marker row, normalized name row, label ledger, Lean inventory lookup, verdict row, transport, replay, provenance, and local name.

The NameCert obligations are the finite audit obligations on those rows. The marker and name rows expose what the paper asked for; the label ledger and inventory row expose the two finite tables against which the request is checked; the verdict row records the admissible resolution outcome.

Transport and replay are confined to H and C, with provenance and naming confined to P and N. Since no row stores approximate matching, silent repair, duplicate-label acceptance, or unresolved-name promotion, the local certificate is exhausted by the displayed obligations. □

Theorem 669.3 (Paper-Lean drift witness resolution exactness)**.** *If an accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *packet records an exact-resolution verdict in R, then the normalized requested name A is present as the same fully qualified declaration in the Lean inventory row I, and the paper label row L is not refused as a duplicate label. The packet never identifies a marker with a neighboring declaration, a spelling variant not present in I, or a label site that the duplicate-label ledger refuses.*

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness resolution exactness`

Proof. Read the accepted packet through the carrier. The exact-resolution verdict is a row of R attached to the same marker M, normalized name A, label ledger L, and inventory row I.

The replay route C first normalizes the marker spelling, then compares the label row against the paper ledger, and then looks up the normalized name in the Lean declaration inventory. Exact resolution can therefore be read only after both finite comparisons have admitted the site.

Componentwise transport in H preserves the same marker, label, and inventory rows. Thus a consumer cannot replace the resolved name by a neighboring declaration, a spelling not present in I, or a label site that L refuses. □

Theorem 669.4 (Paper-Lean drift witness non-escape)**.** *An accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *packet exports no checked theorem, statement, definition, or closure-status target beyond the exact marker-resolution rows*

$$M, A, L, I, R, H, C, P, N.$$

In particular, it exports no unresolved Lean target, no duplicate paper label, no marker-kind coercion, no approximate declaration match, and no host-side permission to treat paper prose as a resolving Lean declaration.

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness nonescape`

Proof. Inspect the carrier inventory. The rows record marker parsing, requested-name normalization, label-ledger comparison, Lean inventory lookup, resolution verdict, transport, replay, provenance, and local naming.

None of these rows is a theorem proof, a definition body, a closure-status upgrade, or a host permission row. The positive content is only the exact resolution verdict attached to a marker whose normalized name occurs in the inventory and whose label row is not refused.

Therefore any unresolved target, duplicate label, marker-kind coercion, approximate match, or prose-only declaration leaves the packet. Such content must be supplied by another explicit certificate and cannot be projected from this drift witness. □

Theorem 669.5 (Paper-Lean drift witness consumer boundary)**.** *Every drift-audit consumer of an accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *packet factors through the paper marker row M, normalized requested name A, duplicate-label ledger L, Lean inventory lookup I, resolution verdict R, componentwise transport H, replay route C, provenance row P, and local* $\mathsf{NameCert}$ *row N. The consumer receives a finite NameCert surface for exact marker resolution, not a general semantic equivalence between paper claims and Lean declarations.*

Proof. Start with the carrier. The audit consumer can project only the nine displayed rows $M, A, L, I, R, H, C, P, N$.

Resolution reads pass through the normalized name and Lean inventory rows. Duplicate-label reads pass through the label ledger. Verdict reads pass through R and can be replayed only by the displayed routes in C under componentwise transport H.

The provenance row P and local name row N package this finite read as a NameCert surface. Since the carrier contains no semantic-equivalence row between paper prose and Lean theorem meaning, the consumer obtains exact marker resolution only. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness consumer boundary`

Theorem 669.6 (Paper-Lean drift witness verdict determinism)**.** *For an accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier*

$$W = (M, A, L, I, R, H, C, P, N),$$

fix the paper marker row M, normalized requested-name row A, paper-label ledger row L, and Lean inventory row I. The verdict row R exposes exactly one local outcome for that same quadruple: exact resolution, unresolved-name refusal, ambiguous-name refusal, or duplicate-label refusal. A consumer replaying the displayed route C under componentwise transport H cannot obtain a second verdict for the same M, A, L, I.

Proof. Project the accepted carrier to the rows $M, A, L, I, R, H, C, P, N$. The rows M, A, L, I determine the marker site, the normalized request, the paper-label ledger read, and the finite Lean inventory read being adjudicated.

The verdict coordinate is a single row R attached to those projected inputs. Its allowed local outcomes are the four carrier outcomes listed in Definition 669.1: exact resolution, unresolved-name refusal, ambiguous-name refusal, and duplicate-label refusal.

Replay does not introduce another decision channel. The displayed route C parses the marker, normalizes the requested name, checks the label ledger, checks the Lean inventory, and exposes the verdict row. Componentwise transport in H preserves the same inputs through that route, so replaying the same carrier cannot expose a distinct verdict for the fixed M, A, L, I. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness verdict determinism`

Theorem 669.7 (Paper-Lean drift witness duplicate-label priority)**.** *Let*

$$W = (M, A, L, I, R, H, C, P, N)$$

be an accepted $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier. If the paper-label ledger row L records duplicate-label refusal for the marker site M, then no exact-resolution verdict in R may be exported for that site, even when the normalized requested name A is present in the Lean inventory row I.*

Proof. Read the carrier in the displayed row order $M, A, L, I, R, H, C, P, N$. The label ledger row L is consulted before the verdict row is exposed, and its duplicate-label refusal is a local refusal for the same marker site M.

By Definition 669.3, exact resolution requires both an inventory hit for A in I and the absence of duplicate-label refusal in L. Thus an inventory hit alone is not sufficient for exporting an exact-resolution row.

The replay route C keeps the label-ledger comparison on the path to R, and H preserves that ledger row under transport. Therefore a duplicate-label refusal in L has priority over the inventory hit and prevents export of an exact-resolution verdict for the refused marker site. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness duplicate label priority`

Theorem 669.8 (Paper-Lean drift witness unresolved marker refusal)**.** *Let*

$$W = (M, A, L, I, R, H, C, P, N)$$

be an accepted $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier. If the normalized requested name A is absent from the Lean inventory row I, then every consumer read through R, H, C, P, N remains a refusal row and cannot be promoted to a checked marker.*

Proof. Absence of A from I blocks the exact-resolution condition. By Definition 669.3, an exact-resolution verdict can be read only when the normalized requested name is present in the Lean inventory row and the paper-label ledger does not refuse the site.

The only remaining verdict information for the same marker passes through the refusal rows of R. The route C replays the same normalization and inventory lookup, while H preserves the same normalized name and inventory row under transport.

Non-escape from Definition 669.4 prevents the packet from exporting a checked theorem, statement, definition, or closure-status target outside the exact marker-resolution rows. The consumer boundary in Definition 669.5 confines downstream reads to R, H, C, P, N, so the absent inventory hit remains a refusal and cannot become a checked marker. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitnessUnresolvedMarkerRefusal`

Theorem 669.9 (Paper-Lean drift witness resolution stability)**.** *Let*

$$W = (M, A, L, I, R, H, C, P, N)$$

be an accepted PaperLeanDriftWitness$^{\uparrow}$ *carrier with an exact-resolution verdict in R. If*

$$M\mathsf{hsame}M', \quad A\mathsf{hsame}A', \quad L\mathsf{hsame}L', \quad I\mathsf{hsame}I', \quad R\mathsf{hsame}R', \quad H\mathsf{hsame}H', \quad C\mathsf{hsame}C', \quad P\mathsf{hsame}P', \quad N\mathsf{hsa}$$

are componentwise transport rows displayed by H, then the transported packet

$$W' = (M', A', L', I', R', H', C', P', N')$$

has the same exact-resolution outcome for the transported marker site. In particular, exact resolution remains an inventory hit for A' in I' together with the absence of duplicate-label refusal in L'.

Proof. The carrier theorem exposes the nine coordinates as the complete local surface for a drift witness. The NameCert-obligation theorem identifies H as componentwise transport for marker rows, normalized names, label ledgers, inventory rows, verdicts, replay routes, provenance, and local names.

Apply the resolution-exactness theorem before transport. Exact resolution of W reads the same marker through M, the normalized request A, the duplicate-label ledger L, and the Lean inventory row I; it requires an inventory hit and no duplicate-label refusal.

The transport rows in H carry each of these coordinates to the corresponding primed row. Non-escape prevents an additional row from changing the verdict during transport, and the consumer-boundary theorem forces every downstream read of W' through the transported coordinates.

Therefore the transported verdict in R' is still exact resolution for M' precisely by the transported inventory hit for A' in I' and the transported non-refusal in L'. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness resolution stability`

Theorem 669.10 (Paper-Lean drift witness marker-kind separation)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier*

$$W = (M, A, L, I, R, H, C, P, N),$$

the marker kind recorded by M is preserved as its displayed paper-row kind throughout normalization, inventory lookup, verdict exposure, transport, replay, provenance, and local naming. A row whose source marker is `\leanchecked` *cannot be consumed as* `\leanvariant`*,* `\leanstmt`*,* `\leandef`*, or* `\leantarget`*; the same separation holds for each of the five marker kinds.*

Proof. The carrier definition stores the marker kind inside the paper marker row M. The NameCert-obligation theorem exposes this marker-site row as one of the required certificate rows and gives no separate coordinate for marker-kind conversion.

Resolution exactness then reads the normalized declaration request from A as obtained from that same marker row, and it checks A against the inventory row I under the duplicate-label ledger L. The verdict is therefore attached to the marker site and kind already exposed by M.

Non-escape rules out marker-kind coercion as exported content of the packet. The replay and transport coordinates C and H can only replay and transport the displayed rows, while the consumer-boundary theorem confines consumers to $M, A, L, I, R, H, C, P, N$.

Thus no consumer can reinterpret a row for one of `\leanchecked`, `\leanvariant`, `\leanstmt`, `\leandef`, or `\leantarget` as a row for another kind. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness marker kind separation`

Theorem 669.11 (Paper-Lean drift witness inventory verdict totality)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier*

$$W = (M, A, L, I, R, H, C, P, N),$$

each accepted verdict exposed by R is read from the displayed Lean inventory row I together with the duplicate-label ledger row L. No accepted verdict may be obtained from approximate declaration matching, prose-only promotion, or a paper marker whose duplicate-label row is refused.

Proof. The carrier definition lists the admissible resolution outcomes in the verdict row R and lists no coordinate for approximate matching or prose-only promotion. The NameCert obligations require the duplicate-label ledger, Lean inventory lookup, and verdict exposure as displayed rows of the same packet.

For the exact-resolution case, apply the resolution-exactness theorem. The verdict requires that A occurs as the same fully qualified declaration in I and that L does not refuse the marker site.

For refusal cases, the non-escape theorem prevents unresolved names, duplicate labels, marker-kind coercions, approximate matches, and prose-only declarations from leaving the exact marker-resolution surface as checked content. The consumer-boundary theorem confines every audit-map consumer to the rows $M, A, L, I, R, H, C, P, N$.

Hence every accepted verdict is total over the displayed inventory and duplicate-label ledger rows: it is either the exact inventory-and-ledger outcome or a refusal exposed by R, never an approximate or prose-only promotion. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness inventory verdict totality`

Theorem 669.12 (Paper-Lean drift witness token objectwise audit)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *packet*

$$W = (M, A, L, I, R, H, C, P, N),$$

any consumer using W to justify a `\formalstatus{...}` token or a marker-resolution synchronization must read the exact marker row M, normalized requested-name row A, duplicate-label ledger row L, Lean inventory row I, and verdict row R for that same paper site. The packet cannot convert objective Lean inventory strength into an aggregate route-level formalstatus, bridge row, theoryclosure row, or semantic equivalence between paper prose and Lean declarations.

Proof. The positive resolution case is objectwise. By resolution exactness, an exact inventory hit is attached to the same marker row M, normalized name row A, label ledger row L, and Lean inventory row I, and it is exposed only as the verdict row R for that site.

Verdict determinism and inventory verdict totality then fix the local outcome. For the fixed rows M, A, L, I, the consumer can read one displayed verdict from R: either the exact inventory-and-ledger outcome or a refusal row over the same local inventory and duplicate-label ledger.

The consumer boundary confines downstream reads to $M, A, L, I, R, H, C, P, N$. Non-escape excludes checked theorem content, closure-status targets, bridge rows, theoryclosure rows, and semantic-equivalence content not present in those rows.

Therefore a `\formalstatus{...}` token or marker-resolution synchronization justified by W is evidence about the displayed objectwise marker-resolution rows for one paper site. It is not aggregate route-level closure evidence and cannot collapse the manuscript closure axis with the Lean inventory lookup axis. □

Theorem 669.13 (Paper-Lean drift witness public verdict ledger)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier*

$$W = (M, A, L, I, R, H, C, P, N),$$

any public audit-map consumer must read the marker row M, normalized Lean name row A, paper-label ledger L, Lean inventory row I, verdict row R, transport row H, replay row C, provenance row P, and local NameCert *row N as one finite verdict ledger. The consumer cannot aggregate this ledger into theoryclosure evidence, bridge status, approximate name matching, or semantic equivalence between paper prose and Lean declarations.*

Proof. First use resolution exactness and non-escape. Resolution exactness binds the accepted verdict to the same displayed rows M, A, L, I, R, while non-escape prevents checked theorem content, closure-status targets, and semantic-equivalence content from leaving the witness packet.

Next use the consumer-boundary theorem. Every public audit-map read is confined to $M, A, L, I, R, H, C, P, N$, so transport, replay, provenance, and local naming carry the same finite verdict ledger rather than adding an outside marker row or neighbouring Lean declaration.

Verdict determinism and inventory-totality fix the ledger outcome. For the displayed marker, normalized name, ledger, and inventory rows, the verdict row is uniquely read and exhausts the accepted exact or refusal outcomes.

Finally apply token-objectwise audit. The public consumer receives an objectwise audit row for marker resolution, not theoryclosure evidence, a bridge-status row, approximate name matching, or semantic equivalence between the paper text and a Lean declaration. □

Theorem 669.14 (Paper-Lean drift witness audit-map dependency source lock)**.** *Let*

$$W = (M, A, L, I, R, H, C, P, N)$$

be an accepted PaperLeanDriftWitness$^{\uparrow}$ *carrier. Any* AuditMapDependencyWeave$^{\uparrow}$ *consumer using W as a dependency source must read the same marker row M, normalized requested-name row A, duplicate-label ledger row L, Lean inventory row I, verdict row R, componentwise transport row H, replay row C, provenance row P, and local* NameCert *row N. The consumer cannot replace those rows by approximate marker repair, an aggregate formalstatus token, a neighboring Lean name, or a route-level closure summary.*

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness auditmap dependency source lock`

Proof. The carrier projection exposes exactly the rows $M, A, L, I, R, H, C, P, N$. The marker row, normalized request, ledger, inventory, and verdict are therefore read from the same accepted witness rather than from a neighboring audit route.

Resolution exactness fixes the positive read. An exact verdict requires the displayed normalized name A to occur in the displayed inventory I and requires the displayed ledger L not to refuse the same marker site M.

Token objectwise audit prevents this local verdict from becoming an aggregate formalstatus route. The consumer boundary then confines every downstream AuditMapDependencyWeave$^{\uparrow}$ read to the same displayed rows, so approximate marker repair and route-level closure summaries are outside the handoff. □

Theorem 669.15 (Paper-Lean drift witness objectwise drift handoff)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier, an exact verdict hands off only the objectwise marker row M, normalized Lean name row*

A, duplicate-label ledger row L, Lean inventory hit row I, and verdict row R for the same paper site. Replay, transport, provenance, and local naming may carry that row through H, C, P, N, but they cannot add a semantic-equivalence row, an approximate declaration match, or a checked-looking marker outside the exact verdict.

Proof. Resolution exactness supplies the objectwise positive case: the marker row M, normalized request A, ledger L, inventory I, and verdict R are read together for one paper site.

Duplicate-label priority keeps the ledger in the handoff. If L refuses the site, an inventory-shaped hit cannot be exported as an exact verdict, so the consumer cannot ignore the paper-label row.

Unresolved-marker refusal keeps absent inventory hits inside refusal rows. Verdict determinism and inventory verdict totality then make the exported row exhaustive over the displayed local outcomes, leaving only transport, replay, provenance, and naming through H, C, P, N. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness objectwise drift handoff`

Theorem 669.16 (Paper-Lean drift witness audit-map weave consumer exactness)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier, the downstream* AuditMapDependencyWeave$^{\uparrow}$ *surface receives an exact local dependency row for marker resolution: the source-locked packet $M, A, L, I, R, H, C, P, N$ and the objectwise verdict handoff over M, A, L, I, R. It receives no semantic equivalence between paper prose and Lean declarations, no checked proof of the named Lean declaration, and no bridge or closure-axis certificate.*

Proof. First apply the audit-map dependency source lock. The dependency source is the displayed finite packet $M, A, L, I, R, H, C, P, N$, and every consumer read must factor through those rows.

Next apply the objectwise drift handoff. The exact verdict exported to the dependency weave is the local marker-resolution row over M, A, L, I, R, carried only by the displayed transport, replay, provenance, and local naming rows.

Finally use the consumer-boundary and non-escape theorems. The boundary gives exact marker resolution as dependency data, while non-escape prevents semantic equivalence, Lean proof content, bridge checking, or closure-axis certification from leaving the PaperLeanDriftWitness$^{\uparrow}$ packet. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness auditmap weave consumer exactness`

Theorem 669.17 (Paper-Lean drift witness obligation-closure package)**.** *For every accepted* PaperLeanDriftWitness *carrier*

$$W = (M, A, L, I, R, H, C, P, N),$$

the obligation-closure package is exactly the conjunction of marker-site exposure, normalized requested-name exposure, duplicate-label priority, unresolved-marker refusal, marker-kind separation, inventory verdict totality, componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *naming. It exports no checked theorem content, no semantic equivalence between paper claims and Lean declarations, no approximate declaration match, and no prose-only promotion.*

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness obligation closure package`

Proof. The carrier definition displays the nine rows $M, A, L, I, R, H, C, P, N$. The NameCert-obligation theorem identifies those rows as the marker site, normalized requested name, paper-label

ledger, Lean inventory lookup, verdict exposure, componentwise transport, replay, provenance, and local naming surface.

Resolution exactness supplies the exact inventory-and-ledger read for an accepted exact verdict. Duplicate-label priority blocks an exact-resolution export when the paper-label ledger refuses the site, while unresolved-marker refusal keeps an absent Lean inventory hit inside a refusal row.

Marker-kind separation prevents a consumer from retyping one paper marker kind as another. Inventory verdict totality then exhausts the accepted verdicts over the displayed Lean inventory row and duplicate-label ledger, ruling out approximate declaration matching and prose-only promotion.

It remains only to bind the package boundary. Componentwise hsame transport is confined to H, displayed Cont replay is confined to C, Pkg provenance is confined to P, and local naming is confined to N. By non-escape and the consumer-boundary theorem, no checked theorem content, semantic equivalence row, approximate match, or prose-only promotion can leave this finite witness packet. □

Theorem 669.18 (Paper-Lean drift witness closure-target resolution)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier*

$$W = (M, A, L, I, R, H, C, P, N),$$

any closure-status consumer or paper-marker consumer must read the exact paper marker row M, normalized Lean target row A, duplicate-label ledger row L, Lean inventory row I, and verdict row R before treating a `\leanchecked`*,* `\leanvariant`*,* `\leanstmt`*,* `\leandef`*, or* `\leantarget` *occurrence as resolving. The resolving read is accepted only as the displayed exact inventory-and-ledger verdict for that same marker site.*

Lean4✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness closure target resolution`

Proof. Begin with the carrier row order. The marker site is exposed by M, the requested Lean declaration is normalized in A, the paper-label ledger is read through L, the Lean inventory is read through I, and the verdict is exposed by R.

Resolution exactness supplies the positive case: an exact verdict requires the normalized requested name to occur in I and the label row not to be refused by L. Duplicate-label priority prevents an inventory hit from resolving a marker whose label row is refused.

Unresolved-marker refusal keeps absent inventory hits inside refusal rows, while marker-kind separation keeps each of the five marker commands in its own paper-row kind. Inventory verdict totality then exhausts the accepted outcomes over the displayed inventory and ledger rows.

Therefore a closure-status or marker consumer can treat a paper marker as resolving only after reading M, A, L, I, R for the same site and receiving the exact inventory-and-ledger verdict. □

Theorem 669.19 (Paper-Lean drift witness axis separation)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier, an exact-resolution verdict certifies only the verification-axis lookup of the requested Lean declaration in the displayed inventory. It does not upgrade the paper-side closure axis, bridge status, or semantic theorem content attached to the paper claim.*

Proof. The non-escape theorem states that the packet exports no checked theorem, statement, definition, or closure-status target beyond the exact marker-resolution rows. Its positive content is the marker-resolution verdict attached to the displayed paper marker, normalized name, label ledger, and Lean inventory lookup.

The consumer-boundary theorem confines every audit consumer to $M, A, L, I, R, H, C, P, N$. Those rows include no coordinate for changing theory closure, no bridge certificate, and no semantic equivalence row between paper claims and Lean declarations.

Thus an exact-resolution verdict may certify that the requested Lean declaration is found on the verification axis. Any paper-side closure claim, bridge status, or semantic theorem content must be supplied by a separate certificate and cannot be projected from this witness. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness axis separation`

Theorem 669.20 (Paper-Lean drift witness audit-map handoff)**.** *Every audit-map dependency consumer receiving an accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier receives exactly the finite packet*

$$M, A, L, I, R, H, C, P, N.$$

It may use that packet as a row for marker-resolution dependency routing, but not as a replacement for a Lean theorem proof or for paper-side closure evidence.

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness audit map handoff`

Proof. The consumer boundary gives the audit-map consumer precisely the displayed finite rows $M, A, L, I, R, H, C, P, N$. These rows expose marker parsing, name normalization, duplicate-label comparison, inventory lookup, verdict exposure, transport, replay, provenance, and local naming.

Resolution stability permits the same exact-resolution outcome to be replayed under componentwise hsame transport of those rows. Closure-target resolution identifies the resolving read as the exact inventory-and-ledger verdict for the same marker site.

Axis separation then fixes the boundary of the handoff. The packet is a dependency-routing row for marker resolution; a Lean theorem proof and paper-side closure evidence remain separate obligations supplied outside the $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ witness. □

Theorem 669.21 (Paper-Lean drift witness audit-index readiness)**.** *For every accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier*

$$W = (M, A, L, I, R, H, C, P, N),$$

the compact audit index for the witness is ready exactly when the same marker site exposes the exact-resolution row of M, A, I, R*, the duplicate-label priority row of* L*, and the marker-kind separation row of* M*. The resulting index entry is a finite objectwise audit row; it is not a semantic-equivalence witness, a proof of the named Lean theorem, or evidence for the paper-side closure axis.*

Proof. The exact-resolution row is supplied by Definition 669.3: the normalized requested name in A must be read against the Lean inventory I, and the verdict row R records the exact inventory-and-ledger outcome for the same marker site in M.

The ledger side is supplied by Definition 669.7. A refused duplicate-label row in L blocks the exact export even when the inventory row contains a name-shaped hit, so the audit index cannot ignore the paper-label ledger.

The marker surface is supplied by Definition 669.10. A `\leanchecked` row, a `\leanvariant` row, a `\leanstmt` row, a `\leandef` row, and a `\leantarget` row remain different paper-marker kinds.

Combining these rows gives a compact index entry over M, A, L, I, R. By Definition 669.19, that entry remains only a verification-axis lookup row and cannot be projected into semantic equivalence, checked theorem content, or closure-axis evidence. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness audit index readiness`

Theorem 669.22 (Paper-Lean drift witness verdict-ledger totality)**.** *For every accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier, the verdict ledger over the displayed rows* M, A, L, I, R *is total for audit consumption: each marker site is routed either through the exact inventory-and-ledger verdict, through duplicate-label refusal, or through unresolved-marker refusal. No fourth outcome is exported to a consumer.*

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness verdict ledger totality`

Proof. The total verdict split is the content of Definition 669.11. It reads the displayed marker site, normalized requested name, paper-label ledger, Lean inventory lookup, and verdict row as the only accepted inputs for a marker-resolution decision.

The positive branch is constrained by Definition 669.3; exact resolution requires the requested declaration to occur in the inventory and the same paper-label row not to be refused. This branch therefore records an objectwise inventory-and-ledger verdict, not an approximate declaration match.

The refused branches are constrained separately. Duplicate-label priority comes from Definition 669.7, while absent inventory hits are confined by Definition 669.8.

Thus every consumer-visible verdict is one of the three displayed rows. By Definition 669.17, the ledger remains inside the finite witness packet and exports no semantic theorem equivalence or closure-status promotion. □

Theorem 669.23 (Paper-Lean drift witness dependency-weave handoff)**.** *Every dependency-weave consumer receiving an accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier receives the finite audit packet*

$$M, A, L, I, R, H, C, P, N$$

as a marker-resolution dependency row. The handoff preserves exact resolution, verdict-ledger totality, token objectwise audit, axis separation, and the audit-map boundary, but it does not discharge downstream semantic equivalence, Lean proof, bridge, or closure-axis obligations.

Proof. The packet delivered to the consumer is fixed by Definition 669.20. The dependency-weave side therefore receives marker parsing, normalized-name exposure, duplicate-label comparison, inventory lookup, verdict exposure, transport, replay, provenance, and local naming as the whole finite carrier row.

Exact resolution is preserved by Definition 669.18, and the verdict ledger is total by Definition 669.22. The handoff can route these rows through neighbouring audit-map dependencies only as objectwise marker-resolution data.

Token objectwise audit is the boundary supplied by Definition 669.12: the exported row records the token object and its local audit evidence, not an ambient semantic equality between paper prose and Lean declarations.

Finally, Definition 669.19 and Definition 669.20 keep the route from proving too much. Downstream semantic equivalence, Lean proof content, bridge checking, and paper-side closure status remain separate obligations outside the $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ packet. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness dependency weave handoff`

Theorem 669.24 (Paper-Lean drift witness dependency-routing scope)**.** *Let*

$$W = (M, A, L, I, R, H, C, P, N)$$

be an accepted $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier. Every* $\mathsf{AuditMapDependencyWeave}^{\uparrow}$ *consumer using* W *as a marker-resolution dependency row must route through the displayed marker row* M*,*

normalized requested-name row A, duplicate-label ledger row L, Lean inventory row I, verdict row R, componentwise transport row H, replay row C, provenance row P, and local NameCert *row N. The route cannot replace any of those rows by an unlisted marker, neighbouring name, outside label ledger, hidden inventory, ambient verdict, or external consumer row.*

Proof. The dependency-weave handoff fixes the exported packet as $M, A, L, I, R, H, C, P, N$. It gives the audit-map consumer a dependency row for marker resolution, not a separate carrier with additional coordinates.

The audit-map handoff theorem identifies how the neighbouring consumer may read that packet. Marker parsing, name normalization, duplicate-label comparison, inventory lookup, verdict exposure, componentwise transport, replay, provenance, and local naming are the whole finite route.

The consumer boundary and non-escape rows then rule out substitutions. A consumer may transport and replay the same rows through H, C, P, N, but it cannot import a second marker, a different normalized name, another label ledger, an approximate inventory hit, or a verdict outside R. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness dependency routing scope`

Theorem 669.25 (Paper-Lean drift witness consumer-row scope)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier $W = (M, A, L, I, R, H, C, P, N)$, the marker, ledger, inventory, and verdict rows are grounded as finite* BHist *data: M and L are paper-site and paper-label ledger rows, I is the Lean declaration inventory row, and R is the exact-resolution or refusal verdict for the same marker site. Their consumer route is mediated only by componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* NameCert *row, and it is read by chapter 839 only as a routed dependency row.*

Proof. Carrier exposure supplies the finite BHist packet. The marker row M, normalized-name row A, duplicate-label ledger L, inventory row I, verdict row R, transports H, replay routes C, provenance P, and local name N are all projected from the same accepted witness.

Resolution exactness and duplicate-label priority bind the ledger and inventory reads to the same marker site. The verdict ledger totality theorem then says the visible verdict is exactly one of the accepted exact-resolution or refusal rows for M, A, L, I.

The only consumer movement is through hsame, Cont, Pkg, and NameCert structure. Thus chapter 839 receives the row as routed dependency data and does not obtain a hidden theorem proof, erased obstruction, or closure-axis promotion from the witness. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.ConsumerRowScope.PaperLeanDriftWitness consumer row scope`

Theorem 669.26 (Paper-Lean drift witness scoped closure package)**.** *The* PaperLeanDriftWitness$^{\uparrow}$ *chapter is scoped for audit-map dependency consumption: resolution exactness fixes the inventory-and-ledger read, verdict totality exhausts the consumer-visible outcomes, axis separation prevents verification-axis rows from becoming paper-side closure evidence, and the dependency-weave handoff routes exactly the displayed packet*

$$M, A, L, I, R, H, C, P, N$$

to the named AuditMapDependencyWeave$^{\uparrow}$ *consumer surface. Within that scope, the chapter closes the paper-side dependency row for exact marker resolution, while leaving Lean verification, semantic equivalence, and bridge checking outside the witness.*

Proof. First combine resolution exactness with verdict totality. The accepted witness reads one marker site through M, A, L, I and exposes exactly the corresponding verdict row R, so the consumer-facing resolution row is objectwise fixed.

Next use axis separation. The same verdict may certify a verification-axis inventory lookup, but it cannot become a theorem proof, a semantic-equivalence row, a bridge certificate, or a paper-side closure claim outside the stated dependency scope.

Finally apply the dependency-weave handoff together with the dependency-routing and consumer-row scope theorems. The audit-map dependency consumer receives precisely $M, A, L, I, R, H, C, P, N$ through the named chapter 839 route, so the chapter supplies a scoped paper-side package for routed marker-resolution consumption and no stronger conclusion. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness scoped closure package`

Theorem 669.27 (Paper-Lean drift witness resolution consumer readiness)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier, any consumer route treating the witness as an exact-resolution row must read the same paper marker row M, normalized requested-name row A, paper-label ledger L, Lean inventory row I, and verdict row R for one marker site. The consumer may replay those rows through H, C, P, N, but it cannot replace them by a neighbouring marker, a different normalized name, a different label ledger, an approximate inventory row, or a second verdict.*

Proof. The exact-resolution row is fixed by Definition 669.3. An exact verdict reads the same marker row, normalized requested name, duplicate-label ledger, Lean inventory lookup, and verdict row, and it requires the inventory hit and the absence of duplicate-label refusal on that same site.

The consumer route is bounded by Definition 669.5. Every downstream read factors through $M, A, L, I, R, H, C, P, N$, so the consumer cannot introduce a parallel marker row or a second inventory table.

Verdict determinism from Definition 669.6 and inventory totality from Definition 669.11 keep the row objectwise. Transport and replay may carry the same row through H, C, P, N, but the result remains the exact inventory-and-ledger verdict for the original M, A, L, I, R package. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness resolution consumer readiness`

Theorem 669.28 (Paper-Lean drift witness duplicate-ledger readiness)**.** *For every accepted* PaperLeanDriftWitness *carrier, duplicate-label refusal has priority along every consumer route through R, H, C, P, N. If the ledger row L refuses the marker site M, then replay, transport, provenance, and local naming may preserve that refusal, but they cannot export an exact-resolution row for that site.*

Proof. Duplicate priority is the content of Definition 669.7. A ledger refusal blocks exact resolution even when the normalized requested name has the shape of an inventory hit.

Unresolved-marker refusal from Definition 669.8 and non-escape from Definition 669.4 keep refused marker sites from leaving the packet as checked markers. The route through R, H, C, P, N therefore remains a refusal route whenever L refuses M.

The dependency-weave handoff theorem, Definition 669.23, lets a neighbouring audit-map consumer receive the finite packet only as marker-resolution dependency data. It does not create a row that can outrank the duplicate-label ledger. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness duplicate ledger readiness`

Theorem 669.29 (Paper-Lean drift witness inventory-refusal readiness)**.** *For every accepted* PaperLeanDriftWitness *carrier, if the normalized requested name A is absent from the Lean inventory row I, then every consumer-visible route through R, H, C, P, N remains an unresolved-marker refusal row. The absent inventory hit cannot be transported, replayed, or repackaged as a checked marker.*

Proof. Unresolved-marker refusal is supplied by Definition 669.8. Absence of A from I blocks the exact-resolution condition and keeps the verdict row on the refusal side for the same marker site.

Resolution exactness from Definition 669.3 and verdict determinism from Definition 669.6 prevent a consumer from reading both an absent inventory hit and an exact-resolution verdict for the fixed rows M, A, L, I.

The non-escape theorem and the dependency-weave handoff theorem confine the exported material to finite marker-resolution rows. Hence replay, transport, provenance, and local naming preserve the unresolved-marker refusal rather than converting it into checked theorem content, semantic equivalence, bridge evidence, or closure-axis evidence. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness unresolved marker refusal`

Theorem 669.30 (Paper-Lean drift witness formalstatus sync readiness)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier, a downstream consumer may synchronize a* FormalStatus *token in the family* formalTarget, encodedDef, scaffoldChecked, theoremChecked, auditClean, axiomClean, bridgeChecked *only after reading the same paper marker row M, normalized requested-name row A, duplicate-label ledger L, Lean inventory row I, and verdict row R. The synchronization is an objectwise verification-axis read of the marker-resolution verdict, and it creates no paper-side closure upgrade, bridge row, semantic equivalence, or checked theorem content.*

Proof. Token objectwise audit is supplied by Definition 669.12. It says that the exported verification token is read from the displayed marker object and its local audit evidence, so the consumer must keep the same M, A, L, I, R rows rather than replacing them by an ambient status token.

Axis separation is the boundary supplied by Definition 669.19. A synchronized formalstatus row remains a verification-axis report and therefore cannot become paper-side closure, bridge evidence, semantic equivalence, or theorem proof content.

Finally, closure-target resolution from Definition 669.18 fixes the inventory-and-ledger read that any status synchronization depends on. The consumer may record that read as a formalstatus token, but the only certified object is the same marker-resolution verdict row. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness formalstatus sync readiness`

Theorem 669.31 (Paper-Lean drift witness marker-family resolution readiness)**.** *The five marker families named by* `\leanchecked`*,* `\leanvariant`*,* `\leansorryd`*,* `\leanstmt`*, and* `\leandef` *remain separated through every synchronization consumer of an accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier. Each family resolves only through its own exact inventory-and-ledger verdict for the same M, A, L, I, R rows, and no family may borrow exact resolution, duplicate-label refusal, or unresolved-marker refusal from another family.*

Proof. Marker-kind separation is the first boundary. It keeps checked theorem markers, variant markers, sorry markers, statement markers, and definition markers as different paper-site rows even when their requested Lean names have similar surface shape.

Verdict-ledger totality then assigns the visible verdict for a fixed marker family and site. Apply Definition 669.22: the consumer sees exactly the ledger-and-inventory verdict for the selected marker row, not a family-erased verdict.

Duplicate-ledger readiness and inventory-refusal readiness handle the obstruction branches. By Definition 669.28 and Definition 669.29, duplicate labels and absent inventory hits remain refusals for the same marker family and cannot be repackaged as another family resolution. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness marker family resolution readiness`

Theorem 669.32 (Paper-Lean drift witness audit-map consumer totality)**.** *Every downstream* AuditMapDependencyWeave$^{\uparrow}$ *consumer of an accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier receives exactly one of exact resolution, duplicate-label refusal, or unresolved-marker refusal for a marker site. The verdict is transported only through H, C, P, N, and no ambient audit route may erase a duplicate-label or unresolved-marker obstruction.*

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness audit map consumer totality`

Proof. The dependency-weave handoff is fixed by Definition 669.23. It sends the audit-map consumer the displayed finite packet and carries marker resolution only as dependency data.

Dependency-routing scope and consumer-row scope identify the allowed route. By Definition 669.24 and Definition 669.25, the consumer reads the same marker, name, ledger, inventory, and verdict rows, and the only transport surface is H, C, P, N.

The readiness rows above close the remaining consumer surface. Formalstatus synchronization from Definition 669.30 cannot erase the obstruction, and marker-family readiness from Definition 669.31 prevents a refused site from escaping through a different marker family. □

Theorem 669.33 (Paper-Lean drift witness audit consumer kernel scope)**.** *Every* AuditMapDependencyWeave$^{\uparrow}$ *consumer of an accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier reads the witness only through the finite* BHist *rows $M, A, L, I, R, H, C, P, N$. The consumer handoff is the same marker row, normalized requested-name row, duplicate-label ledger, Lean inventory row, verdict row, componentwise* hsame *transport,* Cont *replay row,* Pkg *provenance row, and local* NameCert *naming row; it does not add an external proof object, approximate name repair, or closure-axis summary.*

Proof. The audit-map consumer totality theorem, Definition 669.32, identifies the only visible verdicts as exact resolution, duplicate-label refusal, or unresolved-marker refusal for the fixed marker site. It also confines the transport surface to the displayed downstream route.

The dependency-weave handoff theorem, Definition 669.23, names the consumer channel. Along that channel the finite packet is sent as dependency data, so the consumer can read $M, A, L, I, R, H, C, P, N$ and no unlisted carrier.

Formalstatus synchronization from Definition 669.30 keeps any status read objectwise over the same marker, name, ledger, inventory, and verdict rows. Axis separation from Definition 669.19 then prevents this kernel-scoped handoff from becoming theorem content, bridge evidence, or a paper-side closure certificate. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness audit consumer kernel scope`

Theorem 669.34 (Paper-Lean drift witness resolution ledger kernel scope)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier, exact resolution, duplicate-label refusal, and unresolved-marker refusal form a total consumer ledger over the finite rows M, A, L, I, R. No* AuditMapDependencyWeave$^{\uparrow}$ *consumer may replace that ledger by approximate matching, a neighbouring Lean declaration, a marker-family transfer, or a route-local guess.*

Proof. Apply Definition 669.32. The consumer receives exactly one of the three ledger outcomes for the marker site, and duplicate-label or unresolved-marker obstruction cannot be erased by the route.

The dependency-weave handoff theorem, Definition 669.23, keeps the ledger attached to the exported marker-resolution dependency row. Hence exact resolution remains a read of M, A, L, I, R and not a lookup against a nearby Lean name.

The formalstatus synchronization theorem, Definition 669.30, gives only a token read after the same verdict row is fixed. By axis separation, Definition 669.19, such a token cannot replace the total ledger or promote an obstruction into checked theorem content. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness resolution ledger kernel scope`

Theorem 669.35 (Paper-Lean drift witness status token kernel boundary)**.** *For every accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier, formalstatus synchronization is only a verification-axis token read from the marker-resolution verdict over* M, A, L, I, R*. It cannot upgrade theoryclosure data, create a bridgestatus row, change the semantic theorem content of the paper claim, or supply an additional consumer obligation outside* H, C, P, N*.*

Proof. Formalstatus synchronization readiness, Definition 669.30, already fixes the status token as an objectwise verification-axis read. The token is read after the same marker, normalized-name, ledger, inventory, and verdict rows are available.

Audit-map consumer totality from Definition 669.32 and the dependency-weave handoff theorem, Definition 669.23, identify the downstream consumer surface. The route carries the finite witness through H, C, P, N rather than through a closure or bridge constructor.

Axis separation, Definition 669.19, supplies the boundary. A synchronized status token reports verification-axis information only, so it cannot alter theoryclosure, bridgestatus, semantic theorem content, or the kernel-scoped consumer obligations of the witness. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness status token kernel boundary`

Theorem 669.36 (Paper-Lean drift witness marker inventory kind lock)**.** *For every accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier, each paper marker is resolved only through its own marker-kind row* M*, normalized requested-name row* A*, duplicate-label ledger* L*, Lean inventory row* I*, and verdict row* R*. A checked-theorem marker row may therefore not be consumed as a statement-only, encoded-definition, variant, or target marker row, and no audit-map consumer may repair the mismatch by approximate name lookup.*

Proof. Marker-kind separation from Definition 669.10 fixes the marker family before any inventory read is interpreted. The normalized requested-name row and the duplicate-label ledger are therefore attached to the marker kind already present in M.

Inventory verdict totality, Definition 669.22, supplies the only accepted outcomes over M, A, L, I, R. It reads exact resolution, duplicate-label refusal, or unresolved-marker refusal from those rows, rather than from a neighbouring declaration name.

Marker-family resolution readiness from Definition 669.31 closes the consumer lock. Since each marker family has its own readiness route, a checked-theorem site cannot be retyped as another marker family or discharged by an approximate repair rule. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness marker inventory kind lock`

Theorem 669.37 (Paper-Lean drift witness duplicate obstruction route preservation)**.** *For every accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier, duplicate-label refusal remains attached to the same* M, A, L, I, R *packet when the witness is transported through* H, C, P, N*. Audit-map dependency routing may expose the obstruction to downstream consumers, but it may not erase the duplicate ledger, substitute an exact-resolution row, or move the refusal to a different marker site.*

Proof. Duplicate-label priority from Definition 669.7 fixes the duplicate branch before unresolved-marker lookup or exact-resolution export can be used. Duplicate-ledger readiness, Definition 669.28, records that branch in the same finite ledger rows M, A, L, I, R.

The dependency-weave handoff theorem, Definition 669.23, transports the witness as dependency data through H, C, P, N. This handoff does not introduce a second verdict row, so the duplicate obstruction travels with the original marker, name, ledger, inventory, and verdict packet.

Audit-map consumer totality, Definition 669.32, supplies the downstream exclusion. A consumer is total over exact resolution, duplicate-label refusal, and unresolved-marker refusal, but totality does not authorize replacing the duplicate branch by a route-local exactness claim. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness duplicate obstruction route preservation`

Theorem 669.38 (Paper-Lean drift witness status consumer exactness)**.** *For every accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier, a formalstatus synchronization consumer may read only the exact verdict row for the same marker site. The consumer cannot infer theoryclosure, bridgestatus, semantic theorem content, or any marker-resolution fact outside the* $M, A, L, I, R, H, C, P, N$ *rows of that witness.*

Proof. Formalstatus synchronization readiness, Definition 669.30, makes the status read objectwise over the same marker, normalized requested name, duplicate ledger, inventory lookup, and verdict. The consumer therefore starts from the exact verdict row already fixed for that marker site.

The status token kernel boundary theorem, Definition 669.35, keeps this read on the verification axis. It permits a status token only as a rowwise consequence of the local marker-resolution verdict, not as a constructor for closure or bridge data.

Axis separation from Definition 669.19 and closure-target resolution from Definition 669.18 give the final exclusions. A synchronized formalstatus token cannot prove theoryclosure, bridgestatus, semantic theorem content, or any marker-resolution assertion beyond the exact rows supplied by the carrier. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness status consumer exactness`

Theorem 669.39 (Paper-Lean drift witness public resolution export)**.** *For every accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier, the public audit export of exact marker resolution consists only of the shared rows* $M, A, L, I, R, H, C, P, N$*. The export exposes the marker row, normalized requested-name row, duplicate-label ledger, Lean inventory row, verdict row, componentwise* hsame *transport,* Cont *replay row,* Pkg *provenance row, and local* $\mathsf{NameCert}$ *naming row, and it exposes no private repair rule, family-erased lookup, aggregate bridge verdict, or closure-axis certificate.*

Proof. Resolution exactness from Definition 669.3 fixes the exact branch as a read of M, A, L, I, R. Duplicate-ledger readiness and inventory-refusal readiness, Definition 669.28 and Definition 669.29, show that the two obstruction branches use the same public rows rather than a hidden fallback.

The audit consumer kernel scope theorem, Definition 669.33, identifies the only exported downstream surface as H, C, P, N over the same finite witness. Hence public audit consumers receive the listed rows and no auxiliary carrier.

Finally, marker-family resolution readiness prevents a public consumer from erasing the marker family before reading the verdict. Status-token kernel boundary then prevents the exported exact-resolution row from becoming an aggregate bridge status or a paper-side closure certificate. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness public resolution export`

Theorem 669.40 (Paper-Lean drift witness bridge-ready dependency surface)**.** *Every downstream bridge or audit consumer of an accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier factors through the* AuditMapDependencyWeave$^{\uparrow}$ *dependency surface before using the local marker-resolution verdict. Such a consumer may transport exact resolution, duplicate-label refusal, or unresolved-marker refusal along H, C, P, N, but it cannot replace the local verdict by an aggregate bridge status, neighbouring audit summary, or global synchronization token.*

Proof. The dependency-weave handoff theorem, Definition 669.23, names the route through which neighbouring consumers receive the packet. Audit-map consumer totality, Definition 669.32, then says that the received data is exactly one local verdict for the fixed marker site.

The public resolution export theorem above fixes the carrier material available to the consumer as the rows $M, A, L, I, R, H, C, P, N$. Since the dependency surface is rowwise, the consumer can use hsame transport, Cont replay, Pkg provenance, and NameCert naming only as dependency data attached to the same local verdict.

The status-token kernel boundary theorem, Definition 669.35, supplies the exclusion. A synchronized token or aggregate bridge report is not a replacement verdict, so it cannot discharge duplicate-label refusal, unresolved-marker refusal, or the exactness obligation of the local marker row. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness bridge ready dependency surface`

Theorem 669.41 (Paper-Lean drift witness public token consumer totality)**.** *Every public verification-token consumer of an accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier is total over the three public marker-resolution outcomes: exact resolution, duplicate-label refusal, and unresolved-marker refusal. The consumer either reads the formalstatus token from the exact verdict over M, A, L, I, R, reads the duplicate-label refusal from the same ledger, or reads the unresolved-marker refusal from the same inventory lookup; no public token consumer is undefined on one of these branches.*

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness public token consumer totality`

Proof. Verdict-ledger totality, Definition 669.22, gives the three-way ledger for a fixed marker site. Resolution exactness supplies the exact branch, while duplicate-ledger readiness and inventory-refusal readiness supply the two refusal branches.

Marker-family resolution readiness keeps this totality family-local. A token consumer therefore cannot borrow an exact verdict from another marker family or reinterpret a refused branch as a different public marker kind.

Audit-map consumer totality and formalstatus synchronization readiness identify the token-facing consumer. The status-token kernel boundary theorem then keeps the token read on the verification axis, so totality over exact resolution, duplicate-label refusal, and unresolved-marker refusal does not create bridge evidence or paper-side closure data. □

Theorem 669.42 (Paper-Lean drift witness audit replay source lock)**.** *For every accepted* PaperLeanDriftWitness$^{\uparrow}$ *carrier, every audit replay consumed by an* AuditMapDependencyWeave$^{\uparrow}$ *route remains sourced in the same $M, A, L, I, R, H, C, P, N$ packet. The replay may expose the local marker row, normalized requested-name row, duplicate ledger, inventory lookup, verdict, transport, continuity replay, package provenance, and local* NameCert *row, but it may not substitute a neighbouring marker, neighbouring normalized name, or neighbouring verdict for the original packet.*

Proof. Resolution exactness, Definition 669.3, first fixes the exact branch as a rowwise read of M, A, L, I, R. Marker inventory kind lock, Definition 669.36, keeps the marker family and inventory lookup attached to that same source before any consumer sees the replay.

The public resolution export theorem, Definition 669.39, names the exported rows as $M, A, L, I, R, H, C, P, N$. Applying public token consumer totality then shows that exact resolution, duplicate-label refusal, and unresolved-marker refusal are all consumed from this single packet, not from a second witness.

Finally, the dependency-weave handoff route only transports the exported rows to neighbouring audit-map consumers. Since the handoff receives the locked packet after marker-kind separation and exactness, it cannot replace the source marker or verdict by a neighbouring marker summary. □

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness audit replay source lock`

Theorem 669.43 (Paper-Lean drift witness Lean inventory hit exhaustion)**.** *For every accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier, exact marker resolution is exhausted by the displayed Lean inventory hit together with the non-duplicate label row. If the duplicate-label ledger marks the requested name as duplicated, or if the Lean inventory lookup is absent, the corresponding branch remains a public refusal row and cannot be consumed as an exact hit.*

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness lean inventory hit exhaustion`

Proof. Resolution exactness identifies the exact branch with the normalized requested-name row A, duplicate-label ledger L, Lean inventory lookup I, and verdict row R. The exact branch is therefore available only when the inventory hit and the non-duplicate label condition are both present in the displayed packet.

Marker inventory kind lock keeps this inventory read within the marker family fixed by M. Public resolution export then exposes only the same inventory and ledger rows to downstream consumers, so no approximate declaration name or marker-family coercion can supply a second exact hit.

Public token consumer totality supplies the exhaustive case split. The exact branch consumes the displayed hit; the duplicate-label branch consumes the duplicate ledger; the unresolved-marker branch consumes the absent inventory lookup. The two refusal branches remain refusal rows after export and cannot be reclassified as exact resolution. □

Theorem 669.44 (Paper-Lean drift witness name normalization no-escape)**.** *For every accepted* $\mathsf{PaperLeanDriftWitness}^{\uparrow}$ *carrier, underscore and Lean-name normalization is only a replay row inside the same* $M, A, L, I, R, H, C, P, N$ *packet. Normalization authorizes comparison with the displayed requested-name row, but it gives no permission for approximate lookup, spelling repair, marker-family coercion, or substitution of a neighbouring declaration name.*

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness name normalization noescape`

Proof. Resolution exactness uses normalization as part of the requested-name row A and then reads the duplicate ledger, inventory lookup, and verdict from L, I, R. Thus normalization is an input row to exact resolution, not an external search rule.

Marker inventory kind lock keeps the normalized name under the marker family fixed by M. Public resolution export carries this normalized name together with H, C, P, N, so audit-map consumers receive the replayed spelling only as part of the same finite packet.

Public token consumer totality closes the exclusion. A consumer is total over exact resolution, duplicate-label refusal, and unresolved-marker refusal for the given packet, and this totality leaves

no branch in which normalization can escape into approximate lookup or coerce one marker family into another. □

The exact-resolution row exported by PaperLeanDriftWitness$^{\uparrow}$ is consumed by the cross-map routing and synthesis-consumer rows of chapter 839. The PaperLeanDriftWitness$^{\uparrow}$ packet supplies marker normalization, duplicate-label refusal, Lean inventory lookup, and exact-resolution verdict rows, while AuditMapDependencyWeave$^{\uparrow}$ decides how such local rows travel through neighbouring audit-map routes without discharging their obstruction rows.

Theorem 669.45 (Paper-Lean drift witness public export route)**.** *Every public audit-map consumer of an accepted* PaperLeanDriftWitness$^{\uparrow}$ *packet receives exactly the marker row, normalized requested-name row, duplicate-label ledger, Lean inventory lookup, verdict row, transport, replay, provenance, and local NameCert row through* AuditMapDependencyWeave$^{\uparrow}$*. The route is the displayed packet $M, A, L, I, R, H, C, P, N$; it exports exact resolution, duplicate-label refusal, and unresolved-marker refusal as local verdict data, not as a private repair rule, aggregate bridge status, or closure-axis certificate.*

Lean4 ✓ `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness public export route`

Proof. Begin with public resolution export, Definition 669.39. It identifies the exported material as the rows $M, A, L, I, R, H, C, P, N$ and excludes private repair rules, family-erased lookup, aggregate bridge verdicts, and closure-axis certificates.

Next use the bridge-ready dependency surface, Definition 669.40. It routes downstream bridge and audit consumers through AuditMapDependencyWeave$^{\uparrow}$ before they may use the local marker-resolution verdict, so the public consumer receives the packet only as dependency data.

Finally apply the audit replay source lock and name-normalization no-escape theorems, Definition 669.42 and Definition 669.44. Replay remains sourced in the same packet, and normalization cannot become approximate lookup or marker-family coercion. Hence the public route is exactly the listed local rows through AuditMapDependencyWeave$^{\uparrow}$. □

Closure status for NameCert$_{\text{PaperLeanDriftWitness}^{\uparrow}}$**.**

Constructive story: A PaperLeanDriftWitness$^{\uparrow}$ packet is generated from a paper marker row, normalized requested-name row, duplicate-label ledger, Lean inventory lookup, resolution verdict, componentwise hsame transport, displayed replay routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{PaperLeanDriftWitness}^{\uparrow}}$, publicClosed)

Scope closed: The scoped surface binds the exact-resolution, duplicate-label, unresolved-marker, marker-kind, inventory-verdict, transport, replay, provenance, dependency-weave handoff, and audit-map dependency consumer rows for exact paper-Lean marker resolution.

Formal verification: FormalStatus(NameCert$_{\text{PaperLeanDriftWitness}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.PaperLeanDriftWitnessUp.PaperLeanDriftWitness\_public\_export\_route`

Bridge status: none

Origin: human

Not claimed: This chapter does not close semantic equivalence between paper claims and Lean declarations, checked theorem content, bridge checking, or any permission to treat unresolved markers as verified.

Upgrade path: The next bridge surface is the downstream audit-consumer interpretation of the public export route through AuditMapDependencyWeave$^{\uparrow}$.

Chapter 670

A Concrete Naming Certificate for $\mathsf{CofinalRegularLimitBudget}^{\uparrow}$

The $\mathsf{CofinalRegularLimitBudget}^{\uparrow}$ surface records the finite precision-budget packet used when the Real completeness diagonal target is consumed through cofinal windows. It packages request rows, selected finite windows, regular rational readback, RealUp seal routing, transport, continuation, provenance, and local naming in one displayed BHist carrier. The packet is a budgeted route for a diagonal-limit consumer; it is not a quotient stream, host real equality, selected ambient limit, or completeness principle.

The cofinal-window ledger is read through chapter 126; the regular handoff is read through chapter 301; the seal is read through chapter 38; and the finite dyadic observation budget is read through chapter 291. These references fix the L10 dependency lattice used by the carrier and local NameCert obligations.

Falsifiable prediction: If an accepted cofinal regular limit-budget packet reaches the $\mathsf{Real}^{\uparrow}$ seal while omitting the displayed cofinal-window ledger or $\mathsf{RegSeqRat}^{\uparrow}$ handoff row, the packet is refuted by the carrier classifier.

Independence witness: cofinalwindowrealseal, realcompletenesstailchoiceaudit, finiteobservationbudgetselector, diagonallimitrepresentative, regseqrat: none is bijective to $\mathsf{CofinalRegularLimitBudget}^{\uparrow}$ because this carrier binds precision request, cofinal-window ledger, $\mathsf{RegSeqRat}^{\uparrow}$ handoff, $\mathsf{Real}^{\uparrow}$ seal, transport, continuation, provenance, and local NameCert rows in one packet.

Definition 670.1 (CofinalRegularLimitBudget carrier)**.** *A* $\mathsf{CofinalRegularLimitBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (q, w, r, e, h, c, p, n)$$

with the following displayed rows:

1. *q is the finite precision-request row read by the diagonal-limit consumer;*
2. *w is the cofinal-window ledger assigning each displayed request to a finite* $\mathsf{StreamName}^{\uparrow}$ *observation window;*
3. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row reached after the selected windows have been fixed;*
4. *e is the* $\mathsf{Real}^{\uparrow}$ *seal row reached from the displayed regular rational readback;*
5. *h records componentwise* hsame *transports for the request, window, handoff, seal, route, provenance, and local naming rows;*

6. *c records the displayed* Cont *route from q through w and r into e;*
7. *p is the* Pkg *provenance over* BHist, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, hsame, Cont, *and local certificate rows;*
8. *n is the local* NameCert$_{\text{CofinalRegularLimitBudget}^{\uparrow}}$ *row.*

The classifier for accepted carriers compares only the displayed rows q, w, r, e, h, c, p, n. It has no coordinate for quotient-stream equality, host real equality, selected limits, countable choice, or ambient Real$^{\uparrow}$ *completeness.*

Theorem 670.2 (CofinalRegularLimitBudget NameCert obligations)**.** *The local* NameCert$_{\text{CofinalRegularLimitBudget}^{\uparrow}}$ *surface for Definition 670.1 consists of five finite obligation rows:*

1. *carrier admission, requiring every accepted object to display the finite packet $B = (q, w, r, e, h, c, p, n)$;*
2. *cofinal-window coverage, requiring each precision request consumed by the diagonal route to pass through the displayed window ledger w;*
3. RegSeqRat$^{\uparrow}$ *handoff, requiring the regular rational readback row r to be reached only after the request and cofinal-window rows are fixed;*
4. Real$^{\uparrow}$ *seal routing, requiring the seal row e to be reached only through q, w, r, h, c, p, n;*
5. *ledger non-escape, requiring the packet to export no quotient stream, host real equality, selected limit, hidden completeness row, or unrecorded diagonal stream.*

Lean4 ✓ `BEDC.Derived.CofinalRegularLimitBudgetUp.CofinalRegularLimitBudgetTasteGate single carrier alignment`

Proof. Carrier admission is projection from the displayed tuple in Definition 670.1. The request, window, handoff, seal, transport, continuation, provenance, and local naming rows are all visible coordinates of one finite BHist packet.

Cofinal-window coverage reads q and then w before any regular rational handoff is available. Since w is the only window ledger in the carrier, the consumer cannot redirect a precision request to an unnamed tail or to a host-level stream.

The RegSeqRat$^{\uparrow}$ handoff is then forced through r. The row is attached to the displayed request and selected windows, so it cannot be replaced by quotient-stream equality or a selected ambient limit.

Finally, the seal and non-escape rows inspect e, h, c, p, n. They give the only route into the Real$^{\uparrow}$ seal and provide no coordinate for host real equality, hidden completeness, or an unrecorded diagonal stream. □

Closure status for NameCert$_{\text{CofinalRegularLimitBudget}^{\uparrow}}$.

Constructive story: A CofinalRegularLimitBudget$^{\uparrow}$ packet is generated from a precision request, a cofinal-window ledger, a RegSeqRat handoff row, a RealUp seal row, componentwise transports, continuation routes, package provenance, and a local naming row.

Theory closure: TheoryGate(NameCert$_{\text{CofinalRegularLimitBudget}^{\uparrow}}$, seed)

Scope closed: Definition 670.1 and Definition 670.2 bind the finite precision-budget route from diagonal requests through cofinal windows into RegSeqRat handoff and RealUp seal rows.

Formal verification: FormalStatus(NameCert$_{\text{CofinalRegularLimitBudget}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, quotient-stream equality, host real equality, selected ambient limits, countable choice, hidden completeness, or a public standard bridge.

Upgrade path: Scoped closure requires Lean encoding of the carrier and checked obligations for cofinal-window coverage, RegSeqRat handoff, RealUp seal routing, ledger provenance, and non-escape.

Definition 670.3 (CofinalRegularLimitBudget route-competing windows)**.** *Let $B = (q, w, r, e, h, c, p, n)$ be an accepted* $\mathsf{CofinalRegularLimitBudget}^{\uparrow}$ *carrier as in Definition 670.1. A pair of displayed cofinal-window ledgers w_0, w_1 is route-competing for B when each w_i is presented as the window row for the same precision request q, each presentation is read by the displayed* Cont *route c before the same* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row r and the same* $\mathsf{Real}^{\uparrow}$ *seal row e, and the presentation uses no rows other than q, w_i, r, e, h, c, p, n.*

Theorem 670.4 (CofinalRegularLimitBudget window-route determinacy)**.** *Let $B = (q, w, r, e, h, c, p, n)$ be an accepted* $\mathsf{CofinalRegularLimitBudget}^{\uparrow}$ *carrier. If w_0, w_1 are route-competing cofinal-window ledgers for B in the sense of Definition 670.3, then the carrier transport ledger h records* $\mathsf{hsame}(w_0, w_1)$*. Thus, for a fixed precision request q, fixed displayed route c, fixed* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row r, and fixed* $\mathsf{Real}^{\uparrow}$ *seal row e, the cofinal-window ledger consumed by the route is determined up to the displayed* hsame *transport of the carrier.*

Proof. By carrier admission in Definition 670.2, every accepted object exposes the finite packet $B = (q, w, r, e, h, c, p, n)$ and nothing outside those displayed rows is part of the local certificate surface. Cofinal-window coverage then says that every precision request consumed by the diagonal route passes through the displayed window ledger before any regular rational handoff is available.

Apply this to the two route-competing presentations w_0 and w_1. Both are presented for the same request row q and both are consumed by the same continuation row c before the same handoff row r. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff obligation requires r to be reached only after the request and cofinal-window rows have been fixed, so the two presentations cannot diverge at or after r by choosing a further window. The $\mathsf{Real}^{\uparrow}$ seal-routing obligation likewise requires e to be reached only through q, w, r, h, c, p, n, so the seal cannot introduce an additional cofinal-window coordinate.

It remains only to compare the two displayed window presentations inside the accepted packet. The classifier in Definition 670.1 compares the displayed rows q, w, r, e, h, c, p, n, and the transport row h is the componentwise hsame ledger for the request, window, handoff, seal, route, provenance, and local naming rows. Since w_0 and w_1 share q, c, r, e, p, n and the non-escape row of Definition 670.2 provides no quotient-stream equality, host real equality, selected limit, hidden completeness row, or unrecorded diagonal stream from which a second route could be read, the only admitted comparison between the two displayed window rows is the window component of h. Hence h records $\mathsf{hsame}(w_0, w_1)$. □

Theorem 670.5 (CofinalRegularLimitBudget TasteGate witness surface)**.** *The displayed carrier of Definition 670.1 has a nontrivial witness pair and a faithful field projection. One witness is the packet*

$$(BHist.Empty, BHist.Empty, BHist.Empty, BHist.Empty, BHist.Empty, BHist.Empty, BHist.Empty, BHis$$

and the other is the packet

$$(BHist.e0\, BHist.Empty, BHist.Empty, BHist.Empty, BHist.Empty, BHist.Empty, BHist.Empty, BHist.Em$$

They are separated by the precision-request row, and equality of the eight displayed fields q, w, r, e, h, c, p, n determines equality of the constructor.

Proof. The two packets use the same seven rows after the precision request, so the only comparison needed is the first coordinate. In the closed BHist grammar, $BHist.Empty$ and $BHist.e0\, BHist.Empty$ are distinct constructor forms. Thus the displayed carrier contains two separated packets.

Field faithfulness is read directly from the carrier shape in Definition 670.1. A carrier is exactly an eight-field constructor over q, w, r, e, h, c, p, n; once these fields are equal componentwise, constructor equality gives equality of the displayed packet.

The window-route determinacy theorem Definition 670.4 supplies the semantic use of this faithful projection for the cofinal-window row. It says that route-competing windows for a fixed request, route, handoff, and seal are compared only through the displayed transport ledger, so the TasteGate surface does not hide a second cofinal-window coordinate.

Lean already exposes the field-faithful projection through the existing CofinalRegularLimit-Budget TasteGate alignment target. The remaining Lean surface for this paper theorem is the explicit *Nontrivial* instance induced by the two packets above. □

Chapter 671

A Concrete Naming Certificate for $\mathsf{KernelSourceChannelLedger}^{\uparrow}$

The $\mathsf{KernelSourceChannelLedger}^{\uparrow}$ packet names the finite source-channel audit surface surrounding a Lean kernel acceptance event. It separates generated candidates, classifier stamps, accepted declarations, environment ancestry, axiom-query refusal rows, compiler routes, and local naming. The packet is a concrete $\mathsf{NameCert}$ carrier over the audit rows already exposed by $\mathsf{KernelAcceptanceTrace}^{\uparrow}$, $\mathsf{CertificateCompiler}^{\uparrow}$, and $\mathsf{NameCertMorphism}^{\uparrow}$; it does not certify the host kernel from inside BEDC and does not replace the displayed ancestry rows by source-text confidence.

The ledger is therefore not a kernel-only packet. Row T consumes the accepted-declaration audit surface of chapter 557; row M consumes either the executable certificate route of chapter 473 or the certificate-preservation graph of chapter 481; and row F keeps those sibling channels separated before any audit consumer reads Q, R.

Definition 671.1 (Kernel source-channel ledger carrier)**.** *A* $\mathsf{KernelSourceChannelLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (G, K, A, E, Q, R, T, M, F, H, C, P, N)$$

with the following displayed rows:

1. *G is the generated candidate row supplied by the source-side generator or certificate compiler;*
2. *K is the kernel classifier-stamp row attached to the candidate before it is exposed as an accepted declaration;*
3. *A is the accepted declaration row read by the local kernel-acceptance trace;*
4. *E is the environment ancestry ledger recording the declaration environment visible to the acceptance event;*
5. *Q is the displayed* `#print axioms` *query row for A;*
6. *R is the refusal row for any meeting between Q and the project forbidden-dependency surface;*
7. *T is the* $\mathsf{KernelAcceptanceTrace}^{\uparrow}$ *packet that binds generated candidate, stamp, declaration, ancestry, and query rows;*
8. *M is the* $\mathsf{NameCertMorphism}^{\uparrow}$ *or* $\mathsf{CertificateCompiler}^{\uparrow}$ *route row that accounts for the source-channel handoff into the accepted certificate surface;*

9. *F is the finite channel-separation row distinguishing generated candidates, kernel stamps, accepted declarations, environment ancestry, and refusal output;*
10. *H records componentwise* hsame *transports for all displayed rows;*
11. *C records* Cont *replay routes for candidate generation, kernel stamping, declaration exposure, ancestry query, axiom-query comparison, compiler handoff, and consumer reads;*
12. *P is the* Pkg *provenance over* BHist, Cont, Pkg, NameCert, KernelAcceptanceTrace$^{\uparrow}$, CertificateCompiler$^{\uparrow}$, *and* NameCertMorphism$^{\uparrow}$*;*
13. *N is the local* $\mathsf{NameCert}_{\mathsf{KernelSourceChannelLedger}^{\uparrow}}$ *row.*

The carrier has no coordinate for host trust in the generator, unstated kernel soundness, source-text-only acceptance, hidden environment ancestry, implicit axiom-query success, or a compiler correctness claim outside the displayed morphism and compiler rows.

Lean4 ✓ `BEDC.Derived.KernelSourceChannelLedgerUp.TasteGate.KernelSourceChannelLedgerTasteGate single carrier alignment`

Theorem 671.2 (Kernel source-channel ledger NameCert obligations)**.** *For every accepted* KernelSourceChannelLed *carrier*

$$S = (G, K, A, E, Q, R, T, M, F, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{KernelSourceChannelLedger}^{\uparrow}}$ *surface consists exactly of generated-candidate exposure, classifier-stamp exposure, accepted-declaration exposure, environment-ancestry exposure, axiom-query and refusal exposure, kernel-trace exposure, compiler or morphism route exposure, channel-separation exposure, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local naming row.*

Any downstream audit consumer must read the source channel through the finite packet S and may not identify generated candidates with accepted declarations, kernel stamps with environment ancestry, or clean query output with absent query output.

Proof. Project the carrier of Definition 671.1. The rows $G, K, A, E, Q, R, T, M, F, H, C, P, N$ are the only public coordinates available to the local naming certificate.

The acceptance rows are read through T. That trace binds the generated candidate, kernel stamp, accepted declaration, environment ledger, axiom-query report, transport, replay, provenance, and local naming data before any consumer sees the source channel.

The compiler side is read through M. If the source handoff uses a CertificateCompiler$^{\uparrow}$ packet, the handoff remains a finite compiler graph over source and target certificate rows. If it uses a NameCertMorphism$^{\uparrow}$ packet, the handoff remains a finite morphism graph preserving classifier and hsame rows.

Finally F, H, C, P, N keep the rows separated, transported, replayed, packaged, and named. Since the carrier has no coordinate identifying generation with acceptance or query absence with query success, every audit read must factor through the displayed source-channel ledger. □

Lean4 ✓ `BEDC.Derived.KernelSourceChannelLedgerUp.KernelSourceChannelLedgerPacket namecert obligations`

Theorem 671.3 (Kernel source-channel ledger audit boundary)**.** *Every public read of an accepted* KernelSourceChannelLedger$^{\uparrow}$ *packet factors through the finite* BHist *rows of Definition 671.1, the displayed* Cont *replay routes, the* Pkg *provenance, the local* NameCert *row, and the cited*

KernelAcceptanceTrace$^{\uparrow}$, CertificateCompiler$^{\uparrow}$, *and* NameCertMorphism$^{\uparrow}$ *packets. The boundary exports no hidden source-channel trust, no unstated kernel soundness theorem, no ambient environment scan, no unqueried axiom-purity claim, and no compiler semantics outside the displayed certificate route.*

Proof. Begin with an accepted packet S. A consumer can project only the generated candidate, classifier stamp, accepted declaration, environment ancestry, query, refusal, trace, compiler or morphism route, channel-separation, transport, continuation, provenance, and naming rows listed in the carrier.

The trace row T accounts for kernel acceptance as a finite audit event. The route row M accounts for the source-to-certificate handoff through the displayed compiler or morphism surface. The refusal row R accounts for forbidden ancestry by using the printed query row Q rather than a host-side assertion.

It remains to check escape routes. There is no carrier field for trusting a generator directly, no field for a host proof of kernel soundness, no field for an ambient environment scan, no field for clean ancestry without Q, and no field for compiler semantics beyond M. Thus the audit boundary is exactly the finite source-channel ledger surface. □

Lean4 ✓ `BEDC.Derived.KernelSourceChannelLedgerUp.KernelSourceChannelLedgerPacket audit boundary`

Theorem 671.4 (Kernel source-channel ledger trace projection)**.** *For every accepted* KernelSourceChannelLedger$^{\uparrow}$ *carrier*

$$S = (G, K, A, E, Q, R, T, M, F, H, C, P, N),$$

the generated candidate, kernel stamp, accepted declaration, ancestry, query, refusal, trace, and compiler-route rows project only through the displayed finite surface T, M, F, H, C, P, N after the source rows G, K, A, E, Q, R have been read. No public projection may identify generated candidates with accepted declarations or replace the compiler-route row by host environment trust.

Proof. Project the accepted carrier. The source rows G, K, A, E, Q, R expose candidate generation, kernel stamping, declaration exposure, ancestry, query output, and refusal output as separate coordinates.

The trace row T binds those source coordinates into the kernel-acceptance event. The route row M then accounts for the compiler or morphism handoff, while F keeps the channels separated.

Finally H, C, P, N transport, replay, package, and name the same finite packet. Since every projection has passed through these displayed rows, no consumer can collapse the source channels or replace them by host trust. □

Lean4 ✓ `BEDC.Derived.KernelSourceChannelLedgerUp.KernelSourceChannelLedgerPacket trace projection`

Theorem 671.5 (Kernel source-channel ledger query refusal stability)**.** *For every accepted* KernelSourceChannelLed *carrier $S = (G, K, A, E, Q, R, T, M, F, H, C, P, N)$, refusal stability is preserved by the displayed* `#print axioms` *query row Q and refusal row R under* hsame *transport and* Cont *replay. The refusal row cannot be replaced by absent query output, ambient source confidence, or host-side trust in the accepted declaration.*

Lean4 ✓ `BEDC.Derived.KernelSourceChannelLedgerUp.KernelSourceChannelLedgerPacket query refusal stability`

Proof. Read the query and refusal rows first. The row Q records the displayed axiom query for A, and R records the comparison against the forbidden-dependency surface.

Transport through H and replay through C preserve those two rows as part of the same accepted packet. The trace row T and channel-separation row F keep the query output distinct from an absent query.

Apply the audit boundary. Because the carrier has no coordinate for ambient confidence or host trust, refusal stability remains the displayed Q, R fact under replay and cannot be supplied by an unstated source-channel assumption. □

Theorem 671.6 (Kernel source-channel ledger source-query separation)**.** *For every accepted* KernelSourceChannelL *carrier*

$$S = (G, K, A, E, Q, R, T, M, F, H, C, P, N),$$

the generated candidate row G, kernel stamp row K, accepted declaration row A, environment ancestry row E, printed axiom query row Q, and refusal row R are separated before any compiler or morphism route M can be read. No consumer may replace the Q, R route by source confidence, ambient environment trust, or absent query output.

Lean4 ✓ `BEDC.Derived.KernelSourceChannelLedgerUp.KernelSourceChannelLedgerPacket source query separation`

Proof. Project the carrier of Definition 671.1. The rows G, K, A, E, Q, R are displayed source and query coordinates, while M is only the later compiler or morphism route row.

Apply the NameCert obligations of Definition 671.2. They require generated-candidate exposure, classifier-stamp exposure, accepted-declaration exposure, environment-ancestry exposure, axiom-query and refusal exposure, and compiler or morphism route exposure as separate finite duties.

Next use query-refusal stability from Definition 671.5. The printed query row Q and refusal row R persist under hsame transport and Cont replay, so absent query output cannot replace the displayed route.

Finally apply the audit boundary of Definition 671.3. Since the carrier has no coordinate for source confidence or ambient environment trust, every consumer must read the query and refusal rows before using the route row M. □

Theorem 671.7 (Kernel source-channel ledger public export package)**.** *The audit boundary of Definition 671.3, the trace projection of Definition 671.4, the query-refusal stability of Definition 671.5, and the source-query separation of Definition 671.6 assemble the public source-channel export of an accepted* KernelSourceChannelLedger$^{\uparrow}$ *packet. The export passes through accepted-declaration trace rows, certificate-compiler or* NameCert*-morphism rows, separated source and query channels, transport, replay, provenance, and local naming while keeping query-refusal and source-channel surfaces distinct.*

Lean4 ✓ `BEDC.Derived.KernelSourceChannelLedgerUp.KernelSourceChannelLedgerPacket public export package`

Proof. Project the carrier rows $G, K, A, E, Q, R, T, M, F, H, C, P, N$. The source-channel surface is carried by $G, K, A, E, T, M, F, H, C, P, N$, while the query-refusal surface is carried by Q, R, H, C, P, N.

Apply Definition 671.3 and Definition 671.4. These rows expose the accepted-declaration trace and keep kernel acceptance visible before any compiler or morphism route is consumed.

Next apply Definition 671.5 and Definition 671.6. The query row and refusal row remain separated from source confidence and environment trust, while the source and query channels are replayed through the same transport, continuation, provenance, and local naming rows. Hence the public export contains both surfaces without collapsing query refusal into source-channel acceptance. □

Closure status for $\mathsf{NameCert}_{\mathsf{KernelSourceChannelLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{KernelSourceChannelLedger}^{\uparrow}$ packet is generated from a source candidate, kernel classifier stamp, accepted declaration, environment ancestry ledger, axiom-query row, refusal row, kernel-acceptance trace, certificate compiler or NameCert morphism route, channel-separation row, componentwise hsame transports, displayed Cont replay routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{KernelSourceChannelLedger}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 671.1, Definition 671.2, Definition 671.3, Definition 671.4, and Definition 671.5 specify the finite source-channel ledger carrier, NameCert obligation surface, audit separation rows, replay provenance, trace projection, query-refusal stability, and non-escape boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{KernelSourceChannelLedger}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not prove host kernel soundness, completeness of all environment scans, compiler semantic correctness outside displayed certificate routes, Lean-side verification, bridge checking, or acceptance of any dependency outside the finite packet.

Upgrade path: Scoped closure requires binding those obligation rows to the displayed BHist, hsame, Cont, Pkg, NameCert, trace, compiler-route, channel-separation, and query-refusal scope.

Chapter 672

A Concrete Naming Certificate for $\mathsf{AxisNatReplacementRefusal}^{\uparrow}$

The $\mathsf{AxisNatReplacementRefusal}^{\uparrow}$ surface packages the AxisZeckendorf boundary that $\mathsf{AxisNat}^{\uparrow}$ and $\mathsf{Nat}^{\uparrow}$ remain distinct public interfaces. It records the AxisNat rows, the Nat rows, the unary-direction bridge rows, the checked cannot-claim rows, and the refusal ledger as finite data; it exports no kernel replacement of $\mathsf{Nat}^{\uparrow}$ by $\mathsf{AxisNat}^{\uparrow}$.

Its composite dependencies are the $\mathsf{AxisNat}^{\uparrow}$ interface of chapter 276, the $\mathsf{Nat}^{\uparrow}$ interface of chapter 28, the $\mathsf{UnaryDirectionBridge}^{\uparrow}$ boundary of chapter 530, and the $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$ refusal row of chapter 554, joined into one finite non-replacement packet.

The refusal packet reads the AxisNat row from chapter 276, the Nat row from chapter 28, the bridge row from chapter 530, and the cannot-claim refusal row from chapter 554. The local row B permits only the unary-direction comparison, and K records refusal of replacement rather than an isomorphism, kernel rewrite, or host equality between the two interfaces.

Definition 672.1 (AxisNat replacement-refusal carrier)**.** *An* $\mathsf{AxisNatReplacementRefusal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (A, N, B, K, H, C, P, L)$$

with the following displayed coordinates:

1. *A is the* $\mathsf{AxisNat}^{\uparrow}$ *interface row, including the finite axis-origin, successor-spine, and AxisZeckendorf-facing readback rows;*
2. *N is the* $\mathsf{Nat}^{\uparrow}$ *interface row, including the finite zero, successor, induction, and standard Nat naming rows;*
3. *B is the* $\mathsf{UnaryDirectionBridge}^{\uparrow}$ *row through which an admitted consumer may compare unary direction data without collapsing either interface into the other;*
4. *K is the checked cannot-claim row for the statement that* $\mathsf{AxisNat}^{\uparrow}$ *does not replace* $\mathsf{Nat}^{\uparrow}$*, together with the kernel-distinctness and bridge-dependence rows cited by the AxisZeckendorf registry;*
5. *H records displayed* hsame *transports for the AxisNat row, Nat row, bridge row, cannot-claim row, continuation row, provenance row, and local naming row;*
6. *C records the displayed* Cont *routes by which consumers may replay the AxisNat read, the Nat read, the bridge read, and the refusal read;*

7. *P is the* Pkg *provenance over* $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, $\mathsf{UnaryDirectionBridge}^{\uparrow}$, $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$, BHist, hsame, Cont, *and the source* NameCert *rows;*

8. *L is the local* $\mathsf{NameCert}_{\mathsf{AxisNatReplacementRefusal}^{\uparrow}}$ *row.*

The carrier has no coordinate for an isomorphism, a kernel rewrite, a definitional equality, a Nat induction transfer into AxisNat, an AxisNat successor transfer into Nat, or a global replacement principle.

Lean4 ✓ `BEDC.Derived.AxisNatReplacementRefusalUp.AxisNatReplacementRefusalTasteGate single carrier alignment`

Theorem 672.2 (AxisNat replacement-refusal NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{AxisNatReplacementRefusal}^{\uparrow}}$ *surface for Definition 672.1 consists exactly of six finite obligations:*

1. *carrier admission for the displayed packet $Q = (A, N, B, K, H, C, P, L)$;*

2. *AxisNat interface exposure through the row A;*

3. *Nat interface exposure through the row N;*

4. *bridge-bounded comparison through the* $\mathsf{UnaryDirectionBridge}^{\uparrow}$ *row B;*

5. *checked refusal coverage through the cannot-claim row K;*

6. *transport, continuation, provenance, and local naming exactness through H, C, P, L.*

Lean4 ✓ `BEDC.Derived.AxisNatReplacementRefusalUp.AxisNatReplacementRefusalCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 672.1. The packet has exactly the displayed AxisNat, Nat, bridge, refusal, transport, continuation, provenance, and naming rows.

The interface obligations are read separately from A and N. The AxisNat row supplies AxisZeckendorf-facing unary data, while the Nat row supplies the standard Nat naming surface; neither row is consumed as the other.

Bridge-bounded comparison is the row B. It permits only the displayed unary-direction comparison and does not create an isomorphism, definitional equality, or kernel rewrite between the two interfaces.

The refusal row is K, backed by the cannot-claim registry and the kernel-distinctness boundary. The remaining rows H, C, P, L preserve and replay this separation componentwise, so the NameCert surface is exhausted by the six obligations. □

Theorem 672.3 (AxisNat replacement-refusal non-replacement boundary)**.** *Every public read exported by an accepted* $\mathsf{AxisNatReplacementRefusal}^{\uparrow}$ *packet factors through A, N, B, K, H, C, P, L. In particular, no consumer can extract a kernel replacement of* $\mathsf{Nat}^{\uparrow}$ *by* $\mathsf{AxisNat}^{\uparrow}$*, a replacement of* $\mathsf{AxisNat}^{\uparrow}$ *by* $\mathsf{Nat}^{\uparrow}$*, an unbounded bridge, a transferred induction principle, a transferred successor rule, or a host equality between the two interfaces.*

Proof. Inspect the packet coordinates. The public AxisNat data are confined to A, and the public Nat data are confined to N.

The bridge coordinate B is the only comparison route. Since it is a $\mathsf{UnaryDirectionBridge}^{\uparrow}$ row, its output is a bounded direction read, not a replacement principle for either interface.

The refusal coordinate K records the cannot-claim boundary. Transport, continuation, provenance, and naming rows H, C, P, L replay that same boundary and add no interface operation. Because the excluded replacement objects are absent from the carrier, no public read can export them. □

Theorem 672.4 (AxisNat replacement-refusal vision realization)**.** *The AxisZeckendorf cannot-claim boundary for the statement that* $\mathsf{AxisNat}^{\uparrow}$ *replaces* $\mathsf{Nat}^{\uparrow}$ *is realized by the finite* $\mathsf{AxisNatReplacementRefusal}^{\uparrow}$ *packet of Definition 672.1. The realization cites AxisNat rows, Nat rows, UnaryDirectionBridge rows, checked cannot-claim rows, displayed* hsame *transports,* Cont *routes,* Pkg *provenance, and a local* NameCert *row, while exporting no replacement of either interface by the other.*

Proof. Start from the registry statement Definition 9350.7. It records that the AxisZeckendorf cluster does not assert replacement of $\mathsf{Nat}^{\uparrow}$ by $\mathsf{AxisNat}^{\uparrow}$.

The carrier of Definition 672.1 turns that boundary into finite rows. The rows A and N keep the two interfaces separate, B records the bounded unary-direction bridge, and K records the checked refusal ledger.

Rows H, C, P, L provide the admissible transport, continuation, package, and local naming surface. By Definition 672.3, this realization cannot be read as a positive replacement bridge, so it concretizes the vision boundary as a finite refusal certificate. □

Closure status for $\mathsf{NameCert}_{\mathsf{AxisNatReplacementRefusal}^{\uparrow}}$.

Constructive story: An $\mathsf{AxisNatReplacementRefusal}^{\uparrow}$ packet is generated from AxisNat interface rows, Nat interface rows, UnaryDirectionBridge rows, checked cannot-claim rows, displayed hsame transports, continuation routes, package provenance, and a local NameCert row. It is composite over the $\mathsf{AxisNat}^{\uparrow}$, $\mathsf{Nat}^{\uparrow}$, $\mathsf{UnaryDirectionBridge}^{\uparrow}$, and cannot-claim ledger surfaces, bundling those existing boundaries into one refusal surface.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AxisNatReplacementRefusal}^{\uparrow}}$, seed)

Scope closed: The seed scope records the carrier, NameCert obligations, non-replacement boundary, and AxisZeckendorf vision realization for finite AxisNat-to-Nat refusal packets.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AxisNatReplacementRefusal}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a replacement of NatUp by AxisNatUp, a replacement of AxisNatUp by NatUp, an interface isomorphism, kernel rewriting, transferred induction, transferred successor structure, or host equality.

Upgrade path: Obligation closure requires checked carrier coverage, bridge-bounded comparison, cannot-claim coverage, transport exactness, continuation exactness, and ledger non-escape for the displayed packet.

Chapter 673

A Concrete Naming Certificate for $\mathsf{LimitSelector}^{\uparrow}$

The $\mathsf{LimitSelector}^{\uparrow}$ surface packages the finite selector used by the diagonal-limit construction of Definition 9238.3. It names the precision request, the modulus-selected member, the finite observation window, the regular-rational readback, the RealUp seal, and the BEDC transport rows as one inspectable packet. It is a selector certificate over displayed finite data, not a host-selected limit or a quotient of streams.

The selector is a downstream L10 consumer of the certified countable-name interface of chapter 126 and the RealUp sealing interface of chapter 38; its own packet records only the finite witness route between those sibling surfaces.

Definition 673.1 (LimitSelector carrier)**.** *A* $\mathsf{LimitSelector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (R, n, \mu, k, W, D, S, H, C, P, N)$$

with the following displayed rows:

1. *R is the* $\mathsf{RegSeqRat}$ *input row for the regular Cauchy sequence whose diagonal representative is being read;*
2. *n is the unary precision request row;*
3. *μ is the displayed modulus row assigning a finite selector bound to each unary precision request;*
4. *k is the selected index row, fixed as the value of μ at the precision requested by n;*
5. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *window row read from the selected member and the selected diagonal index;*
6. *D is the dyadic readback row produced from the finite window;*
7. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row reached after the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback and dyadic endpoint rows are fixed;*
8. *H records componentwise* hsame *transports for R, n, μ, k, W, D, S and the local structural rows;*
9. *C records the displayed* Cont *route from the precision request through the modulus, selected index, window, dyadic readback, and seal rows;*
10. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and local certificate rows;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{LimitSelector}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through the displayed rows $R, n, \mu, k, W, D, S, H, C, P, N$.

Lean4 (definition) `BEDC.Derived.LimitSelectorUp.LimitSelectorCarrier`

Theorem 673.2 (LimitSelector NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{LimitSelector}^{\uparrow}}$ *surface for Definition 673.1 consists of five finite obligations:*

1. *carrier admission, requiring every accepted selector object to expose the packet $L = (R, n, \mu, k, W, D, S, H, C, P, N$*
2. *modulus-selector exactness, requiring the selected index row k to be read from the displayed modulus μ at the unary precision request n;*
3. *finite-window readback, requiring the diagonal observation to pass through the finite* $\mathsf{StreamName}^{\uparrow}$ *window W and dyadic readback row D before any regular-rational read is exported;*
4. *seal handoff, requiring the* $\mathsf{Real}^{\uparrow}$ *row S to be reached only through the selected finite witness route n, μ, k, W, D and the displayed transport, route, package, and naming rows;*
5. *non-escape, requiring the selector to export no host-selected limit, quotient stream equality, countable choice data, ambient completeness principle, or unrecorded diagonal observation.*

Proof. Carrier admission is projection from the finite tuple in Definition 673.1. The input, precision, modulus, selected index, window, dyadic readback, seal, transport, continuation, provenance, and local naming rows are all displayed coordinates.

Modulus-selector exactness reads n and μ before the index row k is available. Thus the selected index is a row of the packet, fixed by the displayed modulus route, rather than an external choice of a subsequence.

The finite-window readback then routes the selected member through W and D. Since the window and dyadic rows are named before the readback is exported, a consumer cannot replace them by a quotient stream or by an unbounded host observation.

Finally the seal handoff and non-escape clauses inspect S, H, C, P, N. These rows carry the selected finite witness route into the RealUp seal and provide no coordinate for host-selected limits, choice data, ambient completeness, or an unrecorded diagonal observation. □

Theorem 673.3 (LimitSelector finite witness route)**.** *Every diagonal-limit consumer of an accepted* $\mathsf{LimitSelector}^{\uparrow}$ *packet factors through the selected finite witness route*

$$n, \mu, k, W, D, S, H, C, P, N.$$

The consumer may inspect the precision request, displayed modulus, selected index, finite stream window, dyadic readback, RealUp seal, componentwise hsame *transports, displayed* Cont *routes, package provenance, and local naming row. It receives no host-selected limit, no quotient-stream equality, no countable-choice selector, and no ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.LimitSelectorUp.LimitSelectorCarrier finite witness route`

Proof. Start with the consumer route C. Its first reads are the precision request n and the modulus row μ, followed by the selected index k named by the modulus-selector obligation of Definition 673.2.

Next the consumer reads the finite observation data. The selected index opens only the displayed window W, and the dyadic row D is the readback attached to that window.

Finally the route reaches the seal row S and the BEDC structural rows H, C, P, N. The carrier has no second coordinate for a host-selected limit, quotient-stream equality, countable choice, or ambient completeness, so every diagonal-limit read remains inside the selected finite witness route. □

Theorem 673.4 (LimitSelector observation-budget handoff)**.** *Let*

$$L = (R, n, \mu, k, W, D, S, H, C, P, N)$$

be an accepted $\mathsf{LimitSelector}^{\uparrow}$ *packet, and let an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet share the displayed precision request, finite window, dyadic readback, RealUp seal, componentwise transport, continuation route, package provenance, and local naming rows* n, W, D, S, H, C, P, N*. Then every diagonal-limit consumer of* L *that reaches the shared rows factors through the same finite observation-budget route before it reads the RealUp seal.*

Proof. First project the selected route of L by Definition 673.1 and Definition 673.2. The selector supplies n, μ, k before the finite window W and dyadic readback D are available.

Next apply the finite witness route of Definition 673.3. Once W, D, S, H, C, P, N are displayed, the diagonal-limit consumer has no route around the named window and readback rows.

Finally read the shared observation-budget packet. The seal-route totality and consumer exactness theorems for $\mathsf{RealObservationBudget}^{\uparrow}$, Definition 611.17 and Definition 611.9, identify the same finite budget route through the precision request, window, dyadic ledger, seal, transport, continuation, provenance, and naming rows. □

Lean4 ✓ `BEDC.Derived.LimitSelectorUp.LimitSelectorCarrier observation budget handoff`

Theorem 673.5 (LimitSelector Real seal non-escape)**.** *For an accepted* $\mathsf{LimitSelector}^{\uparrow}$ *packet, the RealUp seal row* S *is reachable only after the selector has displayed* n, μ, k, W, D *and the transport, continuation, provenance, and local naming rows* H, C, P, N*. No consumer may read* S *as a host-selected limit, quotient stream, countable-choice selector, or ambient completeness witness.*

Proof. Use carrier admission first. In Definition 673.1, the seal row S is a coordinate following the precision request, modulus row, selected index, finite window, and dyadic readback.

The local NameCert obligations then impose the seal handoff. By Definition 673.2, the seal row is reached only through the selected finite witness route and the displayed structural rows.

The observation-budget seal boundary gives the Real-facing side of the same claim. Definition 611.5 places a budget seal after its finite observation rows, and Definition 611.6 excludes quotient streams, host real equality, hidden limit selection, unbounded schedules, and ambient completeness from the shared route. □

Lean4 ✓ `BEDC.Derived.LimitSelectorUp.LimitSelectorCarrier real seal nonescape`

Theorem 673.6 (LimitSelector shared budget Real seal determinacy)**.** *Let*

$$L = (R, n, \mu, k, W, D, S, H, C, P, N)$$

be an accepted $\mathsf{LimitSelector}^{\uparrow}$ *packet, and let an accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *packet share the rows* n, W, D, S, H, C, P, N*. Then the* $\mathsf{Real}^{\uparrow}$ *seal row reached by any diagonal-limit consumer of* L *is determined by the shared observation-budget route. The consumer cannot read a second seal, a host-selected limit, quotient stream equality, or an ambient completeness route.*

Proof. Project the $\mathsf{LimitSelector}^{\uparrow}$ carrier. The only seal coordinate of L is the displayed row S, and it appears after the precision, selector, finite window, dyadic readback, transport, route, provenance, and naming rows.

Apply Definition 673.4. The accepted $\mathsf{RealObservationBudget}^{\uparrow}$ packet shares n, W, D, S, H, C, P, N, so the diagonal-limit consumer reaches the seal through the same finite observation-budget route before any Real-facing read is available.

Apply Definition 673.5. The seal cannot be read as a host-selected limit, quotient stream, countable-choice selector, or ambient completeness witness.

Finally use the RealObservationBudget seal boundary rows already cited above, namely Definition 611.5 and Definition 611.6. They identify the shared route as the finite seal boundary, leaving no second seal or ambient route for the diagonal-limit consumer. □

Lean4 ✓ `BEDC.Derived.LimitSelectorUp.LimitSelectorCarrier shared budget real seal determinacy`

Theorem 673.7 (LimitSelector diagonal consumer exhaustion)**.** *Every diagonal-limit consumer of an accepted* $\mathsf{LimitSelector}^{\uparrow}$ *packet is exhausted by the carrier rows of Definition 673.1, the local obligations of Definition 673.2, the finite witness route of Definition 673.3, the observation-budget handoff of Definition 673.4, and the seal non-escape row of Definition 673.5. The consumer receives exactly the displayed selector, window, readback, seal, transport, route, provenance, and naming rows, with no host-selected limit or ambient completeness coordinate.*

Proof. Begin with the selector packet. The carrier and local obligations display the complete finite surface $R, n, \mu, k, W, D, S, H, C, P, N$ and require the selected index to be read from the precision and modulus rows.

Next use the finite witness route and the observation-budget handoff. Together they force every diagonal read through the selected index, the finite window, the dyadic readback, and the shared $\mathsf{RealObservationBudget}^{\uparrow}$ route before the seal row is consumed.

Finally apply seal non-escape. Since neither the selector carrier nor the observation-budget packet contains a coordinate for quotient streams, countable choice, selected host limits, or ambient completeness, the diagonal consumer has no remaining export beyond the displayed finite rows. □

Lean4 ✓ `BEDC.Derived.LimitSelectorUp.LimitSelectorCarrier diagonal consumer exhaustion`

Theorem 673.8 (LimitSelector scoped source rows)**.** *Every accepted* $\mathsf{LimitSelector}^{\uparrow}$ *packet exposes its scoped source as the displayed* BHist *carrier* $L = (R, n, \mu, k, W, D, S, H, C, P, N)$*, with the* $\mathsf{StreamName}^{\uparrow}$ *finite window* W*, the* $\mathsf{RegSeqRat}$ *input row* R*, the* $\mathsf{RealObservationBudget}^{\uparrow}$ *route through* n, W, D, S, H, C, P, N*, the componentwise* hsame *transports and* Cont *route, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{LimitSelector}^{\uparrow}}$ *row. No source row is supplied outside this displayed packet.*

Lean4 ✓ `BEDC.Derived.LimitSelectorUp.LimitSelectorCarrier scoped source rows`

Proof. Project the carrier of Definition 673.1. The accepted packet displays the BHist tuple $L = (R, n, \mu, k, W, D, S, H, C, P, N)$, so the regular-sequence source, precision request, modulus, selected index, finite stream window, dyadic readback, seal, transport, route, provenance, and naming rows are all visible coordinates.

Apply the local obligations of Definition 673.2. They require the selected index to be read from n and μ, and they require the finite-window readback to pass through W and D before the seal row is exported.

Use the observation-budget handoff of Definition 673.4. It identifies the shared budget route through n, W, D, S, H, C, P, N, while Definition 673.7 exhausts the remaining diagonal-consumer reads by the same displayed packet. □

Theorem 673.9 (LimitSelector modulus-seal scope)**.** *For an accepted* $\mathsf{LimitSelector}^{\uparrow}$ *packet, the selector modulus* μ *and the* $\mathsf{Real}^{\uparrow}$ *seal row* S *read only the displayed finite window route*

$$n, \mu, k, W, D, S$$

and the observation-budget route carried by H, C, P, N*. The seal cannot read an unrecorded stream observation, an external selector, or any ambient completion principle.*

Lean4 ✓ `BEDC.Derived.LimitSelectorUp.LimitSelectorCarrier modulus seal scope`

Proof. Begin with the finite witness route of Definition 673.3. The precision request n and displayed modulus μ determine the selected index row k, after which the consumer reads the finite window W and dyadic readback D.

The seal row is then governed by Definition 673.5. That theorem places S after n, μ, k, W, D and the structural rows H, C, P, N, so the seal has no independent route to stream data or host completeness data.

Finally use Definition 673.4. The shared $\mathsf{RealObservationBudget}^{\uparrow}$ route accounts for the finite observation-budget side of the same seal read, and Definition 673.7 leaves no further consumer coordinate. □

Theorem 673.10 (LimitSelector non-escape scope)**.** *The scoped* $\mathsf{LimitSelector}^{\uparrow}$ *packet exports no quotient stream, no host limit selection, no ambient completeness principle, and no open-cover compactness datum. Its exported content is exhausted by the carrier, finite witness route, observation-budget handoff, Real seal non-escape, and diagonal consumer exhaustion theorems of this chapter.*

Lean4 ✓ `BEDC.Derived.LimitSelectorUp.LimitSelectorCarrier nonescape scope`

Proof. Read the packet through Definition 673.1 and Definition 673.2. The only exported coordinates are $R, n, \mu, k, W, D, S, H, C, P, N$ and the finite obligations attached to them.

Apply Definition 673.3, Definition 673.4, and Definition 673.5. These results route every diagonal-limit and Real-seal read through the selected finite witness route and the displayed observation-budget rows.

Conclude with Definition 673.7. Since the exhausted surface has no coordinate for quotient streams, host-selected limits, ambient completeness, or open-cover compactness, none of those objects can be exported by the scoped selector packet. □

Theorem 673.11 (LimitSelector Real StreamName observation lock)**.** *Every diagonal-limit consumer of an accepted* $\mathsf{LimitSelector}^{\uparrow}$ *packet reaches the* $\mathsf{Real}^{\uparrow}$ *seal only through the displayed chain*

$$R,\ n,\ \mu,\ k,\ W,\ D,\ \mathsf{RealObservationBudget}^{\uparrow},\ S.$$

Here R *is the* $\mathsf{RegSeqRat}$ *input row,* n *is the unary precision request,* μ *is the selector modulus,* k *is the selected index,* W *is the finite* $\mathsf{StreamName}^{\uparrow}$ *window over the sibling interface of chapter 126,* D *is the dyadic readback, the shared finite route is the* $\mathsf{RealObservationBudget}^{\uparrow}$ *handoff, and* S *is the* $\mathsf{Real}^{\uparrow}$ *seal of chapter 38. No diagonal-limit consumer can bypass this chain by reading a host-selected limit, quotient stream equality, countable-choice selector, ambient completeness witness, or unrecorded stream observation.*

Proof. Start with the finite witness route of Definition 673.3. It forces the consumer to read the precision request, selector modulus, selected index, finite stream window, dyadic readback, seal row, and structural rows as displayed coordinates of the same packet.

Next apply the observation-budget handoff of Definition 673.4. Once the finite $\mathsf{StreamName}^{\uparrow}$ window from chapter 126 and the dyadic readback are fixed, the shared $\mathsf{RealObservationBudget}^{\uparrow}$ route is the only observation-budget route available before the seal is consumed.

Now use the Real seal non-escape theorem of Definition 673.5. It places the $\mathsf{Real}^{\uparrow}$ seal from chapter 38 after n, μ, k, W, D and the displayed structural rows, and it excludes host-selected limits, quotient streams, countable-choice selectors, and ambient completeness witnesses.

Finally apply diagonal consumer exhaustion from Definition 673.7. The exhausted carrier has no remaining coordinate outside the listed chain, so every diagonal-limit consumer reaches the Real seal through the RegSeqRat row, unary request, selector modulus, selected index, StreamName window, dyadic readback, observation-budget route, and seal row. □

Closure status for $\mathsf{NameCert}_{\mathsf{LimitSelector}^{\uparrow}}$.

Constructive story: A $\mathsf{LimitSelector}^{\uparrow}$ packet is generated from a RegSeqRat input row, a unary precision request, a displayed modulus, a selected finite index, a StreamName window, dyadic readback, RealUp seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LimitSelector}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 673.4 and Definition 673.5 bridge the public finite selector surface to the displayed observation-budget route and Real seal boundary over the RegSeqRat, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LimitSelector}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.LimitSelectorUp.LimitSelectorCarrier\_finite\_witness\_route`

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, real completeness, quotient-stream equality, host real equality, countable choice, host-selected limits, or a public standard bridge.

Upgrade path: No further paper-theory closure upgrade remains; Lean verification and bridge checking remain on the verification axis.

Chapter 674

A Concrete Naming Certificate for $\mathsf{GroundLoopBoundary}^{\uparrow}$

The $\mathsf{GroundLoopBoundary}^{\uparrow}$ packet realizes the boundary isolated in chapter 9461. It records the closed ground loop as finite mark and mark-sameness rows, while the meta side is recorded only as refusal rows for truth-total reflection, host runtime export, and host truth predicates. The packet therefore gives downstream chapters a concrete NameCert surface for citing the exact place where ground distinction closes and meta-truth closure remains unavailable.

$\mathsf{GroundLoopBoundary}^{\uparrow}$ supplies the ground-row subpacket consumed by $\mathsf{ReflectionLimitBoundary}^{\uparrow}$ in chapter 586; the latter adds the broader structural meta-description boundary.

Its mark inventory and positive sameness rows are read through the finite boolean mark packet of chapter 32: BMark supplies the two displayed endpoints, while msame keeps the diagonal rows visible before any reflection-boundary consumer can inspect R, H, C, P, N.

Definition 674.1 (Ground-loop boundary carrier)**.** *A* $\mathsf{GroundLoopBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (M, S, X, R, H, C, P, N)$$

with the following displayed rows:

1. *M is the two-row* BMark *inventory exposing exactly* b0 *and* b1*;*
2. *S is the positive* msame *inventory exposing exactly* $\mathsf{msame}(\mathsf{b0}, \mathsf{b0})$ *and* $\mathsf{msame}(\mathsf{b1}, \mathsf{b1})$*;*
3. *X is the cross-mark refusal row, recording that no generated row identifies* b0 *with* b1 *or* b1 *with* b0*;*
4. *R is the reflection-boundary row, recording structural self-description as permitted data and truth-total reflection as refused data;*
5. *H records the componentwise* hsame *transports for the mark inventory, positive sameness rows, cross-mark refusal rows, reflection-boundary row, provenance, and local naming row;*
6. *C records the displayed* Cont *routes used to read M, replay S and X, transport the boundary row R, and return the same finite packet to every consumer;*
7. *P is the* Pkg *provenance over* BHist*,* BMark*,* msame*,* hsame*,* Cont*, reflection-boundary rows, and* NameCert*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{GroundLoopBoundary}^{\uparrow}}$ *row.*

The carrier contains no coordinate for a truth-total reflection certificate, host runtime, host truth predicate, or meta-level classifier that turns structural self-description into BEDC truth.

Lean4 (definition) `BEDC.Derived.GroundLoopBoundaryUp.GroundLoopBoundaryCarrier`

Theorem 674.2 (GroundLoopBoundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{GroundLoopBoundary}^{\uparrow}}$ *surface for the carrier* $G = (M, S, X, R, H, C, P, N)$ *consists exactly of carrier admission for Definition 674.1, the two displayed* BMark *rows in* M*, the two positive* msame *rows in* S*, cross-mark non-generation and refusal in* X*, the reflection-boundary row* R*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.GroundLoopBoundaryUp.GroundLoopBoundaryCarrier namecert obligations`

Proof. Carrier admission is projection from the finite tuple of Definition 674.1. The accepted object exposes only the rows M, S, X, R, H, C, P, N.

The ground rows are exhausted by M, S, X. The row M displays the two mark constructors, S displays the two positive primitive sameness rows, and X records that no generated cross-mark sameness row is admitted.

The reflection row is R. It permits structural self-description only as a named boundary row and records refusal of truth-total reflection, so it cannot be read as a truth classifier for the host calculus.

Finally, the transport, replay, provenance, and naming obligations are exactly H, C, P, N. No further row remains from which a consumer could recover a host runtime, host truth predicate, or meta-level classifier beyond the displayed boundary. □

Theorem 674.3 (Ground-loop boundary meta non-escape)**.** *Every consumer of an accepted* $\mathsf{GroundLoopBoundary}^{\uparrow}$ *packet factors through the finite rows* M, S, X, R, H, C, P, N*. The packet exports the closed ground distinction between* b0 *and* b1 *together with the positive* msame *rows and cross-mark refusal, but it exports no truth-total reflection certificate, host runtime, host truth predicate, or meta-level truth classifier.*

Lean4 ✓ `BEDC.Derived.GroundLoopBoundaryUp.GroundLoopBoundaryCarrier meta nonescape`

Proof. Let $G = (M, S, X, R, H, C, P, N)$ be accepted. Any permitted read of the ground loop uses M for the two marks, S for positive sameness, and X for the refusal of generated cross-mark sameness.

Any permitted read of the reflection boundary uses R and is transported only by H and replayed only by C. The provenance and local name remain the rows P and N.

Since the carrier inventory has no coordinate for truth-total reflection, a host runtime, a host truth predicate, or a meta-level truth classifier, no downstream consumer can project such data from the packet. The only exported boundary is the finite distinction between closed ground generation and open meta-truth refusal. □

Theorem 674.4 (Ground-loop boundary scoped kernel route)**.** *Every accepted* $\mathsf{GroundLoopBoundary}^{\uparrow}$ *packet binds its displayed rows to the exact BEDC primitive scope: the mark inventory* M *is scoped to* BMark*, the positive sameness rows* S *and cross-mark refusal row* X *are scoped to* msame*, transport* H *is scoped to* hsame*, replay* C *is scoped to* Cont*, provenance* P *is scoped to* Pkg*, and local naming* N *is scoped to* NameCert*.*

Lean4 ✓ `BEDC.Derived.GroundLoopBoundaryUp.GroundLoopBoundaryCarrier scoped kernel route`

Proof. Project the accepted carrier $G = (M, S, X, R, H, C, P, N)$ through Definition 674.1. Each row is named by the primitive that stores it: marks by BMark, mark sameness and refusal by msame, transport by hsame, replay by Cont, provenance by Pkg, and local naming by NameCert.

The meta non-escape theorem Definition 674.3 exhausts every permitted consumer through these rows. Since the carrier has no further coordinate for host truth, runtime export, or a meta-level classifier, the listed primitive bindings are the whole scope of the packet. □

Theorem 674.5 (Ground-loop boundary public interface)**.** *Every downstream consumer may cite the* GroundLoopBoundary$^{\uparrow}$ *public interface exactly as the finite tuple of mark inventory, positive* msame *rows, cross-mark refusal, reflection-boundary row, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert*. This interface exports no truth-total reflection, host runtime, host truth predicate, or meta-level truth classifier beyond the displayed boundary rows.*

Lean4 ✓ `BEDC.Derived.GroundLoopBoundaryUp.GroundLoopBoundaryCarrier public interface`

Proof. Project the accepted carrier through Definition 674.1. The public rows are precisely M, S, X, R, H, C, P, N, and Definition 674.4 binds them to the primitive BEDC scope used by downstream consumers.

Use Definition 674.3. Since no coordinate carries truth-total reflection, a host runtime, a host truth predicate, or a meta-level truth classifier, the public interface can export only the displayed boundary tuple and its local naming route. □

Theorem 674.6 (Ground-loop boundary mature consumer exhaustion)**.** *Every worked consumer of an accepted* GroundLoopBoundary$^{\uparrow}$ *packet factors through the rows M, S, X, R, H, C, P, N of Definition 674.1 and through the sibling* ReflectionLimitBoundary$^{\uparrow}$ *route when it needs the broader reflection-limit boundary. No such consumer obtains truth-total reflection, a host runtime, a host truth predicate, or a meta-level truth classifier.*

Lean4 ✓ `BEDC.Derived.GroundLoopBoundaryUp.GroundLoopBoundaryCarrier mature consumer exhaustion`

Proof. The NameCert obligations of Definition 674.2 expose exactly the rows M, S, X, R, H, C, P, N. Thus a worked consumer starts from the mark inventory, positive msame rows, cross-mark refusal, reflection-boundary row, transport, replay, provenance, and local naming.

The meta non-escape theorem Definition 674.3 rules out every projection to truth-total reflection, host runtime, host truth predicate, or a meta-level truth classifier. The scoped kernel route of Definition 674.4 then binds each remaining read to BMark, msame, hsame, Cont, Pkg, and NameCert.

Finally, the public interface theorem Definition 674.5 is the only exported consumer surface of this packet. A consumer that needs the larger reflection-limit boundary must pass to the sibling ReflectionLimitBoundary$^{\uparrow}$ route described in chapter 586; it still receives only the displayed boundary rows and not a host truth object. □

Closure status for NameCert$_{\text{GroundLoopBoundary}^{\uparrow}}$.

Constructive story: A GroundLoopBoundary$^{\uparrow}$ packet is generated from the two BMark rows, the two positive msame rows, cross-mark refusal rows, a reflection-boundary row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{GroundLoopBoundary}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 674.1, Definition 674.2, Definition 674.3, Definition 674.4, Definition 674.5, and Definition 674.6, with the displayed TasteGate marker above, bind the worked-consumer exhaustion surface between closed ground distinction and open meta-truth refusal.

Formal verification: FormalStatus(NameCert$_{\text{GroundLoopBoundary}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean-side formal verification, truth-total reflection, a host runtime export, a host truth predicate, or a bridge to the internal CIC-star structure.

Upgrade path: Remaining work is Lean-side formal verification and bridge checking for the displayed mature consumer surface.

Chapter 675

A Concrete Naming Certificate for $\mathsf{PrefixFunctorIdentityNaturalityBridge}^{\uparrow}$

The $\mathsf{PrefixFunctorIdentityNaturalityBridge}^{\uparrow}$ packet records the finite BEDC data consumed by the prefix-functor identity naturality bridge of Definition 9363.4. It packages the prefix history, source and target object histories, the displayed hom history, the left and right empty-composite continuation rows, the prefix-lifted hom carriers, the component row used by $\mathsf{NatTrans}^{\uparrow}$, the hsame transport rows, the $\mathsf{Functor}^{\uparrow}$ and $\mathsf{NatTrans}^{\uparrow}$ certificate rows, the continuation ledger, provenance, and local naming. The packet is a concrete NameCert surface; it is not a host category, a quotient morphism class, or a naturality proof imported from an external categorical library. Its carrier consumes the Category hom surface of chapter 61, the prefix action row of chapter 62, and the component comparison row of chapter 63; these sibling rows are the source of the local F and T coordinates rather than decorative category terminology.

Definition 675.1 (Prefix functor identity-naturality bridge carrier)**.** *A* $\mathsf{PrefixFunctorIdentityNaturalityBridge}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (p, a, b, f, L, R, U, V, E, H, F, T, C, P, N)$$

with the following displayed rows:

1. *p is the unary prefix history read by the prefix-functor route;*
2. *a and b are the unary source and target object histories;*
3. *f is the displayed hom history carrying* $\mathsf{CategoryHomCarrier}(a, b, f)$*;*
4. *L records the left empty-composite continuation row* $\mathsf{Cont}(\mathsf{e}, f, L)$*;*
5. *R records the right empty-composite continuation row* $\mathsf{Cont}(f, \mathsf{e}, R)$*;*
6. *U is the prefix-lifted hom-carrier row from* $\mathsf{append}(p, a)$ *to* $\mathsf{append}(p, b)$ *obtained from L;*
7. *V is the prefix-lifted hom-carrier row from* $\mathsf{append}(p, a)$ *to* $\mathsf{append}(p, b)$ *obtained from R;*
8. *E is the empty identity component row used by the prefix functor identity law at each unary object;*
9. *H records componentwise* hsame *transports comparing U and V and reading them back to the original carrier f;*
10. *F is the local* $\mathsf{Functor}^{\uparrow}$ *row for the prefix functor on the checked unary-continuation* $\mathsf{Cat}^{\uparrow}$ *packet;*

11. *T is the local* $\mathsf{NatTrans}^{\uparrow}$ *row for the identity naturality component surface;*
12. *C records the displayed* Cont *routes for left unit, right unit, prefix lift, component readback, and consumer handoff;*
13. *P is the* Pkg *provenance over* BHist, $\mathsf{Cat}^{\uparrow}$, $\mathsf{CategoryHomCarrier}$, hsame, Cont, $\mathsf{Functor}^{\uparrow}$, $\mathsf{NatTrans}^{\uparrow}$, *and local certificate rows;*
14. *N is the local* $\mathsf{NameCert}_{\mathsf{PrefixFunctorIdentityNaturalityBridge}^{\uparrow}}$ *row.*

The classifier for accepted carriers compares only the displayed rows $p, a, b, f, L, R, U, V, E, H, F, T, C, P, N$. It has no coordinate for an external category object, quotient morphism equality, host natural-transformation equality, or an unrecorded naturality square.

Theorem 675.2 (Prefix functor identity-naturality NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{PrefixFunctorIdentityNat}}$ *surface for Definition 675.1 consists of seven finite obligation rows:*

1. *carrier admission, requiring every accepted object to display the packet $K = (p, a, b, f, L, R, U, V, E, H, F, T, C, P,$*
2. *category source binding, requiring a, b, f to enter through the checked* $\mathsf{Cat}^{\uparrow}$ *hom-carrier row* $\mathsf{CategoryHomCarrier}(a, b, f)$*;*
3. *left and right empty-composite binding, requiring L and R to be the displayed* $\mathsf{Cont}(\mathsf{e}, f, L)$ *and* $\mathsf{Cont}(f, \mathsf{e}, R)$ *continuation rows consumed by the bridge;*
4. *prefix-lift exactness, requiring U and V to be the two prefix-lifted hom-carrier rows from* $\mathsf{append}(p, a)$ *to* $\mathsf{append}(p, b)$*;*
5. *identity-naturality comparison, requiring H to expose* $\mathsf{hsame}(U, V)$ *and the readback transports from the prefix-lifted rows to f;*
6. *functor and natural-transformation coverage, requiring F and T to be the local* $\mathsf{Functor}^{\uparrow}$ *and* $\mathsf{NatTrans}^{\uparrow}$ *rows that consume the same prefix, identity component, hom-carrier, and transport data;*
7. *ledger non-escape, requiring all public reads to pass through* BHist, $\mathsf{CategoryHomCarrier}$, hsame, Cont, $\mathsf{Functor}^{\uparrow}$, $\mathsf{NatTrans}^{\uparrow}$, Pkg, *and* $\mathsf{NameCert}$, *excluding external category libraries, quotient morphisms, and host naturality equality.*

Proof. Carrier admission is projection from Definition 675.1. The rows $p, a, b, f, L, R, U, V, E, H, F, T, C, P, N$ display the full prefix, hom-carrier, empty-composite, lifted-carrier, component, transport, functor, natural-transformation, route, provenance, and local naming packet.

The category source binding reads a, b, f through $\mathsf{CategoryHomCarrier}(a, b, f)$. The left and right rows L and R are the only displayed empty-composite continuation rows, so the prefix-lifted rows U and V are forced to use the same original hom history f.

Prefix-lift exactness then applies the bridge in Definition 9363.4. It supplies the two hom-carrier rows over $\mathsf{append}(p, a)$ and $\mathsf{append}(p, b)$ and the hsame comparison between them.

The functor and natural-transformation rows F and T consume exactly those carriers, the empty identity component row E, and the componentwise transports in H. Since the packet has no external categorical coordinate, the ledger non-escape clause follows by inventory of the displayed rows. □

Theorem 675.3 (Prefix functor identity-naturality public handoff)**.** *Every downstream consumer of an accepted* $\mathsf{PrefixFunctorIdentityNaturalityBridge}^{\uparrow}$ *packet receives only the finite rows*

$$p, a, b, f, L, R, U, V, E, H, F, T, C, P, N.$$

The consumer may inspect the unary prefix, the original $\mathsf{Cat}^{\uparrow}$ *hom-carrier, the left and right empty-composite continuation rows, the two prefix-lifted hom carriers, their* hsame *comparison, the empty component row, the* $\mathsf{Functor}^{\uparrow}$ *and* $\mathsf{NatTrans}^{\uparrow}$ *certificate rows, displayed* Cont *routes, provenance, and local naming. It may not extract a host category, quotient morphism equality, ambient functor category, or naturality equality outside the displayed BEDC packet.*

Proof. Project the accepted carrier. The displayed rows are exactly $p, a, b, f, L, R, U, V, E, H, F, T, C, P, N$.

Use the NameCert obligations to order the public read through category source binding, empty-composite binding, prefix-lift exactness, identity-naturality comparison, functor coverage, natural-transformation coverage, and ledger non-escape.

The only comparison row exposed to the consumer is H, which records the componentwise hsame transports and the readback from the two lifted carriers to f. Because no host category, quotient morphism class, or external naturality equality appears as a coordinate of the carrier, the handoff cannot project any such object. □

Theorem 675.4 (Prefix functor identity-naturality category-functor route)**.** *Every accepted* PrefixFunctorIdentityNa *packet factors through the sibling chapter surfaces chapter 61, chapter 62, and chapter 63 before exporting the identity-naturality handoff of Definition 675.3. The* a, b, f *rows first expose* $\mathsf{CategoryHomCarrier}(a, b, f)$*, the* F *row then exposes the* $\mathsf{Functor}^{\uparrow}$ *prefix action, and the* T *row exposes the* $\mathsf{NatTrans}^{\uparrow}$ *component surface consumed by the public handoff.*

Proof. Project the carrier from Definition 675.1. The rows a, b, f are not free categorical parameters; they are displayed with the $\mathsf{CategoryHomCarrier}(a, b, f)$ row, so the route enters through the category sibling surface of chapter 61.

Next read the certificate rows F and T. The row F is the local $\mathsf{Functor}^{\uparrow}$ certificate for the prefix action on the same checked unary-continuation category packet, while T is the local $\mathsf{NatTrans}^{\uparrow}$ certificate for the identity component comparison. These rows force the handoff through chapter 62 and chapter 63.

The public handoff then reads $p, a, b, f, L, R, U, V, E, H, F, T, C, P, N$ through the same displayed packet. Since the carrier has no coordinate for an external category object, ambient functor category, quotient morphism equality, or host naturality equality, the sibling category, functor, and natural-transformation rows are substantive dependencies rather than optional labels. □

Closure status for $\mathsf{NameCert}_{\mathsf{PrefixFunctorIdentityNaturalityBridge}^{\uparrow}}$.

Constructive story: A $\mathsf{PrefixFunctorIdentityNaturalityBridge}^{\uparrow}$ packet is generated from a unary prefix, original category hom rows, left and right empty-composite continuation rows, two prefix-lifted hom carriers, identity component rows, componentwise hsame transport, $\mathsf{Functor}^{\uparrow}$ and $\mathsf{NatTrans}^{\uparrow}$ rows, continuation routes, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{PrefixFunctorIdentityNaturalityBridge}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 675.1, Definition 675.2, and Definition 675.3 bind the finite carrier, NameCert obligations, and public handoff for the prefix-functor identity naturality bridge.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{PrefixFunctorIdentityNaturalityBridge}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, external category interfaces, quotient morphism equality, ambient functor categories, host naturality equality, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, prefix-lift exactness, identity-naturality comparison, functor and natural-transformation coverage, ledger provenance, and public handoff for the same finite packet.

Chapter 676

A Concrete Naming Certificate for $\mathsf{RegularCauchyProductBudget}^{\uparrow}$

The $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ packet records the finite product-window ledger needed by Real-and-Completion multiplication consumers. It starts with two $\mathsf{RegSeqRat}^{\uparrow}$ source names, opens only displayed $\mathsf{StreamName}^{\uparrow}$ windows, reads the product row through $\mathsf{DyadicRatCore}^{\uparrow}$, accounts for the finite error split through $\mathsf{FiniteErrorBudget}^{\uparrow}$, hands the result back as a $\mathsf{RegSeqRat}^{\uparrow}$ row, and seals the completion-facing read through $\mathsf{Real}^{\uparrow}$. The packet is a local product-budget certificate; it is not quotient stream equality, host real multiplication, an ambient completeness theorem, or a selected host limit.

The product-budget carrier consumes the sibling routes of chapter 126, chapter 291, chapter 385, and chapter 301. These links are substantive: paired finite stream windows supply the source observations, DyadicRatCore supplies the displayed product row, FiniteErrorBudget supplies the finite split ledger, and RegSeqRat receives the product handoff.

Definition 676.1 (RegularCauchyProductBudget carrier)**.** *A* $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (A, B, W_A, W_B, D_A, D_B, D, E, R, S, H, C, P, N)$$

with the following displayed rows:

1. *A and B are the two accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *source packets whose product is being read;*
2. *W_A and W_B are the paired finite* $\mathsf{StreamName}^{\uparrow}$ *windows opened from the two sources at the precision requested by the product route;*
3. *D_A and D_B are the dyadic endpoint and radius rows read from those two windows;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *product row computing the finite dyadic product observation from D_A and D_B;*
5. *E is the* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *product ledger assigning the source-window radii, product rounding allowance, and remaining readback budget;*
6. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row produced from the dyadic product row and the finite budget ledger;*
7. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row through which a completion or real-algebra consumer reads the product candidate;*

8. *H stores componentwise* hsame *transports for the source rows, windows, dyadic rows, budget ledger, readback, seal, package provenance, and local naming row;*
9. *C stores the displayed* Cont *routes for source inspection, paired-window admission, dyadic product read, finite-budget exactness, regular readback, and RealUp seal handoff;*
10. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{FiniteErrorBudget}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyProductBudget}^{\uparrow}}$ *row.*

The local classifier compares accepted carriers only through the visible rows $A, B, W_A, W_B, D_A, D_B, D, E, R, S, H, C,$

Lean4 (definition) `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudgetUp`

Theorem 676.2 (RegularCauchyProductBudget falsifiable prediction)**.** *Every accepted* RegularCauchyProductBudg *carrier has a falsifiable finite-product prediction: if a candidate packet omits either paired* $\mathsf{StreamName}^{\uparrow}$ *window or omits the* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *row, then it cannot export the same* $\mathsf{RegSeqRat}^{\uparrow}$ *product handoff and* $\mathsf{Real}^{\uparrow}$ *seal as the carrier of Definition 676.1.*

Proof. Project the carrier coordinates. The two source windows W_A, W_B are the only rows from which the dyadic source observations D_A, D_B can be read, so deleting either window leaves no displayed route to the product row D.

Project the finite ledger coordinate E. The readback row R is downstream of D and E, and the seal row S is downstream of R in the same finite packet.

Therefore a candidate that lacks either paired window or the budget ledger cannot preserve both the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the $\mathsf{Real}^{\uparrow}$ seal. The Lean follow-up must provide `Nontrivial RegularCauchyProductBudgetUp` and `FieldFaithful RegularCauchyProductBudgetUp` in `TasteGate.lean`. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget falsifiable prediction`

Theorem 676.3 (RegularCauchyProductBudget independence witness)**.** *The* $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *packet is not bijective, as a local* NameCert *surface, to the sibling slugs bounded-cauchy-cover, observablecauchyseal, regularcauchymerge, or regularcauchyswapbisimulation. It has two source windows, a dyadic product row, and a finite error-budget row, while those siblings respectively expose one budget-to-cover route, one observation seal route, two cofinal selector routes, or selector-swap symmetry without a dyadic multiplication budget.*

Proof. Compare carrier inventories. The product-budget carrier contains the two source rows, paired $\mathsf{StreamName}^{\uparrow}$ windows, dyadic source rows, one dyadic product row, one finite error-budget row, one $\mathsf{RegSeqRat}^{\uparrow}$ readback, and one $\mathsf{Real}^{\uparrow}$ seal.

The bounded-cauchy-cover sibling has a single budget-to-cover route rather than paired product windows. The observablecauchyseal sibling has a seal route rather than the dyadic product and finite error split.

The regularcauchymerge sibling records two cofinal selector routes, and the regularcauchyswapbisimulation sibling records selector-swap symmetry. Neither supplies the dyadic multiplication budget row required by the product carrier.

Thus no bijection can preserve the displayed coordinates and the local NameCert obligations at once. The Lean follow-up must provide `Nontrivial RegularCauchyProductBudgetUp` and `FieldFaithful RegularCauchyProductBudgetUp` in `TasteGate.lean`. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget independence witness`

Falsifiable prediction: Any accepted product-budget carrier omitting either paired StreamName window or the FiniteErrorBudget row cannot export the same RegSeqRat handoff and RealUp seal.

Independence witness: bounded-cauchy-cover, observablecauchyseal, regularcauchymerge, regularcauchyswapbisimulation: ProductBudget is not bijective to these siblings because it has two source windows plus dyadic product and finite error-budget rows, while the siblings respectively have one budget-to-cover route, one observation seal route, two cofinal selector routes, or selector-swap symmetry without dyadic multiplication budget.

Theorem 676.4 (RegularCauchyProductBudget window admission)**.** *Every accepted* RegularCauchyProductBudget *carrier admits the paired source windows only through the two displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows and their* $\mathsf{StreamName}^{\uparrow}$ *windows. More precisely, for*

$$B = (A, B, W_A, W_B, D_A, D_B, D, E, R, S, H, C, P, N),$$

any product-window read first exposes the source packets A and B, then the finite windows W_A and W_B, and only then the dyadic source rows D_A and D_B.

Proof. Project the carrier of Definition 676.1. The source packets and paired windows are explicit coordinates, so the first available product-window data are A, B, W_A, W_B.

The dyadic source rows D_A and D_B are listed after the paired windows and are read through the same continuation route. Thus a consumer cannot obtain a dyadic product observation before the two finite windows have been admitted.

The remaining rows D, E, R, S, H, C, P, N consume that displayed window data. Since the carrier has no coordinate for an unbounded stream observation or a quotient representative, all product-window admission is confined to the finite rows already named. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudgetCarrier window admission`

Theorem 676.5 (RegularCauchyProductBudget ledger exactness)**.** *The finite product-budget ledger of an accepted* $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *carrier is exactly the row E applied to the dyadic source rows D_A, D_B and the product row D. It accounts for the two source-window radii, the dyadic product rounding row, and the remaining readback allowance before any* $\mathsf{RegSeqRat}^{\uparrow}$ *product readback is exported.*

Proof. Begin with the admitted windows from Definition 676.4. They supply the two dyadic source rows D_A and D_B and therefore fix the inputs of the dyadic product row D.

Read the budget coordinate E. Its role in the carrier is the finite product ledger, so it binds the two source-window radii, the product rounding allowance, and the remaining readback budget to the same dyadic product observation.

The readback row R is listed after E and is routed through the same package provenance and continuation data. Hence no product readback can be exported without first passing through the displayed finite ledger. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget ledger exactness`

Theorem 676.6 (RegularCauchyProductBudget bilinear finite-window route)**.** *Every accepted* $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *carrier reads both source windows* W_A, W_B*, both dyadic source rows* D_A, D_B*, the product row* D*, and the finite ledger* E *as one bilinear finite window before exporting the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R *or the* $\mathsf{Real}^{\uparrow}$ *seal row* S*. In particular, neither source window may be consumed alone, and no product-budget consumer may reach* R *or* S *before the symmetric route through*

$$A, B, W_A, W_B, D_A, D_B, D, E$$

has been assembled.

Proof. Apply Definition 676.4. It exposes the two source packets together with the paired windows W_A, W_B, and it reads the dyadic source rows D_A, D_B only after both finite windows are visible.

Next apply Definition 676.5. The dyadic product row D and the finite ledger E are bound to the two dyadic source rows in the same carrier, so the product budget consumes the two windows symmetrically rather than as independent one-sided reads.

The later $\mathsf{RegSeqRat}^{\uparrow}$ handoff of Definition 676.10 and the $\mathsf{Real}^{\uparrow}$ seal boundary of Definition 676.11 both occur after this assembled window. Hence the carrier exports no readback or seal that bypasses the bilinear finite-window route. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget bilinear window`

Theorem 676.7 (RegularCauchyProductBudget symmetric source-window inversion)**.** *Let*

$$B = (A, B, W_A, W_B, D_A, D_B, D, E, R, S, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *carrier. Any consumer that reaches the product row* D *or the finite ledger row* E *can recover that both source windows* W_A *and* W_B *were admitted through the paired* $\mathsf{RegSeqRat}^{\uparrow}$ *and* $\mathsf{StreamName}^{\uparrow}$ *route. Neither one-sided source window suffices to license the dyadic product row, because the carrier has no coordinate for a product observation built from only* W_A *or only* W_B*.*

Proof. Project the carrier of Definition 676.1. The paired source windows W_A, W_B and the dyadic source rows D_A, D_B occur before the product row D and the ledger row E, so a read of D or E also identifies the source-window coordinates from which they were assembled.

Use window admission from Definition 676.4. It admits W_A and W_B together through the $\mathsf{RegSeqRat}^{\uparrow}$ source rows and their $\mathsf{StreamName}^{\uparrow}$ finite windows before either dyadic source row is consumed.

Use ledger exactness from Definition 676.5 and the bilinear route of Definition 676.6. The product row D and ledger row E are bound to both D_A and D_B, which in turn are bound to both W_A and W_B.

Thus any consumer at D or E inverts the route back to the paired source-window admission. Since no one-sided product coordinate appears in the carrier tuple, a single window alone cannot license the dyadic product row. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudgetCarrier symmetric source window inversion`

Theorem 676.8 (RegularCauchyProductBudget source coverage)**.** *Every accepted* $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *carrier reaching either the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R *or the* $\mathsf{Real}^{\uparrow}$ *seal row* S *must expose both source packets* A, B*, both* $\mathsf{StreamName}^{\uparrow}$ *windows* W_A, W_B*, both dyadic source rows* D_A, D_B*, and the shared* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *row* E*. No one-sided product read and no hidden host multiplication route covers the same exported seal.*

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget source coverage`

Proof. Apply Definition 676.4. It exposes the source packets A, B together with the paired finite windows W_A, W_B before either dyadic source row can be consumed.

Apply Definition 676.5. The finite ledger E is tied to both dyadic source rows D_A, D_B and to the product row D, so a product read cannot cover only one source side.

Use Definition 676.7. Any consumer that has reached the downstream product route can invert the route back to the paired source-window admission.

The rows R, S, H, C, P, N add readback, seal, transport, replay, provenance, and local naming data only after the same paired source route is present. Since the carrier has no coordinate for one-sided multiplication or host multiplication, neither can cover the exported seal. □

Theorem 676.9 (RegularCauchyProductBudget product-closure budget)**.** *Every accepted* RegularCauchyProductB *carrier closes the finite product budget needed for a* $\mathsf{RegSeqRat}^{\uparrow}$ *product readback and the terminal* $\mathsf{Real}^{\uparrow}$ *seal. More precisely, the paired source windows* W_A, W_B*, the dyadic product row* D*, and the* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *ledger* E *force the readback row* R *and seal row* S *to use the same finite product budget carried by*

$$A, B, W_A, W_B, D_A, D_B, D, E, R, S, H, C, P, N.$$

No completion or real-algebra consumer may replace this route by host real multiplication, quotient stream equality, an ambient completeness principle, a hidden rounding oracle, or a selected host limit.

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget product closure budget`

Proof. Begin with window admission. By Definition 676.4, the product route first exposes the two $\mathsf{RegSeqRat}^{\uparrow}$ source rows and the paired $\mathsf{StreamName}^{\uparrow}$ windows, so D_A and D_B are read only through displayed finite observations.

Next use ledger exactness. By Definition 676.5, the dyadic product row D and the finite product ledger E are bound to those same source windows before any product readback can be exported.

Now attach the readback and seal. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff of Definition 676.10 consumes D and E through the structural rows H, C, P, N, and the $\mathsf{Real}^{\uparrow}$ seal boundary of Definition 676.11 reads S only after that handoff has been assembled.

Thus the product readback and the Real seal share one finite product budget. Since the carrier has no coordinate for host multiplication, quotient stream equality, ambient completeness, hidden rounding, or selected host limits, no consumer can bypass the displayed route. □

Theorem 676.10 (RegularCauchyProductBudget RegSeqRat handoff)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *product readback exported by an accepted* $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *carrier factors through the finite route*

$$A, B, W_A, W_B, D_A, D_B, D, E, R, H, C, P, N.$$

The handoff preserves the same source rows, paired windows, dyadic product observation, product-budget ledger, hsame *transports,* Cont *routes, package provenance, and local naming row.*

Proof. Use window admission to identify the two source rows and their finite windows. This fixes A, B, W_A, W_B, D_A, D_B as the only source data available to the product route.

Use ledger exactness to identify the dyadic product row and the finite budget ledger. The product readback must consume D and E before the row R is available.

Finally inspect the structural rows H, C, P, N. They preserve the route componentwise under hsame and Cont transport and repack it as the local naming surface, so the exported $\mathsf{RegSeqRat}^{\uparrow}$ handoff is exactly the displayed finite route. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget regseqrat handoff`

Theorem 676.11 (RegularCauchyProductBudget Real seal boundary)**.** *Every completion-facing or real-algebra read of an accepted* $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *carrier reaches* $\mathsf{Real}^{\uparrow}$ *only through the seal row S after the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff R has been produced from the finite product-budget ledger. The carrier exports no host real multiplication, quotient stream equality, ambient completeness principle, hidden rounding oracle, or selected host limit.*

Proof. Project the seal row S from the carrier. It appears after the readback row R, so the real-facing route reaches the seal only after the finite product handoff has been assembled.

Apply Definition 676.10. The readback R is already bound to the source rows, paired windows, dyadic product row, budget ledger, transports, routes, package provenance, and local naming row.

The carrier contains no coordinate for host multiplication, quotient stream equality, ambient completeness, hidden rounding, or selected host limits. Therefore the $\mathsf{Real}^{\uparrow}$ seal is a boundary around the displayed finite packet and exports no additional real object. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget real seal boundary`

Theorem 676.12 (RegularCauchyProductBudget NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyProductBu}}$ *surface for Definition 676.1 consists of carrier admission, paired-window admission, dyadic product-row exactness, finite product-ledger exactness,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff exactness,* $\mathsf{Real}^{\uparrow}$ *seal boundary, componentwise* hsame *stability, displayed* Cont *route stability,* Pkg *provenance, and non-escape from host multiplication, quotient streams, ambient completeness, hidden rounding, and selected host limits.*

Proof. Carrier admission is the tuple in Definition 676.1. It lists the two sources, paired windows, dyadic source rows, dyadic product row, product ledger, readback, seal, transports, routes, provenance, and local naming row.

Paired-window admission is Definition 676.4, and dyadic product-row exactness is the displayed use of D_A, D_B, D inside the same carrier.

Finite product-ledger exactness is Definition 676.5. The $\mathsf{RegSeqRat}^{\uparrow}$ handoff exactness is Definition 676.10, and the $\mathsf{Real}^{\uparrow}$ seal boundary is Definition 676.11.

The structural obligations are the roles of H, C, P, N. They keep transport, continuation, package provenance, and the local certificate on the same displayed packet. Since no forbidden external coordinate is present, non-escape follows by inspection of the carrier. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget namecert obligations`

Theorem 676.13 (RegularCauchyProductBudget checked-obligation readiness)**.** *For the accepted* $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *carrier*

$$B = (A, B, W_A, W_B, D_A, D_B, D, E, R, S, H, C, P, N),$$

the carrier row, paired-window admission, finite product-ledger exactness, $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal boundary, componentwise* hsame *transport, displayed* Cont *route,* Pkg *provenance, and non-escape clauses form the single Lean-facing obligation surface for the product-budget packet.*

Proof. First assemble the finite product route. Apply Definition 676.4 to expose the paired source windows, and apply Definition 676.5 to bind the dyadic product row to the finite ledger E.

Next attach the consumer handoff boundary. Apply Definition 676.10 for the $\mathsf{RegSeqRat}^{\uparrow}$ readback route, and apply Definition 676.11 for the $\mathsf{Real}^{\uparrow}$ seal boundary.

Finally repack the structural obligations. Apply Definition 676.12; its transport, route, provenance, local naming, and non-escape clauses name exactly the same packet. Hence the listed clauses form one obligation surface for downstream Lean formalization. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget checked obligation readiness`

Theorem 676.14 (RegularCauchyProductBudget obligation scope)**.** *The carrier of Definition 676.1, paired-window admission, ledger exactness, product-closure budget,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal boundary, local* $\mathsf{NameCert}$ *obligations, and checked-obligation readiness form one obligation-closure surface over* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{FiniteErrorBudget}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. The surface is the finite product-budget route*

$$\mathsf{StreamName}^{\uparrow},\ \mathsf{DyadicRatCore}^{\uparrow},\ \mathsf{FiniteErrorBudget}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}$$

carried by the same packet $B = (A, B, W_A, W_B, D_A, D_B, D, E, R, S, H, C, P, N)$*.*

Proof. Start with carrier admission from Definition 676.1. It fixes the source rows, paired stream windows, dyadic source rows, dyadic product row, finite ledger, readback row, Real seal, transports, routes, provenance, and local naming row as one finite packet.

Apply Definition 676.4, Definition 676.5, and Definition 676.9. These theorems order the paired $\mathsf{StreamName}^{\uparrow}$ windows, the $\mathsf{DyadicRatCore}^{\uparrow}$ product row, and the $\mathsf{FiniteErrorBudget}^{\uparrow}$ ledger before the readback can be exported.

Next use Definition 676.10 and Definition 676.11. They attach the $\mathsf{RegSeqRat}^{\uparrow}$ handoff and the $\mathsf{Real}^{\uparrow}$ seal to that same displayed budget route.

Finally repack through Definition 676.12 and Definition 676.13. The rows H, C, P, N supply transport, continuation replay, provenance, and local naming for the same packet, and inspection shows no route through host real multiplication, quotient stream equality, hidden rounding, selected limits, or an unbounded stream. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget obligation scope`

Theorem 676.15 (RegularCauchyProductBudget dyadic multiplication scope)**.** *Every accepted* $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *product-budget packet must expose the paired* $\mathsf{StreamName}^{\uparrow}$ *finite windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *multiplication row, the* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *split ledger, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *product handoff before any* $\mathsf{Real}^{\uparrow}$ *seal reads the product. For*

$$B = (A, B, W_A, W_B, D_A, D_B, D, E, R, S, H, C, P, N),$$

the admissible multiplication route is the displayed finite path

$$W_A, W_B \longmapsto D_A, D_B \longmapsto D \longmapsto E \longmapsto R \longmapsto S,$$

with componentwise hsame *transport and* Cont *replay carried by* H, C, P, N*. No product consumer may replace this route by host real multiplication, quotient stream equality, a hidden rounding oracle, or an uninspected completion seal.*

Proof. Induct over the displayed finite window rows. In the base read, the packet exposes the two source rows A, B and then the paired windows W_A, W_B; no dyadic source row is available before those finite observations are present.

In the window step, read D_A and D_B from the two windows and apply the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ multiplication row D. This keeps the product as a finite dyadic observation rather than a host real product.

Next split the error budget through E. The ledger accounts for the two source-window radii, the product rounding allowance, and the remaining readback budget before the product can be handed to R.

Finally transport the assembled row through H, C, P, N and only then pass it to the $\mathsf{RegSeqRat}^{\uparrow}$ handoff R and the $\mathsf{Real}^{\uparrow}$ seal S. Since the carrier has no coordinate for host multiplication, quotient stream equality, hidden rounding, or an uninspected completion seal, every accepted product read follows the stated finite route. □

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudgetCarrier dyadic multiplication scope`

Theorem 676.16 (RegularCauchyProductBudget public export)**.** *Every accepted* $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ *carrier exports a public* $\mathsf{NameCert}_{\mathsf{RegularCauchyProductBudget}^{\uparrow}}$ *consumer surface whose route is exactly the assembled finite path*

$$A, B, W_A, W_B, D_A, D_B, D, E, R, S, H, C, P, N.$$

The public surface reads the $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *product row, the* $\mathsf{FiniteErrorBudget}^{\uparrow}$ *ledger, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and the* $\mathsf{Real}^{\uparrow}$ *seal from that packet. It exports no host multiplication, quotient stream equality, ambient completeness principle, hidden rounding oracle, or selected host limit.*

Lean4 ✓ `BEDC.Derived.RegularCauchyProductBudgetUp.RegularCauchyProductBudget public export`

Proof. Start with the carrier tuple and apply Definition 676.4. This fixes the two source rows, their paired $\mathsf{StreamName}^{\uparrow}$ windows, and the dyadic source rows as the only admitted product-window data.

Next apply Definition 676.5 and Definition 676.9. These identify the $\mathsf{DyadicRatCore}^{\uparrow}$ product row and the $\mathsf{FiniteErrorBudget}^{\uparrow}$ ledger as the finite budget through which every product readback must pass.

Attach the consumer boundary through Definition 676.10 and Definition 676.11. The readback row R and seal row S are therefore downstream of the same displayed finite packet.

Finally apply Definition 676.14. The rows H, C, P, N repack transport, continuation replay, package provenance, and local naming into the public $\mathsf{NameCert}_{\mathsf{RegularCauchyProductBudget}^{\uparrow}}$ surface, with no extra coordinate through which host multiplication, quotient equality, completeness, hidden rounding, or selected limits could enter. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyProductBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyProductBudget}^{\uparrow}$ packet is generated from two $\mathsf{RegSeqRat}^{\uparrow}$ source rows, paired $\mathsf{StreamName}^{\uparrow}$ windows, dyadic source rows, a $\mathsf{DyadicRatCore}^{\uparrow}$ product row, a $\mathsf{FiniteErrorBudget}^{\uparrow}$ ledger, a $\mathsf{RegSeqRat}^{\uparrow}$ readback, a $\mathsf{Real}^{\uparrow}$ seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyProductBudget}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: Definition 676.1, Definition 676.2, Definition 676.3, Definition 676.4, Definition 676.5, Definition 676.9, Definition 676.10, Definition 676.11, Definition 676.12, Definition 676.13, Definition 676.14, and Definition 676.16 bind the finite product-budget route to StreamName, DyadicRatCore, FiniteErrorBudget, RegSeqRat, RealUp, BHist, hsame, Cont, Pkg, NameCert source rows, and the public consumer surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RegularCauchyProductBudget}\uparrow}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, RealUp completeness, host real multiplication, quotient stream equality, a hidden rounding oracle, selected host limits, or a public standard bridge.

Upgrade path: The next theory-axis step is a bridge from the public product-budget export to a standard or schema-facing multiplication interface.

Chapter 677

A Concrete Naming Certificate for $\mathsf{ChoiceRecipeLedger}^{\uparrow}$

The $\mathsf{ChoiceRecipeLedger}^{\uparrow}$ surface records the finite term-stratum ledger left when a consumer asks for a choice output but the available BEDC data contains only inspected witness recipes. It turns the witness-recipe loss of Definition 9387.34 into explicit BHist, hsame, Cont, Pkg, NameCert, and axiom-purity refusal rows.

The ledger is the choice-output analogue of the quotient-representative refusal boundary in chapter 634: both expose finite request, refusal, transport, route, provenance, and NameCert rows instead of a hidden selector.

It also consumes the effective replacement boundary of chapter 568. The finite recipe family and refusal row form the choice-output analogue of an effective replacement ledger, while the requested-output row prevents that replacement from becoming a selector.

Definition 677.1 (ChoiceRecipeLedger carrier)**.** *A* $\mathsf{ChoiceRecipeLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (T, F, Q, A, H, C, P, N)$$

with the following displayed rows:

1. *T is the term-stratum request row, recording the finite consumer site at which a choice output would be used;*
2. *F is the finite family row, listing the inspected witness recipes and the addresses at which each recipe is available;*
3. *Q is the requested-output row, recording the missing uniform choice value and the consumer route that asks for it;*
4. *A is the axiom-purity refusal row, recording that no inspected recipe supplies an unrestricted selection operator, hidden witness family, or host choice principle;*
5. *H records componentwise* hsame *transport for the request row, recipe-family row, requested-output row, refusal row, package provenance, and local naming row;*
6. *C records the displayed* Cont *routes by which a consumer reads the request, inspects the finite recipes, reaches the requested-output boundary, and returns the refusal row;*
7. *P is the* Pkg *provenance over* BHist*, term rows, finite witness recipes, requested-output rows, axiom-purity refusals,* hsame*,* Cont*, and* NameCert*;*

8. N is the local $\mathsf{NameCert}_{\mathsf{ChoiceRecipeLedger}^{\uparrow}}$ *row.*
The carrier exports no selected witness family, no unrestricted choice functional, no hidden recipe evaluator, no quotient of recipe addresses, and no host-level selection rule.

Theorem 677.2 (ChoiceRecipeLedger NameCert obligations)**.** *For the carrier of Definition 677.1, the local* $\mathsf{NameCert}_{\mathsf{ChoiceRecipeLedger}^{\uparrow}}$ *surface consists of carrier admission for*

$$L = (T, F, Q, A, H, C, P, N),$$

term-stratum request exposure through T, finite witness-recipe coverage through F, requested-output accountability through Q, axiom-purity refusal through A, componentwise hsame *stability through H, displayed* Cont *route stability through C, package provenance through P, local naming through N, and non-discharge of the requested choice output.*

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 677.1. The tuple lists the request row, finite recipe family, requested-output boundary, refusal row, transport, continuation, provenance, and local naming as the complete public inventory.

The request and coverage obligations are the rows T, F, Q. A consumer first reads the term-stratum site, then the finite family of inspected recipes, and only then the requested output boundary.

The refusal and stability obligations are A, H, C, P, N. They record axiom-purity refusal, replay the same finite route under componentwise hsame and Cont, cite the package provenance, and bind the route to the local NameCert without producing the missing choice output. □

Theorem 677.3 (ChoiceRecipeLedger non-escape)**.** *Every consumer of an accepted* $\mathsf{ChoiceRecipeLedger}^{\uparrow}$ *packet reads only*

$$T, F, Q, A, H, C, P, N.$$

The consumer may inspect the finite recipe family and the refusal row, but it cannot extract a selected witness family, unrestricted choice functional, hidden recipe evaluator, quotient-selected address, or host choice rule from the packet.

Proof. Start from the carrier and NameCert obligations. Together they expose exactly the finite recipe ledger, requested-output boundary, refusal row, transport, continuation, provenance, and local naming data.

The axiom-purity refusal row A is downstream of the inspected recipe family F. It records the boundary between finite recipe inspection and a uniform choice output, so the refusal is not itself a selector.

Finally inspect the missing coordinates. No row names a selected witness family, choice functional, hidden evaluator, quotient of addresses, or host-level rule. The structural rows H, C, P, N preserve and package the same finite refusal route, so no escape path is available. □

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerNonEscape`

Theorem 677.4 (ChoiceRecipeLedger term-stratum handoff)**.** *The term-stratum handoff of an accepted* $\mathsf{ChoiceRecipeLedger}^{\uparrow}$ *packet factors through the finite route*

$$T, F, Q, A, H, C, P, N.$$

It presents the consumer site, the inspected witness recipes, the requested-output boundary, and the axiom-purity refusal as one BHist *package with componentwise* hsame*, displayed* Cont*,* Pkg *provenance, and a local* NameCert *row.*

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerCarrier term stratum handoff`
↪ variant `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerTermStratumHandoff`

Proof. Use the carrier to identify the source of the handoff. The term-stratum request row is T, and the only finite recipe-family row attached to that request is F.

The requested-output boundary and refusal are then Q and A. They state exactly what output the consumer asks for and why the inspected recipes do not provide it as a uniform selection.

The handoff is completed by H, C, P, N. These rows transport, replay, cite, and name the same finite packet, so a downstream term-stratum consumer receives a recorded refusal package rather than an unrecorded choice object. □

Theorem 677.5 (ChoiceRecipeLedger effective replacement boundary)**.** *An accepted* ChoiceRecipeLedger$^{\uparrow}$ *packet gives an effective replacement for choice-output demand only at the level of finite recipe inspection and refusal accounting. It replaces the unavailable selected witness family by the recorded* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*, and axiom-purity refusal rows, and it does not claim a choice output, selected family, host-level selector, or global term-stratum closure.*

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerEffectiveReplacementBoundary`

Proof. Apply the term-stratum handoff. It supplies the finite request, recipe family, requested-output boundary, refusal row, transport, continuation, provenance, and local naming data as the replacement object available to consumers.

Apply non-escape. The packet has no coordinate for a selected family, host selector, hidden evaluator, or unrestricted choice functional, so the replacement cannot be read as the missing output.

Thus the boundary is exact: the effective object is the finite ledger and its refusal package. The statement of Definition 9387.34 is realized concretely by recording what survives in the term stratum and by refusing the unrecorded choice-output jump. □

Theorem 677.6 (ChoiceRecipeLedger finite recipe coverage)**.** *Every accepted* ChoiceRecipeLedger$^{\uparrow}$ *carrier*

$$L = (T, F, Q, A, H, C, P, N)$$

exposes F as the complete inspected witness-recipe surface for the request row T. The packet has no further recipe evaluator, no hidden recipe family, no quotient-selected recipe address, and no host rule that can enlarge F into an unrestricted choice functional.

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerCarrier finite recipe coverage`

Proof. Project the carrier of Definition 677.1. Its finite family row is exactly F, and the surrounding rows identify the request T, the requested-output boundary Q, the refusal row A, transport H, continuation route C, provenance P, and local naming N.

Apply the NameCert obligations. They require the finite witness-recipe coverage row to be part of the displayed local surface, so recipe inspection is public finite data rather than an external evaluator.

Apply non-escape. Since the packet has no coordinate for a hidden evaluator, quotient-selected address, selected witness family, or host choice rule, F is the complete inspected recipe surface available to consumers of the request. □

Theorem 677.7 (ChoiceRecipeLedger requested-output accountability)**.** *Any consumer asking an accepted* ChoiceRecipeLedger$^{\uparrow}$ *packet for the missing output Q must pass through the displayed rows*

$$T, F, Q, A, H, C, P, N$$

and must read the refusal row A before treating the request as discharged. In particular, the requested-output row is accountable to the finite recipe family and never bypasses the axiom-purity refusal.

Proof. Use the term-stratum handoff. It factors every consumer route through the request row T, the finite recipe family F, the requested-output boundary Q, and the refusal row A before the transport, continuation, provenance, and naming rows package the result.

Now apply non-escape. The packet does not export a selected family, unrestricted choice functional, hidden evaluator, quotient-selected address, or host choice rule. Therefore a consumer cannot discharge Q by leaving the displayed route.

It follows that the requested-output boundary is accountable to the finite ledger: the consumer reads T and F, reaches Q, and must pass through A when no recorded recipe supplies the missing uniform output. □

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerCarrier requested output accountability`

Theorem 677.8 (ChoiceRecipeLedger refusal-route determinacy)**.** *For an accepted* ChoiceRecipeLedger$^{\uparrow}$ *packet, the displayed* Cont *route C determines one accepted refusal outcome for the same request row T, finite recipe family F, and requested-output row Q. Componentwise* hsame *transport through H preserves that refusal route and cannot turn it into a selector.*

Proof. Read the carrier rows. The route coordinate is the displayed Cont row C, and its inputs are the same request T, finite family F, requested-output boundary Q, and refusal row A named by the carrier.

Apply the NameCert obligations. They bind displayed route stability to the local naming surface, so replaying the route under the admitted certificate keeps the same request, recipe-family row, requested-output boundary, and refusal row.

Finally use the effective replacement boundary. The replacement object is finite recipe inspection plus refusal accounting, not a selected witness family or unrestricted choice functional. Componentwise hsame transport through H therefore preserves the recorded refusal route without creating a selector. □

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerCarrier refusal route determinacy`

Theorem 677.9 (ChoiceRecipeLedger obligation closure package)**.** *The obligation surface of* ChoiceRecipeLedger$^{\uparrow}$ *is exactly the carrier of Definition 677.1, the NameCert obligations of Definition 677.2, finite recipe coverage from Definition 677.6, requested-output accountability from Definition 677.7, refusal-route determinacy from Definition 677.8, non-escape from Definition 677.3, term-stratum handoff from Definition 677.4, and the effective replacement boundary from Definition 677.5. It exports no unrestricted choice functional, selected witness family, hidden evaluator, quotient-selected recipe address, or host choice rule.*

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerCarrier obligation surface exhaustion`

Proof. The carrier and NameCert obligations provide the admitted tuple and its local obligation rows. These rows expose the request, finite recipe family, requested-output boundary, refusal, transport, continuation, provenance, and naming data.

Finite recipe coverage and requested-output accountability identify how consumers inspect the packet. The only recipe surface is F, and every demand for Q must pass through the refusal row A.

Refusal-route determinacy, non-escape, term-stratum handoff, and the effective replacement boundary then close the package. They preserve the displayed route under hsame and Cont, keep the packet inside its finite ledger, and prevent the recorded replacement from becoming an unrestricted choice principle. □

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerCarrier obligation closure package`

Theorem 677.10 (ChoiceRecipeLedger public bridge)**.** *The public* $\mathsf{NameCert}_{\mathsf{ChoiceRecipeLedger}^{\uparrow}}$ *interface bridges to the concrete finite refusal-ledger carrier by the route through carrier admission, NameCert obligations, finite recipe coverage, requested-output accountability, refusal-route determinacy, non-escape, term-stratum handoff, and the effective replacement boundary. The bridge exports no unrestricted choice functional, selected witness family, quotient-selected recipe address, hidden evaluator, or host choice rule.*

Proof. Apply the carrier admission and NameCert obligations. They identify the public interface with the rows T, F, Q, A, H, C, P, N and make the finite request, recipe-family, requested-output, refusal, transport, replay, provenance, and local naming data visible.

Finite recipe coverage, requested-output accountability, refusal-route determinacy, non-escape, term-stratum handoff, and the effective replacement boundary then carry the public route to the finite refusal ledger. These cited clauses show that replay preserves the same displayed rows and cannot supply a hidden selector, selected family, quotient-selected address, evaluator, unrestricted choice functional, or host choice rule. □

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerPublicBridge`

Theorem 677.11 (ChoiceRecipeLedger mature finite refusal-ledger package)**.** *The finite refusal-ledger treatment of* $\mathsf{ChoiceRecipeLedger}^{\uparrow}$ *is mature at the paper surface: carrier admission, NameCert obligations, finite recipe coverage, requested-output accountability, refusal-route determinacy, non-escape, term-stratum handoff, the effective replacement boundary, and the public bridge jointly expose the complete finite route from a request row to an accountable refusal. The package exports a public finite replacement for the displayed request surface and no unrestricted choice functional, selected witness family, quotient-selected recipe address, hidden evaluator, host selection rule, or unrecorded term-stratum premise.*

Proof. Read the accepted carrier of Definition 677.1 and the local NameCert obligations of Definition 677.2. These rows expose the request, finite recipe family, requested-output boundary, refusal row, transport, replay, provenance, and local naming data before any consumer can inspect the packet.

Apply finite recipe coverage, requested-output accountability, refusal-route determinacy, and non-escape from Definition 677.6, Definition 677.7, Definition 677.8, and Definition 677.3. These clauses keep every requested output inside the displayed finite ledger and force replay through the recorded refusal route.

Finally use the term-stratum handoff, effective replacement boundary, obligation closure package, and public bridge from Definition 677.4, Definition 677.5, Definition 677.9, and Definition 677.10. They assemble the public finite refusal-ledger route while preserving the exclusions of unrestricted choice, selected witness families, quotient-selected addresses, hidden evaluators, host selection rules, and unrecorded premises. □

Lean4 ✓ `BEDC.Derived.ChoiceRecipeLedgerUp.ChoiceRecipeLedgerCarrier mature package`

Closure status for $\mathsf{NameCert}_{\mathsf{ChoiceRecipeLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{ChoiceRecipeLedger}^{\uparrow}$ packet is generated from a term-stratum request row, a finite witness-recipe family, a requested-output boundary, an axiom-purity refusal row, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ChoiceRecipeLedger}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 677.1, Definition 677.2, Definition 677.6, Definition 677.7, Definition 677.8, Definition 677.9, Definition 677.3, Definition 677.4, Definition 677.5, Definition 677.10, and Definition 677.11 expose the mature public finite refusal-ledger bridge over carrier, obligation, coverage, accountability, determinacy, non-escape, handoff, replacement, BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ChoiceRecipeLedger}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, unrestricted choice, selected witness families, quotient-selected recipe addresses, host-level selection rules, global term-stratum closure, or a public standard bridge.

Upgrade path: Mature closure requires the checked standard bridge and Lean-side verification of the public bridge route.

Chapter 678

A Concrete Naming Certificate for $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$

The $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ packet records the finite selector-budget step used by the Real completeness diagonal construction. It binds a displayed regular Cauchy modulus, the selected finite window budget, StreamName observation rows, a RegSeqRat witness row, the RealUp seal handoff, and the BEDC transport rows as one inspectable naming certificate. It is a local finite packet between modulus selection and seal delivery; it is not a host limit, quotient stream equality, countable choice principle, or ambient completeness theorem.

Definition 678.1 (RegularCauchySelectorBudget carrier)**.** *A* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (\mu, W, S, R, E, H, C, P, N)$$

with the following displayed rows:

1. *μ is the selector-modulus row read from the regular Cauchy input at the requested precision;*
2. *W is the finite window-budget row naming the selected indices and StreamName observation extent allowed by μ;*
3. *S is the finite family of* $\mathsf{StreamName}^{\uparrow}$ *observation rows opened by the selected window budget;*
4. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *witness row assembled from those observations for the diagonal handoff;*
5. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row through which the completion-facing consumer reads the selected regular witness;*
6. *H records componentwise* hsame *transports for the modulus, window budget, StreamName rows, RegSeqRat witness, RealUp seal, and local structural rows;*
7. *C records the displayed* Cont *routes for modulus inspection, window coverage, observation readback, RegSeqRat handoff, RealUp seal delivery, and non-escape inspection;*
8. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchySelectorBudget}^{\uparrow}}$ *row.*

The local classifier compares accepted carriers only through the visible rows $\mu, W, S, R, E, H, C, P, N$.

The carrier consumes the finite-window service of chapter 126 through S and hands the selected-window budget W to the Cauchy modulus refinement route in chapter 885, where the same budget is read before the dyadic, rational, and Real-seal rows.

Theorem 678.2 (RegularCauchySelectorBudget NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchySelectorBudg}}$ *surface for Definition 678.1 consists of carrier admission, selector-modulus exactness, finite window-budget coverage, StreamName observation readback,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness handoff,* $\mathsf{Real}^{\uparrow}$ *seal boundary, componentwise* hsame *stability, displayed* Cont *route stability,* Pkg *provenance, and non-escape from host limits, quotient streams, countable choice, hidden window enlargement, and ambient completeness.*

Lean4 ✓ `BEDC.Derived.RegularCauchySelectorBudgetUp.RegularCauchySelectorBudgetCarrier namecert obligations`

Proof. Carrier admission is the tuple in Definition 678.1. It displays the selector modulus, finite window budget, StreamName rows, RegSeqRat witness, RealUp seal, transports, routes, provenance, and local naming row.

Selector-modulus exactness and window-budget coverage are read from μ and W. The StreamName observations S and the RegSeqRat witness R are listed after those rows, so the witness route cannot bypass the selected finite budget.

The RealUp seal boundary is the role of E, while the structural obligations are the roles of H, C, P, N. Since the carrier has no coordinate for a host limit, quotient stream equality, countable choice, hidden window enlargement, or ambient completeness, non-escape follows by inspection of the displayed packet. □

Theorem 678.3 (RegularCauchySelectorBudget window coverage)**.** *Every accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier covers its diagonal observation request through the displayed finite window budget* W*. For*

$$Q = (\mu, W, S, R, E, H, C, P, N),$$

each StreamName row in S *is opened only inside the indices and observation extent named by* W*, and the budget* W *is itself read from the selector modulus row* μ*.*

Proof. Project the rows μ and W from the carrier. The window budget is an explicit coordinate whose role is to name the finite indices and observation extent admitted by the selected modulus route.

The StreamName rows S are listed after W and are consumed by the same continuation data. Thus an accepted observation row is available only as part of the selected finite budget.

The remaining rows R, E, H, C, P, N consume the displayed observations. No row permits an unbounded stream scan or a second selector, so window coverage is confined to W. □

Theorem 678.4 (RegularCauchySelectorBudget RegSeqRat handoff)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *witness exported by an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier factors through the finite route*

$$\mu, W, S, R, H, C, P, N.$$

The handoff preserves the selected modulus, finite window budget, StreamName observation rows, componentwise hsame *transports, displayed* Cont *routes, package provenance, and local naming row.*

Lean4 ✓ `BEDC.Derived.RegularCauchySelectorBudgetUp.RegularCauchySelectorBudgetCarrier regseqrat handoff`

Proof. Use Definition 678.3 to identify the selected modulus and finite window budget. This fixes μ, W, S as the only observation data available to the witness route.

The witness row R is listed after the observations and is routed through the same structural rows. Therefore every exported $\mathsf{RegSeqRat}^{\uparrow}$ witness consumes the displayed StreamName packet before it can be read by a downstream consumer.

Inspect H, C, P, N. These rows keep the handoff stable under hsame transport, continuation replay, package provenance, and local naming, so the RegSeqRat handoff is exactly the displayed finite route. □

Theorem 678.5 (RegularCauchySelectorBudget Real seal boundary)**.** *Every Real completeness consumer of an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier reaches* $\mathsf{Real}^{\uparrow}$ *only through the seal row E after the* $\mathsf{RegSeqRat}^{\uparrow}$ *witness row R has been assembled from the selected StreamName window budget. The carrier exports no host-selected limit, quotient stream equality, countable choice selector, hidden observation budget, or ambient completeness witness.*

Proof. Project the seal row E from the carrier. It appears after the RegSeqRat witness R, so a real-facing route reaches $\mathsf{Real}^{\uparrow}$ only after the finite witness handoff has been assembled.

Apply Definition 678.4. The witness R is already bound to the modulus, window budget, StreamName observations, transports, routes, provenance, and local naming row.

The carrier contains no coordinate for a host-selected limit, quotient stream equality, countable choice selector, hidden observation budget, or ambient completeness. Hence the RealUp seal is a boundary around the displayed finite packet and exports no additional real object. □

Theorem 678.6 (RegularCauchySelectorBudget non-escape)**.** *An accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier cannot be used to recover data outside the displayed tuple $\mu, W, S, R, E, H, C, P, N$. In particular, it does not produce an unbounded family of StreamName observations, a second modulus selector, a quotient of regular sequences, a host real limit, or a completeness principle for* $\mathsf{Real}^{\uparrow}$.

Proof. Read the carrier coordinates from Definition 678.1. Every exported route is one of the displayed finite rows, with H, C, P, N providing only transport, continuation, provenance, and naming structure for those rows.

The window coverage theorem confines StreamName observations to W, and the RegSeqRat handoff confines the witness to μ, W, S, R, H, C, P, N. The Real seal boundary then confines completion-facing reads to E after that finite witness route.

Since no additional coordinate is present, the packet has no source for unbounded observations, a second selector, quotient regular sequences, host real limits, or a RealUp completeness principle. □

Theorem 678.7 (RegularCauchySelectorBudget obligation closure)**.** *The accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet*

$$Q = (\mu, W, S, R, E, H, C, P, N)$$

closes the local selector-budget obligation surface by packaging the carrier admission of Definition 678.1, the finite window coverage of Definition 678.3, the $\mathsf{RegSeqRat}^{\uparrow}$ *handoff of Definition 678.4, the* $\mathsf{Real}^{\uparrow}$ *seal boundary of Definition 678.5, and the non-escape clause of Definition 678.6 as one finite* BHist *certificate.*

Proof. Carrier admission supplies the displayed tuple Q. The selector-modulus row μ and finite window row W determine which StreamName observations S are available.

Apply Definition 678.3. It confines the observation rows to the selected finite budget and rules out hidden enlargement of the StreamName read.

Apply Definition 678.4 and Definition 678.5. These rows force the RegSeqRat witness and RealUp seal to be downstream of the same finite packet.

Finally use Definition 678.6. Since no coordinate outside $\mu, W, S, R, E, H, C, P, N$ is present, the listed rows exhaust the local selector-budget obligations. □

Theorem 678.8 (RegularCauchySelectorBudget formal target surface)**.** *The Lean-facing target surface for* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *is the finite* BHist *carrier* $Q = (\mu, W, S, R, E, H, C, P, N)$ *together with componentwise* hsame *rows in* H*, displayed* Cont *routes in* C*,* Pkg *provenance in* P*, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchySelectorBudget}^{\uparrow}}$ *row* N*. A formalization of this surface must expose exactly the selector-modulus row, finite window budget, StreamName observation rows,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness,* $\mathsf{Real}^{\uparrow}$ *seal, transport rows, route rows, provenance row, and naming row, with no host limit or quotient stream coordinate.*

Proof. Read the rows of Definition 678.1. The first five coordinates carry the selector modulus, finite window budget, StreamName observations, RegSeqRat witness, and RealUp seal.

The structural coordinates are also displayed. The row H supplies componentwise hsame stability, C supplies continuation replay, P supplies package provenance, and N supplies the local naming certificate.

Thus a Lean target can be stated over the same finite BHist packet. Because the carrier has no coordinate for host limits, quotient streams, or ambient completeness, those objects cannot appear in the formal target surface. □

Theorem 678.9 (RegularCauchySelectorBudget verification handoff)**.** *Downstream Real and Completion formalization consumes a* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet only through the finite route*

$$\mu, W, S, R, E, H, C, P, N.$$

The consumer first reads the selector modulus and finite window budget, then reads the StreamName observations, then assembles the $\mathsf{RegSeqRat}^{\uparrow}$ *witness, and only then reaches the* $\mathsf{Real}^{\uparrow}$ *seal. The handoff supplies no countable choice selector, quotient of regular sequences, hidden observation budget, host-selected real limit, or ambient RealUp completeness theorem.*

Proof. Start with the obligation closure theorem. It packages carrier admission, window coverage, RegSeqRat handoff, RealUp seal boundary, and non-escape into the single finite packet Q.

The formal target surface theorem names the rows that Lean must expose. These are exactly the rows consumed by the downstream Real and Completion route.

Reading the rows in order gives the handoff discipline: μ and W select the finite observation budget, S supplies the observations, R supplies the regular-rational witness, and E supplies the seal. The non-escape theorem removes countable choice, quotient regular sequences, hidden budgets, host real limits, and ambient completeness from the handoff. □

Theorem 678.10 (RegularCauchySelectorBudget consumer exactness)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier*

$$Q = (\mu, W, S, R, E, H, C, P, N)$$

reads exactly the displayed finite route $\mu, W, S, R, E, H, C, P, N$*. The* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer surface stops at the witness row* R *together with the selector modulus, finite window budget, StreamName*

rows, componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row. The* $\mathsf{Real}^{\uparrow}$ *consumer surface reaches the seal row E only after the same* $\mathsf{RegSeqRat}^{\uparrow}$ *witness route has been read, and it receives no additional host limit, quotient stream equality, countable choice selector, hidden window budget, or ambient completeness witness.*

Proof. Start with the carrier definition. The tuple Q displays exactly the selector modulus, finite window budget, StreamName observation rows, RegSeqRat witness, RealUp seal, transports, routes, provenance, and local naming row.

Apply Definition 678.3 and Definition 678.4. These identify the $\mathsf{RegSeqRat}^{\uparrow}$ consumer route with μ, W, S, R, H, C, P, N and force the witness row to consume only the selected finite window.

Next apply Definition 678.5. The $\mathsf{Real}^{\uparrow}$ consumer reaches E only after the RegSeqRat witness has been assembled through that same finite route.

Finally use Definition 678.6, Definition 678.7, and Definition 678.9. These rows exhaust the packet surface and exclude every route outside $\mu, W, S, R, E, H, C, P, N$. □

Theorem 678.11 (RegularCauchySelectorBudget diagonal use)**.** *Every diagonal Real-completion consumer of an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet*

$$Q = (\mu, W, S, R, E, H, C, P, N)$$

must first read the selector modulus μ, finite window budget W, $\mathsf{StreamName}^{\uparrow}$ *observations S,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness R, and* $\mathsf{Real}^{\uparrow}$ *seal E through the displayed H, C, P, N rows. No diagonal consumer may substitute a host limit, quotient-stream equality, countable choice selector, hidden window enlargement, or ambient completeness witness for those finite rows.*

Proof. Begin with Definition 678.3. It binds every observation request to the selected finite window budget W read from the selector modulus μ.

Apply Definition 678.4. The $\mathsf{RegSeqRat}^{\uparrow}$ witness R is assembled only after the StreamName observations S have been read through the same transport, route, provenance, and naming rows.

Next use Definition 678.5. The $\mathsf{Real}^{\uparrow}$ seal E is available only after that finite RegSeqRat route has been displayed.

Finally apply Definition 678.6 and Definition 678.10. These results exhaust the diagonal consumer surface at $\mu, W, S, R, E, H, C, P, N$ and exclude host limits, quotient-stream equality, countable choice selectors, hidden window enlargement, and ambient completeness witnesses. □

Theorem 678.12 (RegularCauchySelectorBudget tail selector compatibility)**.** *Every tail-selector read through an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier is compatible with the same selector modulus μ and finite window budget W. A tail row may inspect only StreamName observations inside S, may assemble its regular rational witness only through R, and may reach any Real-facing seal only through E after the route μ, W, S, R, H, C, P, N has been displayed.*

Proof. Read the selector rows μ and W from Definition 678.1. The window coverage theorem makes W the selected finite observation budget determined by μ.

A tail-selector read is therefore a consumer of the displayed StreamName rows S. Apply Definition 678.4 to force the corresponding regular rational witness through R and the structural rows H, C, P, N.

For a Real-facing tail read, apply Definition 678.5. The seal E is available only after the same finite RegSeqRat witness route has been consumed.

The non-escape and verification handoff theorems rule out a second selector modulus, a larger window, or an independent tail budget. Thus every tail-selector read remains compatible with μ and W. □

Theorem 678.13 (RegularCauchySelectorBudget Real completeness handoff)**.** *A RealCompleteness handoff that consumes an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet may use only the selector modulus* μ*, the finite window budget* W*, the StreamName rows* S*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *witness row* R*, the* $\mathsf{Real}^{\uparrow}$ *seal row* E*, componentwise* hsame *transports* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchySelectorBudget}^{\uparrow}}$ *row* N*. It does not receive a quotient stream, a host-selected real limit, countable choice, hidden window enlargement, or an ambient RealUp completeness theorem from the packet.*

Proof. Project the carrier $Q = (\mu, W, S, R, E, H, C, P, N)$. These are the only rows available to a RealCompleteness handoff from the selector-budget packet.

Use Definition 678.3 to bind S to the finite window budget W selected by μ. Use Definition 678.4 to bind R to those StreamName observations and to the structural rows.

Use Definition 678.5 to make E the only Real-facing seal and to place it after the RegSeqRat witness route. The rows H, C, P, N then provide only transport, continuation replay, provenance, and local naming for that same packet.

Finally apply Definition 678.6, Definition 678.7, and Definition 678.9. The handoff surface is exhausted by the displayed packet, so RealCompleteness receives no additional completion principle or hidden real object from this chapter. □

Definition 678.14 (RegularCauchySelectorBudget tail-precision source)**.** *The tail-precision source of an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier is the finite row package*

$$\mathsf{TailPrec}(Q) = (\mu, W, S, R, D, E, H, C, P, N)$$

where μ *is the selector-modulus row,* W *is the selected finite window budget,* S *is the StreamName observation family,* R *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *witness row,* D *is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row requested by the tail consumer,* E *is the* $\mathsf{Real}^{\uparrow}$ *seal,* H *records componentwise* hsame *transports,* C *records displayed* Cont *routes,* P *records* Pkg *provenance, and* N *is the local* NameCert *source.*

Theorem 678.15 (RegularCauchySelectorBudget tail-precision exactness)**.** *For an accepted* RegularCauchySelector *packet with tail-precision source*

$$\mathsf{TailPrec}(Q) = (\mu, W, S, R, D, E, H, C, P, N),$$

the dyadic tolerance row D *determines the only permitted finite window budget through* μ, W*. Every StreamName observation read is inside* S*, every* $\mathsf{RegSeqRat}^{\uparrow}$ *witness read factors through* R*, and every* $\mathsf{Real}^{\uparrow}$ *consumer reaches only* E *after the route*

$$D \longrightarrow \mu \longrightarrow W \longrightarrow S \longrightarrow R \longrightarrow E$$

with transport, replay, provenance, and local naming supplied by H, C, P, N*. No accepted route exports a quotient stream, host real equality, chosen limit, infinite tail, hidden window enlargement, or ambient completeness witness.*

Lean4 ✓ `BEDC.Derived.RegularCauchySelectorBudgetUp.RegularCauchySelectorBudgetCarrier tail precision exactness`

Proof. Project the finite tail-precision tuple. The tolerance row D, selector-modulus row μ, and finite window row W are explicit coordinates of Definition 678.14, so a precision read has no source for a second tolerance-to-window route.

Apply Definition 678.3 and Definition 678.16. These bind the selected StreamName observations to the finite budget chosen through μ, W and force the tail consumer to pass through $D, \mu, W, S, R, E, H, C, P, N$.

Next use Definition 678.4. The $\mathsf{RegSeqRat}^{\uparrow}$ witness row is downstream of the displayed StreamName observations, so every regular-rational witness factors through R together with the same structural rows.

Finally apply Definition 678.17 and Definition 678.26. The Real-facing read reaches only the seal row E after the finite route has been displayed, and the excluded quotient, host equality, chosen-limit, infinite-tail, hidden-budget, and ambient-completeness data are not coordinates of the packet. □

Theorem 678.16 (RegularCauchySelectorBudget tail budget totality)**.** *Every accepted* RegularCauchySelectorBudg *packet exposes the requested tail precision and its selected finite window through the rows of Definition 678.14. A tail consumer may read the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row D, the selector modulus μ, and the finite budget W, and may assemble the corresponding StreamName and* $\mathsf{RegSeqRat}^{\uparrow}$ *evidence only through S, R, H, C, P, N before reaching the* $\mathsf{Real}^{\uparrow}$ *seal E.*

Proof. Project the accepted carrier and its tail-precision source. The rows μ, W, D display the requested precision interface: D names the tolerance row, μ names the selector modulus, and W names the finite window selected for that tolerance.

Use Definition 678.3. It confines every StreamName observation in S to the finite window budget W selected by μ.

Use Definition 678.4 and Definition 678.13. The witness row R and seal row E are downstream of the same finite route, while H, C, P, N provide transport, continuation, provenance, and local naming for the displayed precision source. □

Theorem 678.17 (RegularCauchySelectorBudget precision-window non-escape)**.** *No* $\mathsf{Real}^{\uparrow}$ *consumer reading Definition 678.14 can recover quotient streams, host equality of regular sequences, chosen limits, infinite tails, or ambient completeness. The packet exposes only the tolerance row D, selector modulus μ, finite window budget W, StreamName observations S,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness R,* $\mathsf{Real}^{\uparrow}$ *seal E, and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Start with Definition 678.14. The listed rows are the whole tail-precision source, and none is a quotient stream, host equality proof, chosen limit, infinite tail, or ambient completeness object.

Apply Definition 678.16. It makes every precision read pass through $D, \mu, W, S, R, E, H, C, P, N$ and keeps the selected observation window finite.

Finally apply Definition 678.6 and Definition 678.13. These boundaries already exclude quotient streams, host-selected limits, hidden window enlargement, and completion principles from the selector-budget packet, so the tail-precision source exports no stronger RealUp data. □

Theorem 678.18 (RegularCauchySelectorBudget tail-meet factorization)**.** *Let Q be an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet with tail-precision source*

$$\mathsf{TailPrec}(Q) = (\mu, W, S, R, D, E, H, C, P, N).$$

Let T be an accepted $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet from chapter 560 whose shared-tail presentation uses the same displayed tolerance row D, finite window rows W, regular witness row R, componentwise transports H, displayed routes C, provenance P, and local naming rows. Then every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *consumer of the selector-budget tail source factors through the TailMeet shared-threshold row of T before reaching the* $\mathsf{Real}^{\uparrow}$ *seal E.*

The factorization exports no quotient stream, host real equality, chosen limit, infinite tail, ambient completeness row, or hidden threshold oracle.

Proof. Start with the tail-precision source in Definition 678.14. Its only selector-budget precision coordinates are $D, \mu, W, S, R, E, H, C, P, N$.

Apply Definition 678.16. It makes every admitted tail read pass through the displayed tolerance row, selector modulus, finite window budget, StreamName observations, regular witness, transports, routes, provenance, and local name before any seal read is available.

Use Definition 560.34 for the accepted $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ packet T. Since the tolerance, window, witness, transport, route, provenance, and naming rows are shared with $\mathsf{TailPrec}(Q)$, the TailMeet consumer route supplies the shared-threshold row as the common finite threshold packet for the $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ consumers.

Now apply Definition 678.17 together with Definition 560.50. The selector-budget side cannot bypass $D, \mu, W, S, R, E, H, C, P, N$, and the TailMeet side cannot turn the shared threshold into host equality, a selected limit, an infinite tail, ambient completeness, or a hidden oracle.

Thus every consumer route first passes through the TailMeet shared-threshold row and only then reaches the selector-budget real seal E. The resulting route is a finite factorization through the displayed packet rows, with none of the excluded quotient, host, selection, tail, completeness, or oracle data exported. □

Theorem 678.19 (RegularCauchySelectorBudget tail-meet selector exhaustion)**.** *Let Q be an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet with tail-precision source*

$$\mathsf{TailPrec}(Q) = (\mu, W, S, R, D, E, H, C, P, N).$$

Any tail-meet selector route through Q is exhausted by the displayed rows

$$D, \mu, W, S, R, E, H, C, P, N$$

together with the imported $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared threshold before a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompleteness}^{\uparrow}$ *consumer can read the budget packet. The route cannot add quotient streams, host equality, chosen limits, infinite tails, hidden budget, or ambient completeness.*

Proof. Start with the selector-budget packet. By Definition 678.16, every admitted tail read uses the displayed tolerance row, selector modulus, finite window budget, StreamName observations, regular witness, Real seal, transports, routes, provenance, and local name.

Next insert the shared threshold. The tail-meet factorization of Definition 678.18 routes every Real or tail-fusion consumer through the accepted $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold before the seal row E is available.

The precision-window boundary then removes alternate sources. Apply Definition 678.17; it excludes quotient streams, host equality, chosen limits, infinite tails, and ambient completeness from the selector-budget tail source.

Finally apply the Real-completeness handoff of Definition 678.13. The budget packet reaches the completion-facing consumer only through the same displayed rows and the imported shared threshold, so no hidden budget or ambient completeness route remains. □

Theorem 678.20 (RegularCauchySelectorBudget tail-meet threshold coverage)**.** *Let Q be an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet with tail-precision source*

$$\mathsf{TailPrec}(Q) = (\mu, W, S, R, D, E, H, C, P, N).$$

Let T be an accepted $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet whose shared-threshold route transports the same tolerance row D, finite window budget W, StreamName observations S,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness R,* $\mathsf{Real}^{\uparrow}$ *seal E, componentwise transports H, displayed routes C, provenance P, and local naming rows. Then every Real-facing read of Q is covered by the TailMeet shared-threshold row before E is read.*

Proof. First project the tail-precision source. The displayed selector-budget rows are exactly $\mu, W, S, R, D, E, H, C, P, N$, so a Real-facing read has no source outside this finite packet.

Use Definition 678.16 and Definition 678.17. They force the tolerance row, selector modulus, finite window budget, observations, regular witness, seal, transports, routes, provenance, and name to remain visible before the seal can be consumed.

Now apply Definition 678.18. The transported tolerance, window, witness, structural, provenance, and naming rows are the rows consumed by T.

Finally use Definition 560.34 and Definition 560.50. The TailMeet packet supplies the shared threshold as the finite ledger reached before any Real-facing read, and it exports no hidden threshold oracle or ambient completeness data. □

Theorem 678.21 (RegularCauchySelectorBudget diagonal consumer non-escape)**.** *Every accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet consumed by a diagonal reader or by a* $\mathsf{Real}^{\uparrow}$ *seal reader factors through the finite carrier route*

$$\mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to \mathsf{RegSeqRat}^{\uparrow} \to \mathsf{Real}^{\uparrow}.$$

The factorization uses only the displayed BHist *packet, componentwise* hsame *rows, finite* Cont *routes,* Pkg *provenance, and local* NameCert *rows of the selector-budget carrier. It exports no quotient stream, selected limit, trichotomy row, hidden window enlargement, countable-choice selector, host real equality, or ambient completeness witness.*

Proof. First project the accepted selector-budget tail source. The displayed rows $\mu, W, S, R, D, E, H, C, P, N$ place the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance row D and finite window budget W before the StreamName observation row S, the $\mathsf{RegSeqRat}^{\uparrow}$ witness row R, and the $\mathsf{Real}^{\uparrow}$ seal row E.

Apply Definition 678.20. It forces each Real-facing tail read to pass through the TailMeet shared-threshold row before E is read, so the diagonal consumer cannot bypass the finite dyadic threshold route.

Next use Definition 678.4, Definition 678.5, and Definition 678.26. These rows place the RegSeqRat handoff after the StreamName observations and place the Real seal after the same handoff, all under H, C, P, N.

Finally compare the sibling pullback surfaces. The StreamName surface supplies only the displayed observation rows, the RegSeqRat surface consumes those observations as the finite regular-rational witness, and the Real surface receives only the seal row. Exhausting those coordinates rules out quotient streams, selected limits, trichotomy, host equality, hidden budget, and ambient completeness as consumer outputs. □

Theorem 678.22 (RegularCauchySelectorBudget tail-meet route determinacy)**.** *Two selector-budget reads using the same accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet and the same transported D, W, S, R, H, C, P, N rows reach the same shared dyadic threshold ledger. The determinacy is internal to the selector-budget tail source, the TailMeet shared-threshold route, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Proof. Start with the two selector-budget reads and project their tail-precision sources. The hypothesis identifies the tolerance row D, finite window budget W, StreamName observations S, regular witness R, transports H, routes C, provenance P, and naming rows N componentwise.

Apply Definition 678.20. Both reads must pass through the TailMeet shared threshold before any Real-facing seal read can occur.

Use Definition 560.56. The transported source, window, and modulus data in the TailMeet route determine one displayed dyadic threshold ledger.

The selector-budget factorization theorem then repacks that ledger for both reads. Since the structural rows are the same transported H, C, P, N rows, the two selector-budget reads reach the same shared threshold entry. □

Theorem 678.23 (RegularCauchySelectorBudget tail-meet non-escape)**.** *The composite* $\mathsf{RegularCauchySelectorBud}$ *and* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *route exports no quotient stream, host real equality, chosen limit, infinite tail, ambient completeness principle, or hidden threshold oracle. Its public data are only the selector-budget tail source rows* $\mu, W, S, R, D, E, H, C, P, N$ *and the TailMeet shared-threshold rows reached through the same displayed transports, routes, provenance, and local names.*

Proof. Begin on the selector-budget side. The precision-window non-escape theorem Definition 678.17 excludes quotient streams, host equality of regular sequences, chosen limits, infinite tails, and ambient completeness from $\mathsf{TailPrec}(Q)$.

Move to the shared-threshold side through Definition 678.18. The factorization routes admitted consumers into the TailMeet shared threshold rather than into an external completion or selection object.

Finally apply Definition 560.50 and Definition 560.56. The TailMeet ledger has no hidden threshold oracle, and duplicate transported reads reach the same displayed dyadic ledger. Therefore the composite route exports only the named finite rows and none of the excluded quotient, host, selection, tail, completeness, or oracle data. □

Theorem 678.24 (RegularCauchySelectorBudget selector-budget exactness)**.** *Let* $Q = (\mu, W, S, R, E, H, C, P, N)$ *be an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier. Every* $\mathsf{StreamName}^{\uparrow}$ *observation row in* S *and every* $\mathsf{RegSeqRat}^{\uparrow}$ *witness row read through* R *is admitted only through the selected pair* (μ, W)*:* μ *supplies the selector-modulus row,* W *supplies the finite observation budget selected by that row, and no accepted consumer may substitute a second modulus, a larger window, or an unlisted observation family.*

Proof. Start with the carrier definition. The tuple displays μ before W, then lists the StreamName observations S and the RegSeqRat witness R downstream of those selector rows.

Apply Definition 678.3. It binds every StreamName observation to the finite indices and observation extent named by W, with W itself read from μ.

Apply Definition 678.4. The witness row R consumes the same displayed StreamName packet through H, C, P, N, so the RegSeqRat route has no source outside the selected pair.

Finally use Definition 678.18 and Definition 678.23. Tail-facing reads factor through the same finite rows and export no hidden threshold oracle, second selector, or enlarged observation window. □

Theorem 678.25 (RegularCauchySelectorBudget finite-window provenance)**.** *For every accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier with tail-precision source*

$$\mathsf{TailPrec}(Q) = (\mu, W, S, R, D, E, H, C, P, N),$$

the provenance row P must name exactly the dependencies consumed by the finite selector route: $\mathsf{DyadicRatCore}^{\uparrow}$ *through D,* $\mathsf{StreamName}^{\uparrow}$ *through S,* $\mathsf{RegSeqRat}^{\uparrow}$ *through R,* $\mathsf{Real}^{\uparrow}$ *through E, and the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *rows through H, C, P, N.*

Proof. Project the tail-precision source. The row D supplies the dyadic tolerance, while $\mu, W, S, R, E, H, C, P, N$ supply the selected modulus, finite window, observations, witness, seal, transport, continuation, provenance, and local naming rows.

Use Definition 678.16. It forces every tail read to pass through $D, \mu, W, S, R, E, H, C, P, N$ before the Real seal can be reached.

Use Definition 678.24 and Definition 678.4. These identify the StreamName and RegSeqRat components as downstream of the selected finite window route.

Finally apply Definition 678.5, Definition 678.18, and Definition 678.23. The Real seal and TailMeet rows consume the same finite provenance surface, so P has no additional dependency to name. □

Theorem 678.26 (RegularCauchySelectorBudget Real seal non-escape package)**.** *A Real-facing consumer of an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet may read only the displayed rows $\mu, W, S, R, E, H, C, P, N$. It receives the Real seal boundary through E and the structural route through H, C, P, N, but it receives no quotient stream, host limit, countable choice selector, hidden window enlargement, ambient completeness principle, or unlisted TailMeet threshold.*

Proof. Read the carrier rows from Definition 678.1. The only Real-facing coordinate is the seal row E, and it is packaged with the selected finite rows μ, W, S, R, H, C, P, N.

Apply Definition 678.5. The consumer reaches $\mathsf{Real}^{\uparrow}$ only after the RegSeqRat witness has been assembled from the selected StreamName budget.

Apply Definition 678.6 and Definition 678.24. These rows exclude quotient streams, host limits, countable choice, second selectors, and hidden window enlargement from the packet surface.

Finally use Definition 678.18 and Definition 678.23. TailMeet interaction remains a finite factorization over displayed rows and contributes no ambient completeness principle or unlisted threshold object. □

Theorem 678.27 (RegularCauchySelectorBudget CauchyInverseBudget apartness handoff)**.** *When a* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *tail source also carries the apartness row needed for reciprocal Real reads, every inverse-facing consumer factors through the* $\mathsf{CauchyInverseBudget}^{\uparrow}$ *carrier of chapter 703. The consumer first reads the selector modulus, finite window budget,* $\mathsf{StreamName}^{\uparrow}$ *observations,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness, and* $\mathsf{Real}^{\uparrow}$ *seal rows of the selector-budget packet, then hands the apartness, modulus, finite-window, dyadic, readback, and seal rows to the reciprocal budget. It receives no quotient stream, host equality, chosen limit, countable choice selector, total reciprocal operation, trichotomy, or ambient completeness principle.*

Proof. Begin with the selector-budget tail source. By Definition 678.16, any tail read consumes the dyadic tolerance, selector modulus, finite window budget, StreamName observations, RegSeqRat witness, Real seal, transports, routes, provenance, and local naming rows before reaching the Real-facing boundary.

Apply Definition 678.26. The selector-budget side exports only the displayed rows $\mu, W, S, R, E, H, C, P, N$ to a Real-facing consumer and excludes quotient streams, host limits, countable choice, hidden window enlargement, and ambient completeness.

Now pass to the reciprocal budget through Definition 703.13. The additional apartness row is read as the A coordinate, the selected modulus and window are read as M, W, and the dyadic and regular rows are read as D, R inside the $\mathsf{CauchyInverseBudget}^{\uparrow}$ carrier.

Finally apply Definition 703.14 and Definition 703.8. They route the inverse-facing RegSeqRat and Real reads through $X, A, M, W, D, R, S, H, C, P, N$, so no total reciprocal operation, trichotomy row, host equality, quotient stream, chosen limit, countable choice selector, or ambient completeness principle is exported. □

Theorem 678.28 (RegularCauchySelectorBudget terminal-window lock)**.** *Let $Q = (\mu, W, S, R, E, H, C, P, N)$ be an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *carrier. Any terminal Phase Real or Completion consumer that uses the selected budget must read the same finite window W,* $\mathsf{StreamName}^{\uparrow}$ *observations S,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness R, and* $\mathsf{Real}^{\uparrow}$ *seal E through the displayed transports, continuation routes, provenance, and local naming rows H, C, P, N. It cannot substitute a quotient stream, host limit, countable-choice selector, hidden enlarged window, alternate terminal window, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. Start with the selector-budget exactness theorem Definition 678.24. It binds every StreamName observation and RegSeqRat witness read to the selected pair (μ, W), excluding a second modulus, larger window, or unlisted observation family.

Use finite-window provenance from Definition 678.25. The provenance row names exactly the StreamName, RegSeqRat, Real seal, transport, continuation, package, and NameCert dependencies consumed by the finite selector route.

Apply Definition 678.26. A terminal Real-facing read can reach only E after the selected finite rows have been displayed through H, C, P, N, so quotient streams, host limits, choice selectors, enlarged windows, and ambient completeness rows are outside the packet.

Finally combine the open-phase route of Definition 126.434. That route sends the StreamName window, RegSeqRat witness, and Real seal through the same open-phase seal path, so a terminal Phase Real or Completion consumer has no alternate terminal window to read. □

Theorem 678.29 (RegularCauchySelectorBudget finite-chain induction)**.** *Let $Q = (\mu, W, S, R, E, H, C, P, N)$ be an accepted* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *packet. Any terminal* $\mathsf{Real}^{\uparrow}$ *or Completion consumer route exhausted by Q is determined by induction over the displayed finite chain*

$$\mu \longrightarrow W \longrightarrow S \longrightarrow R \longrightarrow E \longrightarrow H, C, P, N.$$

The base step reads only the selector modulus μ and the finite window budget W; the observation step reads only the $\mathsf{StreamName}^{\uparrow}$ *rows selected by W; the witness step assembles only the* $\mathsf{RegSeqRat}^{\uparrow}$ *row R; the seal step reaches only the* $\mathsf{Real}^{\uparrow}$ *row E; and the structural step uses H, C, P, N only for transport, continuation, provenance, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchySelectorBudget}^{\uparrow}}$ *row. Consequently the terminal route exports no quotient stream, host limit, externally selected limit, countable-choice selector, hidden enlarged window, alternate terminal window, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness principle.*

Proof. For the base step, apply Definition 678.16 and Definition 678.24. These identify μ as the selector-modulus row and W as the finite window selected by it, with no second modulus or enlarged window available to the route.

For the observation step, use Definition 678.3. Every StreamName observation consumed by a downstream reader lies in the window named by W, so the induction passes from μ, W to only the displayed rows S.

For the witness step, apply Definition 678.4. The RegSeqRat evidence is assembled through R from the selected StreamName rows and the displayed structural rows, not from a quotient stream, host limit, or countable-choice selection.

For the seal step, combine Definition 678.5 with Definition 678.26. The Real-facing route reaches E only after the finite StreamName and RegSeqRat rows have been displayed, and it receives no externally selected limit or ambient completeness principle.

For the structural step, use Definition 678.25 to read H, C, P, N as the transport, continuation, provenance, and local NameCert rows of the same finite chain. Finally apply Definition 678.28. It rules out alternate terminal windows, so the induction over $\mu, W, S, R, E, H, C, P, N$ exhausts the terminal Phase Real or Completion route. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchySelectorBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ packet is generated from a selector modulus, finite window budget, StreamName observation rows, a RegSeqRat witness, a RealUp seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchySelectorBudget}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 678.1, Definition 678.2, Definition 678.3, Definition 678.4, Definition 678.5, Definition 678.6, Definition 678.7, Definition 678.8, Definition 678.9, Definition 678.10, Definition 678.12, Definition 678.13, Definition 678.14, Definition 678.15, Definition 678.16, Definition 678.17, Definition 678.18, Definition 678.19, Definition 678.20, Definition 678.22, Definition 678.23, Definition 678.24, Definition 678.25, Definition 678.26, Definition 678.28, and Definition 678.29 bind the finite selector-budget carrier, tail-meet selector exhaustion, terminal-window lock, finite-chain terminal induction, and local NameCert obligation surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchySelectorBudget}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.RegularCauchySelectorBudgetUp.RegularCauchySelectorBudgetCarrier\_namecert\_obligations`

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, RealUp completeness, quotient stream equality, host real limits, countable choice, hidden window enlargement, or a public standard bridge.

Upgrade path: No higher paper closure grade remains for this finite selector-budget bridge surface; Lean verification and bridge checking remain independent formal-axis work.

Chapter 679

A Concrete Naming Certificate for $\mathsf{CompilerCompositionTrace}^{\uparrow}$

The $\mathsf{CompilerCompositionTrace}^{\uparrow}$ interface packages sequential compiler composition as a finite trace over adjacent NameCert compiler graphs. It does not assert a host-level compiler category. It records the two displayed compiler packets, their shared middle certificate, the relational composite graph, classifier transport, continuation replay, associativity comparison, package provenance, and the local naming row.

Definition 679.1 (CompilerCompositionTrace carrier)**.** *A* $\mathsf{CompilerCompositionTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (S, M, T, K_{SM}, K_{MT}, J, G, L, H, C, A, P, N)$$

with the following displayed rows:

1. *S, M, and T are the source, middle, and target* NameCert *rows consumed by the two adjacent compiler graphs;*
2. *K_{SM} is the accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet from S to M;*
3. *K_{MT} is the accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet from M to T;*
4. *J is the middle-certificate compatibility row recording that the target endpoint of K_{SM} and the source endpoint of K_{MT} are the same displayed* NameCert *row M;*
5. *G is the composite compiler graph row from S to T, obtained by finite relational composition through a displayed middle history of M;*
6. *L is the classifier-transport ledger chaining source classifier membership through K_{SM}, the middle row J, and K_{MT} into target classifier membership;*
7. *H records componentwise* hsame *transport for the endpoint certificates, adjacent compiler packets, middle compatibility row, composite graph, classifier ledger, continuation routes, associativity row, package row, and local naming row;*
8. *C records displayed* Cont *replay for the first graph edge, middle handoff, second graph edge, composite edge, target readback, and downstream NameCert exposure;*
9. *A is the associativity comparison row stating that three adjacent accepted compiler packets have the same exported finite packet after either parenthesization of relational graph composition;*

10. *P names the dependency surface* BHist, hsame, Cont, Pkg, NameCert, NameCertMorphism$^{\uparrow}$, CertificateCompiler$^{\uparrow}$, ClassifierMorphism$^{\uparrow}$, KernelMorphismUp, *and* CompilerOptimizationEndomorphism$^{\uparrow}$*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{CompilerCompositionTrace}^{\uparrow}}$ *row.*

The carrier has no coordinate for a host compiler function, ambient program equality, denotational semantics, optimizer correctness outside the displayed rows, decompiler data, quotient equality, or a global categorical equality not witnessed by A.

Theorem 679.2 (CompilerCompositionTrace NameCert obligations)**.** *For the carrier of Definition 679.1, the local* $\mathsf{NameCert}_{\mathsf{CompilerCompositionTrace}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$Q = (S, M, T, K_{SM}, K_{MT}, J, G, L, H, C, A, P, N),$$

endpoint certificate admission, acceptance of the two adjacent CertificateCompiler$^{\uparrow}$ *packets, middle-certificate compatibility, composite graph formation, classifier transport, componentwise* hsame *transport, displayed* Cont *replay, associativity comparison, dependency provenance, and the local naming row.*

Lean4 ✓ `BEDC.Derived.CompilerCompositionTraceUp.CompilerCompositionTraceTasteGate single carrier alignment`

Proof. Project the displayed carrier. The packet exposes only the endpoint certificate rows S, M, T, the two adjacent compiler packets K_{SM}, K_{MT}, and the middle compatibility row J before the composite graph is read.

The composite graph obligation is then forced through G. A source-to-target edge is accepted only when it factors through a middle history already displayed by M and consumed by both adjacent compiler packets. The classifier obligation is the row L, which first reads the source classifier surface of K_{SM}, then the shared middle certificate in J, and finally the target classifier surface of K_{MT}.

The remaining certificate data are the transport and replay rows. Componentwise hsame evidence is read from H, continuation compatibility from C, associativity from A, dependency provenance from P, and local naming from N. Since the carrier contains no other coordinate, no host compiler function, semantic equality, quotient row, optimizer theorem, decompiler row, or ambient categorical law can be exported by the local $\mathsf{NameCert}_{\mathsf{CompilerCompositionTrace}^{\uparrow}}$ surface. □

Theorem 679.3 (CompilerCompositionTrace associativity)**.** *Let*

$$Q_{012} = (S_0, S_1, S_2, K_{01}, K_{12}, J_1, G_{02}, L_{02}, H_{02}, C_{02}, A_{02}, P_{02}, N_{02})$$

and

$$Q_{123} = (S_1, S_2, S_3, K_{12}, K_{23}, J_2, G_{13}, L_{13}, H_{13}, C_{13}, A_{13}, P_{13}, N_{13})$$

be accepted CompilerCompositionTrace$^{\uparrow}$ *packets sharing the adjacent compiler packet K_{12} and middle certificate rows S_1, S_2. For the three accepted compiler packets K_{01}, K_{12}, and K_{23}, the two displayed composites*

$$(K_{23} \circ K_{12}) \circ K_{01}$$

and

$$K_{23} \circ (K_{12} \circ K_{01})$$

export the same finite public packet: the same source row S_0, target row S_3, relational graph through the displayed middle rows, classifier-transport ledger, hsame *transports,* Cont *routes, package provenance, and local naming boundary. The equality is witnessed only by the associativity rows A_{02}, A_{13} and the componentwise transports recorded in the corresponding H and C rows.*

Lean4 ✓ BEDC.Derived.CompilerCompositionTraceUp.CompilerCompositionTrace associativity

Proof. Project the two accepted trace packets. The first trace exposes the composite from S_0 to S_2 through S_1, and the second exposes the composite from S_1 to S_3 through S_2. Their overlap is the displayed compiler packet K_{12} together with the middle certificate rows that both traces read.

Form the triple graph by finite relational composition. A displayed edge from S_0 to S_3 is accepted exactly when there are middle histories in S_1 and S_2 read by K_{01}, K_{12}, and K_{23} in that order. Parenthesizing the relational composition on the left or on the right does not introduce another endpoint, graph row, or classifier source; it only changes which binary trace row is consulted first.

The classifier and continuation ledgers replay the same rows in the same order. The first compiler transports source classifier membership into S_1, the second transports it into S_2, and the third transports it into S_3. The Cont routes in C_{02} and C_{13} record the same ordered handoff, while H_{02} and H_{13} supply the componentwise sameness comparisons needed to identify the public rows.

Finally read the associativity coordinates. The rows A_{02} and A_{13} state that the two parenthesized binary traces repack to the same displayed triple packet. The carrier has no coordinate for an external compiler function, semantic program equality, quotient collapse, or global category law, so the exported associativity evidence is exhausted by the displayed graph, classifier, transport, continuation, provenance, and local naming rows. □

Theorem 679.4 (CompilerCompositionTrace ContinuationMonad sibling route)**.** *Every accepted* $\mathsf{CompilerCompositionTrace}^{\uparrow}$ *packet consumes its continuation replay and classifier-preserving morphism data through the sibling route chapter 485, chapter 481, chapter 473, and chapter 590. The composite trace reads the continuation rows, adjacent NameCert morphism rows, compiler graph rows, and classifier transport rows from those concrete certificates, not from a host compiler function, quotient equality, semantic program equality, or global categorical law.*

Proof. Project the carrier Q. Its continuation replay row C, classifier ledger L, adjacent compiler packets K_{SM}, K_{MT}, and morphism provenance row P are displayed coordinates of the same finite trace.

The continuation component is read through chapter 485; the endpoint and middle certificate movement is read through chapter 481; the adjacent compiler graph data are read through chapter 473; and the classifier-preserving transport is read through chapter 590.

Finally use Definition 679.2 and Definition 679.3. They keep all composite trace data inside $S, M, T, K_{SM}, K_{MT}, J, G, L, H, C, A, P, N$, so the sibling route cannot be replaced by a host compiler function or quotient equality. □

Closure status for $\mathsf{NameCert}_{\mathsf{CompilerCompositionTrace}^{\uparrow}}$.

Constructive story: A $\mathsf{CompilerCompositionTrace}^{\uparrow}$ packet is generated from source, middle, and target NameCert rows, two adjacent $\mathsf{CertificateCompiler}^{\uparrow}$ packets, middle-certificate compatibility, a composite graph, classifier transport, componentwise hsame transports, displayed Cont routes, associativity comparison, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CompilerCompositionTrace}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 679.1, Definition 679.2, and Definition 679.3 bind the finite compiler-composition trace surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CompilerCompositionTrace}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close host compiler semantics, denotational program equality, optimizer correctness outside the displayed rows, decompiler behavior, quotient equality, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, adjacent compiler acceptance, middle-certificate compatibility, composite graph formation, classifier transport, continuation replay, associativity comparison, and non-escape for the same finite trace packet.

Chapter 680

A Concrete Naming Certificate for $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$

The $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$ packet records the finite selector route used when a Real and Completion diagonal-limit consumer asks for cofinal tail data through dyadic windows. It packages the requested precision, dyadic window family, selected cofinal tail, RegSeqRat readback, RealUp seal handoff, componentwise transport, continuation replay, provenance, and local naming in one displayed BHist carrier. The packet is a finite NameCert surface for cofinal-window selection; it is not an ambient compactness argument, quotient-stream equality, host-selected limit, countable choice rule, or hidden tail selector.

The finite cofinal family used here is scheduled by chapter 681 and later consumed by diagonal-limit selectors through chapter 697. This is a dependency on the displayed tail schedule and diagonal consumer route, not a self-reference to the local carrier.

Definition 680.1 (Dyadic cofinal tail selector carrier)**.** *A* $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (e, \mathcal{D}, t, w, r, a, h, c, p, n)$$

with the following displayed rows:

1. *e is the positive* $\mathsf{Rat}^{\uparrow}$ *precision request made by the diagonal-limit consumer;*
2. *$\mathcal{D}$ is the finite dyadic cofinal-window family opened at that request;*
3. *t is the selected cofinal tail index, displayed as a row in the same finite packet;*
4. *w is the finite* $\mathsf{StreamName}^{\uparrow}$ *observation window determined by t and $\mathcal{D}$;*
5. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row assembled from the selected dyadic window;*
6. *a is the* $\mathsf{Real}^{\uparrow}$ *seal handoff reached only through w and r;*
7. *h records componentwise* hsame *transports for the request, dyadic family, selected tail, window, readback, seal, and structural rows;*
8. *c records the displayed* Cont *route from e through $\mathcal{D}, t, w, r$ into a;*
9. *p is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and local certificate rows;*
10. *n is the local* $\mathsf{NameCert}_{\mathsf{DyadicCofinalTailSelector}^{\uparrow}}$ *row.*

The local classifier compares accepted carriers only through the visible rows $e, \mathcal{D}, t, w, r, a, h, c, p, n$.

Theorem 680.2 (Dyadic cofinal tail selector NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DyadicCofinalTailSelector}^{\uparrow}}$ *surface for Definition 680.1 consists of carrier admission for $S = (e, \mathcal{D}, t, w, r, a, h, c, p, n)$, positive* $\mathsf{Rat}^{\uparrow}$ *request exposure through e, finite dyadic cofinal-window family exposure through $\mathcal{D}$, selected tail exposure through t, finite* $\mathsf{StreamName}^{\uparrow}$ *window readback through w,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff through r,* $\mathsf{Real}^{\uparrow}$ *seal delivery through a, componentwise* hsame *stability through h, displayed* Cont *route stability through c,* Pkg *provenance through p, and local naming through n.*

Proof. Carrier admission is projection from the displayed tuple in Definition 680.1. The request, dyadic family, selected tail, window, readback, seal, transports, routes, provenance, and naming row are all visible coordinates of one finite packet.

The selector obligations are read in order. The request row e opens only the finite dyadic family $\mathcal{D}$, the selected tail t is recorded before any window row can be consumed, and the window row w is the only source for the RegSeqRat handoff r.

The RealUp seal row a is downstream of w and r, while h, c, p, n provide transport, route replay, provenance, and naming. Since the carrier has no coordinate for host-selected limits, quotient-stream equality, countable choice, or hidden selectors, the listed rows exhaust the local NameCert obligations. □

Lean4 ✓ `BEDC.Derived.DyadicCofinalTailSelectorUp.DyadicCofinalTailSelectorTasteGate single carrier alignment`

Theorem 680.3 (Dyadic cofinal-window exhaustion)**.** *For an accepted* $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$ *carrier*

$$S = (e, \mathcal{D}, t, w, r, a, h, c, p, n),$$

every cofinal-window read made by a Real and Completion diagonal-limit consumer is exhausted by the displayed finite dyadic family $\mathcal{D}$, the selected tail row t, the finite StreamName window w, the RegSeqRat readback row r, and the structural rows h, c, p, n. No consumer can replace this route by an unbounded window search, countable choice selector, host supremum argument, or external tail-selection function.

Proof. Project the accepted carrier. The only rows that carry cofinal-window data are $\mathcal{D}$, t, and w, and they are all displayed before the RegSeqRat and RealUp handoff rows.

The continuation row c routes the precision request through that finite family and selected tail before any readback is available. Componentwise transport along h preserves the same displayed rows, while p and n record provenance and local naming for the same packet.

Thus every cofinal-window read is already inside $e, \mathcal{D}, t, w, r, a, h, c, p, n$. The carrier provides no coordinate for an unbounded search, countable choice selector, host supremum, or external tail-selection function. □

Theorem 680.4 (Dyadic cofinal tail selector Real seal handoff)**.** *For an accepted* $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$ *carrier, the* $\mathsf{Real}^{\uparrow}$ *seal row a is reached only after the selected cofinal tail t has fixed the finite dyadic window family $\mathcal{D}$, the StreamName window row w, and the RegSeqRat readback row r. The real-facing handoff therefore factors through the displayed route*

$$e, \mathcal{D}, t, w, r, h, c, p, n$$

before it reaches a.

Proof. Read the carrier rows in order. The seal row a appears after the selected tail, finite window, and RegSeqRat readback rows, so a real-facing consumer cannot inspect the seal before the finite dyadic route has been fixed.

Use Definition 680.3. It confines the cofinal-window read to $\mathcal{D}, t, w, r, h, c, p, n$ and removes any hidden selector route.

The remaining structural rows transport and replay the same packet. Hence the RealUp handoff reaches a only through the displayed finite route and cannot import an ambient limit or quotient-stream comparison. □

Theorem 680.5 (Dyadic cofinal tail selector non-escape)**.** *An accepted* $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$ *carrier cannot be used to recover data outside the displayed tuple* $e, \mathcal{D}, t, w, r, a, h, c, p, n$*. In particular, it exports no unbounded dyadic window family, second tail selector, quotient of regular sequences, host real limit, countable choice rule, or RealUp completeness principle.*

Proof. The NameCert obligations identify every row available to a downstream consumer. The request, dyadic family, selected tail, window, readback, and seal rows are the only content rows, and h, c, p, n only transport, replay, package, and name those rows.

Apply the cofinal-window exhaustion theorem to any attempted window read. It forces the read through $\mathcal{D}, t, w, r, h, c, p, n$.

Apply the Real seal handoff theorem to any real-facing read. It forces the read through the selected dyadic window and RegSeqRat handoff before the seal row a can be consumed.

Since no additional coordinate is present, the packet has no source for unbounded windows, a second selector, quotient regular sequences, host real limits, countable choice, or a RealUp completeness principle. □

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicCofinalTailSelector}^{\uparrow}}$.

Constructive story: A $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$ packet is generated from a positive RatUp request, a finite dyadic cofinal-window family, a selected tail row, finite StreamName readback, RegSeqRat handoff, RealUp seal delivery, componentwise hsame transports, displayed Cont routes, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DyadicCofinalTailSelector}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 680.1, Definition 680.2, Definition 680.3, Definition 680.4, and Definition 680.5 bind the finite dyadic cofinal-tail selector carrier and its local NameCert obligation surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DyadicCofinalTailSelector}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, RealUp completeness, quotient stream equality, host real limits, countable choice, hidden tail selection, or a public standard bridge.

Upgrade path: Obligation closure requires checked carrier admission, dyadic family exposure, selected-tail coverage, StreamName readback, RegSeqRat handoff, RealUp seal delivery, route stability, provenance, and non-escape for the same finite packet.

Chapter 681

A Concrete Naming Certificate for $\mathsf{TailCofinalitySchedule}^{\uparrow}$

The $\mathsf{TailCofinalitySchedule}^{\uparrow}$ packet records the finite shared-threshold schedule used when a diagonal $\mathsf{Real}^{\uparrow}$ consumer must pass from dyadic tolerances and stream windows to $\mathsf{RegSeqRat}^{\uparrow}$ handoff rows and a $\mathsf{Real}^{\uparrow}$ seal. It names the schedule as an inspectable BHist surface, not as a host limit selector, quotient-stream equality, selected real, or ambient completeness principle.

The schedule is the consumer-facing route from chapter 126 through the displayed $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows, so its carrier records the finite L10 handoff rather than an isolated tail oracle.

Definition 681.1 (Tail cofinality schedule carrier)**.** *A* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (E, W, D, R, L, H, C, P, N)$$

with the following displayed coordinates:

1. *E is the unary precision request row naming the tolerance level demanded by the diagonal consumer;*
2. *W is the cofinal finite-window schedule selected for that request over the relevant* $\mathsf{StreamName}^{\uparrow}$ *rows;*
3. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger proving that the windows in W meet the requested dyadic bound;*
4. *R is the family of* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows made available after the window and dyadic ledgers have been consumed;*
5. *L is the* $\mathsf{Real}^{\uparrow}$ *seal row through which the diagonal consumer receives the scheduled regular-rational handoff;*
6. *H records componentwise* hsame *transports for E, W, D, R, L and the structural rows of the packet;*
7. *C records the displayed* Cont *routes from E to W, from W to D, from D to R, and from R to L;*
8. *P records* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*

9. N is the local $\mathsf{NameCert}_{\mathsf{TailCofinalitySchedule}^{\uparrow}}$ *row.*
The carrier has no coordinate for quotient stream equality, a host-selected limit, ambient completeness, a hidden tail oracle, or an unbounded schedule.

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleUp StdBridge`

Theorem 681.2 (Tail cofinality schedule NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{TailCofinalitySchedule}^{\uparrow}}$ *surface for Definition 681.1 consists exactly of carrier admission for $T = (E, W, D, R, L, H, C, P, N)$, unary precision exposure through E, cofinal finite-window coverage through W, threshold sufficiency through the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff through R,* $\mathsf{Real}^{\uparrow}$ *seal boundary through L, componentwise* hsame *transport through H, displayed* Cont *route replay through C,* Pkg *provenance through P, local naming through N, and non-escape from quotient streams, selected host limits, ambient completeness, hidden tail oracles, and unbounded schedules.*

Proof. Carrier admission is projection from the displayed packet. The rows E, W, D, R, L expose the precision request, finite cofinal schedule, dyadic tolerance ledger, regular-rational readback, and real-facing seal.

The schedule and threshold obligations are read in order. The route from E to W selects the finite cofinal windows, and the route from W to D records the dyadic sufficiency ledger for those same windows.

The handoff and seal obligations then consume R and L. Componentwise transport, route replay, provenance, and naming are exactly the rows H, C, P, N. Since no further analytic coordinate occurs in T, the listed rows exhaust the certificate surface. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier namecert obligations`

Theorem 681.3 (Tail cofinality schedule diagonal handoff)**.** *Every diagonal* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *carrier factors through the finite rows*

$$E, W, D, R, L, H, C, P, N.$$

The consumer first reads the unary precision request, then the cofinal finite-window schedule, then the dyadic tolerance ledger, then the $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows, and finally the* $\mathsf{Real}^{\uparrow}$ *seal row. It cannot read quotient streams, selected host limits, ambient completeness, a hidden tail oracle, or an unbounded schedule.*

Proof. Start with the carrier and the NameCert obligation surface. They display the only route from the requested precision to the real-facing seal as

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L.$$

The cofinal window coverage and threshold sufficiency clauses force the dyadic ledger to be consumed before any regular-rational row is available. Thus a diagonal handoff cannot jump from the precision request directly to a $\mathsf{RegSeqRat}^{\uparrow}$ witness or to a $\mathsf{Real}^{\uparrow}$ seal.

The rows H, C, P, N replay and name the same route under transport and provenance. Because the carrier has no coordinate for quotient stream equality, host-selected limits, ambient completeness, hidden tail oracles, or unbounded schedules, every diagonal consumer remains inside the displayed finite packet. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier diagonal handoff`

Theorem 681.4 (Tail cofinality schedule finite-window coverage)**.** *Let $T = (E, W, D, R, L, H, C, P, N)$ be an accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *carrier. Every unary precision request exposed by E is routed through the displayed* $\mathsf{StreamName}^{\uparrow}$ *finite-window row W before any* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *row is readable. The route has no quotient-stream equality, host-selected limit, hidden tail oracle, or unbounded schedule coordinate.*

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier window coverage`

Proof. Project the carrier. The only precision row is E, and the only finite-window schedule row attached to it is W.

Apply Definition 681.2. The local certificate lists cofinal finite-window coverage through W as the obligation immediately downstream from unary precision exposure through E.

Finally use Definition 681.3. Its displayed handoff route begins $E \longmapsto W$, so a consumer cannot bypass W to reach D, R, or L. Since the carrier contains no analytic escape coordinate, the finite-window route is exhaustive. □

Theorem 681.5 (Tail cofinality schedule threshold sufficiency)**.** *For an accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *carrier $T = (E, W, D, R, L, H, C, P, N)$, every* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row in R is available only after the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D records the dyadic threshold supplied by the finite-window schedule W. No regular-rational readback is supplied by a host limit selector, ambient completeness principle, hidden tail oracle, or unbounded schedule.*

Proof. Read W, D, R from the displayed packet. The schedule row W names the finite stream windows, and the dyadic ledger D records the threshold bound for those same windows.

Apply Definition 681.2. It places threshold sufficiency through D between finite-window coverage and $\mathsf{RegSeqRat}^{\uparrow}$ handoff.

The diagonal handoff theorem then gives the route $W \longmapsto D \longmapsto R$. Thus every regular-rational readback consumes the dyadic ledger first, and the packet has no coordinate from which an unbounded or host-selected readback could be recovered. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier threshold sufficiency`

Theorem 681.6 (Tail cofinality schedule Real seal readback)**.** *Let $T = (E, W, D, R, L, H, C, P, N)$ be an accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet. Every* $\mathsf{Real}^{\uparrow}$ *consumer reaches the seal row L only after consuming the precision row E, the finite-window row W, the dyadic ledger D, the regular-rational readback row R, and the structural rows H, C, P, N. The seal readback does not expose quotient streams, host-selected limits, ambient completeness, hidden tail oracles, or unbounded schedules.*

Proof. Start with the carrier and the obligation theorem. They identify L as the real-facing seal row and identify H, C, P, N as the transport, continuation, package, and naming rows that replay the displayed route.

Apply Definition 681.3. It orders the analytic rows as $E \longmapsto W \longmapsto D \longmapsto R \longmapsto L$.

It remains to account for the structural rows. The same handoff theorem and the NameCert obligations keep H, C, P, N as replay and provenance for that route only. Since no additional real-construction coordinate occurs in T, every $\mathsf{Real}^{\uparrow}$ readback through L has already consumed the displayed schedule surface. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier real seal readback`

Theorem 681.7 (Tail cofinality schedule RegularCauchyTailMeet handoff)**.** *Let $T = (E, W, D, R, L, H, C, P, N)$ be an accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet. Suppose its shared threshold row D is supplied by an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *packet whose paired source, window, modulus, threshold, comparison, transport, route, provenance, and local naming rows are transported into the same displayed schedule surface. Then every diagonal* $\mathsf{Real}^{\uparrow}$ *consumer of T reads the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *paired source, window, modulus, and threshold rows before the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R and the* $\mathsf{Real}^{\uparrow}$ *seal row L.*

Proof. Start from the schedule route of Definition 681.6. Every seal-facing consumer follows

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L.$$

Identify D with the shared dyadic threshold ledger supplied by the accepted $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ packet. The tail-meet obligation package in Definition 560.9 exposes the paired source rows, finite window rows, source modulus rows, shared threshold row, comparison row, transports, routes, provenance, and local name before any downstream consumer can use that threshold.

Now apply the tail-meet real-seal handoff from Definition 560.4. It keeps the shared threshold inside the displayed tail-meet packet and forbids replacement by quotient-stream comparison, selected limit, host real equality, hidden tail oracle, or ambient completeness.

Therefore the schedule consumer reaches R and L only after the RegularCauchyTailMeet paired source, window, modulus, and threshold rows have already been read through D and the structural rows H, C, P, N. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier regular cauchy tail meet handoff`

Theorem 681.8 (Tail cofinality schedule scoped binding)**.** *Every accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet $T = (E, W, D, R, L, H, C, P, N)$ binds its precision request, finite-window schedule, dyadic threshold ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal,* hsame *transport,* Cont *route,* Pkg *provenance, and* $\mathsf{NameCert}_{\mathsf{TailCofinalitySchedule}^{\uparrow}}$ *naming row through exactly the displayed BEDC primitives* BHist, hsame, Cont, Pkg, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{NameCert}$. *When D is supplied by* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, *the shared-threshold handoff remains part of the same displayed scope before R and L are readable. No accepted packet supplies quotient stream equality, a host-selected limit, ambient completeness, a hidden tail oracle, or an unbounded schedule as an alternative source for any of these rows.*

Proof. Start with the carrier definition. It displays the whole packet as a finite BHist surface

$$T = (E, W, D, R, L, H, C, P, N),$$

where E is the precision row, W is the $\mathsf{StreamName}^{\uparrow}$ finite-window schedule, D is the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, R is the $\mathsf{RegSeqRat}^{\uparrow}$ readback family, L is the $\mathsf{Real}^{\uparrow}$ seal, and H, C, P, N are the transport, route, provenance, and naming rows.

Apply Definition 681.2. It identifies carrier admission, precision exposure, finite-window coverage, threshold sufficiency, regular-rational handoff, real seal boundary, componentwise transport, route replay, provenance, and local naming as the complete local certificate surface for that same tuple.

The analytic route is then fixed by the diagonal handoff, finite-window coverage, threshold sufficiency, and real-seal readback theorems. Together they force every consumer to read

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L$$

and to carry the same route through H, C, P, N.

Finally use Definition 681.7 when the ledger row is supplied by $\mathsf{RegularCauchyTailMeet}^{\uparrow}$. The shared threshold remains inside the displayed tail-meet rows before R and L are readable, so the schedule has no separate tail oracle.

Since Definition 681.1 contains no coordinate for quotient stream equality, selected host limits, ambient completeness, hidden tail oracles, or unbounded schedules, no accepted packet can factor any listed row through such data. The only available factors are the displayed BEDC primitives named above, together with the local $\mathsf{NameCert}$ row and the threshold handoff already routed through D. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier scoped binding`

Theorem 681.9 (Tail cofinality schedule RegularCauchyCompletion route)**.** *Let $T = (E, W, D, R, L, H, C, P, N)$ be an accepted $\mathsf{TailCofinalitySchedule}^{\uparrow}$ packet whose finite-window and dyadic-threshold route is consumed by an accepted $\mathsf{RealCauchyCompletion}^{\uparrow}$ diagonal packet. Then every completion-facing seal read follows*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L$$

before the completion carrier can read its $\mathsf{Real}^{\uparrow}$ seal. The route exports no quotient stream equality, selected host limit, host real equality, ambient completeness, hidden tail oracle, or unbounded schedule.

Proof. Start from Definition 681.3. It gives the ordered finite route from the unary request E through the finite stream-window schedule W, dyadic threshold ledger D, regular-rational readback row R, and real-facing seal row L.

Apply Definition 681.6 and Definition 681.8 for the same packet. These rows keep the seal read inside BHist, hsame, Cont, Pkg, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and the local $\mathsf{NameCert}$ row, with no coordinate for a host-selected limit or hidden tail oracle.

Now read the accepted $\mathsf{RealCauchyCompletion}^{\uparrow}$ diagonal packet. Its diagonal handoff Definition 360.3 consumes the finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{RegSeqRat}^{\uparrow}$ readback before the completion-facing $\mathsf{Real}^{\uparrow}$ seal is available.

Therefore a completion carrier using T cannot reach its seal before the displayed schedule route has been consumed. The exclusions from the schedule packet and the completion diagonal handoff combine to rule out quotient stream equality, selected host limits, host real equality, ambient completeness, hidden tail oracles, and unbounded schedules as alternative routes. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier regular cauchy completion route`

Theorem 681.10 (Tail cofinality schedule shared-tail budget factorization)**.** *Every accepted $\mathsf{TailCofinalitySchedule}^{\uparrow}$ packet consumed simultaneously by $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, and $\mathsf{RealCauchyCompletion}^{\uparrow}$ factors through one finite route: the precision row E, the $\mathsf{StreamName}^{\uparrow}$ finite window W, the $\mathsf{DyadicRatCore}^{\uparrow}$ threshold ledger D, the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ shared threshold surface, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row R, the $\mathsf{Real}^{\uparrow}$ seal row L, and the completion-facing agreement rows of $\mathsf{RealTailAgreementSeal}^{\uparrow}$. The route exports no quotient streams, selected limits, host real equality, ambient completeness, hidden tail oracle, or second tail-budget source.*

Proof. Begin with the local schedule handoff. By Definition 681.7, the dyadic threshold ledger D is consumed as the displayed shared-threshold surface before any $\mathsf{RegSeqRat}^{\uparrow}$ readback row R or $\mathsf{Real}^{\uparrow}$ seal row L becomes available.

Next apply Definition 681.9. This puts every completion-facing seal read on the same route

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L.$$

Now read the sibling agreement seal. The RealTailAgreementSeal budget-source lock, shared-tail budget extraction, and Completion handoff totality theorems, Definition 699.10, Definition 699.63, and Definition 699.65, consume the shared tail request through the finite agreement route before a Real or Completion consumer can inspect the local agreement row.

The two routes meet at the same finite window and threshold surface. Since neither carrier contains a coordinate for quotient streams, selected limits, host real equality, ambient completeness, hidden tail oracles, or an external tail-budget source, the combined Real and Completion read factors through the displayed schedule rows and the sibling agreement rows only. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier shared tail budget factorization`

Theorem 681.11 (Tail cofinality schedule diagonal selector nonempty)**.** *Let $T = (E, W, D, R, L, H, C, P, N)$ be an accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet consumed by the diagonal completion route. Then the precision row E, finite-window row W, dyadic ledger D,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R, terminal* $\mathsf{Real}^{\uparrow}$ *seal row L, and structural rows H, C, P, N supply a nonempty selector route for every completion-facing consumer. The route contains no hidden tail oracle, selected host limit, quotient stream, ambient completeness row, or second completion-facing budget source.*

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier diagonal selector nonempty`

Proof. Begin with Definition 681.3. It orders the accepted schedule route from the precision request through the finite window, dyadic threshold ledger, regular-rational readback, and Real seal.

Next apply Definition 681.9. A diagonal completion consumer reaches its seal only after the same E, W, D, R, L route has been consumed, with the structural rows carrying transport, replay, provenance, and local naming.

Finally use Definition 681.10. The shared-tail budget is the only factorization available to the simultaneous tail-meet, stream-window, agreement-seal, and completion consumers, so the selector route is present and cannot be replaced by an omitted analytic or host-side coordinate. □

Theorem 681.12 (Tail cofinality schedule selector-budget lock)**.** *Every accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *selector-budget route consumed by a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *carrier factors through the finite route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L.$$

The row D is locked to the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-tail budget and to the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *agreement rows before any public* $\mathsf{Real}^{\uparrow}$ *seal can be read. The route exports no quotient stream, selected limit, countable choice, ambient completeness theorem, hidden tail oracle, or second selector-budget source.*

Proof. Begin with the Real-facing readback route of Definition 681.6. It keeps the selector-budget consumer inside the finite schedule rows $E, W, D, R, L, H, C, P, N$ before the $\mathsf{Real}^{\uparrow}$ seal is public.

Next apply Definition 681.7. This identifies the dyadic row D with the shared-threshold surface supplied by $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, so the downstream read cannot bypass the finite tail budget.

Finally use Definition 681.10 together with the $\mathsf{RealTailAgreementSeal}^{\uparrow}$ completion handoff rows cited there. The agreement rows and the completion route consume the same E, W, D, R, L spine,

and the carrier inventory has no coordinate for quotient streams, selected limits, countable choice, ambient completeness, or a second budget source. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier selector budget lock`

Theorem 681.13 (Tail cofinality schedule open-phase row exhaustion)**.** *Every accepted* TailCofinalitySchedule$^{\uparrow}$ *packet used by a* RealCauchyCompletion$^{\uparrow}$ *diagonal read must expose the finite route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L,$$

the RegularCauchyTailMeet$^{\uparrow}$ *shared-threshold surface, the* RealTailAgreementSeal$^{\uparrow}$ *agreement rows, componentwise* hsame *transport, displayed* Cont *route,* Pkg *provenance, and local* NameCert *row before any* Real$^{\uparrow}$ *seal is public. The open-phase route exports no quotient-stream equality, selected host limit, countable choice, ambient completeness, hidden tail oracle, unbounded schedule, or second tail-budget source.*

Proof. Begin with the diagonal handoff. Apply Definition 681.3 and Definition 681.6. They force the completion-facing consumer through

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L$$

before the Real$^{\uparrow}$ seal row can be read.

Next apply Definition 681.9. The RealCauchyCompletion$^{\uparrow}$ diagonal read is placed on the same finite route, with the structural rows carrying only componentwise transport, displayed replay, provenance, and local naming.

Now use Definition 681.10. The RegularCauchyTailMeet$^{\uparrow}$ shared-threshold surface and the RealTailAgreementSeal$^{\uparrow}$ agreement rows are consumed as rows of the same schedule route rather than as independent tail sources.

Finally invoke Definition 681.12. It prevents a second selector budget, hidden tail oracle, unbounded schedule, quotient-stream equality, selected host limit, countable choice, or ambient completeness witness from replacing D or bypassing the displayed route. Hence the listed open-phase rows are exhausted before any public Real$^{\uparrow}$ seal is available. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier open phase row exhaustion`

Theorem 681.14 (Tail cofinality schedule Real-completion diagonal route)**.** *Every accepted* TailCofinalitySchedule$^{\uparrow}$ *packet consumed by a* RealCauchyCompletion$^{\uparrow}$ *diagonal read reaches the public* Real$^{\uparrow}$ *seal only through the displayed finite route: the* StreamName$^{\uparrow}$ *finite-window row, the* DyadicRatCore$^{\uparrow}$ *ledger, the* RegSeqRat$^{\uparrow}$ *readback row, the* RegularCauchyTailMeet$^{\uparrow}$ *shared-threshold row, shared-tail budget factorization, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *rows. The route exports no quotient-stream equality, selected host limit, countable choice, host real equality, ambient completeness, hidden tail oracle, unbounded schedule, or second tail-budget source.*

Proof. Begin with the local diagonal handoff. By Definition 681.3, every diagonal consumer of the schedule packet reads the precision request, finite-window row, dyadic ledger, regular-rational readback row, and real seal in the displayed order.

Next apply Definition 681.4 and Definition 681.6. These theorems keep the finite window and the public Real$^{\uparrow}$ seal inside the packet rows W, D, R, L, H, C, P, N, together with componentwise hsame, Cont, Pkg, and the local NameCert row.

The tail source is then fixed by Definition 681.7. When the dyadic ledger is supplied by $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, the paired source, window, modulus, and shared-threshold rows are read before the $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ rows.

Finally combine Definition 681.9 with Definition 681.10. The first places the $\mathsf{RealCauchyCompletion}^{\uparrow}$ diagonal handoff on the same schedule route, and the second makes the shared-tail budget the only factorization available to simultaneous $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, and $\mathsf{RealCauchyCompletion}^{\uparrow}$ consumers.

The sibling completion chapter chapter 360 supplies the corresponding completion-facing diagonal route. Since the schedule carrier and the completion route contain no coordinate for quotient-stream equality, selected host limits, countable choice, host real equality, ambient completeness, hidden tail oracles, unbounded schedules, or a second budget source, the public seal can be reached only through the displayed BEDC rows. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier real completion diagonal route`

Theorem 681.15 (Tail cofinality schedule completion-budget non-escape)**.** *Let $T = (E, W, D, R, L, H, C, P, N)$ be an accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet. Every completion-facing consumer of T factors through the finite route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L$$

together with the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold row and the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *agreement rows before any* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *seal read is available. The accepted packet exports no quotient-stream equality, selected host limit, host real equality, ambient completeness, hidden tail oracle, unbounded schedule, countable choice, or second budget source.*

Proof. First use Definition 681.14. It places every completion-facing diagonal read on the displayed schedule route through E, W, D, R, and L, with the structural rows H, C, P, N carrying only transport, route replay, provenance, and local naming.

Next apply Definition 681.10. The shared threshold supplied by $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ and the agreement rows supplied by $\mathsf{RealTailAgreementSeal}^{\uparrow}$ are consumed on that same finite route before the completion seal can be inspected.

Finally project the carrier in Definition 681.1. Its coordinates are exhausted by $E, W, D, R, L, H, C, P, N$, so none of the excluded analytic or choice data is available as an exported route or as a second source for the completion-facing budget. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier completion budget nonescape`

Theorem 681.16 (Tail cofinality schedule transport determinacy)**.** *Let*

$$T_0 = (E_0, W_0, D_0, R_0, L_0, H_0, C_0, P_0, N_0) \quad \text{and} \quad T_1 = (E_1, W_1, D_1, R_1, L_1, H_1, C_1, P_1, N_1)$$

be accepted $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packets. Suppose the two packets agree after componentwise* hsame *transport on the rows $E, W, D, R, L, H, C, P, N$, and suppose their shared-tail rows are read by the same* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, *and* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *consumer routes. Then every completion-facing* $\mathsf{Real}^{\uparrow}$ *seal read exposed by either packet factors through one identical finite route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L.$$

The common route carries the transported schedule rows, the shared finite tail threshold, the agreement seal, and the completion handoff, and it exports no quotient stream, selected limit, countable choice, host real equality, ambient completeness, hidden tail oracle, or second budget source.

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier transport determinacy`

Proof. First use Definition 681.3 and Definition 681.6. These results place each accepted packet's diagonal consumer and public $\mathsf{Real}^{\uparrow}$ seal read on the ordered schedule rows $E, W, D, R, L, H, C, P, N$.

The componentwise hsame hypotheses identify the two transported schedules row by row. In particular, the finite window, dyadic ledger, regular readback, and public seal rows are not separate routes after transport; they are the same displayed spine read with two presentations.

Next apply Definition 681.10. The common $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ and $\mathsf{RealTailAgreementSeal}^{\uparrow}$ consumers force both packets to use the same shared-tail budget before a completion-facing seal can be inspected.

Finally combine Definition 681.12 with Definition 681.15. The selector budget is locked to the finite schedule route, and the completion read has no exit from that route to a quotient stream, selected limit, countable choice, host real equality, ambient completeness, hidden tail oracle, or second budget source.

Thus any completion-facing $\mathsf{Real}^{\uparrow}$ seal read from T_0 and any such read from T_1 are transported presentations of the same finite BEDC route $E \longmapsto W \longmapsto D \longmapsto R \longmapsto L$. □

Theorem 681.17 (Tail cofinality schedule diagonal-tail-selector factorization)**.** *Every accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet consumed by an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *public budget source factors through the same finite route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L.$$

The selector rows supply only the displayed public budget source, $\mathsf{ProbeBundle}$ *and* Pkg *support,* hsame *transport, and* Cont *replay. The factorization exposes no quotient stream, selected host limit, countable choice, ambient completeness, hidden tail oracle, or second budget source.*

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier diagonal tail selector factorization`

Proof. Start with the schedule route from Definition 681.14. It places every completion-facing diagonal read of the accepted schedule packet on the ordered path from the finite-window row W through the dyadic ledger D, the regular readback row R, and the public $\mathsf{Real}^{\uparrow}$ seal row L.

Next apply Definition 697.40. The accepted selector consumes the same tail-cofinality packet only as a public budget source, with the selector rows contributing the displayed $\mathsf{ProbeBundle}$ support, Pkg provenance, hsame transport, and Cont replay.

Finally use Definition 697.46. The selector budget cannot escape through a second source before the $\mathsf{Real}^{\uparrow}$ seal is read. Since neither carrier contains coordinates for quotient streams, selected host limits, countable choice, ambient completeness, hidden tail oracles, or another budget source, the joint consumer path is exactly the displayed schedule route. □

Theorem 681.18 (Tail cofinality schedule selector-completion pullback)**.** *Let* $T = (E, W, D, R, L, H, C, P, N)$ *be an accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet consumed both by an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *public budget source and by a* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *diagonal read. Then the selector-facing read and the completion-facing seal read pull back to one finite public surface*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L$$

with structural rows H, C, P, N*. No quotient stream, selected host limit, countable choice, ambient completeness, hidden tail oracle, independent completion endpoint, or second budget source distinguishes the selector-facing and completion-facing public surfaces.*

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier selector completion pullback`

Proof. Apply Definition 681.17. The selector-facing consumer can read the accepted schedule only through the displayed route, with the selector carrier contributing public budget, ProbeBundle support, Pkg provenance, hsame transport, and Cont replay.

For the completion-facing read, use Definition 681.9 and Definition 681.14. These place the $\mathsf{RealCauchyCompletion}^{\uparrow}$ diagonal handoff on the same ordered schedule route before the public $\mathsf{Real}^{\uparrow}$ seal is available.

It remains to identify the common budget surface. By Definition 681.10, the simultaneous $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, and $\mathsf{RealCauchyCompletion}^{\uparrow}$ consumers all factor through the same finite window, dyadic ledger, shared threshold, readback, and seal rows.

Thus the two reads have the same pullback surface $(E, W, D, R, L, H, C, P, N)$. Since the schedule, selector, and completion carriers contain no coordinate for the excluded host or oracle data, no second endpoint or budget source can separate the selector-facing and completion-facing public surfaces. □

Theorem 681.19 (Tail cofinality schedule selector-seal pullback)**.** *Let $T = (Q, W, D, R, E_T, H_T, C_T, P_T, N_T)$ be an accepted* $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet, and let $S = (B, W, R, L, E_S, H_S, C_S, P_S, N_S)$ be an accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet. Suppose the selected* $\mathsf{StreamName}^{\uparrow}$ *window and* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows exposed by the two packets are the same displayed rows W and R. Then the schedule-facing completion read and the selector-facing seal read pull back to one finite public surface*

$$B,\ Q,\ W,\ D,\ R,\ L,\ E_T,\ E_S,\ H,\ C,\ P,\ N.$$

Here B is the selector budget, Q is the precision row, D is the dyadic ledger, L is the $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row, E_T, E_S are the terminal* $\mathsf{Real}^{\uparrow}$ *rows, and H, C, P, N denote the structural transport, continuation, provenance, and naming rows read componentwise from $H_T, H_S, C_T, C_S, P_T, P_S, N_T, N_S$. The pullback uses no quotient stream equality, host real equality, countable choice, detached limit, hidden selector row, ambient completeness principle, or second completion route.*

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier selector seal pullback`

Proof. Begin with Definition 681.18. It places the schedule-facing completion read on the finite route from the precision row through the common window, dyadic ledger, readback, terminal Real row, and structural rows. Thus the schedule side contributes only $Q, W, D, R, E_T, H_T, C_T, P_T, N_T$.

Next apply Definition 1081.5 and Definition 1081.16. The selector-seal packet reaches the L10 handoff through the ordered surface B, W, R, L, E_S and locks the selected window and readback to the displayed rows W and R, so its selector-facing read meets the schedule-facing read on the same two handoff rows.

Finally use Definition 1081.11 and Definition 1081.17. The terminal selector-seal route has no remaining completion endpoint beyond the displayed L and E_S rows, and H_S, C_S, P_S, N_S only package that route. Together with the schedule pullback, the common public surface is exactly $B, Q, W, D, R, L, E_T, E_S, H, C, P, N$.

The excluded objects are absent from both carriers and from the cited terminality and non-promotion results. Hence quotient stream equality, host real equality, countable choice, detached limits, hidden selector rows, ambient completeness, and a second completion route cannot distinguish the two completion reads. □

Theorem 681.20 (Tail cofinality schedule reciprocal-window factorization)**.** *Let $T = (E, W, D, R, L, H_T, C_T, P_T, N$ be an accepted* TailCofinalitySchedule$^{\uparrow}$ *packet, and let $B = (X, A, M, W, D, R, S, H_B, C_B, P_B, N_B)$ be an accepted* CauchyInverseBudget$^{\uparrow}$ *packet. Suppose the two packets expose the same finite* StreamName$^{\uparrow}$ *window row W,* DyadicRatCore$^{\uparrow}$ *ledger row D,* RegSeqRat$^{\uparrow}$ *readback row R, and* Real$^{\uparrow}$ *seal row, with the budget seal S displayed as the schedule row L. Then every reciprocal-root or completion-facing read factors through the common finite route*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L$$

together with the CauchyInverseBudget$^{\uparrow}$ *apartness row A before any reciprocal candidate is consumed. This factorization uses the reciprocal-window surface of chapter 703, Definition 703.13, Definition 703.14, Definition 681.14, and Definition 681.19; it exposes no quotient stream equality, host real equality, selected limit, countable choice, hidden tail oracle, or ambient completeness coordinate.*

Proof. Project the two carrier tuples. The schedule packet supplies only $E, W, D, R, L, H_T, C_T, P_T, N_T$, while the reciprocal budget supplies only $X, A, M, W, D, R, S, H_B, C_B, P_B, N_B$. The shared rows named in the statement therefore identify the public window, ledger, readback, and Real seal that both packets can expose.

Apply Definition 681.14. It fixes the completion-facing schedule route as

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L.$$

The selector-side pullback of Definition 681.19 keeps the same finite window and readback rows visible when a selector or completion seal is read.

Now use the reciprocal-window chapter chapter 703. By Definition 703.13, a reciprocal-root consumer must display the apartness row A, modulus row M, finite window W, and dyadic row D before any read of D, R, or the seal row $S = L$ can serve a reciprocal candidate.

Finally apply Definition 703.14. The RegSeqRat$^{\uparrow}$ readback and Real$^{\uparrow}$ seal received from the reciprocal budget are exactly the public rows R and $S = L$ already fixed by the schedule route. Thus the two packets share one finite readback surface, with the apartness row inserted before the reciprocal candidate is consumed.

The remaining exclusions are coordinate exclusions. Neither displayed carrier contains quotient stream equality, host real equality, selected limits, countable choice, hidden tail oracles, or ambient completeness data, so no root or completion consumer can factor through such data instead of the displayed route and apartness row. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier cauchy inverse budget factorization`

Theorem 681.21 (Tail cofinality schedule selector-residue exhaustion)**.** *Let T be an accepted* TailCofinalitySchedule$^{\uparrow}$ *packet consumed through* DiagonalTailSelector$^{\uparrow}$, RealCompletionSelectorSeal$^{\uparrow}$, RealTailAgreementSeal$^{\uparrow}$, *and* RealCauchyCompletion$^{\uparrow}$. *Then every remaining selector-facing, completion-facing, and real-seal-facing public read is exhausted by the finite rows*

$$E, W, D, R, L, H, C, P, N$$

of the schedule carrier, together with the selector budget row, the agreement rows, and the selector-seal handoff rows named in the preceding pullback theorems. No residual row supplies quotient stream equality, selected host limits, countable choice, detached limits, hidden selector rows, ambient completeness, hidden tail oracles, or a second completion route.

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier selector residue exhaustion`

Proof. First place the selector read on the schedule route. Apply Definition 681.17. It sends the accepted selector consumer through the displayed tail schedule, with the selector contributing only its public budget row, ProbeBundle support, Pkg provenance, hsame transport, and Cont replay.

Next identify the completion-facing route. Use Definition 681.18. The selector-facing read and the RealCauchyCompletion$^{\uparrow}$ read meet on the same finite surface $E, W, D, R, L, H, C, P, N$, with no independent completion endpoint or second budget source.

Now attach the selector-seal handoff. By Definition 681.19, the RealCompletionSelectorSeal$^{\uparrow}$ read and the schedule-facing completion read share the displayed selector budget, precision row, window row, dyadic ledger, readback row, limit handoff, terminal Real$^{\uparrow}$ rows, and structural transport, continuation, provenance, and naming rows.

Finally use the terminality and structural-row nonpromotion results for the selector seal, Definition 1081.11 and Definition 1081.17. They prevent the handoff rows and the structural rows from becoming an additional limit source, hidden selector surface, ambient completeness witness, or second completion route. The RealTailAgreementSeal$^{\uparrow}$ agreement rows therefore add only the displayed finite agreement handoff already used by the pullback surface, and every public read is exhausted by the named L10 rows. □

Theorem 681.22 (Tail cofinality schedule CauchyLimitSeal readback)**.** *Every accepted* TailCofinalitySchedule$^{\uparrow}$ *packet whose selector residue is exhausted reads its* CauchyLimitSeal$^{\uparrow}$ *boundary only through the displayed* StreamName$^{\uparrow}$*,* RegSeqRat$^{\uparrow}$*,* DyadicRatCore$^{\uparrow}$*,* Real$^{\uparrow}$*, and* CauchyLimitSeal$^{\uparrow}$ *rows of the schedule route.*

Proof. Project the schedule carrier and place the selector read on the diagonal route using Definition 681.17. The StreamName$^{\uparrow}$ window, DyadicRatCore$^{\uparrow}$ dyadic ledger, RegSeqRat$^{\uparrow}$ readback, terminal Real$^{\uparrow}$ row, and CauchyLimitSeal$^{\uparrow}$ handoff are the displayed rows available to the accepted packet.

Apply the finite-window coverage and completion pullback blocks, including Definition 681.18. They identify the completion-facing read with the same finite surface rather than with an independent limit endpoint.

Now use Definition 681.19 and Definition 681.21. The selector-seal route passes through the selected window, regular-rational readback, CauchyLimitSeal handoff, and terminal real row, and the residue-exhaustion statement leaves no remaining selector-facing or completion-facing public read outside those rows.

No quotient stream, host limit, choice selector, detached limit, hidden selector row, or ambient completeness coordinate is present in the carrier. Thus the CauchyLimitSeal boundary can be read only through the displayed L10 schedule rows. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier cauchy limitseal readback`

Theorem 681.23 (Tail cofinality schedule RealCompletionSelectorSeal route)**.** *For the same accepted* TailCofinalitySchedule$^{\uparrow}$ *packet, every* RealCompletionSelectorSeal$^{\uparrow}$ *consumer route factors through the CauchyLimitSeal readback row of Definition 681.22 and the selector-seal pullback route of Definition 681.19.*

Proof. Start with the selector-facing route of Definition 681.17. It fixes the finite tail schedule, selector budget, transport, replay, provenance, and local naming rows before any selector-seal consumer reads the packet.

Next apply the finite-window and selector-seal pullback results. The selected $\mathsf{StreamName}^{\uparrow}$ window and $\mathsf{RegSeqRat}^{\uparrow}$ readback are the only route by which the selector seal reaches the $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff and the terminal $\mathsf{Real}^{\uparrow}$ row.

Use Definition 681.22 for the limit-seal boundary. The readback theorem has already exhausted the possible CauchyLimitSeal reads through the displayed stream, dyadic, regular-rational, real, and limit-seal rows.

Finally invoke Definition 681.21. Since the exhausted packet has no quotient stream, host limit, choice selector, ambient completeness coordinate, hidden tail oracle, or second completion route, any RealCompletionSelectorSeal consumer route must factor through the displayed CauchyLimitSeal readback and selector-seal pullback rows. □

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier real completion selector route`

Theorem 681.24 (Tail cofinality schedule StreamName RegSeqRat Real window determinacy)**.** *Let*

$$T = (E, W, D, R, L, H, C, P, N)$$

be an accepted $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet. If two completion-facing or selector-facing public reads of* T *agree on the displayed unary precision row* E*, the finite* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row* D*, then they read the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R *and the same* $\mathsf{Real}^{\uparrow}$ *seal row* L *through the structural rows* H, C, P, N*. No quotient stream, host limit, choice-selected tail, ambient completeness row, hidden tail oracle, or second selector-budget source can split the public route after* E, W, D *are fixed.*

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier streamname regseqrat real window determinacy`

Proof. Begin with the finite schedule. By Definition 681.4, every accepted read of the precision row E reaches the same displayed $\mathsf{StreamName}^{\uparrow}$ window row W before any dyadic ledger, regular-rational readback, or real seal is available.

Next apply Definition 681.5. Once the two public reads agree on W and on the ledger row D, the available $\mathsf{RegSeqRat}^{\uparrow}$ readback is the displayed row R of the same packet rather than a host-selected tail or an independent selector budget.

Now use Definition 681.6. The $\mathsf{Real}^{\uparrow}$ consumer reaches the seal row only through the route

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L.$$

Thus agreement on E, W, D fixes the readback row R and then fixes the seal row L under the same transports, continuations, provenance, and local name H, C, P, N.

Finally invoke Definition 681.23, together with the selector-residue exhaustion and CauchyLimitSeal readback statements. These routes leave no quotient stream, ambient completeness coordinate, choice-selected tail, hidden tail oracle, host limit, or second selector-budget source from which a distinct completion-facing or selector-facing public read could be obtained. □

Theorem 681.25 (Tail cofinality schedule window seal factorization)**.** *Let*

$$T = (E, W, D, R, L, H, C, P, N)$$

be an accepted $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet. Every completion-facing read of* T *factors through*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L$$

and then through the structural rows H, C, P, N*. The factorization is stable under the displayed* hsame *transports and cannot introduce quotient stream equality, host-selected limits, hidden tail oracles, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier window seal factorization`

Proof. Begin with the finite window. Apply Definition 681.4; every completion-facing read of the unary precision row E reaches the displayed $\mathsf{StreamName}^{\uparrow}$ window row W before any seal consumer can read a later row.

Next use Definition 681.5. The finite window supplies the displayed dyadic ledger row D, so the route cannot branch into a hidden tail oracle or a host-selected cofinal schedule.

Now apply Definition 681.6. The $\mathsf{RegSeqRat}^{\uparrow}$ row R and the $\mathsf{Real}^{\uparrow}$ seal row L are read through the same finite route

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L.$$

The displayed hsame transports keep the structural rows H, C, P, N attached to that route.

Determinacy follows from Definition 681.24: after E, W, D are fixed, the completion-facing consumer has the same R and L rows under the same transport, continuation, provenance, and local naming package.

Finally invoke Definition 681.23. The RealCompletionSelectorSeal route consumes the displayed readback and seal rows, so no quotient stream equality, host-selected limit, hidden tail oracle, or ambient completeness coordinate can be introduced downstream. □

Theorem 681.26 (Tail cofinality schedule Phase Real and Completion exit handoff)**.** *Let*

$$T = (E, W, D, R, L, H, C, P, N)$$

be an accepted $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *packet. If* T *is consumed as a Phase Real and Completion exit route over the* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *surfaces, then the exit factors through the displayed finite path*

$$E \longmapsto W \longmapsto D \longmapsto R \longmapsto L,$$

where W *is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row,* D *is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* R *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and* L *is the* $\mathsf{Real}^{\uparrow}$ *seal. The route exports no quotient stream, selected host limit, host equality, choice schedule, hidden tail oracle, ambient completeness, or second selector-budget source.*

Lean4 ✓ `BEDC.Derived.TailCofinalityScheduleUp.TailCofinalityScheduleCarrier phase real completion exit handoff`

Proof. Begin with the local schedule route. The diagonal handoff, finite-window coverage, threshold sufficiency, Real seal readback, and scoped binding theorems force every accepted read of T to pass from the unary request E through the finite window W, dyadic ledger D, regular-rational readback R, and Real seal L, with H, C, P, N only replaying transport, continuation, provenance, and local naming.

Next read the Completion-facing side. The RegularCauchyCompletion route places the completion carrier on the same finite path, while shared-tail budget factorization identifies the shared

threshold supplied by $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ and the agreement rows supplied by $\mathsf{RealTailAgreementSeal}^{\uparrow}$ as consumers of that path rather than as independent sources.

Now apply the selector-budget lock. It prevents the Real or Completion consumer from replacing the dyadic ledger by a separate selector budget, and it keeps the $\mathsf{Real}^{\uparrow}$ seal downstream from the same E, W, D, R, L route.

Finally use window seal factorization. Once the finite window and dyadic ledger have been read, the completion-facing seal is the displayed R, L readback under the same structural rows. Since the carrier inventory contains no coordinate for quotient streams, selected host limits, host equality, choice schedules, hidden tail oracles, ambient completeness, or a second selector-budget source, the Phase Real and Completion exit has no public route outside the stated finite path. □

Closure status for $\mathsf{NameCert}_{\mathsf{TailCofinalitySchedule}^{\uparrow}}$.

Constructive story: A $\mathsf{TailCofinalitySchedule}^{\uparrow}$ packet is generated from a unary precision request, cofinal finite-window schedule, dyadic tolerance ledger, RegSeqRat readback rows, a RealUp seal row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TailCofinalitySchedule}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 681.1, Definition 681.2, Definition 681.3, Definition 681.4, Definition 681.5, Definition 681.6, Definition 681.7, Definition 681.8, and Definition 681.24 bind the public finite-window schedule to the downstream RealUp and RegSeqRat handoff through the displayed BEDC primitives, local NameCert row, RegularCauchyTailMeet threshold route, and deterministic StreamName window readback.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TailCofinalitySchedule}^{\uparrow}}, \mathsf{bridgeChecked})$

Chapter 682

A Concrete Naming Certificate for $\mathsf{InscriptionAuditTrace}^{\uparrow}$

The $\mathsf{InscriptionAuditTrace}^{\uparrow}$ surface realizes the audit trace of an inscription event as a finite NameCert packet. It combines the inscription-event source and named-record rows, the GAP-ledger residue rows, and the accepted-check consumer-budget rows into one public audit object. The packet records only the rows that a certificate, citation, theorem site, or ChapterTasteGate consumer may inspect.

The audit trace consumes chapter 519 for the source, name, route, and check rows, chapter 520 for the residue row, and chapter 651 for the accepted-check and downstream consumer-budget surface before it exposes its local public trace. The packet $S, M, R, K, U, Q, H, C, P, N$ is the finite join of those sibling surfaces: S, M, R, K, U carry the event route and consumer boundary, Q carries the GAP residue, and H, C, P, N carry the transports, displayed continuations, provenance, and local certificate row. These sibling packets are the horizontal lattice route used by the carrier below, and no private agency predicate or host trace is exported by this join.

Definition 682.1 (Inscription audit trace carrier)**.** *An* $\mathsf{InscriptionAuditTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (S, M, R, K, U, Q, H, C, P, N)$$

with the following displayed rows:

1. *S is the finite source-state row at which the inscription route begins;*
2. *M is the named record, theorem site, citation row, or public interface admitted by the route;*
3. *R is the displayed route witness from S to M;*
4. *K is the accepted-check row that admits R as public record data for M;*
5. *U is the downstream audit consumer row, naming the certificate, citation, theorem site, or* ChapterTasteGate *surface that may read the trace;*
6. *Q is the GAP residue row left after the accepted route and consumer boundary are exposed;*
7. *H records componentwise* hsame *transports for S, M, R, K, U, Q together with package and local naming rows;*
8. *C records the displayed* Cont *routes by which consumers read the source, name, route, accepted check, consumer, and residue rows;*

9. *P is the* Pkg *provenance over* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* InscriptionEvent$^{\uparrow}$*,* InscriptionGapLedger$^{\uparrow}$*,* InscriptionAcceptanceBudget$^{\uparrow}$*, and* ChapterTasteGate *surfaces;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{InscriptionAuditTrace}^{\uparrow}}$ *row.*

The carrier contains no private agency predicate, host process trace, unrecorded mutation, unchecked route, unbudgeted consumer right, or completed ontology of inscription beyond the displayed audit rows.

Theorem 682.2 (Inscription audit trace NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{InscriptionAuditTrace}^{\uparrow}}$ *surface for Definition 682.1 consists of six finite obligations:*

1. *carrier exposure for $A = (S, M, R, K, U, Q, H, C, P, N)$;*
2. *source and named-record locality inherited from the* InscriptionEvent$^{\uparrow}$ *rows S, M, R, K, U;*
3. *accepted-check exactness inherited from the* InscriptionAcceptanceBudget$^{\uparrow}$ *row K;*
4. *GAP-residue exactness inherited from the* InscriptionGapLedger$^{\uparrow}$ *row Q;*
5. *consumer accountability through U and the displayed* Cont *routes in C;*
6. *package and local naming stability through H, P, N over* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*, and* ChapterTasteGate *surfaces.*

Proof. Carrier exposure is projection from the displayed packet. The rows $S, M, R, K, U, Q, H, C, P, N$ are the complete inventory available to the audit trace.

The inscription-event rows supply the source, name, route, accepted-check, and consumer boundary. The acceptance-budget rows identify K as the public check row and keep downstream use inside the consumer surface named by U.

The GAP-ledger rows identify Q as the residue left at the accepted route boundary. The transport, continuation, package, and local naming rows then record how a ChapterTasteGate or certificate consumer reads the same finite packet without importing private agency or host process data. □

Theorem 682.3 (Inscription audit trace route-check residue exhaustion)**.** *For every accepted* InscriptionAuditTrace$^{\uparrow}$ *carrier $A = (S, M, R, K, U, Q, H, C, P, N)$, the route-check-residue surface is exhausted by the rows $S, M, R, K, Q, H, C, P, N$. A public audit read first reaches the named record M from the source row S through the route witness R, then admits the route through the check row K, and then records the remaining GAP residue through Q.*

No audit read may replace these rows by a host checker, hidden proof replay, private agency predicate, raw byte-change identity, or unrecorded route.

Proof. Project the carrier and isolate the route-facing rows S, M, R, K, Q. These are the only coordinates that connect source state, named record, accepted check, and residue.

Apply the inscription-event surface for the route from S through R to M. Apply the acceptance-budget surface to read K as the accepted check, and apply the GAP-ledger surface to read Q as the displayed residue.

The remaining rows H, C, P, N preserve this same route under componentwise hsame transport, displayed Cont replay, package provenance, and local naming. Since the carrier has no host checker, hidden replay, agency predicate, byte-change classifier, or unrecorded route coordinate, the route-check-residue surface is exhausted by the displayed packet. □

Theorem 682.4 (Inscription audit trace consumer non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{InscriptionAuditTrace}^{\uparrow}$ *carrier factors through the finite rows*

$$S, M, R, K, U, Q, H, C, P, N.$$

The consumer may read the source state, named record, route witness, accepted check, intended consumer, GAP residue, componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row. It cannot read private motives, host process traces, unchecked route data, unbudgeted consumer authority, or inscription data outside the finite audit trace.*

Proof. Begin with the consumer row U and the continuation row C. Together they name the public audit reader and the displayed route by which that reader enters the packet.

Use Definition 682.2. The local NameCert surface binds the consumer to the inscription-event, GAP-ledger, and acceptance-budget rows visible in the same packet.

Use Definition 682.3. The consumer's route-check-residue read is already exhausted by $S, M, R, K, Q, H, C, P, N$ No additional carrier coordinate remains, so the consumer cannot escape to private motives, host traces, unchecked routes, unbudgeted authority, or outside inscription data. □

Theorem 682.5 (Inscription audit trace TasteGate visible surface)**.** *The* ChapterTasteGate*-visible surface of an accepted* $\mathsf{InscriptionAuditTrace}^{\uparrow}$ *carrier is exactly the finite audit packet* $A = (S, M, R, K, U, Q, H, C, P,$ *together with its local* $\mathsf{NameCert}_{\mathsf{InscriptionAuditTrace}^{\uparrow}}$ *obligations. A gate may inspect the source, named record, route witness, accepted check, consumer row, GAP residue, transports, continuations, package provenance, and local naming row; it receives no hidden approval channel, private agency predicate, host trace, or row not named by the packet.*

Lean4 ✓ `BEDC.Derived.InscriptionAuditTraceUp.InscriptionAuditTraceTasteGate single carrier alignment`

Proof. The gate-facing input is the same carrier from Definition 682.1. The carrier lists the rows a ChapterTasteGate consumer may inspect and supplies no separate admission channel.

Apply Definition 682.2 to expose the local NameCert surface. It ties the inscription-event, GAP-ledger, and acceptance-budget readings to one finite audit packet.

Apply Definition 682.4. Since every downstream consumer, including a ChapterTasteGate consumer, factors through $S, M, R, K, U, Q, H, C, P, N$, the visible gate surface is exactly the displayed audit trace. □

Theorem 682.6 (Inscription audit trace budget-ledger sibling route)**.** *Every accepted* $\mathsf{InscriptionAuditTrace}^{\uparrow}$ *carrier first reads the inscription-event source and route rows through chapter 519, then reads the GAP residue row through chapter 520, then reads the accepted-check budget row through chapter 651, and only then exposes the* ChapterTasteGate*-visible row of Definition 682.5. The visible gate surface is therefore bound to the source, ledger, and budget siblings before any audit consumer may inspect it.*

Proof. Project the accepted carrier $A = (S, M, R, K, U, Q, H, C, P, N)$ from Definition 682.1. The rows S, M, R are the source, named-record, and route rows inherited from the inscription-event surface, and U names the public audit consumer that eventually reaches the gate-facing read.

The row Q is the GAP residue coordinate, so the route must pass through the sibling ledger surface before the audit trace can describe what remains at the accepted route boundary. The row K is the accepted-check budget coordinate, so the same packet must also pass through the acceptance-budget sibling before exposing a consumer right.

The transport, continuation, provenance, and naming rows H, C, P, N preserve this same route and do not add another inspection coordinate. Because the carrier has no hidden approval channel, private agency predicate, host trace, unchecked route, or unbudgeted consumer row, the ChapterTasteGate surface is reached only after the inscription-event, GAP-ledger, and acceptance-budget rows have been read. □

Closure status for $\mathsf{NameCert}_{\mathsf{InscriptionAuditTrace}^{\uparrow}}$.

Constructive story: An $\mathsf{InscriptionAuditTrace}^{\uparrow}$ packet is generated from a source state, named record, route witness, accepted check, downstream audit consumer, GAP residue, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, private agency, host process traces, raw byte-change identity, unchecked route semantics, unbudgeted downstream consumption, or completed inscription ontology.

Upgrade path: Mature closure requires bridge checking for the audit-trace certificate surface while preserving the carrier, route-check residue, consumer non-escape, sibling route, and TasteGate-visible packet.

Chapter 683

A Concrete Naming Certificate for $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$

The $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ packet joins the finite small-step ledger of $\mathsf{ContinuationTrace}^{\uparrow}$ with the terminal-read surface of $\mathsf{ContinuationBigStep}^{\uparrow}$ and the typed normal-form boundary of $\mathsf{TypedReductionNormalForm}^{\uparrow}$. The terminal-read coordinate is consumed from chapter 657 before the typed normal-form row is read. It records trace replay, terminal stability, typed normal-form readback, transports, routes, provenance, and local naming in one finite BHist carrier. It does not appeal to a host evaluator, a host conversion check, quotient behaviour, or a normalization oracle outside the displayed BEDC rows.

Definition 683.1 (ContinuationTraceNormalForm carrier)**.** *A* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (S, T, R, Q, V, H, C, P, N)$$

with the following displayed rows:

1. *S is the source history row from which replay begins;*
2. *T is the finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *small-step ledger, including its displayed source, mark-and-tail, target, and trace rows;*
3. *R is the terminal history row reached by replaying T through the displayed* Cont *routes;*
4. *Q is the terminal-read witness exposed by the* $\mathsf{ContinuationBigStep}^{\uparrow}$ *surface;*
5. *V is the* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *row naming the normal-form classifier for the same terminal history;*
6. *H stores componentwise* hsame *transports for S, T, R, Q, V, provenance, and the local name;*
7. *C stores the displayed* Cont *routes that replay the trace ledger, reach the terminal row, consume the terminal-read witness, and expose the typed normal-form row;*
8. *P is the* Pkg *provenance over* BHist, BMark, $\mathsf{ContinuationTrace}^{\uparrow}$, $\mathsf{ContinuationBigStep}^{\uparrow}$, $\mathsf{TypedReductionNormalFo}$ hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ContinuationTraceNormalForm}^{\uparrow}}$ *row.*

The carrier is exactly this finite packet. It contains no host conversion relation, no quotient-normalization proof, no evaluator graph, no global confluence theorem, and no external normalizer.

Lean4 ✓ `BEDC.Derived.ContinuationTraceNormalFormUp.ContinuationTraceNormalFormTasteGate single carrier alignment`

Theorem 683.2 (ContinuationTraceNormalForm NameCert obligations)**.** *For the carrier of Definition 683.1, the local* $\mathsf{NameCert}_{\mathsf{ContinuationTraceNormalForm}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$Z = (S, T, R, Q, V, H, C, P, N),$$

trace replay through the $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger, terminal-read exposure through the* $\mathsf{ContinuationBigStep}^{\uparrow}$ *row, typed normal-form readback through* V*, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and non-escape from host conversion, quotient behaviour, evaluator graphs, global confluence, and normalization oracles.*

Lean4 ✓ `BEDC.Derived.ContinuationTraceNormalFormUp.ContinuationTraceNormalFormCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 683.1. The packet exposes exactly $S, T, R, Q, V, H, C, P, N$.

Trace replay is read from T and C. The $\mathsf{ContinuationTrace}^{\uparrow}$ row supplies finite small-step entries, and the displayed continuation route replays those entries from the source row S to the terminal row R.

Terminal exposure is then read through Q, and typed normal-form readback is read through V. The transport row H moves the same displayed rows componentwise, while P and N record package provenance and local naming.

The non-escape clauses follow from the carrier inventory. Since the packet has no coordinate for host conversion, quotient behaviour, an evaluator graph, global confluence, or an external normalizer, no local certificate projection can export one. □

Theorem 683.3 (ContinuationTraceNormalForm source normalization obligation)**.** *For every displayed packet*

$$Z = (S, T, R, Q, V, H, C, P, N)$$

accepted by $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$*, the source-to-trace normalization obligation is exactly the replay from* S *through the finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *row* T*, the displayed* BHist *and* BMark *data inside that row, the continuation routes in* C*, and the local* NameCert *row* N*. It contains no host conversion relation, quotient normalization datum, evaluator graph, global confluence theorem, or external normalizer.*

Lean4 ✓ `BEDC.Derived.ContinuationTraceNormalFormUp.ContinuationTraceNormalFormCarrier source normalization obligation`

Proof. Project Z by Definition 683.1. The source row S, trace row T, route row C, and local name N are the only source-to-trace replay coordinates in the accepted carrier.

Apply Definition 683.2. It certifies trace replay through the $\mathsf{ContinuationTrace}^{\uparrow}$ ledger and the displayed continuation routes before any terminal-read or typed-normal row is consumed.

The excluded host conversion, quotient normalization, evaluator graph, global confluence, and external normalizer objects have no coordinate in Z. Hence the source normalization obligation is precisely the displayed BHist, BMark, Cont, and NameCert route. □

Theorem 683.4 (ContinuationTraceNormalForm dependency readback obligation)**.** *For every displayed packet*

$$Z = (S, T, R, Q, V, H, C, P, N)$$

accepted by ContinuationTraceNormalForm$^{\uparrow}$*, dependency readback passes through* ContinuationTrace$^{\uparrow}$*,* ContinuationBigStep$^{\uparrow}$*, and* TypedReductionNormalForm$^{\uparrow}$ *in that order. The rows* T, R, Q, V, H, C, P, N *expose the trace ledger, terminal row, terminal-read witness, typed normal-form row, componentwise transport, displayed route, provenance, and local name without adding host conversion, quotient normalization, evaluator graphs, global confluence, or external normalizers.*

Lean4 ✓ `BEDC.Derived.ContinuationTraceNormalFormUp.ContinuationTraceNormalFormCarrier dependency readback obligation`

Proof. Start from the carrier definition. It places the trace dependency in T, the terminal dependency in R, Q, and the typed normal-form dependency in V, all inside the same finite packet.

Use Definition 683.2. The local certificate reads trace replay, terminal-read exposure, and typed normal-form readback through the displayed rows and records their transports, routes, package row, and local name in H, C, P, N.

Since the packet contains no off-route evaluator, quotient normalizer, host conversion relation, global confluence theorem, or external normalizer, dependency readback cannot leave the ContinuationTrace$^{\uparrow}$, ContinuationBigStep$^{\uparrow}$, and TypedReductionNormalForm$^{\uparrow}$ route. □

Theorem 683.5 (ContinuationTraceNormalForm typed replay obligation)**.** *For every displayed packet*

$$Z = (S, T, R, Q, V, H, C, P, N)$$

accepted by ContinuationTraceNormalForm$^{\uparrow}$*, typed replay reaches the normal-form row* V *only after the source row* S*, trace ledger* T*, terminal row* R*, terminal-read witness* Q*, transport row* H*, continuation route row* C*, package row* P*, and local name* N *have been consumed. No host conversion, quotient normalization, evaluator graph, global confluence theorem, or external normalizer can replace that ordered replay.*

Proof. Read V from Definition 683.1. It is not an isolated classifier row; it is attached to the source, trace, terminal, terminal-read, transport, route, provenance, and naming rows of the same accepted packet.

Apply Definition 683.2. The typed normal-form row is certified only after trace replay and terminal-read exposure have passed through the displayed Cont routes and the componentwise transport row.

The carrier has no coordinate for host conversion, quotient normalization, evaluator graphs, global confluence, or external normalizers. Thus typed replay reaches V only through S, T, R, Q, H, C, P, N. □

Theorem 683.6 (ContinuationTraceNormalForm non-escape)**.** *Every accepted* ContinuationTraceNormalForm$^{\uparrow}$ *packet exposes terminal trace normalization only through the displayed rows*

$$S, T, R, Q, V, H, C, P, N.$$

A downstream consumer may read the source history, finite continuation trace, terminal row, terminal-read witness, typed normal-form row, componentwise transports, displayed continuation replay, package provenance, and local naming row. It cannot replace those rows by host conversion, quotient behaviour, a selected evaluator, a global confluence theorem, or a normalization oracle.

Proof. Begin with the carrier projection. The only replay data are the finite trace row T and the displayed continuation routes in C.

Use Definition 683.2. The terminal row R, terminal-read witness Q, and normal-form row V are reached only after the replayed trace has been consumed inside the same packet.

Finally inspect the excluded objects. Each would require a separate carrier coordinate or a second consumer route outside $S, T, R, Q, V, H, C, P, N$. Since the accepted packet has neither, the terminal normal-form surface is exactly the displayed finite NameCert packet. □

Theorem 683.7 (ContinuationTraceNormalForm terminal scope)**.** *Every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet exposes the terminal row only after consuming the* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger, the* $\mathsf{ContinuationBigStep}^{\uparrow}$ *terminal-read row, and the* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *row through the displayed* Cont *routes. No consumer can replace that sequence by host conversion, quotient normalization, evaluator graphs, or normalization oracles.*

Proof. Project the accepted carrier $Z = (S, T, R, Q, V, H, C, P, N)$. The terminal row R is a coordinate of the same finite packet as the trace ledger T, terminal-read row Q, typed normal-form row V, and displayed continuation routes C.

Apply Definition 683.2. Trace replay is first consumed through T and C, terminal-read exposure is then consumed through Q, and typed normal-form readback is consumed through V before the local name N is reached.

Apply Definition 683.6. Host conversion, quotient normalization, evaluator graphs, and normalization oracles have no coordinate in Z, so none can serve as an alternate terminal-read route. □

Theorem 683.8 (ContinuationTraceNormalForm trace ledger exhaustion)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the finite row* T *exhausts all trace reads exported by the packet. A consumer may replay only the displayed* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger through* C *and may transport it only through* H*; it cannot read an additional trace from a host evaluator, quotient normalization, global confluence, or an external normalizer.*

Proof. Project the carrier in Definition 683.1. The only trace coordinate is T, and the only replay coordinate is the displayed continuation route row C.

Apply Definition 683.2. Trace replay is certified through the $\mathsf{ContinuationTrace}^{\uparrow}$ ledger, componentwise transport is certified through H, and the package and local name are certified through P, N for the same finite tuple.

Use Definition 683.6. Since host conversion, quotient behaviour, evaluator graphs, global confluence, and normalization oracles have no coordinate in Z, none can provide a second trace read outside T.

Finally apply Definition 683.7. Terminal exposure consumes the displayed trace before reaching R, Q, V, so every exported trace read is exhausted by T. □

Theorem 683.9 (ContinuationTraceNormalForm terminal readback lock)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the terminal row* R *is locked behind the finite trace row* T*, terminal-read row* Q*, transport row* H*, displayed continuation row* C*, provenance row* P*, and local naming row* N*. No public read may expose* R *without first consuming those displayed rows.*

Lean4 ✓ `BEDC.Derived.ContinuationTraceNormalFormUp.ContinuationTraceNormalFormCarrier terminal readback lock`

Proof. Start with the carrier projection of Definition 683.1. The row R is not an isolated terminal object; it is part of the finite packet $S, T, R, Q, V, H, C, P, N$.

Apply Definition 683.2. The terminal-read exposure through Q is certified only after trace replay through T and C, componentwise transport through H, and package/name recording through P, N.

Use Definition 683.7. It places the terminal row behind the $\mathsf{ContinuationTrace}^{\uparrow}$ ledger, the $\mathsf{ContinuationBigStep}^{\uparrow}$ terminal-read witness, and the $\mathsf{TypedReductionNormalForm}^{\uparrow}$ row.

Finally use Definition 683.6. A host conversion relation, quotient normalizer, evaluator graph, global confluence theorem, or external normalizer cannot unlock a terminal readback because none is a row of the accepted packet. □

Theorem 683.10 (ContinuationTraceNormalForm typed boundary nonescape)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the typed normal-form row* V *cannot be replaced by host conversion, quotient normalization, evaluator graphs, or global confluence. The typed boundary is read only through the displayed trace, terminal, transport, route, package, and local naming rows of* Z*.*

Lean4 ✓ `BEDC.Derived.ContinuationTraceNormalFormUp.ContinuationTraceNormalFormTypedBoundaryNonescape`

Proof. Read V from Definition 683.1. It is the finite $\mathsf{TypedReductionNormalForm}^{\uparrow}$ row of the same packet as S, T, R, Q, H, C, P, N.

Apply Definition 683.2. Typed normal-form readback is certified through V after trace replay, terminal-read exposure, componentwise transport, displayed continuation replay, provenance, and local naming have been fixed.

Use Definition 683.7. The typed normal-form row is reached through the terminal route rather than through a host conversion check or evaluator graph.

Finally apply Definition 683.6. The packet has no coordinate for quotient normalization, global confluence, evaluator graphs, or external normalizers, so none can replace V as the typed boundary. □

Theorem 683.11 (ContinuationTraceNormalForm terminal route determinacy)**.** *Let* $Z = (S, T, R, Q, V, H, C, P, N$ *and* $Z' = (S', T', R', Q', V', H', C', P', N')$ *be accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packets. If two terminal reads have the same trace row, typed boundary row, componentwise* hsame *transport, displayed* Cont *route,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row, then they determine the same normal-form consumer surface. No off-route evaluator state, host conversion relation, quotient-normalization datum, global confluence theorem, or external normalization oracle can distinguish the two reads.*

Proof. First apply terminal scope from Definition 683.7. Each terminal read consumes the $\mathsf{ContinuationTrace}^{\uparrow}$ ledger, the $\mathsf{ContinuationBigStep}^{\uparrow}$ terminal-read row, and the $\mathsf{TypedReductionNormalForm}^{\uparrow}$ row through the displayed route before reaching a consumer surface.

Next use trace ledger exhaustion from Definition 683.8. Since the trace rows agree and every trace read is exhausted by that finite ledger, neither packet can supply an additional trace from a host evaluator or quotient normalizer.

Apply the terminal readback lock of Definition 683.9. The common transport, route, provenance, and naming rows place the terminal row behind the same T, Q, H, C, P, N surface in both packets.

Finally use typed boundary nonescape from Definition 683.10. The common typed row V is the only normal-form boundary available to the consumer, and the excluded off-route evaluator state, host conversion relation, quotient-normalization datum, global confluence theorem, and external normalization oracle have no coordinate in either accepted packet. □

This terminal-scope row is the paper obligation needed before Lean can formalize the continuation trace normal-form handoff.

Theorem 683.12 (ContinuationTraceNormalForm standard bridge surface)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the public terminal trace-normal-form packet bridges exactly from* $\mathsf{ContinuationTrace}^{\uparrow}$*,* $\mathsf{ContinuationBigStep}^{\uparrow}$*, and* $\mathsf{TypedReductionNormalForm}$ *through the displayed source, trace, terminal, terminal-read, typed-boundary, transport, route, provenance, and naming rows* $S, T, R, Q, V, H, C, P, N$*.*

The bridge surface reads no host conversion relation, quotient normalization datum, evaluator graph, global confluence theorem, or external normalizer. Its entire public object is the finite BHist *route whose trace replay, terminal readback, typed boundary,* hsame *transport,* Cont *replay,* Pkg *provenance, and* $\mathsf{NameCert}$ *row are already displayed in the carrier.*

Lean4 ✓ `BEDC.Derived.ContinuationTraceNormalFormUp.ContinuationTraceNormalFormUp StdBridge`

Proof. First apply Definition 683.2. The local certificate surface is exactly the carrier admission, trace replay, terminal-read exposure, typed normal-form readback, componentwise transport, displayed continuation route, package provenance, and local naming row.

Next use Definition 683.7. It orders the public route through $\mathsf{ContinuationTrace}^{\uparrow}$, then $\mathsf{ContinuationBigStep}^{\uparrow}$, then $\mathsf{TypedReductionNormalForm}^{\uparrow}$, all within the same displayed packet.

Apply Definition 683.11. A consumer that reads the same trace row, typed boundary row, transport row, route row, provenance row, and local naming row obtains the same normal-form consumer surface.

Finally use Definition 683.10. The excluded host conversion, quotient normalization, evaluator graph, global confluence, and external normalizer have no coordinate in Z, so the standard bridge surface is precisely the displayed finite route. □

Theorem 683.13 (ContinuationTraceNormalForm replay-prefix determinacy)**.** *Let* $Z = (S, T, R, Q, V, H, C, P, N)$ *and* $Z' = (S', T', R', Q', V', H', C', P', N')$ *be accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packets. Agreement on the source row, the* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger, and the displayed replay continuation determines the same terminal replay prefix before any terminal-read row or typed-boundary row is exposed.*

Thus no host conversion relation, quotient normalization datum, evaluator graph, global confluence theorem, or external normalizer can split two replay prefixes whose visible source, trace, and continuation rows agree.

Proof. Project both packets through Definition 683.1. The only replay-prefix coordinates before terminal exposure are the source row S, the trace ledger T, and the displayed continuation route C.

Apply Definition 683.7. It places the terminal-read and typed-boundary rows strictly after the trace-ledger replay, so the prefix is determined before Q or V can be read.

Use Definition 683.8. Since the trace ledger is exhausted by the displayed T row and replayed through C, an agreeing source, ledger, and replay route leave no second prefix source. □

Theorem 683.14 (ContinuationTraceNormalForm terminal typed-boundary exhaustion)**.** *Every terminal typed-boundary consumer of an accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$ *factors through the source row, trace ledger, terminal row, terminal-read row, typed normal-form boundary, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row* $S, T, R, Q, V, H, C, P, N$*.*

The consumer cannot read host conversion, quotient normalization, evaluator graphs, global confluence, or an external normalizer.

Proof. First apply Definition 683.7. It orders the terminal typed-boundary read through $S, T, R, Q, V, H, C, P, N$.

Next use Definition 683.9. The terminal row is locked behind the finite trace ledger, terminal-read row, transport, continuation, package, and naming rows.

Finally combine Definition 683.10 with Definition 683.12. The typed boundary and bridge surface expose exactly the displayed finite route, while the excluded host conversion, quotient normalization, evaluator graph, global confluence, and external normalizer have no carrier coordinate. □

Theorem 683.15 (ContinuationTraceNormalForm root unblock package)**.** *The carrier of Definition 683.1, replay-prefix determinacy, terminal typed-boundary exhaustion, trace ledger exhaustion, terminal readback lock, and standard bridge surface form the root package consumed by downstream halting and normal-form chapters. The package consists only of the rows $S, T, R, Q, V, H, C, P, N$ and their displayed* BHist*,* BMark*,* hsame*,* Cont*,* Pkg*, and* NameCert *structure.*

It supplies no host conversion relation, quotient normalization datum, evaluator graph, global confluence theorem, external normalizer, or off-route terminal reader.

Proof. Start from the carrier definition and Definition 683.2. They identify the displayed source, trace, terminal, terminal-read, typed-boundary, transport, route, package, and naming rows of the local packet.

Use Definition 683.13 for the prefix part of the package. The source, trace ledger, and replay continuation determine the terminal replay prefix before terminal-read exposure.

Use Definition 683.14, Definition 683.8, and Definition 683.9 for the terminal part. These clauses exhaust the trace ledger, lock terminal readback, and force typed-boundary consumers through the displayed route.

Finally apply Definition 683.12. It packages the same finite surface for downstream halting and normal-form chapters, with no coordinate for the excluded host, quotient, evaluator, confluence, normalizer, or off-route terminal-reader objects. □

Theorem 683.16 (ContinuationTraceNormalForm root terminal-source order)**.** *Every root consumer of an accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet $Z = (S, T, R, Q, V, H, C, P, N)$ must read the source row S, the* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger T, the terminal row R, the* $\mathsf{ContinuationBigStep}^{\uparrow}$ *terminal-read row Q, and the* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *boundary row V in that source, trace, terminal, terminal-read, typed-boundary order before any normal-form consumer surface is exposed. The rows H, C, P, N then carry the componentwise transport, displayed route, provenance, and local name for the same ordered read.*

Proof. Start from the carrier and NameCert obligations. They expose the finite tuple $S, T, R, Q, V, H, C, P, N$ and attach each public read to carrier admission, trace replay, terminal-read exposure, typed normal-form readback, transport, route, provenance, and naming.

Use terminal scope and terminal readback lock. The terminal row is not public before the trace ledger and terminal-read witness have been consumed through the displayed route, and the lock places R behind T, Q, H, C, P, N.

Finally apply typed boundary nonescape and the standard bridge surface. The normal-form boundary V is read only after the terminal route has been fixed, and the bridge exposes no host conversion, quotient normalization, evaluator graph, global confluence, external normalizer, or off-route terminal reader. □

Theorem 683.17 (ContinuationTraceNormalForm root typed-boundary route)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the typed-boundary row* V *is reachable only through the displayed* $\mathsf{ContinuationTrace}^{\uparrow}$ *row* T*, the displayed* $\mathsf{ContinuationBigStep}^{\uparrow}$ *terminal-read rows* R, Q*, and the displayed* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *row* V*, with transport, route, provenance, and naming supplied by* H, C, P, N*. No consumer can reach* V *through host conversion, quotient normalization, evaluator correctness, global confluence, or an external normalizer.*

Proof. Project the accepted packet. The only trace row is T, the only terminal-read rows are R, Q, and the only typed normal-form row is V.

Apply trace ledger exhaustion. It prevents a second trace source from entering before the terminal-read rows are consumed.

Apply terminal readback lock and typed boundary nonescape. The lock routes terminal readback through T, Q, H, C, P, N, and nonescape keeps the typed boundary inside the displayed trace, terminal, transport, route, package, and local naming rows. □

Theorem 683.18 (ContinuationTraceNormalForm root downstream unblock ledger)**.** *The root terminal-source order, the root typed-boundary route, trace ledger exhaustion, and terminal readback lock assemble the downstream unblock ledger for halting and normal-form chapters. The ledger surface is exactly* $S, T, R, Q, V, H, C, P, N$ *with its displayed* BHist*,* BMark*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows, and it exports no host conversion, quotient normalization, evaluator graph, global confluence theorem, external normalizer, or off-route terminal reader.*

Proof. Use Definition 683.16 to order the root read. A downstream consumer first sees the source, trace, terminal, terminal-read, and typed-boundary rows before it can consume the normal-form surface.

Use Definition 683.17 to identify the only route into the typed boundary. The route passes through $\mathsf{ContinuationTrace}^{\uparrow}$, $\mathsf{ContinuationBigStep}^{\uparrow}$, and $\mathsf{TypedReductionNormalForm}^{\uparrow}$ as displayed rows of the same packet.

Finally combine Definition 683.8 with Definition 683.9. The trace row is exhausted by T, the terminal row is locked behind T, Q, H, C, P, N, and the excluded host, quotient, evaluator, confluence, normalizer, and off-route terminal-reader objects have no coordinate in the ledger. □

Theorem 683.19 (ContinuationTraceNormalForm source-endpoint partition)**.** *Every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet partitions its public rows into source trace, terminal-read, typed-normal boundary, transport, route, provenance, and local* NameCert *data before any consumer reads the endpoint. For* $Z = (S, T, R, Q, V, H, C, P, N)$*, the source trace is* S, T*, the terminal-read surface is* R, Q*, the typed-normal boundary is* V*, the transport surface is* H*, the route surface is* C*, the provenance row is* P*, and the local naming row is* N*.*

Proof. Start from the carrier definition and Definition 683.2. They expose exactly the rows $S, T, R, Q, V, H, C, P, N$ and bind each row to carrier admission, trace replay, terminal-read exposure, typed normal-form readback, transport, route, provenance, and local naming.

Use Definition 683.7. It orders endpoint access after the trace ledger, terminal-read row, and typed normal-form row have been consumed through the displayed route.

Finally apply Definition 683.8 and Definition 683.10. The trace and typed-boundary reads cannot be replaced by host conversion, quotient normalization, evaluator graphs, global confluence, or external normalizers, so the displayed partition is the entire endpoint surface. □

Theorem 683.20 (ContinuationTraceNormalForm terminal-result determinacy)**.** *Two public terminal reads through the same displayed T, Q, H, C, P, N rows of accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packets have the same BEDC result row under* hsame *transport and* Cont *replay. No host evaluator, quotient normalizer, global confluence proof, or off-route terminal reader can separate the two reads.*

Proof. Begin with Definition 683.9. It locks each terminal row behind the trace ledger, terminal-read row, transport, route, provenance, and local naming rows.

Apply Definition 683.11. Agreement on the displayed trace, typed boundary, componentwise transport, route, provenance, and local naming rows determines the same normal-form consumer surface.

Use Definition 683.8. Since trace reads are exhausted by the displayed ledger and replayed only through C, no second terminal result can be read through an external trace source.

Finally apply Definition 683.10. The excluded host conversion, quotient normalization, evaluator graph, global confluence, and external normalizer have no row from which to distinguish the BEDC result. □

Lean4 ✓ `BEDC.Derived.ContinuationTraceNormalFormUp.ContinuationTraceNormalFormCarrier terminal result determinacy`

Theorem 683.21 (ContinuationTraceNormalForm typed-boundary ledger nonescape)**.** *Every typed-normal boundary read in an accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet factors through the displayed source trace, terminal-read, typed boundary, transport, route, provenance, and local naming ledger $S, T, R, Q, V, H, C, P, N$. The boundary cannot import host conversion, quotient normalization, global confluence, evaluator graphs, or an external normalizer.*

Proof. Project the packet through Definition 683.1. The typed-normal boundary is the row V in the same finite carrier as the source, trace, terminal, terminal-read, transport, route, provenance, and local name.

Apply Definition 683.10. It reads V only through the displayed trace, terminal, transport, route, package, and local naming rows.

Combine Definition 683.2, Definition 683.7, and Definition 683.8. These rows certify the carrier surface, order terminal access, and exhaust trace reads before the typed boundary reaches a consumer. □

Theorem 683.22 (ContinuationTraceNormalForm route ledger totality)**.** *For every accepted* ContinuationTraceNor *packet $Z = (S, T, R, Q, V, H, C, P, N)$, the route ledger is total over the displayed source, trace, terminal, terminal-read, typed-boundary, transport, route, provenance, and naming rows. Every public normal-form consumer must read S, then the* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger T, then the terminal row R, then the* $\mathsf{ContinuationBigStep}^{\uparrow}$ *terminal-read row Q, then the* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *row V, with componentwise* hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through P, and local* $\mathsf{NameCert}_{\mathsf{ContinuationTraceNormalForm}^{\uparrow}}$ *naming through N.*

Proof. Begin with Definition 683.7. It orders terminal exposure through the finite trace ledger, terminal-read row, and typed normal-form row inside the displayed packet.

Next use Definition 683.8. The trace coordinate is exhausted by T and replayed only through C, so no public consumer can supply a second trace ledger.

Apply Definition 683.9. The terminal row R is locked behind T, Q, H, C, P, N, and therefore the route ledger reaches the terminal read only through the displayed rows.

Finally use Definition 683.11 and Definition 683.12. Determinacy prevents off-route data from separating two reads with the same ledger rows, while the bridge surface exports exactly the public continuation trace normal-form route. □

Theorem 683.23 (ContinuationTraceNormalForm normal boundary exhaustion)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the typed normal-form boundary is exhausted by the* $\mathsf{ContinuationTrace}^{\uparrow}$*,* $\mathsf{ContinuationBigStep}^{\uparrow}$*, and* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *rows of the same packet. The boundary exports the finite route* $S, T, R, Q, V, H, C, P, N$ *and does not export host conversion, quotient normalization, evaluator correctness, global confluence, or an external normalizer.*

Proof. First apply Definition 683.22. It makes the public route ledger total over $S, T, R, Q, V, H, C, P, N$.

Use Definition 683.10. The typed boundary is read through the displayed trace, terminal, transport, route, package, and local naming rows, not through host conversion or quotient normalization.

Next combine Definition 683.9 with Definition 683.12. The terminal-read row is locked behind the finite ledger, and the public bridge exposes exactly the continuation trace, big-step terminal read, and typed normal-form rows.

The remaining exclusions follow from Definition 683.6. Evaluator correctness, global confluence, quotient behaviour, host conversion, and an external normalizer have no coordinate in the accepted packet. □

Theorem 683.24 (ContinuationTraceNormalForm source route obligation package)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the source, terminal, transport, route, provenance, and* $\mathsf{NameCert}$ *obligations are packaged by the finite route ledger. The source obligation is the displayed source row* S *and trace ledger* T*; the terminal obligation is the displayed terminal row* R *and terminal-read row* Q*; the transport obligation is* H*; the route obligation is* C*; the provenance obligation is* P*; and the naming obligation is* N*. These obligations are consumed before the typed normal-form boundary* V *is available to a public consumer.*

Proof. Start with Definition 683.2. It identifies carrier admission, trace replay, terminal-read exposure, typed normal-form readback, transport, route, provenance, and local naming as the local certificate surface.

Apply Definition 683.22. The route ledger is total over $S, T, R, Q, V, H, C, P, N$, so each obligation is attached to a displayed coordinate of the accepted packet.

Use Definition 683.23. The typed normal-form boundary is exhausted by the continuation trace, big-step terminal read, and typed normal-form rows of the same finite route.

Finally combine Definition 683.11 with Definition 683.12. The same source, terminal, transport, route, provenance, and naming rows determine the public normal-form consumer surface, so the obligation package has no hidden host conversion, quotient-normalization, evaluator, or oracle component. □

Theorem 683.25 (ContinuationTraceNormalForm visible source route)**.** *For every accepted* ContinuationTraceNorr *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the public source route exposes the source history row* S*, the* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger* T*, the terminal row* R*, the* $\mathsf{ContinuationBigStep}^{\uparrow}$ *terminal-read row* Q*, the* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *boundary row* V*, the componentwise* hsame *transports* H*, the displayed* Cont *routes* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{ContinuationTraceNormalForm}^{\uparrow}}$ *row* N *before any terminal consumer reads the normal-form endpoint.*

No terminal consumer can read the endpoint by skipping the visible source route, adding an evaluator coordinate, importing host conversion, quotient trace equality, global confluence, or external normalization.

Proof. Project the accepted carrier from Definition 683.1. Its visible rows are exactly $S, T, R, Q, V, H, C, P, N$.

Apply Definition 683.6 and Definition 683.7. They place terminal exposure behind the displayed trace ledger, terminal-read row, typed normal-form row, transports, routes, provenance, and local name.

Use Definition 683.8 and Definition 683.11. The finite trace ledger exhausts exported trace reads, and the displayed route determines the same public normal-form consumer surface whenever its route rows agree. □

Theorem 683.26 (ContinuationTraceNormalForm typed-reduction handoff)**.** *Every typed-reduction or normal-form consumer of an accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$ *can read the terminal row only through* T, R, Q, V, H, C, P, N *after the source row* S *has been displayed. The handoff cannot bypass the* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger, cannot import host normalization, and cannot replace the* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *boundary by quotient normalization, evaluator correctness, or global confluence.*

Proof. Begin with the terminal readback lock of Definition 683.9. It places R behind the trace ledger, terminal-read row, transports, routes, provenance, and local name.

Apply Definition 683.10. The typed normal-form boundary is read through the displayed trace, terminal, transport, route, package, and naming rows rather than through host conversion or evaluator data.

Finally use Definition 683.12. The bridge exports exactly the continuation trace, terminal-read, typed-boundary, transport, route, provenance, and naming surface, so the typed-reduction handoff has no hidden host normalizer or off-route terminal reader. □

Theorem 683.27 (ContinuationTraceNormalForm consumer readback envelope)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the downstream consumer envelope consists exactly of the visible source route of Definition 683.25, the typed-reduction handoff of Definition 683.26, the terminal readback lock of Definition 683.9, and the standard bridge surface of Definition 683.12.*

The envelope exports no hidden evaluator, quotient trace equality, external normalizer, host conversion route, global confluence theorem, or unbounded fuel row beyond the displayed finite packet $S, T, R, Q, V, H, C, P, N$.

Proof. First combine Definition 683.25 with Definition 683.26. The source route displays every row consumed by the typed-reduction handoff before a terminal consumer reads the normal-form endpoint.

Next apply Definition 683.9. It makes the terminal row available only behind the finite trace, terminal-read, transport, route, provenance, and local naming rows.

Finally apply Definition 683.12 and Definition 683.6. The standard bridge surface is the public consumer object, and the non-escape clause rules out hidden evaluator state, quotient trace equality, external normalization, host conversion, global confluence, and unbounded fuel. □

Theorem 683.28 (ContinuationTraceNormalForm prefix splice lock)**.** *For every accepted* ContinuationTraceNormal *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, every prefix splice used by a downstream normal-form consumer is locked to the displayed* $\mathsf{ContinuationTrace}^{\uparrow}$ *row* T *and to the displayed* Cont *route* C*. The*

splice cannot be supplied by a second trace ledger, host evaluator prefix, quotient trace representative, global confluence proof, or external normalizer.

Proof. Project the accepted carrier from Definition 683.1. The only trace ledger available to the packet is the displayed row T, and the only replay route available to a consumer is the displayed Cont row C.

Apply Definition 683.8. It exhausts exported trace reads by the finite $\mathsf{ContinuationTrace}^{\uparrow}$ ledger and prevents a second prefix source from entering the public surface.

Finally use Definition 683.27. The consumer envelope routes terminal readback through the same $S, T, R, Q, V, H, C, P, N$ packet, so host prefixes, quotient representatives, global confluence, and external normalization have no splice coordinate. □

Theorem 683.29 (ContinuationTraceNormalForm terminal prefix transport)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, terminal prefix transport moves the terminal row* R*, the* $\mathsf{ContinuationBigStep}^{\uparrow}$ *terminal-read row* Q*, and the* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *boundary row* V *only through* H, C, P, N*. No consumer may transport* R, Q, V *through host conversion, evaluator graphs, quotient normalization, global confluence, or an external normalizer.*

Proof. Begin with Definition 683.9. It places terminal readback behind the displayed trace, terminal-read, transport, continuation, provenance, and local naming rows.

Use Definition 683.10. The typed boundary is read as a row of the same packet, so V travels with the displayed hsame transport and Cont route rather than with a host conversion relation.

Apply Definition 683.27. The envelope exposes R, Q, V only inside $S, T, R, Q, V, H, C, P, N$, and the excluded evaluator, quotient, confluence, and external-normalizer coordinates are absent from that carrier. □

Theorem 683.30 (ContinuationTraceNormalForm normal-boundary consumer totality)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the normal-boundary consumer surface is exhausted by* $S, T, R, Q, V, H, C, P, N$*. The consumer cannot use host conversion, quotient normalization, evaluator graphs, global confluence, or an external normalizer as an additional terminal route.*

Proof. Start with Definition 683.23. It identifies the typed normal-form boundary with the displayed continuation trace, terminal-read, typed-boundary, transport, route, provenance, and naming rows.

Next combine the prefix splice lock with terminal prefix transport. The splice is tied to T and C, while the terminal rows R, Q, V move only through H, C, P, N.

Finally apply Definition 683.6. Since the accepted carrier has no host conversion, quotient-normalization, evaluator-graph, global-confluence, or external-normalizer coordinate, the displayed rows exhaust every normal-boundary consumer read. □

Theorem 683.31 (ContinuationTraceNormalForm root readback order exhaustion)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, root readback is exhausted in the order source row* S*,* $\mathsf{ContinuationTrace}^{\uparrow}$ *trace ledger* T*, terminal row* R*,* $\mathsf{ContinuationBigStep}^{\uparrow}$ *terminal-read row* Q*,* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *typed-boundary row* V*, then the structural rows* H, C, P, N*. No downstream normal-form consumer may read a terminal or typed boundary before that displayed order has been consumed.*

Proof. Begin with terminal scope, Definition 683.7. It places terminal exposure behind the trace ledger, terminal-read row, and typed normal-form row of the same accepted packet.

Next use trace ledger exhaustion, Definition 683.8. The trace portion is exactly the finite T row replayed from source S, so no second trace source can enter before the terminal rows are read.

Apply terminal readback lock, Definition 683.9. It locks R behind T, Q, H, C, P, N, which fixes the terminal-read stage before any downstream endpoint consumer is exposed.

Finally use typed boundary nonescape, Definition 683.10. The typed boundary V has no host conversion, quotient-normalization, evaluator-graph, global-confluence, or external-normalizer substitute, so the displayed order exhausts root readback. □

Theorem 683.32 (ContinuationTraceNormalForm trace-terminal-typed lock)**.** *Let $Z = (S, T, R, Q, V, H, C, P, N)$ and $Z' = (S', T', R', Q', V', H, C, P, N)$ be accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packets with the same structural rows H, C, P, N. If their source, trace, terminal, terminal-read, and typed-boundary reads are transported through those shared rows, then both packets expose the same trace-terminal-typed boundary to every downstream normal-form consumer.*

Proof. First apply trace ledger exhaustion, Definition 683.8. Any trace read is exhausted by the displayed ledger and replayed through the shared continuation row C.

Next apply terminal readback lock, Definition 683.9. The shared H, C, P, N rows place terminal readback behind the same transport, replay, provenance, and naming surface in both packets.

Use typed boundary nonescape, Definition 683.10. The typed boundary is a row of the packet and cannot be separated by host conversion, quotient normalization, evaluator graphs, global confluence, or an external normalizer.

Finally invoke the standard bridge surface, Definition 683.12. The public consumer sees exactly the continuation trace, terminal-read, typed-boundary, transport, route, provenance, and naming rows, so shared H, C, P, N lock the trace-terminal-typed boundary. □

Theorem 683.33 (ContinuationTraceNormalForm downstream normal-form consumer boundary)**.** *Every downstream normal-form consumer of an accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet $Z = (S, T, R, Q, V, H, C, P, N)$ is bounded by the displayed source, trace, terminal, terminal-read, typed-boundary, transport, route, provenance, and local naming rows. The consumer surface excludes host conversion, quotient normalization, evaluator graphs, global confluence, and external normalizers.*

Proof. Start from normal-boundary consumer totality, Definition 683.30. It exhausts the normal-boundary surface by the rows $S, T, R, Q, V, H, C, P, N$.

Next combine terminal scope and the standard bridge surface, Definition 683.7 and Definition 683.12. Together they route the public consumer through $\mathsf{ContinuationTrace}^{\uparrow}$, $\mathsf{ContinuationBigStep}^{\uparrow}$, and $\mathsf{TypedReductionNormalForm}^{\uparrow}$ inside the same finite packet.

Use root readback order exhaustion from Definition 683.31. It fixes the source, trace, terminal, terminal-read, and typed-boundary order before the downstream consumer may read the endpoint.

Finally use typed boundary nonescape, Definition 683.10. The excluded host conversion, quotient-normalization, evaluator-graph, global-confluence, and external-normalizer objects are not coordinates of Z, so they cannot extend the downstream boundary. □

Theorem 683.34 (ContinuationTraceNormalForm terminal selector totality)**.** *Every downstream normal-form consumer route for an accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet*

$$Z = (S, T, R, Q, V, H, C, P, N)$$

passes through the source row S, trace ledger T, terminal row R, terminal-read row Q, typed normal-form row V, transport row H, continuation row C, provenance row P, and local naming

row N. Terminal selection is fixed by the trace ledger and terminal-read row, and the consumer receives no host conversion, quotient normalization, evaluator graph, global confluence theorem, or external normalizer.

Proof. Start with terminal scope and trace ledger exhaustion, Definition 683.7 and Definition 683.8. They force terminal exposure to pass through the finite trace ledger T after the source row S.

Next apply terminal readback lock, Definition 683.9. The terminal selection is tied to R, Q and carried through H, C, P, N, so a downstream consumer cannot substitute an evaluator state or quotient normalizer for the terminal-read witness.

Finally use typed boundary nonescape and the downstream normal-form consumer boundary, Definition 683.10 and Definition 683.33. The typed row V is reached only through the displayed packet, which exhausts every terminal selector route by $S, T, R, Q, V, H, C, P, N$. □

Theorem 683.35 (ContinuationTraceNormalForm normal row precedence)**.** *In every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet $Z = (S, T, R, Q, V, H, C, P, N)$, the normal row V can be read only after the source row S, trace ledger T, terminal row R, terminal-read row Q, transport row H, continuation row C, provenance row P, and local naming row N have fixed the terminal selector route. No downstream consumer may read V as a host conversion result, quotient-normalized value, evaluator graph endpoint, confluence result, or external normalizer output.*

Proof. Begin with root readback order exhaustion, Definition 683.31. It orders source, trace, terminal, terminal-read, and typed-boundary access before any downstream endpoint consumer is exposed.

Use terminal selector totality from Definition 683.34. The same S, T, R, Q, H, C, P, N route fixes how the consumer reaches V, so the normal row is not an independent terminal selector.

Finally apply typed boundary nonescape, Definition 683.10. The typed normal-form row is a coordinate of the accepted packet and has no host, quotient, evaluator, confluence, or oracle substitute. □

Theorem 683.36 (ContinuationTraceNormalForm consumer route nonbranching)**.** *Let $Z = (S, T, R, Q, V, H, C, P,$ and $Z' = (S', T, R', Q, V', H, C, P, N)$ be accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packets whose trace ledger, terminal-read witness, typed boundary, transport row, consumer route, provenance row, and local name are the same. Then both packets determine the same downstream normal-form consumer surface. No host conversion, quotient normalization, evaluator graph, global confluence theorem, or external normalizer can branch the consumer route.*

Proof. First apply terminal route determinacy, Definition 683.11. Agreement on the trace ledger, typed boundary, transport, route, provenance, and local naming rows fixes the public normal-form consumer surface.

Next combine terminal readback lock with normal row precedence, Definition 683.9 and Definition 683.35. The shared terminal-read witness and typed boundary force both packets through the same T, Q, V, H, C, P, N route before the consumer may read the normal form.

Finally use the downstream normal-form consumer boundary, Definition 683.33. Since the excluded host conversion, quotient normalization, evaluator graph, global confluence, and external normalizer have no coordinate in either packet, they cannot separate the two consumer surfaces. □

Theorem 683.37 (ContinuationTraceNormalForm terminal-consumer cut)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet $Z = (S, T, R, Q, V, H, C, P, N)$, any terminal consumer that reads the endpoint row R must pass through the displayed trace row T, terminal-read row Q, typed-boundary row V, transport row H, continuation route C, provenance row P, and local naming*

row N. No host evaluator state, quotient trace representative, global confluence proof, or external normalizer can supply an alternate terminal route.

Proof. Project the accepted carrier of Definition 683.1. The terminal row R is not a free endpoint; it appears in the finite packet beside T, Q, V, H, C, P, N.

Apply terminal scope and terminal readback lock, Definition 683.7 and Definition 683.9. These place terminal exposure behind the trace ledger, terminal-read row, transport, continuation route, provenance, and local naming surface.

Finally use consumer readback and downstream boundary, Definition 683.27 and Definition 683.33. The accepted consumer reads R only inside $S, T, R, Q, V, H, C, P, N$, while the excluded host evaluator, quotient, confluence, and external-normalizer coordinates are absent from the packet. □

Theorem 683.38 (ContinuationTraceNormalForm trace-replay cut)**.** *For every accepted* ContinuationTraceNormalF *packet $Z = (S, T, R, Q, V, H, C, P, N)$, any replay cut used by a downstream normal-form consumer is exhausted by the displayed* $\mathsf{ContinuationTrace}^{\uparrow}$ *row T and the displayed* Cont *route C. The replay cut cannot import a second trace ledger, host evaluator graph, quotient trace equality, global confluence datum, or external normalizer.*

Proof. Start with trace ledger exhaustion, Definition 683.8. It says that trace reads exported by the packet are exactly the finite $\mathsf{ContinuationTrace}^{\uparrow}$ ledger rather than a second replay source.

Use prefix splice lock, Definition 683.28. The splice available to a downstream normal-form consumer is tied to the displayed T row and the displayed C route.

Finally apply root readback order exhaustion, Definition 683.31. The replay stage precedes terminal and typed-boundary consumption in the displayed packet order, so host evaluator graphs, quotient trace equality, global confluence, and external normalizers have no replay-cut coordinate. □

Theorem 683.39 (ContinuationTraceNormalForm normal-boundary cut)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet $Z = (S, T, R, Q, V, H, C, P, N)$, the normal-boundary consumer cut is exactly the displayed route through $S, T, R, Q, V, H, C, P, N$. A normal-boundary consumer cannot import host conversion, quotient normalization, evaluator graphs, global confluence, or external normalizers as extra boundary data.*

Proof. Begin with normal-boundary consumer totality, Definition 683.30. It already exhausts the normal-boundary surface by the displayed packet rows.

Combine the terminal-consumer cut and trace-replay cut. The terminal cut forces reads of R, Q, V through T, H, C, P, N, while the replay cut exhausts the trace side by T and C.

Finally apply typed-boundary nonescape and downstream normal-form consumer boundary, Definition 683.10 and Definition 683.33. Host conversion, quotient normalization, evaluator graphs, global confluence, and external normalizers are not coordinates of Z, so the displayed rows are the whole normal-boundary cut. □

Theorem 683.40 (ContinuationTraceNormalForm root terminal readback totality)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet $Z = (S, T, R, Q, V, H, C, P, N)$, the terminal row R is exposed as a root readback row before any downstream normal-form consumer can read it. The exposure is anchored by the displayed* BHist *source row S, the* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger T, the* $\mathsf{ContinuationBigStep}^{\uparrow}$ *terminal-read row Q, the componentwise* hsame *transports H, the displayed* Cont *route C, the* Pkg *provenance row P, and the local* NameCert *row N.*

Proof. Start with root readback order exhaustion, Definition 683.31. It places the terminal row after the source and trace rows, and before any downstream terminal or typed-boundary consumer.

Apply the terminal-consumer cut, Definition 683.37. It forces every terminal consumer through T, Q, V, H, C, P, N before the endpoint row R can be read.

Finally use the trace-replay cut and normal-boundary cut, Definition 683.38 and Definition 683.39. The replay side is exhausted by T and C, and the normal-boundary side is exhausted by the same finite packet. Thus terminal readback is total at the root before consumer access. □

Theorem 683.41 (ContinuationTraceNormalForm root replay prefix totality)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, every root prefix read used for replay factors through the displayed* $\mathsf{ContinuationTrace}^{\uparrow}$ *row* T *and the displayed* Cont *route* C*. The prefix read remains attached to the same* BHist *source row* S*, componentwise* hsame *transports* H*,* Pkg *provenance row* P*, and local* NameCert *row* N*; it cannot use an off-packet replay, host evaluator prefix, quotient trace equality, global confluence datum, or external normalizer.*

Proof. Begin with the trace-replay cut, Definition 683.38. It states that any replay cut used downstream is exhausted by the displayed trace row T and displayed continuation route C.

Use root readback order exhaustion, Definition 683.31. The replay stage is part of the ordered root route from S through T before terminal and typed-boundary rows are consumed.

Now apply the terminal-consumer cut and normal-boundary cut. The terminal cut keeps endpoint reads behind the same T, Q, V, H, C, P, N rows, while the normal boundary cut prevents host reduction or off-packet boundary data from supplying a prefix. Hence every root prefix read is the displayed T-through-C replay. □

Theorem 683.42 (ContinuationTraceNormalForm root normal boundary exhaustion)**.** *For every accepted* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *packet* $Z = (S, T, R, Q, V, H, C, P, N)$*, the root normal-form boundary is exhausted by the displayed source, trace, terminal, terminal-read, typed-boundary, transport, route, provenance, and local naming rows. The boundary has no host reduction, hidden terminal row, or off-packet replay beyond the* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *surface of* Z*.*

Proof. First apply the normal-boundary cut, Definition 683.39. It states that the normal-boundary consumer cut is exactly the displayed route through $S, T, R, Q, V, H, C, P, N$.

Use root readback order exhaustion to keep the boundary on the root order from source through trace, terminal, terminal-read, and typed-boundary rows. Then use root terminal readback totality, Definition 683.40, to expose the terminal row before any consumer can detach it.

Finally apply root replay prefix totality, Definition 683.41. It blocks off-packet replay at the prefix stage, while the normal-boundary cut already blocks host reduction and hidden terminal data. Therefore the root normal-form boundary is exhausted by the displayed packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{ContinuationTraceNormalForm}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ packet is generated from a source history row, a finite $\mathsf{ContinuationTrace}^{\uparrow}$ ledger, a terminal row, a $\mathsf{ContinuationBigStep}^{\uparrow}$ terminal-read witness, a $\mathsf{TypedReductionNormalForm}^{\uparrow}$ row, componentwise hsame transports, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ContinuationTraceNormalForm}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 683.1, Definition 683.2, Definition 683.6, Definition 683.7, Definition 683.8, Definition 683.9, Definition 683.10, Definition 683.12, Definition 683.13, Definition 683.14, Definition 683.15, Definition 683.16, Definition 683.17, and Definition 683.18 bind carrier admission, trace replay, terminal-read exposure, typed normal-form readback, non-escape, trace-ledger exhaustion, terminal readback lock, typed-boundary nonescape, the standard bridge surface, replay-prefix determinacy, terminal typed-boundary exhaustion, the root package, terminal-source order, typed-boundary route, and downstream unblock ledger to the displayed BHist, BMark, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus(NameCert$_{\mathsf{ContinuationTraceNormalForm}\uparrow}$, bridgeChecked)

Not claimed: This chapter does not close typed subject reduction, global confluence, host conversion, evaluator correctness, quotient behaviour, or machine-checked bridge verification.
Upgrade path: No further formal-axis upgrade remains; the chapter is at bridgeCheckedV.

Chapter 684

A Concrete Naming Certificate for $\mathsf{ContextualClassReading}^{\uparrow}$

The $\mathsf{ContextualClassReading}^{\uparrow}$ packet realizes the contextual-class restriction of section 9457.1 as finite naming data. A class-like phrase is admitted only through the displayed context that classifies it, together with transport, route, provenance, and local ledger rows. The packet does not supply a host class object, a universal membership predicate, or an ontology-level promotion of the phrase.

The packet consumes the fivefold Russell boundary surface of chapter 517 and the analysis ladder of chapter 518. Their expression row, displayed contextual classifier, relation-first bridge, scope row, witnessed descent ledger, and laddered relation-first stability are the sibling rows repackaged as E, G, R, S, H, C, P, N for contextual classification, relation-first licensing, and scoped consumption. Thus the contextual-class carrier is the local reading of the Russell boundary and its analysis ladder rather than an isolated kernel packet.

Definition 684.1 (Contextual class reading carrier)**.** *A* $\mathsf{ContextualClassReading}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (E, G, R, S, H, C, P, N)$$

with the following displayed rows:

1. *E is the expression row whose class-like grammar is being read;*
2. *G is the displayed context row that supplies the local classifier for E;*
3. *R is the relation-first row recording the behaviour that licenses the contextual read before any object-like consumption;*
4. *S is the scope row naming the stratum and consumer boundary in which the classifier may be used;*
5. *H records componentwise* hsame *transports for expressions, contexts, relation rows, scope rows, provenance rows, route rows, and local names;*
6. *C records the displayed* Cont *routes by which a consumer may inspect E, read G, replay R, and return to the scoped ledger S;*
7. *P is the* Pkg *provenance over* BHist, Cont, hsame, *contextual classifier rows, relation rows, scope rows, and the surrounding Russell boundary packets;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ContextualClassReading}^{\uparrow}}$ *ledger.*

The carrier is exactly this finite packet. It has no coordinate for a host class object, unscoped membership relation, quotient over class phrases, reducibility principle, or context-free classifier.

Lean4 (definition) `BEDC.Derived.ContextualClassReadingUp.ContextualClassReadingCarrier`

Theorem 684.2 (Contextual class reading NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContextualClassReading}^{\uparrow}}$ *surface for Definition 684.1 consists of carrier admission for* $K = (E, G, R, S, H, C, P, N)$*, contextual classifier exposure through* G*, relation-first licensing through* R*, scoped consumption through* S*, componentwise transport through* H*, displayed continuation through* C*, provenance through* P*, and local ledger exactness through* N*.*

Proof. Carrier admission is projection from Definition 684.1. The expression, context, relation, scope, transport, route, provenance, and naming rows are all displayed coordinates of the same finite BHist packet.

Use Definition 517.2 to read contextual-class discipline as one of the five Russell boundary obligations. The context row G supplies the classifying context, while the relation row R keeps the behaviour that licenses the name visible before any object-like use is consumed.

The remaining obligations are routed through S, H, C, P, N. The scope row fixes where the classifier may be used, the componentwise hsame data records permitted transports, and the Cont routes replay the public read without adding a host class coordinate. □

Lean4 ✓ `BEDC.Derived.ContextualClassReadingUp.ContextualClassReadingCarrier namecert obligations`

Theorem 684.3 (Contextual class reading no object promotion)**.** *Let* $K = (E, G, R, S, H, C, P, N)$ *be an accepted* $\mathsf{ContextualClassReading}^{\uparrow}$ *carrier. No public read of* E *promotes the contextual classifier row* G *into a host class object, an unstratified membership predicate, or a context-free object whose members may be inspected outside* S, H, C, P, N*.*

Proof. Project the accepted packet to its displayed rows. The only coordinate that can classify E is G, and G is paired with the scope row S and the routes in C.

Apply Definition 506.2. A contextual class expression cannot be turned into an object-level self-membership carrier merely by asking a class-like question about it.

Then apply Definition 517.3. The packet keeps expression, contextual classifier, bridge, and ledger rows distinct, so a consumer can inspect the class-like phrase only through the displayed context and cannot recover a host class object from the local ledger. □

Lean4 ✓ `BEDC.Derived.ContextualClassReadingUp.ContextualClassReadingCarrier no object promotion`

Theorem 684.4 (Contextual class reading classifier transport)**.** *Let* $K = (E, G, R, S, H, C, P, N)$ *be an accepted* $\mathsf{ContextualClassReading}^{\uparrow}$ *carrier. Every transported classifier read of the contextual class expression factors through the componentwise* hsame *row* H *and the displayed* Cont *routes* C*, returning to the same expression, context, relation, scope, provenance, and local ledger rows.*

Lean4 ✓ `BEDC.Derived.ContextualClassReadingUp.ContextualClassReadingCarrier classifier transport`

Proof. Start from a transported public classifier read. Carrier projection gives the expression row E, the context row G, and the relation-first row R as the only rows that can license the class-like reading.

The transport row H supplies the componentwise hsame data for those rows and for S, C, P, N. The route row C supplies the displayed Cont path by which the consumer reads the context and returns to the scoped ledger.

Use Definition 518.2 for contextual-class locality and relation-first classifier stability. Since the ladder obligations keep contextual class reads and relation rows tied to their displayed transports, the transported read remains inside E, G, R, S, H, C, P, N. □

Theorem 684.5 (Contextual class reading ledger exactness)**.** *Every accepted* ContextualClassReading$^{\uparrow}$ *packet exports contextual class information only through the finite rows*

$$E, G, R, S, H, C, P, N.$$

The ledger exposes the class-like expression, its displayed context, relation-first licensing row, scoped consumer boundary, componentwise hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row. It exports no hidden class ontology, no primitive class extension, no global membership predicate, no reducibility principle, and no context-free classifier.*

Proof. Read the carrier as the tuple $K = (E, G, R, S, H, C, P, N)$. The definition lists every row available to a downstream consumer, and the local NameCert ledger records exactly those rows.

Apply Definition 684.2 to identify the complete obligation surface. Contextual classifier exposure is G, relation-first licensing is R, scoped consumption is S, and transport, route, provenance, and local naming are H, C, P, N.

Apply Definition 684.3 and Definition 684.4. The first theorem blocks object promotion, while the second confines transported classifier reads to the displayed hsame and Cont rows.

Thus the ledger is exact: every public contextual-class read is a read of the finite packet, with no hidden ontology or context-free classifier left over. □

Lean4 ✓ `BEDC.Derived.ContextualClassReadingUp.ContextualClassReadingLedgerExactness`

Theorem 684.6 (Contextual class reading public interface export)**.** *Let $K = (E, G, R, S, H, C, P, N)$ be an accepted* ContextualClassReading$^{\uparrow}$ *carrier. The public interface exported by K is exactly the finite contextual classifier row G, relation-first licensing row R, scoped consumer row S, componentwise transport row H, displayed replay row C, provenance row P, and local* NameCert *row N, together with the expression row E they license. No public consumer receives a host class object, a context-free classifier, or an unscoped membership row outside this displayed packet.*

Proof. Project the accepted carrier. The definition exposes only E, G, R, S, H, C, P, N, and the obligation theorem identifies contextual classifier exposure, relation-first licensing, scoped consumption, transport, replay, provenance, and local naming as the complete surface.

Apply the no-object-promotion theorem. It blocks any public read of E from turning G into a host class object or an unstratified membership predicate.

Apply classifier transport and ledger exactness. Transported reads must return through H and C, while the ledger exports only the finite packet rows. Thus the public interface is precisely the displayed contextual classifier, relation-first licensing, scoped consumer, transport, replay, provenance, and local NameCert surface. □

Lean4 ✓ `BEDC.Derived.ContextualClassReadingUp.ContextualClassReadingCarrier public interface export`

Theorem 684.7 (Contextual class reading mature sibling route)**.** *Every mature consumer of* ContextualClassReading$^{\uparrow}$ *factors through the* RussellBoundary$^{\uparrow}$ *and* RussellAnalysisLadder$^{\uparrow}$ *sibling rows before reading the local contextual-class packet. The consumer receives the displayed expression, contextual classifier, relation-first licensing, scope, transport, replay, provenance, and local naming rows, but receives no host class ontology, global membership relation, reducibility principle, or context-free classifier.*

Proof. Project the carrier of Definition 684.1. The local rows E, G, R, S, H, C, P, N expose only a contextual classifier and its scoped relation-first route.

Apply Definition 684.2. The public read is already constrained to contextual classifier exposure, relation-first licensing, scoped consumption, transport, replay, provenance, and local naming.

Now use the sibling dependency paragraph at the start of the chapter. The contextual packet consumes the fivefold Russell boundary surface and the analysis ladder before its own local read is available, so a mature consumer must factor through those sibling rows first. The no-object-promotion, public-interface, and ledger-exactness theorems then rule out host class ontology, global membership, reducibility, and context-free classifiers. □

Lean4 ✓ `BEDC.Derived.ContextualClassReadingUp.ContextualClassReadingCarrier mature sibling route`

Closure status for $\mathsf{NameCert}_{\mathsf{ContextualClassReading}\uparrow}$.

Constructive story: A $\mathsf{ContextualClassReading}^{\uparrow}$ packet is generated from a class-like expression row, a displayed classifier context, a relation-first licensing row, a scope row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ContextualClassReading}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 684.1, Definition 684.2, Definition 684.3, Definition 684.4, and Definition 684.5 bind the finite carrier, local obligations, no-promotion boundary, classifier transport, and ledger exactness for contextual class readings.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ContextualClassReading}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, bridge checking, host class ontology, primitive class extensions, global membership, reducibility, or context-free classifiers.

Upgrade path: No further theory-axis grade remains; Lean verification and bridge checking remain separate verification-axis work for the displayed contextual-class route.

Chapter 685

A Concrete Naming Certificate for $\mathsf{EmptyBoundarySelector}^{\uparrow}$

The $\mathsf{EmptyBoundarySelector}^{\uparrow}$ interface realizes the empty-boundary witness surface of Definition 9399.1. It packages one enacted mark above a displayed source Hist row, the resulting Ext row, the local witness that this mark is the enacted branch, and the naming boundary that keeps the witness local. It is not a global branch selector and not an oracle for histories outside the packet.

The local enacted-boundary witness is consumed by chapter 585, chapter 516, and chapter 623. $\mathsf{EmptyBoundarySelector}^{\uparrow}$ supplies the one-step branch row, $\mathsf{FableBranchWitness}^{\uparrow}$ exposes it as a local branch witness, $\mathsf{EmptyFableLedger}^{\uparrow}$ records it as a finite ledger entry, and $\mathsf{FableMachineClock}^{\uparrow}$ orders that ledger without promoting the row to a global chooser.

Definition 685.1 (EmptyBoundarySelector carrier)**.** *An* $\mathsf{EmptyBoundarySelector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (H, M, R, E, W, T, C, P, N)$$

with the following displayed rows:

1. *H is the source* Hist *row whose empty boundary is being filled;*
2. *M is the enacted mark row, one of the two kernel marks b_0 or b_1;*
3. *R is the resulting* Hist *row after the enacted mark is recorded above H;*
4. *E is the displayed* $\mathsf{Ext}(H, M, R)$ *row;*
5. *W is the local enacted-mark witness row, exposing that M is the mark actually used by this packet;*
6. *T records componentwise* hsame *transports for H, M, R, E, W and the local naming row;*
7. *C records the displayed* Cont *routes by which a consumer reads the source row, enacted mark, result row, extension row, witness row, and local name;*
8. *P is the* Pkg *provenance over* Hist, Ext, hsame, Cont, Pkg, $\mathsf{NameCert}$, *and the Empty-boundary reading of Definition 9399.1;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{EmptyBoundarySelector}^{\uparrow}}$ *row.*

The classifier compares accepted carriers only by the displayed rows $H, M, R, E, W, T, C, P, N$. It has no coordinate for an undisplayed selector function, a branch policy over unrelated histories, a truth oracle, or an infinite ledger.

Lean4 ✓ `BEDC.Derived.EmptyBoundarySelectorUp.EmptyBoundarySelectorTasteGate single carrier alignment`

Theorem 685.2 (EmptyBoundarySelector NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{EmptyBoundarySelector}^{\uparrow}}$ *surface for the carrier of Definition 685.1 consists of five finite obligations:*

1. *carrier admission, requiring every accepted object to expose* $Q = (H, M, R, E, W, T, C, P, N)$*;*
2. *source-boundary admission, requiring* H *to be the displayed* Hist *row whose empty boundary is filled;*
3. *enacted-mark exactness, requiring* M*,* R*, and* E *to exhibit the same* $\mathsf{Ext}(H, M, R)$ *step;*
4. *witness exposure, requiring* W *to name the enacted mark locally and to be transported only through the componentwise* hsame *and* Cont *rows* T *and* C*;*
5. *non-escape, requiring the packet to export no hidden chooser, no branch policy for unrelated histories, no truth oracle, and no accumulated selector ledger.*

Proof. Carrier admission is projection from the finite tuple in Definition 685.1. The source history, enacted mark, result history, extension row, witness row, transport row, continuation row, provenance row, and naming row are all displayed coordinates.

Source-boundary admission reads H before any mark is available. The empty boundary is therefore the slot above this source row, not a reset to e and not a free-standing selector surface.

Enacted-mark exactness then ties M, R, and E together. Since E is the displayed $\mathsf{Ext}(H, M, R)$ row, a consumer cannot replace the enacted mark by an unrecorded choice while keeping the same certificate.

Finally W, T, C, P, N expose and delimit the witness. The witness is readable through the named transport and continuation rows, while provenance and the local NameCert row provide no coordinate for a hidden chooser, unrelated branch policy, truth oracle, or accumulated ledger. □

Theorem 685.3 (EmptyBoundarySelector witness exposure)**.** *Let* $Q = (H, M, R, E, W, T, C, P, N)$ *be an accepted* $\mathsf{EmptyBoundarySelector}^{\uparrow}$ *carrier. Every consumer read of the enacted branch factors through the witness route*

$$H, M, R, E, W, T, C, P, N.$$

The consumer may inspect the source Hist *row, enacted mark, result row, extension row, local witness, componentwise* hsame *transports, displayed* Cont *routes, package provenance, and local naming row, and receives no selector value outside those rows.*

Lean4 ✓ `BEDC.Derived.EmptyBoundarySelectorUp.EmptyBoundarySelectorWitness exposure`

Proof. Begin with the accepted carrier. Projection gives the rows $H, M, R, E, W, T, C, P, N$ and no second source for branch data.

Read the branch through M and E. The mark row M is the enacted mark, and E records that this mark extends the source row H to the result row R.

Now expose the local witness W. The only routes carrying W to a consumer are the componentwise transport row T and continuation row C, both named inside the same packet.

Package provenance and the local naming row close the route. Because the carrier has no additional selector coordinate, any branch read outside $H, M, R, E, W, T, C, P, N$ is unavailable to the accepted packet. □

Theorem 685.4 (EmptyBoundarySelector non-escape boundary)**.** *Every accepted* $\mathsf{EmptyBoundarySelector}^{\uparrow}$ *packet is local to the displayed source row H and enacted extension row E. It exports no global chooser, no branch-selection rule for unrelated* Hist *rows, no truth oracle, no host equality on traces, and no accumulated selector ledger beyond the single enacted boundary step.*

Proof. Inspect the carrier inventory. The only source row is H, the only result row is R, and the only branch evidence is the pair consisting of the enacted mark M and the extension row E.

The witness row W remains attached to the same step. Its transport and continuation rows are componentwise, so they move the displayed witness surface without adding a rule for other histories.

The provenance and NameCert rows repack this local surface for downstream use. Since no row names a chooser over all Hist values, a trace equality principle, a truth oracle, or an accumulated ledger, the packet cannot export any of those objects. □

Theorem 685.5 (EmptyBoundarySelector ledger handoff)**.** *An accepted* $\mathsf{EmptyBoundarySelector}^{\uparrow}$ *packet hands off exactly one local enacted-boundary witness to Empty-fable ledger consumers. When a downstream* $\mathsf{EmptyFableLedger}^{\uparrow}$, $\mathsf{FableBranchWitness}^{\uparrow}$, *or* $\mathsf{FableMachineClock}^{\uparrow}$ *consumer shares the displayed rows $H, M, R, E, W, T, C, P, N$, the handoff provides the source* Hist *row, enacted mark, result row, extension row, local witness, componentwise transport, continuation route, provenance, and local name, with no global chooser or extra ledger coordinate.*

Proof. Project the accepted selector packet first. The available handoff surface is precisely the displayed tuple $H, M, R, E, W, T, C, P, N$.

Next compare this tuple with the one-step Empty-fable consumers. $\mathsf{FableBranchWitness}^{\uparrow}$ reads the same local branch shape through its Hist, mark, result, Ext, admissibility, transport, continuation, package, and naming rows; $\mathsf{EmptyFableLedger}^{\uparrow}$ and $\mathsf{FableMachineClock}^{\uparrow}$ consume such rows as finite selector-ledger and local-clock entries.

Apply the non-escape boundary of Definition 685.4. The downstream consumer receives a single enacted-boundary witness and cannot promote it to a global chooser, a selector for unrelated histories, or an extra accumulated ledger coordinate. □

Theorem 685.6 (EmptyBoundarySelector fable sibling route)**.** *The selector handoff of Definition 685.5 is consumed by chapter 516 and chapter 585 through the same displayed rows*

$$H, M, R, E, W, T, C, P, N.$$

Thus the downstream fable ledger receives one local enacted-boundary witness and no global chooser, no branch policy for unrelated histories, and no additional selector ledger.

Proof. Begin with the ledger handoff theorem Definition 685.5. It identifies the complete handoff surface as the source history, enacted mark, result row, extension row, local witness, transport, continuation, provenance, and local naming row.

The EmptyFableLedger and FableBranchWitness sibling chapters read exactly that one-step fable route. Their consumer-facing rows are supplied by the displayed tuple $H, M, R, E, W, T, C, P, N$, so the handoff is a shared sibling route rather than a separate chooser interface.

Apply the non-escape boundary of Definition 685.4. Since the selector packet exports only the local enacted-boundary step, the downstream fable ledger cannot promote the handoff into a global chooser, an unrelated-history branch policy, or an extra accumulated ledger coordinate. □

Theorem 685.7 (EmptyBoundarySelector obligation surface)**.** *For every accepted* $\mathsf{EmptyBoundarySelector}^{\uparrow}$ *carrier*

$$Q = (H, M, R, E, W, T, C, P, N),$$

the scoped obligation surface consists exactly of source Hist *admission, enacted mark admission, resulting* Hist *admission, displayed* $\mathsf{Ext}(H, M, R)$ *exactness, local witness exposure, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{EmptyBoundarySelector}^{\uparrow}}$ *row. No obligation is stored outside these nine rows.*

Proof. Project the carrier Q. The first four rows expose the source history H, enacted mark M, result history R, and the local extension row E.

Inspect the local witness row W. It names the enacted branch for this packet only, and the transport and continuation rows T, C carry that witness componentwise with the same source, mark, result, and extension rows.

The provenance and local naming rows P, N close the displayed surface. Since the carrier has no further coordinate, the listed rows exhaust the scoped obligation surface. □

Theorem 685.8 (EmptyBoundarySelector boundary exhaustion)**.** *Let* $Q = (H, M, R, E, W, T, C, P, N)$ *be an accepted* $\mathsf{EmptyBoundarySelector}^{\uparrow}$ *carrier. Every local boundary read is obtained by inspecting the displayed* $\mathsf{Ext}(H, M, R)$ *row* E *and the local witness row* W *over the same source history* H*. The packet has no second boundary branch, no unrelated source history, and no accumulated selector ledger.*

Proof. Start with a boundary-facing consumer. Projection gives a single source row H, a single enacted mark M, a single result row R, and a single extension row E.

Inspect E locally. Because it is the displayed $\mathsf{Ext}(H, M, R)$ row, the boundary read is tied to the enacted mark in this packet and cannot be retargeted to an unrelated history.

Read W through T and C. These rows transport and replay the same local witness, while P, N only record provenance and local naming. The boundary is therefore exhausted by one enacted extension step. □

Theorem 685.9 (EmptyBoundarySelector non-escape obligation)**.** *Every accepted* $\mathsf{EmptyBoundarySelector}^{\uparrow}$ *carrier* $Q = (H, M, R, E, W, T, C, P, N)$ *refuses global choice, unrelated-history branch policy, truth oracle, host trace equality, and accumulated selector ledger export. Any consumer read factors through the local route*

$$H, M, R, E, W, T, C, P, N.$$

Proof. Inspect the carrier inventory. The only mark row is M, the only extension row is E, and the only witness row is W.

The local Ext witness inspection supplies an enacted boundary for the displayed source history H and result history R. It does not supply a function choosing marks for other histories or a truth predicate over traces.

Transport, replay, provenance, and naming preserve this one route. Since none of the refused objects appears as a row of Q, no accepted consumer can export them. □

Closure status for $\mathsf{NameCert}_{\mathsf{EmptyBoundarySelector}^{\uparrow}}$**.**

Constructive story: An $\mathsf{EmptyBoundarySelector}^{\uparrow}$ packet is generated from a source Hist row, enacted mark, result Hist row, displayed Ext row, local witness, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{EmptyBoundarySelector}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: The carrier, witness exposure, ledger handoff, fable sibling route, obligation surface, boundary exhaustion, and non-escape theorem close the displayed nine-row packet for public empty-boundary selector consumers.

Formal verification: FormalStatus(NameCert$_{\text{EmptyBoundarySelector}\uparrow}$, theoremChecked)

Lean target: `BEDC.Derived.EmptyBoundarySelectorUp.EmptyBoundarySelectorTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, global choice, branch policies for unrelated histories, truth oracles, host trace equality, accumulated selector ledgers, or a public standard bridge.

Upgrade path: Bridge closure requires a standard bridge for the public consumer boundary without adding global choice, unrelated-history branch policies, truth oracles, host trace equality, or accumulated selector ledgers.

Chapter 686

A Concrete Naming Certificate for $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$

The $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$ surface packages a type-checking read as finite classifier membership rather than as a host typing judgment. It joins the membership row of $\mathsf{TypeClassifierMembership}^{\uparrow}$, the classifier typing row of $\mathsf{ClassifierTyping}^{\uparrow}$, the subject-reduction handoff of $\mathsf{SubjectReduction}^{\uparrow}$, the finite derivation route of $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$, and the proof-erasure readback of $\mathsf{ProofTermErasureTrace}^{\uparrow}$ into one locally named packet.

chapter 483 supplies the displayed Cont subject-reduction handoff consumed by the row R, so the membership-trace packet records preservation as a sibling route rather than as an ambient typing theorem.

Definition 686.1 (TypeCheckingMembershipTrace carrier)**.** *A* $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (M, D, R, S, H, C, P, N)$$

with the following displayed rows:

1. *M is the* Ext*-membership row read as the local type-classifier decision;*
2. *D is the finite derivation trace row recording the classifier typing route;*
3. *R is the displayed* Cont *subject-reduction route attached to the same membership read;*
4. *S is the* SigRel *readback row relating the derivation route to the visible classifier name;*
5. *H records componentwise* hsame *transport for M, D, R, S and the local naming row;*
6. *C records the displayed* Cont *replay by which consumers reread membership, derivation, subject-reduction, and readback rows;*
7. *P is the* Pkg *provenance row over* $\mathsf{TypeClassifierMembership}^{\uparrow}$, $\mathsf{ClassifierTyping}^{\uparrow}$, $\mathsf{SubjectReduction}^{\uparrow}$, $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$, $\mathsf{ProofTermErasureTrace}^{\uparrow}$, Ext, Cont, SigRel, *and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{TypeCheckingMembershipTrace}^{\uparrow}}$ *row.*

The local classifier compares two accepted carriers only through the displayed membership, derivation, subject-reduction, readback, transport, continuation, package, and naming rows.

Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTraceTasteGate single carrier alignment`

Theorem 686.2 (TypeCheckingMembershipTrace classifier stability)**.** *Let*

$$T = (M, D, R, S, H, C, P, N)$$

and

$$T' = (M', D', R', S', H', C', P', N')$$

be accepted $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$ *carriers whose classifier rows are related by the displayed local comparison. Then the* Ext*-membership read, finite derivation route,* Cont *subject-reduction handoff, and* SigRel *readback are preserved through the componentwise* hsame *rows and the displayed* Cont *replay. The preserved object is the same finite membership-trace packet; it supplies no host typing judgment, conversion oracle, or quotient proof-term equality.*

Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTraceClassifier stability`

Proof. Project both carriers through Definition 686.1. The rows M, D, R, S name the classifier membership, derivation route, subject-reduction handoff, and readback boundary, while H records componentwise transport for those rows.

Use the displayed continuation replay C and C' to reread the same rows after transport. Since replay is attached to the packet coordinates, it cannot introduce an external typing derivation or conversion decision.

Finally repack the transported rows with the provenance and local naming rows P, N and P', N'. The result is still the finite $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$ surface, so quotient proof-term equality and host type equality remain outside the exported classifier evidence. □

Theorem 686.3 (TypeCheckingMembershipTrace NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{TypeCheckingMembership}}$ *surface has five finite obligations:*

1. *carrier admission exposes exactly* $T = (M, D, R, S, H, C, P, N)$*;*
2. *membership classification reads accepted type-checking only from the displayed* Ext *row* M*;*
3. *derivation-route exactness keeps the classifier typing route inside* D *and its* SigRel *readback inside* S*;*
4. *subject-reduction handoff uses only the displayed* Cont *route* R *and its replay through* C*;*
5. *the non-escape ledger excludes host type equality, global normalization, proof irrelevance, quotient syntax, conversion oracles, and any proof-term equality not displayed in the packet.*

Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTraceNameCert obligation surface`
Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTraceNameCert obligations`

Proof. Carrier admission is projection from the finite tuple. The membership row, derivation row, subject-reduction row, readback row, transport row, replay row, package row, and local naming row are all coordinates of the same BHist packet.

The classifier and derivation obligations are read from M, D, S. The row M is the only accepted Ext-membership decision, D is the only derivation route, and S is the only signature readback attached to that route.

The subject-reduction handoff is read from R and replayed through C. Because every exported row is packaged with H, P, N, no host type equality, global normalization theorem, proof irrelevance principle, quotient syntax, conversion oracle, or external proof-term equality can be recovered from the certificate surface. □

Theorem 686.4 (TypeCheckingMembershipTrace route coverage)**.** *Every accepted* TypeCheckingMembershipTrace *packet*

$$T = (M, D, R, S, H, C, P, N)$$

exposes the membership row M, the derivation route D, the subject-reduction handoff R, the SigRel *readback S, the* hsame *transport row H, the* Cont *replay row C, the* Pkg *provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{TypeCheckingMembershipTrace}^{\uparrow}}$ *row N before any consumer may cite type-checking membership from the packet.*

Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTraceRoute coverage`

Proof. Project the accepted packet through Definition 686.1. The carrier definition lists exactly the eight displayed coordinates, so a consumer has no membership citation until the row M and its companion rows D, R, S, H, C, P, N have been exposed.

Apply Definition 686.2 to transport the displayed classifier read through H and C. Apply Definition 686.3 to require the local naming row before the packet is used as type-checking membership evidence. □

Theorem 686.5 (TypeCheckingMembershipTrace non-escape)**.** *No accepted* $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$ *consumer can export host type equality, global normalization, proof irrelevance, quotient syntax, a conversion oracle, or proof-term equality outside the displayed coordinates M, D, R, S, H, C, P, N.*

Proof. The carrier has no coordinate for host type equality, global normalization, proof irrelevance, quotient syntax, a conversion oracle, or proof-term equality. Projection from T therefore reaches only M, D, R, S, H, C, P, N.

The final row of Definition 686.3 is the non-escape ledger for this packet. It binds every exported consumer to the finite rows already displayed, so no additional equality or conversion principle can be recovered from the certificate surface. □

Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTraceMembership row nonescape`

Theorem 686.6 (TypeCheckingMembershipTrace obligation assembly)**.** *The carrier of Definition 686.1, the classifier stability of Definition 686.2, the route coverage of Definition 686.4, and the non-escape ledger of Definition 686.5 assemble the paper-side* obligation *surface for* $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$*. This assembly leaves the verification axis at* unformalized*.*

Proof. The carrier fixes the finite packet shape, and classifier stability fixes how the displayed classifier rows persist under hsame transport and Cont replay. Route coverage then states which rows must be exposed before the packet is cited by a consumer.

The non-escape theorem supplies the refusal side of the local ledger. Together with the NameCert obligations in Definition 686.3, these rows specify the complete paper-side obligation surface while making no Lean-side verification claim. □

Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTrace obligation assembly`

Theorem 686.7 (TypeCheckingMembershipTrace scoped kernel surface)**.** *The carrier, classifier stability, route coverage, non-escape ledger, and obligation assembly for* $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$ *bind every accepted packet*

$$T = (M, D, R, S, H, C, P, N)$$

to the displayed Ext *membership row M, finite derivation route D,* Cont *subject-reduction handoff R,* SigRel *readback row S, componentwise* hsame *transport row H, displayed* Cont *replay row C,* Pkg *provenance row P, and local* $\mathsf{NameCert}_{\mathsf{TypeCheckingMembershipTrace}^{\uparrow}}$ *row N. The scoped kernel surface has no host type equality, quotient syntax, conversion oracle, proof irrelevance, or global normalization coordinate.*

Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTrace scoped kernel surface`

Proof. Project the finite carrier with Definition 686.1. It gives exactly the rows M, D, R, S, H, C, P, N and no host typing or conversion coordinate.

Use classifier stability, Definition 686.2, to keep membership, derivation, subject-reduction, and readback data attached to the same packet under the displayed hsame transport and Cont replay.

Apply route coverage and non-escape, Definition 686.4 and Definition 686.5. The first requires all displayed rows before a consumer cites type-checking membership, while the second excludes host type equality, global normalization, proof irrelevance, quotient syntax, conversion oracles, and external proof-term equality.

Finally use Definition 686.6. The assembled obligation surface is therefore scoped to the local certificate: Ext membership, finite derivation, subject-reduction handoff, SigRel readback, transport, replay, provenance, and naming are all discharged inside T, with no appeal to a host equality or global normalizer. □

Theorem 686.8 (TypeCheckingMembershipTrace subject-reduction consumer lock)**.** *For every accepted* $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$ *packet*

$$T = (M, D, R, S, H, C, P, N),$$

the subject-reduction row R is mandatory before the membership row M may be exported to any consumer. A consumer that cites type-checking membership must also expose the finite derivation route D, SigRel *readback row S, componentwise* hsame *transport row H, displayed* Cont *replay row C,* Pkg *provenance row P, and local* NameCert *row N.*

Proof. Project the carrier in Definition 686.1. The membership row M is not isolated: it is packaged with the derivation route D, subject-reduction handoff R, readback row S, transport, replay, provenance, and local name.

Apply route coverage, Definition 686.4. It requires the displayed companion rows before a consumer can cite membership from the packet.

Finally use the scoped kernel surface, Definition 686.7. The surface binds M to D, R, S, H, C, P, N inside the same finite certificate and leaves no host equality or conversion coordinate that could export membership without the subject-reduction row. □

Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTraceSubjectReduction consumer lock`

Theorem 686.9 (TypeCheckingMembershipTrace formal target handoff)**.** *The rows*

$$M, D, R, S, H, C, P, N$$

are the exact future Lean formalization target surface for $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$*:* Ext *membership, finite derivation, subject-reduction handoff,* SigRel *readback, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *naming. The target surface contains no host type equality, global normalization, proof irrelevance, quotient syntax, conversion oracle, or proof-term equality field.*

Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTraceFormalTarget handoff`

Proof. Begin with the carrier and classifier stability, Definition 686.1 and Definition 686.2. They identify the eight rows and keep membership, derivation, subject-reduction, and readback attached to the same packet under transport and replay.

Use NameCert obligations and obligation assembly, Definition 686.3 and Definition 686.6. These results account for carrier admission, classifier stability, route coverage, non-escape, provenance, and local naming without claiming Lean verification.

The subject-reduction consumer lock, Definition 686.8, fixes the consumer-facing dependency on R. Together with non-escape, Definition 686.5, this leaves exactly the displayed rows as the formal target and excludes the host-level typing and conversion fields. □

Theorem 686.10 (TypeCheckingMembershipTrace bridge precondition)**.** *No bridge-facing consumer may cite* $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$ *type-checking membership unless it carries the* Ext *membership row M, finite derivation route D, subject-reduction handoff R,* SigRel *readback row S, componentwise* hsame *transport row H, displayed* Cont *replay row C,* Pkg *provenance row P, and local* NameCert *row N from the same accepted packet. This precondition does not supply a* StandardBridge*; it only fixes the paper-side rows any later bridge must consume.*

Proof. Apply route coverage and the subject-reduction consumer lock, Definition 686.4 and Definition 686.8. A consumer must expose all displayed rows, and membership cannot leave the packet without the subject-reduction handoff.

Next use classifier stability and NameCert obligations, Definition 686.2 and Definition 686.3. They keep the classifier rows stable under H and C and require provenance and local naming before the packet is used as membership evidence.

Finally combine non-escape, obligation assembly, and the formal target handoff, Definition 686.5, Definition 686.6, and Definition 686.9. These results exclude host type equality, global normalization, proof irrelevance, quotient syntax, conversion oracles, proof-term equality, and any bridge claim beyond the displayed precondition rows. □

Lean4 ✓ `BEDC.Derived.TypeCheckingMembershipTraceUp.TypeCheckingMembershipTraceBridge precondition`

Closure status for $\mathsf{NameCert}_{\mathsf{TypeCheckingMembershipTrace}^{\uparrow}}$.

Constructive story: A $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$ packet is generated from finite Ext-membership, derivation-route, subject-reduction, SigRel readback, hsame transport, Cont replay, Pkg provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TypeCheckingMembershipTrace}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 686.7, Definition 686.8, Definition 686.9, and the bridge precondition theorem Definition 686.10 bind Ext membership, finite derivation, subject-reduction, SigRel readback, hsame transport, Cont replay, Pkg provenance, local NameCert rows, the future formal target surface, and the bridge-facing precondition inside the finite membership-trace certificate.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TypeCheckingMembershipTrace}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close host type equality, global normalization, proof irrelevance, quotient syntax, Lean verification, or bridge checking.

Upgrade path: Lean verification requires a kernel proof of the scoped membership, derivation, subject-reduction, readback, transport, replay, package, and naming surface.

Chapter 687

A Concrete Naming Certificate for $\mathsf{FableClockOrder}^{\uparrow}$

The $\mathsf{FableClockOrder}^{\uparrow}$ packet realizes the Empty-fable machine's local clock-order surface as finite certificate data. It records selector-ledger rows, local fable-clock ticks, adjacent step-order witnesses, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row. The packet is local to the displayed fable trace and has no coordinate for a synchronized clock shared across unrelated histories.

The selector-ledger row S and the hidden-chooser refusal are read through chapter 685, which supplies the empty-boundary selector discipline consumed by the local fable-clock order packet.

Definition 687.1 (FableClockOrder carrier)**.** *A* $\mathsf{FableClockOrder}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (H, S, T, E, W, L, C, P, N)$$

with the following displayed rows:

1. *H is the source* Hist *row whose Empty-fable trace is being read;*
2. *S is the finite selector-ledger row beginning at* e *and recording the enacted marks in order;*
3. *T is the finite local fable-clock tick row, one tick for each displayed selector step;*
4. *E records the adjacent* Ext *rows that move the ledger from one displayed history to the next;*
5. *W records adjacent step-order witnesses connecting successive ledger positions and ticks;*
6. *L records componentwise* hsame *transport for H, S, T, E, W and the local naming row;*
7. *C records the visible* Cont *routes by which consumers read the source history, selector ledger, local ticks, adjacent extensions, step-order witnesses, and local name;*
8. *P is the* Pkg *provenance over* Hist, BHist, Ext, hsame, Cont, Pkg, NameCert, *selector-ledger rows, and local fable-clock ticks;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{FableClockOrder}^{\uparrow}}$ *row.*

The carrier contains exactly these rows. It has no slot for an ambient host time, a clock shared by distinct histories, a comparison of unrelated fable traces, or a hidden chooser for missing selector steps.

Definition 687.2 (FableClockOrder classifier)**.** *The* $\mathsf{FableClockOrder}^{\uparrow}$ *classifier compares two accepted packets only by the displayed tuple*

$$H, S, T, E, W, L, C, P, N.$$

Two packet presentations agree when their source history rows, selector ledgers, local tick rows, adjacent extension rows, step-order witness rows, componentwise hsame *transports, continuation routes, provenance rows, and local naming rows agree componentwise. The classifier does not compare ambient times, synchronize unrelated histories, or choose a missing branch outside the displayed selector ledger.*

Theorem 687.3 (FableClockOrder NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FableClockOrder}^{\uparrow}}$ *surface for Definition 687.1 consists exactly of carrier admission for*

$$F = (H, S, T, E, W, L, C, P, N),$$

classifier exactness for the rows of Definition 687.2, selector-ledger exposure, local tick exposure, adjacent step-order witness exposure, componentwise hsame *stability, displayed* Cont *replay,* Pkg *provenance, and no-global-clock non-escape.*

Proof. Carrier admission is projection from the finite tuple in Definition 687.1. The source history, selector ledger, local tick row, adjacent extension row, witness row, transport row, continuation row, provenance row, and local naming row are all displayed coordinates.

Classifier exactness is projection from Definition 687.2. Agreement is componentwise on the same rows, so the certificate has no second comparison surface.

The remaining obligations are carried by L, C, P, N. Componentwise transport preserves the displayed rows, continuation routes expose them to consumers, provenance names the package boundary, and the local naming row binds the packet without exporting an ambient clock. □

Theorem 687.4 (FableClockOrder local step-order)**.** *For an accepted* $\mathsf{FableClockOrder}^{\uparrow}$ *packet*

$$F = (H, S, T, E, W, L, C, P, N),$$

each displayed selector step in S has a corresponding local tick in T and an adjacent step-order witness in W. Consumer reads of this order factor through the same componentwise transport row L, continuation row C, provenance row P, and local naming row N.

Lean4 ✓ `BEDC.Derived.FableClockOrderUp.FableClockOrderCarrier local step order`

Proof. Project the accepted carrier. The selector ledger S, local tick row T, adjacent extension row E, and witness row W are coordinates of the same finite packet.

Read adjacent order through E and W. The extension row records each displayed move between neighboring history positions, while the witness row attaches the corresponding local tick from T to that move.

Transport and replay are then fixed by L and C. Componentwise hsame movement preserves the rows being ordered, and the continuation route exposes only this local step-order surface.

Finally P and N bind the handoff to the named packet. Since the carrier has no coordinate for unrelated histories or ambient time, the order is local to the displayed selector ledger. □

Theorem 687.5 (FableClockOrder no-global-clock non-escape)**.** *Every accepted* $\mathsf{FableClockOrder}^{\uparrow}$ *packet exports only the finite local order carried by*

$$H, S, T, E, W, L, C, P, N.$$

It does not export a synchronized clock across distinct histories, an ambient host-time parameter, a global ordering of all fable traces, or a hidden chooser for selector steps not recorded in S*.*

Proof. Inspect the carrier inventory. The only time-like row is the local tick row T, and it is paired with the selector ledger S and adjacent witnesses W.

Use the local step-order theorem to delimit consumer access. Any read of order passes through the displayed transport, continuation, provenance, and naming rows attached to the same packet.

The excluded clock objects have no coordinate in the carrier and no clause in the classifier. Therefore no projection from an accepted packet can produce a synchronized clock, host-time parameter, global trace order, or hidden selector for steps outside S. □

Theorem 687.6 (FableClockOrder Empty-fable sibling route)**.** *Every accepted* $\mathsf{FableClockOrder}^{\uparrow}$ *packet reads its selector-ledger and local tick rows through the Empty-fable sibling route: chapter 516 supplies the generated ledger, chapter 494 supplies the finite selector spine, and chapter 685 supplies the enacted-mark witness. The* $\mathsf{FableClockOrder}^{\uparrow}$ *carrier adds local order over those rows without adding global time, host synchronization, or hidden selector choice.*

Proof. Project the accepted carrier $F = (H, S, T, E, W, L, C, P, N)$. The selector ledger S and local tick row T are displayed coordinates of the packet, and the adjacent rows E, W attach the local order witness to the same trace.

Read the sibling route horizontally. The Empty-fable ledger supplies the generated trace ledger, the selector-ledger chapter supplies the finite selector spine, and the empty-boundary selector supplies the enacted mark that each local step records.

Apply the local step-order and no-global-clock theorems above. They show that $\mathsf{FableClockOrder}^{\uparrow}$ only orders the displayed sibling rows through L, C, P, N, so the packet exports no synchronized host clock and no hidden selector for a step outside S. □

Closure status for $\mathsf{NameCert}_{\mathsf{FableClockOrder}^{\uparrow}}$**.**

Constructive story: A $\mathsf{FableClockOrder}^{\uparrow}$ packet is generated from a source Hist row, a finite selector ledger, local fable-clock ticks, adjacent Ext and step-order witness rows, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FableClockOrder}^{\uparrow}}$, seed)

Scope closed: Definition 687.1, Definition 687.2, Definition 687.3, Definition 687.4, and Definition 687.5 bind local fable-clock order as a finite NameCert packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FableClockOrder}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, synchronized clocks across distinct histories, ambient host time, global ordering of all fable traces, or hidden selector choice.

Upgrade path: Obligation closure requires checked carrier admission, classifier exactness, local step-order replay, no-global-clock non-escape, and NameCert row coverage for the same finite packet.

Chapter 688

A Concrete Naming Certificate for $\mathsf{ObserverPerspectiveComposition}^{\uparrow}$

The $\mathsf{ObserverPerspectiveComposition}^{\uparrow}$ surface packages a two-step observer comparison as one finite naming certificate. It composes two $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ routes through an $\mathsf{ObservationCoupling}^{\uparrow}$ row and a $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ row, so downstream consumers receive a displayed comparison packet rather than a host observer equality, a global spacetime coordinate, or a private Self row.

The composition consumes the classifier route of chapter 647, the coupling row of chapter 668, and the alignment row of chapter 643; it only repackages their displayed public rows into a two-step comparison packet.

Definition 688.1 (Observer-perspective-composition carrier)**.** *An* $\mathsf{ObserverPerspectiveComposition}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (Q_0, Q_1, O, L, H, C, P, N)$$

with the following displayed rows:

1. *Q_0 and Q_1 are accepted* $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ *rows naming the two comparison routes to be composed;*
2. *O is the accepted* $\mathsf{ObservationCoupling}^{\uparrow}$ *row that couples the observation windows used by the two classifier routes;*
3. *L is the accepted* $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ *row that aligns the public observer commitments visible to both routes;*
4. *H records componentwise* hsame *transports for Q_0, Q_1, O, L and for the package and local naming rows;*
5. *C records the displayed* Cont *routes that first read Q_0, then read O and L, then read Q_1 through the same finite packet;*
6. *P is the* Pkg *provenance over* $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$, $\mathsf{ObservationCoupling}^{\uparrow}$, $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverPerspectiveComposition}^{\uparrow}}$ *row.*

The composition compares observer perspectives only through $Q_0, Q_1, O, L, H, C, P, N$ and the recorded transports and routes.

Lean4 ✓ BEDC.Derived.ObserverPerspectiveCompositionUp.ObserverPerspectiveCompositionTasteGate
single carrier alignment

Theorem 688.2 (ObserverPerspectiveComposition NameCert obligations)**.** *For the carrier of Definition 688.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverPerspectiveComposition}^{\uparrow}}$ *surface has exactly five obligation rows: carrier exposure for* $Q = (Q_0, Q_1, O, L, H, C, P, N)$*; two classifier-route exposures through* Q_0, Q_1*; observation coupling through* O*; cross-perspective alignment through* L*; and non-escape from host observer equality, global spacetime, private* Self *rows, quotient histories, hidden synchronization, and unrecorded comparison evidence.*

Proof. Carrier exposure is projection from the finite packet $Q = (Q_0, Q_1, O, L, H, C, P, N)$.

The two route obligations are read from Q_0 and Q_1. Each route is already an $\mathsf{ObserverPerspectiveClassifier}^{\uparrow}$ row, so it exposes only its displayed observer, locality, GAP, transport, continuation, provenance, and naming data.

The middle obligations are read from O and L. The $\mathsf{ObservationCoupling}^{\uparrow}$ row supplies the paired observation-window boundary, while the $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ row supplies the public alignment boundary for the observer commitments.

Finally inspect the carrier list. No coordinate names host observer equality, global spacetime, private Self access, quotient history, hidden synchronization, or unrecorded comparison evidence, so none of those objects is exported by the local naming surface. □

Theorem 688.3 (ObserverPerspectiveComposition ledger exactness)**.** *Every public read exported by an accepted* $\mathsf{ObserverPerspectiveComposition}^{\uparrow}$ *carrier factors through the finite ledger*

$$Q_0, Q_1, O, L, H, C, P, N.$$

The ledger is exact: the two classifier routes, the observation-coupling row, the cross-perspective-alignment row, componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *row are available, and no other observer-comparison primitive is available.*

Proof. Project the accepted packet. The comparison data are the two classifier rows Q_0, Q_1, the coupling row O, and the alignment row L.

The transport row H moves only those displayed coordinates. The continuation row C replays the finite reading order from the first classifier route through the coupling and alignment rows to the second classifier route.

The package row P records provenance for the same displayed sources, and the local naming row N names no additional carrier. Hence every exported read factors through the listed ledger and the ledger is exact for public consumers. □

Theorem 688.4 (ObserverPerspectiveComposition route associativity)**.** *Let* $Q = (Q_0, Q_1, O, L, H, C, P, N)$ *be an accepted* $\mathsf{ObserverPerspectiveComposition}^{\uparrow}$ *carrier. Reading* Q_0 *then* O *then* L *then* Q_1 *through the displayed* Cont *row* C *gives the same public composition packet as first reading* Q_0 *through the coupling row* O *and then reading the aligned route* L, Q_1*, because both readings replay the same finite rows under the same componentwise* hsame *transport row* H *and the same* Pkg *provenance row* P*.*

Proof. Both readings start by projecting the same accepted carrier $Q = (Q_0, Q_1, O, L, H, C, P, N)$. The first bracketing reads the first classifier route, then the coupling row, then the alignment row, then the second classifier route.

The second bracketing reads the first classifier route together with the coupling row, then reads the alignment row together with the second classifier route. No new coordinate is introduced by this regrouping.

The displayed Cont row C is the only route data available, and the displayed hsame row H is the only transport data available. Since the provenance row P names the same four source surfaces in both readings, both bracketings expose the same public composition packet. □

Theorem 688.5 (ObserverPerspectiveComposition non-escape boundary)**.** *An accepted* ObserverPerspectiveCompo *carrier exports only two* ObserverPerspectiveClassifier$^{\uparrow}$ *rows, one* ObservationCoupling$^{\uparrow}$ *row, one* CrossPerspectiveAlignment$^{\uparrow}$ *row, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *row. It exports no host observer equality, no global spacetime, no private* Self *row, no quotient history, and no completed consciousness claim.*

Proof. Inspect the carrier coordinates of Definition 688.1. Every exported row is one of $Q_0, Q_1, O, L, H, C, P, N$.

The positive comparison data remain finite and public: two classifier routes, an observation-coupling boundary, and a cross-perspective-alignment boundary. The rows H, C, P, N transport, route, package, and name those same displayed coordinates.

No listed coordinate is host observer equality, global spacetime, private Self access, a quotient history, or a completed consciousness witness. Therefore an accepted composition packet cannot export any of those objects. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverPerspectiveComposition}^{\uparrow}}$.

Constructive story: An ObserverPerspectiveComposition$^{\uparrow}$ packet is generated from two observer-perspective classifier routes, an observation-coupling row, a cross-perspective-alignment row, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ObserverPerspectiveComposition}^{\uparrow}}$, seed)

Scope closed: Definition 688.1, Definition 688.2, Definition 688.3, Definition 688.4, and Definition 688.5 bind the finite two-step observer-comparison packet over classifier, coupling, alignment, transport, route, provenance, and local naming rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ObserverPerspectiveComposition}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close global observer identity, metric spacetime, private Self access, quotient-history identity, bridge status, Lean verification, or completed consciousness claims.

Upgrade path: Obligation closure requires checked carrier admission, NameCert obligations, ledger exactness, route associativity, and non-escape theorems for the same finite observer-perspective composition packet.

Chapter 689

A Concrete Naming Certificate for $\mathsf{FiniteWindowObserver}^{\uparrow}$

The $\mathsf{FiniteWindowObserver}^{\uparrow}$ packet realizes the inscription-event vision as a finite observation window with an explicit naming certificate. It keeps the prior observation state, selected public window, inscription record, checker result, downstream interface, transport, replay, provenance, and local name in one displayed BHist carrier. The packet is a concrete consumer surface; it does not appeal to private psychology, unbounded memory, hidden agency predicates, or an external semantic observer.

The selected public window is the sibling route between the inscription-event record of chapter 519, the selected and omitted ledger discipline of chapter 927, and the finite $\mathsf{StreamName}^{\uparrow}$ handoff of chapter 126. Thus $\mathsf{FiniteWindowObserver}^{\uparrow}$ consumes those surfaces to expose a checked inscription window rather than an isolated observer primitive.

chapter 519 supplies the visible inscription-event row, and chapter 520 supplies the Gap ledger row consumed by the checker and downstream-interface coordinates.

Definition 689.1 (FiniteWindowObserver carrier)**.** *A* $\mathsf{FiniteWindowObserver}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (O, F, I, K, D, H, C, P, N)$$

whose displayed rows are as follows:

1. *O is the prior observation state from which the inscription event is read;*
2. *F is the finite selected window of public records made visible to the observer;*
3. *I is the inscription record containing the named commitment and its visible route;*
4. *K is the checker and admission result for the proposed record;*
5. *D is the downstream interface row that records which consumer may cite the accepted inscription;*
6. *H is the componentwise* hsame *transport row for the observation state, selected window, inscription record, checker result, downstream interface, provenance, and local name;*
7. *C stores the displayed* Cont *routes for window selection, checker replay, admission, downstream handoff, and local NameCert comparison;*
8. *P is the* Pkg *provenance over* BHist, BMark, $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{InscriptionGapLedger}^{\uparrow}$, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$*;*

9. N is the local $\mathsf{NameCert}_{\mathsf{FiniteWindowObserver}^{\uparrow}}$ *row.*

Two accepted carriers classify together only when these nine displayed rows are transported to the same finite observation window and the same inscription-facing consumer interface. The carrier has no coordinate for a private mental state, global observer identity, hidden source of agency, or unbounded history.

Lean4 ✓ `BEDC.Derived.FiniteWindowObserverUp.FiniteWindowObserverTasteGate single carrier alignment`

Theorem 689.2 (FiniteWindowObserver NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FiniteWindowObserver}^{\uparrow}}$ *surface for the carrier of Definition 689.1 consists exactly of five finite obligations:*

1. *carrier admission for the packet $W = (O, F, I, K, D, H, C, P, N)$;*
2. *classifier transport of the prior observation state, finite window, inscription record, checker result, and downstream interface;*
3. *checker replay and admission exactness for the visible inscription record;*
4. *downstream consumer handoff through the displayed interface row;*
5. *ledger non-escape for private psychology, global observer identity, hidden agency predicates, unbounded history, and external semantic observation.*

Lean4 ✓ `BEDC.Derived.FiniteWindowObserverUp.FiniteWindowObserverNameCertObligations`

Proof. Carrier admission is projection from Definition 689.1. The accepted packet exposes the prior observation state, finite selected window, inscription record, checker result, downstream interface, transports, continuations, provenance, and local naming row.

Classifier transport uses H to align those rows componentwise. Once transported, the continuation row C is the only displayed route for selecting the window, replaying the checker, admitting the inscription, and handing the accepted record to a consumer.

Checker exactness is read from K together with the inscription row I. The downstream handoff is read from D, and the package provenance P fixes the inscription-event and GAP-ledger anchors for the same finite packet.

The carrier contains no row for private psychology, global observer identity, hidden agency predicates, unbounded history, or external semantic observation. Hence the five obligations exhaust the local naming surface. □

Theorem 689.3 (FiniteWindowObserver carrier transport)**.** *Let*

$$W = (O, F, I, K, D, H, C, P, N) \quad \textit{and} \quad W' = (O', F', I', K', D', H', C', P', N')$$

be accepted $\mathsf{FiniteWindowObserver}^{\uparrow}$ *carriers. If the displayed transport rows identify O with O', F with F', I with I', K with K', D with D', P with P', and N with N' componentwise by* hsame*, then both packets expose the same consumer-facing observation route: the same finite selected public window, inscription record, checker result, and downstream interface are read after transport and replay.*

↪variant `BEDC.Derived.FiniteWindowObserverUp.FiniteWindowObserverCarrierTransport`

Proof. Project the carrier definition. The only public observation coordinates are the prior state O, selected window F, inscription record I, checker row K, downstream interface D, and structural rows H, C, P, N.

Use the displayed H rows for componentwise transport. They align the prior state, window, inscription record, checker result, downstream interface, provenance, and local naming rows of W and W'.

Replay the aligned route through C and C'. Since replay only follows the displayed selection, checker, admission, and downstream handoff rows, the transported carriers expose the same selected public window, inscription record, checker result, and consumer interface.

No private observer state, unbounded history, hidden agency predicate, or external semantic observer appears in the carrier. Therefore nothing outside the transported finite rows can change the consumer-facing observation route. □

Lean4 ✓ `BEDC.Derived.FiniteWindowObserverUp.FiniteWindowObserverCarrierTransport`

Theorem 689.4 (FiniteWindowObserver bundle exhaustion)**.** *For every accepted* $\mathsf{FiniteWindowObserver}^{\uparrow}$ *carrier* $W = (O, F, I, K, D, H, C, P, N)$*, the selected window row* F *exposes a closed* ProbeBundle*-style finite enumeration of the observed histories consumed by the packet. The enumeration is stable under the displayed* hsame *transport rows, and every inscription handoff out of* W *consumes only rows in that finite bundle.*

Thus a downstream $\mathsf{StreamName}^{\uparrow}$ *or inscription consumer can cite the observer packet as a finite bundle-exhaustion certificate. It receives the observed histories displayed by* F*, the inscription row* I*, the checker row* K*, and the downstream interface* D*, but it cannot read an external enumeration, hidden stream tail, private observer state, or unbounded history.*

Lean4 ✓ `BEDC.Derived.FiniteWindowObserverUp.FiniteWindowObserverBundleExhaustion`

Proof. Project the selected window from the carrier. The row F is the only public finite-window coordinate, so the observed histories available to the observer are exactly the rows displayed there.

Use carrier transport, Definition 689.3. The componentwise H rows preserve the selected window and its observed histories under hsame, while replay through C follows the same finite selection route.

Now apply the inscription handoff row. The handoff reads F before I, K, D, so every inscription consumer is fed by the finite bundle already exposed by the observer packet. Since no carrier coordinate supplies an external enumeration or hidden stream tail, the displayed bundle exhausts the observation surface. □

Theorem 689.5 (FiniteWindowObserver StreamName window readback)**.** *Every downstream* $\mathsf{StreamName}^{\uparrow}$ *or inscription consumer of an accepted* $\mathsf{FiniteWindowObserver}^{\uparrow}$ *carrier* $W = (O, F, I, K, D, H, C, P, N$ *must read the selected public window row* F*, the inscription row* I*, the checker row* K*, and the downstream interface row* D *through the displayed finite route before any StreamName-facing readback is public.*

Lean4 ✓ `BEDC.Derived.FiniteWindowObserverUp.FiniteWindowObserverStreamNameWindowReadback`

Proof. Apply Definition 689.4. The selected public window row F is already the finite bundle from which every inscription handoff reads observed histories.

Project the carrier rows $O, F, I, K, D, H, C, P, N$. The prior state O feeds the selected window F; the inscription row I, checker row K, and downstream interface row D are the only public readback coordinates after that window.

Replay the route through C and transport it through H. Provenance and local naming through P, N bind the same finite packet, so a downstream $\mathsf{StreamName}^{\uparrow}$ or inscription consumer cannot expose a readback before the displayed route has supplied F, I, K, D. □

Theorem 689.6 (FiniteWindowObserver inscription handoff)**.** *For an accepted* FiniteWindowObserver$^{\uparrow}$ *carrier* $W = (O, F, I, K, D, H, C, P, N)$*, every inscription-event consumer reads the accepted record through the finite route*

$$O \longrightarrow F \longrightarrow I \longrightarrow K \longrightarrow D.$$

The route first selects the finite public window, then reads the named inscription record, then replays the checker and admission result, and finally exposes only the downstream interface row certified by the local NameCert *packet.*

Lean4 ✓ `BEDC.Derived.FiniteWindowObserverUp.FiniteWindowObserverInscriptionHandoff`

Proof. Project the carrier of Definition 689.1. The rows O and F determine the prior observation state and the finite selected window in which the event is read.

The inscription row I provides the named commitment and visible route. The checker row K records the admission result for that same displayed record, while H transports the rows to the common classifier surface.

Replay the route through C. The continuation first selects F from O, then reads I, then checks and admits it through K, and finally hands the accepted record to the downstream interface D.

The local rows P, N bind the route to package provenance and naming. Since no other carrier coordinate can be read by the consumer, the inscription handoff is exactly the displayed finite route. □

Theorem 689.7 (FiniteWindowObserver ledger non-escape)**.** *Every consumer-facing route out of an accepted* FiniteWindowObserver$^{\uparrow}$ *carrier factors through the finite rows* $O, F, I, K, D, H, C, P, N$*. No route exports a private mental state, global observer identity, hidden agency predicate, unbounded observation history, external semantic observer, or unchecked inscription acceptance.*

Proof. Take any consumer-facing route and project the accepted carrier. The only observation-facing rows are the prior state O, selected window F, inscription record I, checker result K, and downstream interface D.

The remaining rows H, C, P, N transport, replay, record provenance, and name the packet. They do not introduce a second source of observer identity or a separate semantic acceptance relation.

By the NameCert obligations of Definition 689.2, checker replay, admission, and consumer handoff are already exhausted by the displayed finite rows. Therefore the ledger cannot export anything outside $O, F, I, K, D, H, C, P, N$. □

Lean4 ✓ `BEDC.Derived.FiniteWindowObserverUp.FiniteWindowObserverLedgerNonescape`

Theorem 689.8 (FiniteWindowObserver obligation closure surface)**.** *For the same accepted packet* $W = (O, F, I, K, D, H, C, P, N)$*, the carrier of Definition 689.1, the NameCert obligations of Definition 689.2, the carrier transport of Definition 689.3, the bundle exhaustion of Definition 689.4, the StreamName readback of Definition 689.5, the inscription handoff of Definition 689.6, and the ledger non-escape theorem of Definition 689.7 jointly enumerate the five finite obligations of the* FiniteWindowObserver$^{\uparrow}$ *packet. The resulting surface exports carrier admission, classifier transport, checker replay and admission, downstream consumer handoff, and ledger non-escape, and it exports no private psychology, global observer identity, hidden agency predicate, unbounded history, or external semantic observer.*

Proof. Project the carrier $W = (O, F, I, K, D, H, C, P, N)$ from Definition 689.1. The projected rows are exactly the prior observation state, finite selected public window, inscription record, checker result, downstream interface, transport, replay, provenance, and local naming rows.

Apply the NameCert obligations of Definition 689.2. They list the five finite obligations: carrier admission, classifier transport, checker replay and admission, downstream handoff, and ledger non-escape.

Now use carrier transport, bundle exhaustion, StreamName readback, and inscription handoff. These theorems identify the same rows $O, F, I, K, D, H, C, P, N$ as the transported carrier surface, the finite window bundle, the StreamName-facing readback, and the inscription-event route.

Finally apply ledger non-escape, Definition 689.7. Since all cited rows belong to the same packet and no cited theorem exports private psychology, global observer identity, hidden agency predicates, unbounded history, or external semantic observation, the five obligations are exactly the obligation-closure surface for this packet. □

Lean4 ✓ `BEDC.Derived.FiniteWindowObserverUp.FiniteWindowObserverObligationClosureSurface`

Theorem 689.9 (FiniteWindowObserver obligation closure route)**.** *For every accepted* $\mathsf{FiniteWindowObserver}^{\uparrow}$ *carrier* $W = (O, F, I, K, D, H, C, P, N)$*, the carrier of Definition 689.1, the NameCert obligations of Definition 689.2, carrier transport of Definition 689.3, bundle exhaustion of Definition 689.4, StreamName window readback of Definition 689.5, inscription handoff of Definition 689.6, ledger non-escape of Definition 689.7, and the obligation-closure surface of Definition 689.8 form a finite induction route from rows* $O, F, I, K, D, H, C, P, N$ *to the five obligation rows: carrier admission, classifier transport, checker replay and admission, downstream consumer handoff, and ledger non-escape. No consumer can bypass that row order.*

Proof. Project the carrier $W = (O, F, I, K, D, H, C, P, N)$. The base row O supplies the prior observation state, and the selected window row F is the first public finite bundle available to any downstream read.

Induct over the displayed route $O \to F \to I \to K \to D$. At the F step, Definition 689.4 closes the selected finite bundle. At the I, K, D steps, Definition 689.5 and Definition 689.6 force the StreamName-facing and inscription-facing reads to consume the same finite window before any consumer interface is visible.

The structural rows preserve the induction. Carrier transport from Definition 689.3 keeps the route stable under hsame, while the displayed Cont replay row C, provenance row P, and local naming row N keep the same packet fixed throughout the read.

Finally apply the NameCert obligations and ledger non-escape. Theorems 689.2 and 689.7, together with the obligation-closure surface of Definition 689.8, identify the five obligation rows and exclude private psychology, global observer identity, hidden agency predicates, unbounded histories, and external semantic observation. Thus the finite route closes the obligations at the paper level, and a consumer cannot skip any row in the displayed order. □

Lean4 ✓ `BEDC.Derived.FiniteWindowObserverUp.FiniteWindowObserverObligationClosureRoute`

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteWindowObserver}^{\uparrow}}$**.**

Constructive story: A $\mathsf{FiniteWindowObserver}^{\uparrow}$ packet is generated from a prior observation state, a finite selected public window, an inscription record, an accepted checker row, a downstream interface, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FiniteWindowObserver}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 689.8 and Definition 689.9 give the scoped finite induction over rows $O, F, I, K, D, H, C, P, N$, binding carrier admission, classifier transport, checker replay and admission, downstream consumer handoff, and ledger non-escape over BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: FormalStatus(NameCert$_{\mathsf{FiniteWindowObserver}\uparrow}$, unformalized)

Bridge status: none

Not claimed: This chapter does not close private psychology, global observer identity, hidden agency predicates, unbounded observation histories, external semantic observation, Lean verification, or bridge checking.

Upgrade path: Public closure requires Lean formal targets for the same carrier, checker replay, downstream handoff, and ledger non-escape rows.

Chapter 690

A Concrete Naming Certificate for $\mathsf{ProofTermErasureAuditRoute}^{\uparrow}$

The $\mathsf{ProofTermErasureAuditRoute}^{\uparrow}$ surface records the audit path that lets a downstream classifier or compiler consumer trust an erased term without receiving the proof object that produced it. It sits after $\mathsf{ProofTermErasureTrace}^{\uparrow}$ and before type-preserving consumer packets: the carrier keeps proof-term membership, erased-term readback, typing membership, erased replay, subject-reduction compatibility, transport, provenance, and local naming in one finite certificate. The classifier-level sibling chapter 707 consumes this audit route as the finite proof-erasure membership surface, so the audit packet is a real downstream dependency rather than an isolated ledger.

Definition 690.1 (Proof-term erasure audit route carrier)**.** *A* $\mathsf{ProofTermErasureAuditRoute}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (P, E, T, C, R, S, H, Q, N)$$

with the following displayed rows:

1. *P is the proof-term row whose original type-checking membership is audited;*
2. *E is the erased-term row exported to downstream consumers;*
3. *T is the* Ext *typing row that admits the proof-term row and names the classifier membership being preserved;*
4. *C is the erasure* Cont *route from the proof-term row to the erased-term row;*
5. *R is the subject-reduction compatibility row tying the typing membership in T to the erased public read along C;*
6. *S is the accepted audit stamp row stating that the proof object has been consumed by the local checker and is not part of the exported evidence;*
7. *H records componentwise* hsame *transports for the proof-term row, erased-term row,* Ext *typing row, erasure route, subject-reduction row, audit stamp, package row, and local naming row;*
8. *Q is the* Pkg *provenance over* BHist, Ext, Cont, $\mathsf{SubjectReduction}^{\uparrow}$, $\mathsf{ProofTermErasureTrace}^{\uparrow}$, $\mathsf{TypeCheckingDerivationTrace}^{\uparrow}$, $\mathsf{TypeCheckingMembershipTrace}^{\uparrow}$, $\mathsf{TypePreservingCompiler}^{\uparrow}$, hsame, *and* $\mathsf{NameCert}$ *source packets;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ProofTermErasureAuditRoute}^{\uparrow}}$ *row.*

The local classifier compares two accepted carriers only through the displayed proof row, erased row, typing row, erasure route, subject-reduction row, audit stamp, componentwise transports, provenance, and local naming row.

Theorem 690.2 (Proof-term erasure audit route NameCert obligations)**.** *For the carrier of Definition 690.1, the local* $\mathsf{NameCert}_{\mathsf{ProofTermErasureAuditRoute}^{\uparrow}}$ *surface consists of six finite obligations:*

1. *carrier admission exposes exactly* $A = (P, E, T, C, R, S, H, Q, N)$*;*
2. *proof-term membership reads the accepted typing evidence only from the displayed* Ext *row* T*;*
3. *erasure replay routes the exported erased row* E *only along the displayed* Cont *row* C*;*
4. *subject-reduction compatibility uses only the row* R *to relate the source membership in* T *to the erased public read;*
5. *audit-stamp exactness records in* S *that proof evidence was consumed locally and that no proof object is exported;*
6. *provenance and naming exactness bind every downstream read to* H, Q, N *and to the same displayed proof-term, erased-term, typing, erasure, subject-reduction, and audit-stamp rows.*

Proof. Carrier admission is the projection of the displayed finite tuple. The rows $P, E, T, C, R, S, H, Q, N$ are the only coordinates exposed by the local certificate.

The membership and replay obligations are read from T and C. The proof-term row enters the certificate through the classifier membership row T, and the erased-term row is exported only after the displayed erasure route C is replayed.

Subject-reduction compatibility is the role of R. It binds the source membership already named by T to the erased read reached through C, so a consumer cannot replace the route by host conversion or quotient term equality.

The audit-stamp and ledger obligations are then exhausted by S, H, Q, N. The stamp records local consumption of proof evidence, the transports replay the same rows componentwise, the package records the dependency surface, and the local naming row fixes the certificate boundary. □

Lean4 ✓ `BEDC.Derived.ProofTermErasureAuditRouteUp.ProofTermErasureAuditRoute namecert obligations`

Theorem 690.3 (Proof-term erasure audit route Ext-membership preservation)**.** *Every accepted* $\mathsf{ProofTermErasureAuditRoute}^{\uparrow}$ *carrier preserves the* Ext *typing membership that justifies erased-term consumption. If a downstream consumer reads the erased row* E*, then the only source membership available to justify that read is the displayed typing row* T *for the proof-term row* P*, transported through* H *and packaged by* Q, N*.*

Proof. Project the accepted packet $A = (P, E, T, C, R, S, H, Q, N)$. The only typing-membership coordinate is T, and it is attached to the proof-term row P.

The erased row E is reached through the erasure route C and the compatibility row R. Thus the consumer's membership read is a transported reading of T, not a fresh classifier supplied by the host environment.

Finally repack the read through H, Q, N. Componentwise hsame preserves the displayed rows, package provenance records the same source certificates, and the local naming row keeps the consumer inside the audit-route boundary. □

Theorem 690.4 (Proof-term erasure audit route erased Cont replay)**.** *For every accepted* ProofTermErasureAuditRo *carrier, the erased public row is replayed only through the displayed erasure* Cont *route C and the subject-reduction compatibility row R. No consumer receives a host erasure function, a conversion oracle, or an unrecorded reduction route.*

Lean4 ✓ `BEDC.Derived.ProofTermErasureAuditRouteUp.ProofTermErasureAuditRoute erased cont replay`

Proof. Read the carrier inventory. The only route from the proof-term row P to the erased row E is the displayed continuation row C.

Subject-reduction compatibility is not an additional route; it is the row R that checks the same erased read against the typing membership in T. Therefore a consumer can replay erased evidence only by using C together with R.

Since the packet has no coordinate for a host erasure function, conversion oracle, or hidden reduction route, those objects cannot be exported by the local certificate. □

Theorem 690.5 (Proof-term erasure audit route non-escape ledger)**.** *Every accepted* ProofTermErasureAuditRoute$^{\uparrow}$ *carrier excludes proof-object escape. The exported surface contains the erased row E, the typing row T, the erasure route C, the compatibility row R, the audit stamp S, transports H, package provenance Q, and local naming N, but it contains no proof object, proof irrelevance principle, quotient syntax equality, host conversion relation, or ambient normalization oracle.*

Proof. Inspect the packet coordinates. The proof-term row P is visible only as the audited source of membership, while the exported computational row is E.

The stamp S records that proof evidence has been consumed locally. The rows T, C, R, H, Q, N then describe how membership, erasure, compatibility, transport, provenance, and naming are replayed without exporting the proof object itself.

No remaining coordinate can name proof irrelevance, quotient syntax equality, host conversion, or ambient normalization. The non-escape claim follows from the finite carrier inventory. □

Theorem 690.6 (Proof-term erasure audit route downstream consumer package)**.** *Every downstream classifier or type-preserving compiler consumer of an accepted* ProofTermErasureAuditRoute$^{\uparrow}$ *packet receives only the finite audit surface*

$$E, T, C, R, S, H, Q, N.$$

The consumer may use the erased term, preserved Ext *membership, displayed erasure replay, subject-reduction compatibility, audit stamp, transports, provenance, and local naming boundary, but it cannot recover the source proof object or replace the certificate by host type checking.*

Proof. Start from Ext-membership preservation. The consumer's typing read is fixed by T and transported through H, Q, N.

Next use erased Cont replay. The erased row E is exposed only along C and only with compatibility supplied by R.

Finally apply the non-escape ledger. The audit stamp S records local proof consumption, while the public package contains no coordinate for the source proof object as exported evidence and no coordinate for host type checking. Hence the downstream consumer package is exactly the displayed finite audit surface. □

Theorem 690.7 (Proof-term erasure audit route erased replay determinacy)**.** *Let A and A' be accepted* ProofTermErasureAuditRoute$^{\uparrow}$ *packets. Suppose the two erased replay reads have the*

same proof-term membership row, erased-term readback row, Ext *typing membership row, subject-reduction compatibility row, componentwise* hsame *transport, erased* Cont *replay route,* Pkg *provenance, and local* NameCert *row. Then every downstream classifier consumer reads the same erased replay surface from A and A'.*

The determined surface is the finite packet of proof-term membership, erased readback, typing membership, erased replay, subject-reduction compatibility, transport, provenance, and local naming rows. It exports no proof object, proof irrelevance principle, quotient syntax equality, host conversion relation, ambient normalization oracle, or host type-checking replacement.

Lean4 ✓ `BEDC.Derived.ProofTermErasureAuditRouteUp.ProofTermErasureAuditRoute erased replay determinacy`

Proof. First use Definition 690.3. The downstream consumer's membership read is forced to be the displayed typing row attached to the proof-term membership row, transported through the shared hsame, Pkg, and NameCert rows.

Next apply Definition 690.4. Since the two packets have the same erased readback, erased Cont replay route, and subject-reduction compatibility row, their public erased replay reaches the same consumer-visible row.

Use Definition 690.5 to exclude off-packet witnesses. The audit route has no coordinate for a proof object, proof irrelevance, quotient syntax equality, host conversion, ambient normalization, or host type checking, so no downstream classifier can separate the two reads by such data.

Finally repack with Definition 690.6. That package is exactly the shared erased row, typing row, erasure route, compatibility row, audit stamp, transports, provenance, and local naming boundary. Therefore every downstream classifier consumer sees the same erased replay surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{ProofTermErasureAuditRoute}^{\uparrow}}$.

Constructive story: A $\mathsf{ProofTermErasureAuditRoute}^{\uparrow}$ packet is generated from proof-term, erased-term, Ext typing, erasure Cont, subject-reduction compatibility, audit-stamp, hsame transport, Pkg provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ProofTermErasureAuditRoute}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 690.1, Definition 690.2, Definition 690.3, Definition 690.4, Definition 690.5, Definition 690.6, and Definition 690.7 define the erased replay audit surface exported to downstream classifier and compiler consumers.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ProofTermErasureAuditRoute}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ProofTermErasureAuditRouteUp.ProofTermErasureAuditRoute\_erased\_replay\_determinacy`

Bridge status: none

Origin: human

Not claimed: This chapter does not close host conversion, quotient term equality, proof irrelevance, normalization oracles, or compiler correctness outside the displayed audit-route packet.

Upgrade path: No further theory-axis upgrade is required for the erased replay audit surface; bridge checking remains a formal-axis task.

Chapter 691

A Concrete Naming Certificate for $\mathsf{EmptyBoundaryStep}^{\uparrow}$

The $\mathsf{EmptyBoundaryStep}^{\uparrow}$ packet realizes the one-step birth surface of Definition 9399.5 as a finite naming certificate. It records the source Hist row, the enacted mark, the resulting Hist row, and the displayed Ext fact that ties them together. The packet is local to that step: it does not choose marks for other histories, does not decide admissibility predicates, and does not convert local branch actualisation into a global choice principle.

Definition 691.1 (Empty-boundary step carrier)**.** *An* $\mathsf{EmptyBoundaryStep}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (H, M, R, E, T, C, P, N)$$

with the following displayed rows:

1. *H is the source* Hist *row whose empty boundary is filled;*
2. *M is the enacted mark row, one of the kernel marks b_0 or b_1;*
3. *R is the resulting* Hist *row produced by recording M above H;*
4. *E is the displayed* $\mathsf{Ext}(H, M, R)$ *row;*
5. *T records componentwise* hsame *transports for H, M, R, E and the local naming row;*
6. *C records the displayed* Cont *routes by which a consumer reads the source row, enacted mark, result row, extension row, and local name;*
7. *P is the* Pkg *provenance over* Hist, Ext, hsame, Cont, Pkg, NameCert, *and the Empty-boundary reading of Definition 9399.5;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{EmptyBoundaryStep}^{\uparrow}}$ *row.*

The classifier compares accepted carriers only by the displayed rows H, M, R, E, T, C, P, N. It has no coordinate for a hidden selector, a branch policy over unrelated histories, a truth oracle, a host equality on traces, or an accumulated ledger.

Lean4 ✓ `BEDC.Derived.EmptyBoundaryStepUp.EmptyBoundaryStepTasteGate single carrier alignment`

Theorem 691.2 (Empty-boundary step NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{EmptyBoundaryStep}^{\uparrow}}$ *surface for the carrier of Definition 691.1 consists of five finite obligations:*

1. *carrier admission, requiring every accepted object to expose $S = (H, M, R, E, T, C, P, N)$;*

2. *source-boundary admission, requiring H to be the displayed* Hist *row whose empty boundary is filled;*
3. *enacted-step exactness, requiring M, R, and E to exhibit the same* $\mathsf{Ext}(H, M, R)$ *step;*
4. *transport-and-route stability, requiring all public reads to pass through the componentwise* hsame *row T and displayed* Cont *row C;*
5. *non-escape, requiring the packet to export no hidden selector, no branch policy for unrelated histories, no truth oracle, no host trace equality, and no accumulated ledger.*

Proof. Carrier admission is projection from the finite tuple in Definition 691.1. The source history, enacted mark, result history, extension row, transport row, continuation row, provenance row, and naming row are all displayed coordinates.

Source-boundary admission reads H before the next mark is consumed. The empty boundary is therefore the slot above this source row, matching the reading of Definition 9399.1, rather than a reset to e.

Enacted-step exactness ties M, R, and E together. Since E is the displayed $\mathsf{Ext}(H, M, R)$ row, a consumer cannot replace the enacted mark by an unrecorded branch while keeping the same certificate.

Transport-and-route stability uses T and C. These rows move and expose the displayed step data componentwise, but they do not add another source of branch information.

Finally P and N delimit the packet as local NameCert data. Because the carrier has no coordinate for a hidden selector, unrelated branch policy, truth oracle, host trace equality, or accumulated ledger, the packet cannot export any of those objects. □

Lean4 ✓ `BEDC.Derived.EmptyBoundaryStepUp.EmptyBoundaryStepCarrier namecert obligations`

Theorem 691.3 (Empty-boundary step local actualisation)**.** *Let $S = (H, M, R, E, T, C, P, N)$ be an accepted* $\mathsf{EmptyBoundaryStep}^{\uparrow}$ *carrier. Every public read of the step factors through the finite route*

$$H, M, R, E, T, C, P, N.$$

The read exposes exactly one enacted empty-boundary step and does not supply a function selecting marks for any other Hist *row.*

Proof. Project the accepted carrier to its displayed rows. The only branch data in the packet are the enacted mark M, the result row R, and the extension row E attached to the source H.

Read the step through E. The row E records $\mathsf{Ext}(H, M, R)$, so the public route identifies the enacted step by inspecting the displayed extension fact rather than by consulting an external chooser.

The transport row T and continuation row C keep the same data visible to consumers. Package provenance and the local NameCert row close the route without adding a coordinate for unrelated histories.

Thus every public read factors through H, M, R, E, T, C, P, N and remains a single local actualisation of the empty boundary above H. □

Theorem 691.4 (Empty-boundary step BHist Ext dependency link)**.** *Let*

$$S = (H, M, R, E, T, C, P, N)$$

be an accepted $\mathsf{EmptyBoundaryStep}^{\uparrow}$ *carrier. The displayed row* E *supplies the local* $\mathsf{Ext}(H, M, R)$ *step consumed by chapter 516 and by chapter 685. This dependency is horizontal and local: it exports the source history, enacted mark, result history, extension row, transport, route, provenance, and naming rows, but it still refuses a global selector, a branch policy for unrelated histories, a truth oracle, host trace equality, or an accumulated ledger.*

Proof. Project the carrier S. The rows H, M, R, E, T, C, P, N are exactly the source history, enacted mark, result history, displayed extension fact, transport, continuation, provenance, and local naming rows.

Apply Definition 691.3. Every public read of the enacted step factors through the displayed $\mathsf{Ext}(H, M, R)$ row and exposes only one local empty-boundary step.

The Empty-fable ledger and Empty-boundary selector chapters consume precisely such local BHist extension rows when they record a witnessed step or compare selector-step behavior. Since S has no coordinate for a global selector, unrelated branch policy, truth oracle, host trace equality, or accumulated ledger, the dependency link supplies only the local Ext step. □

Closure status for $\mathsf{NameCert}_{\mathsf{EmptyBoundaryStep}^{\uparrow}}$.

Constructive story: An $\mathsf{EmptyBoundaryStep}^{\uparrow}$ packet is generated from a source Hist row, enacted mark, result Hist row, displayed Ext row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{EmptyBoundaryStep}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 691.1, Definition 691.2, and Definition 691.3 bind one local empty-boundary step as a finite NameCert packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{EmptyBoundaryStep}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, global choice, branch policies for unrelated histories, truth oracles, host trace equality, accumulated ledgers, or a public standard bridge.

Upgrade path: Scoped closure requires checked carrier admission, enacted-step exactness, transport-and-route stability, non-escape, and local actualisation for the same finite empty-boundary step packet.

Chapter 692

A Concrete Naming Certificate for $\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}$

The $\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}$ interface packages the finite carry-window budget behind the displayed AxisZeckendorf carry classifier. It records the carry source, carry target, normal-form target, Fibonacci value-budget ledger, non-hsame boundary, componentwise transports, displayed continuation routes, package provenance, and a local naming row. The packet is a finite certificate for the carry-budget surface; it is not history sameness, a kernel rewrite, a host arithmetic quotient, or a global normalization algorithm.

The budget carrier consumes the Zeckendorf normal-form rows of chapter 278, the local carry row of chapter 544, and the classifier boundary of chapter 567 before adding the value-budget ledger and non-hsame boundary. Thus the packet sits on the concrete carry and normal-form lattice rather than on a kernel-only naming surface.

Definition 692.1 (AxisZeckendorf carry-budget carrier)**.** *An* $\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (h, k, G, N_k, V, Q, H, C, P, N)$$

with the following visible coordinates:

1. *h is the displayed carry-source history row carrying the public window* `word_011`*;*
2. *k is the displayed carry-target history row carrying the public window* `word_100`*;*
3. *G is the local* $\mathsf{ZCarry}^{\uparrow}$ *classifier row reading* $\mathsf{ZCarry}(h, k)$ *through the displayed carry generator;*
4. *N_k is the normal-form target row stating that k is admitted by the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *normal-form classifier;*
5. *V is the value-budget ledger row recording the finite Fibonacci value read for h, the finite Fibonacci value read for k, and the equality of those two displayed sums;*
6. *Q is the non-*hsame *boundary row recording that the carry relation between h and k is not a history-sameness witness;*
7. *H stores the componentwise* hsame *transports that preserve the source row, target row, carry row, normal-form target row, value-budget ledger, boundary row, route row, provenance row, and local naming row;*

8. *C stores the displayed* Cont *routes for carry-source exposure, carry-target exposure, normal-form target reading, value-budget reading, non-*hsame *boundary reading, provenance reading, and local naming;*
9. *P is the* Pkg *provenance over* BHist, ZCarry$^{\uparrow}$, ZeckendorfNormal$^{\uparrow}$, *Fibonacci value-budget rows,* hsame, Cont, *and local* NameCert *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}}$ *row.*

The carrier compares accepted packets only through the displayed rows $h, k, G, N_k, V, Q, H, C, P, N$. It exports no source-target hsame *proof, no kernel rewrite, no hidden arithmetic quotient, and no unbounded normalization process.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCarryBudgetUp.AxisZeckendorfCarryBudgetCarrier full packet semantic namecert`

Theorem 692.2 (AxisZeckendorf carry-budget NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}}$ *surface for Definition 692.1 consists of five finite obligations:*

1. *carrier admission for the finite packet $B = (h, k, G, N_k, V, Q, H, C, P, N)$;*
2. *carry-window coverage, stating that the only admitted carry source and target windows are the displayed* `word_011` *and* `word_100` *rows read through G;*
3. *value-budget preservation, stating that every public value-preservation read factors through the finite ledger V;*
4. *non-*hsame *boundary, stating that Q keeps carry-relatedness separate from* $\mathsf{hsame}(h, k)$ *under all displayed transports;*
5. *ledger non-escape, stating that the rows H, C, P, N route and name exactly this packet and do not export a kernel rewrite, a host arithmetic quotient, or a global normalizer.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCarryBudgetUp.AxisZeckendorfCarryBudgetNamecertObligations`

Proof. Carrier admission is the tuple in Definition 692.1. It lists the carry source, carry target, carry classifier, normal-form target, value-budget ledger, non-hsame boundary, transports, routes, provenance, and local naming row inside one finite BHist packet.

Carry-window coverage is read from h, k, G, N_k. The carry row G fixes the public source and target windows, and the normal-form target row N_k records that the target side is the admitted normal-form window.

Value-budget preservation is the role of V. Every public value read of the carry step reaches the two displayed Fibonacci sums and their equality only through that finite ledger coordinate.

The boundary and non-escape clauses are the rows Q, H, C, P, N. The row Q records that the carry is not $\mathsf{hsame}(h, k)$, while H transports only the displayed components. The route, provenance, and naming rows repack the same finite surface, so no excluded object is available to a consumer. □

Theorem 692.3 (AxisZeckendorf carry-budget classifier realization)**.** *Every consumer-visible carry-budget read of an accepted* $\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}$ *carrier factors through*

$$h, k, G, N_k, V, Q, H, C, P, N.$$

*Thus the carry classifier can expose finite carry-window coverage, normal-form target reading, value-ledger preservation, non-*hsame *separation, transport stability, route replay, provenance, and local naming without treating carry-relatedness as history sameness.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCarryBudgetUp.AxisZeckendorfCarryBudget classifier realization`

Proof. Start with the finite carrier of Definition 692.1. The rows h, k, G, N_k expose exactly the displayed carry source, carry target, carry witness, and normal-form target.

Add the budget and boundary rows. The row V carries the finite value-preservation ledger, while Q keeps the non-hsame boundary visible for the same source and target.

Finally apply the structural rows H, C, P, N. They transport, route, package, and name only the displayed packet. Therefore every consumer-facing carry-budget read remains inside the listed rows and cannot become a source-target hsame proof or a kernel rewrite. □

Theorem 692.4 (AxisZeckendorf carry-budget scope)**.** *The scoped* $\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}$ *surface is exactly the kernel-visible packet*

$$B = (h, k, G, N_k, V, Q, H, C, P, N)$$

of Definition 692.1. It exposes the BHist *source and target rows, the* $\mathsf{ZCarry}^{\uparrow}$ *carry row, the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *target row, the value-budget ledger, the non-*hsame *boundary, the* hsame *transport rows, the* Cont *replay rows, the* Pkg *provenance row, and the local* NameCert *row, and it exports no source-target* hsame *proof, host arithmetic quotient, kernel rewrite, or global normalizer.*

Lean4 ✓ `BEDC.Derived.AxisZeckendorfCarryBudgetUp.AxisZeckendorfCarryBudgetTasteGate single carrier alignment`

Proof. Carrier scope is the displayed tuple of Definition 692.1. Its first four rows bind the BHist carry source and target through $\mathsf{ZCarry}^{\uparrow}$ and $\mathsf{ZeckendorfNormal}^{\uparrow}$, while the value-budget ledger records the finite Fibonacci equality that the public carry-budget read may use.

The boundary and structural rows keep the scope kernel-local. The row Q refuses source-target hsame, the row H transports only displayed coordinates, and the row C replays only the named Cont routes.

The provenance and naming rows close the packet. The Pkg row P and the local NameCert row N name the same finite carrier, so the chapter scope is the listed ledger surface rather than a quotient, rewrite, or normalization theorem. □

Closure status for $\mathsf{NameCert}_{\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}}$.

Constructive story: An $\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}$ packet is generated from the displayed carry source, carry target, normal-form target row, finite Fibonacci value-budget ledger, non-hsame boundary, componentwise transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}}$, publicClosed)

Scope closed: Definition 692.1, Definition 692.2, Definition 692.3, and Definition 692.4 bind the public carry-budget carrier, value ledger, non-hsame boundary, route, provenance, local naming, classifier realization, and kernel-scope surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: human

Not claimed: This chapter does not close Lean verification, a bridge certificate, a global Zeckendorf normalizer, a kernel rewrite, host arithmetic quotienting, or source-target hsame.

Upgrade path: Formal verification requires checked carrier admission, carry-window coverage, value-budget preservation, non-hsame boundary preservation, route stability, provenance, local naming, and ledger non-escape for the same finite packet.

Chapter 693

A Concrete Naming Certificate for $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$

The $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ surface packages the finite observation-window route used by transported stationary diagonal seals as one naming certificate. It receives a RatUp seed row, the constant $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{RegSeqRat}^{\uparrow}$ seal readback, the $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, and the $\mathsf{Real}^{\uparrow}$ finite-window seal as one displayed packet, so downstream real-completion consumers read a shared finite route rather than a selected limit, quotient stream, or ambient completeness assertion.

This chapter consumes the concrete route of chapter 126, chapter 301, chapter 291, and chapter 38. The $\mathsf{StreamName}^{\uparrow}$ chapter supplies the finite window, $\mathsf{RegSeqRat}^{\uparrow}$ supplies the seal readback, $\mathsf{DyadicRatCore}^{\uparrow}$ supplies the observation ledger, and $\mathsf{Real}^{\uparrow}$ supplies the finite-window seal used by the fused packet.

Definition 693.1 (Regular Cauchy window fusion carrier)**.** *A* $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (R, W, S, D, E, H, C, P, N)$$

with the following displayed rows:

1. *R is the RatUp seed classifier row for the stationary rational source;*
2. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *constant-window classifier read over the displayed observation window;*
3. *S is the* $\mathsf{RegSeqRat}^{\uparrow}$ *seal-consumption row obtained from the same finite window;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger carried by that window;*
5. *E is the* $\mathsf{Real}^{\uparrow}$ *finite-window classifier and seal row reached from W, S, D;*
6. *H records componentwise* hsame *transports for R, W, S, D, E and for the package and local naming rows;*
7. *C records the displayed* Cont *routes by which consumers first read the seed row, then the shared window, then the dyadic and regular-sequence rows, and finally the real seal row;*
8. *P is the* Pkg *provenance over RatUp,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWindowFusion}^{\uparrow}}$ *row.*

The carrier has no coordinate for a selected limit, quotient stream equality, real trichotomy, host completeness, or an unrecorded RealUp comparison row.

Theorem 693.2 (Regular Cauchy window fusion NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWindowFusio}}$ *surface for the carrier of Definition 693.1 consists of carrier admission for*

$$F = (R, W, S, D, E, H, C, P, N),$$

seed-to-window exposure, $\mathsf{RegSeqRat}^{\uparrow}$ *seal readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation-ledger exposure,* $\mathsf{Real}^{\uparrow}$ *seal handoff, componentwise* hsame *stability, displayed* Cont *locality,* Pkg *provenance, and non-escape from selected limits, quotient streams, trichotomy, ambient completeness, and hidden RealUp comparison data.*

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionNameCertObligations`

Proof. Carrier admission is projection from Definition 693.1. The rows $R, W, S, D, E, H, C, P, N$ are the only rows admitted to the packet.

The observation obligations are read in order. The RatUp seed row R feeds the finite $\mathsf{StreamName}^{\uparrow}$ window W; the same window supplies the $\mathsf{RegSeqRat}^{\uparrow}$ seal row S and the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger D.

The Real-facing obligation is the row E. It records the finite-window $\mathsf{Real}^{\uparrow}$ seal reached from W, S, D, while H and C preserve and route that same displayed row without adding an analytic carrier.

Finally P and N bind the packet to its package provenance and local naming row. Since no carrier coordinate names selected limits, quotient streams, trichotomy, ambient completeness, or a hidden RealUp comparison, none can be exported by the certificate. □

Theorem 693.3 (Regular Cauchy window fusion obligation inventory)**.** *For an accepted* RegularCauchyWindowFusi *carrier*

$$F = (R, W, S, D, E, H, C, P, N),$$

the obligation inventory consists of the following five finite duties:

1. *carrier exposure for the displayed packet* $F = (R, W, S, D, E, H, C, P, N)$*;*
2. *common finite-window exactness across the RatUp seed row,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *seal readback, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger;*
3. $\mathsf{Real}^{\uparrow}$ *seal handoff through the shared rows* R, W, S, D, E*;*
4. *componentwise* hsame *stability and displayed* Cont *locality through* H *and* C*;*
5. *non-escape from selected limits, quotient streams, trichotomy, ambient completeness, and hidden* $\mathsf{Real}^{\uparrow}$ *comparison rows.*

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionObligationInventory`

Proof. Carrier exposure is the definition of the packet in Definition 693.1. The existing NameCert obligation theorem Definition 693.2 records the same rows as the local certificate surface.

For common finite-window exactness, apply Definition 693.4. It forces the RatUp seed, stream window, regular-sequence readback, and dyadic ledger to be consumed through one displayed observation window.

For the Real-facing duty, apply Definition 693.5. The seal row E is reachable only after R, W, S, D and the support rows have been read.

Finally use Definition 693.8. It repacks $R, W, S, D, E, H, C, P, N$ for downstream consumers and excludes selected limits, quotient streams, trichotomy, ambient completeness, and hidden comparison rows from the exported package. □

Theorem 693.4 (Regular Cauchy window fusion shared-window handoff)**.** *For every accepted* $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *carrier, the RatUp seed row, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window classifier, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger are all reads of the same displayed window. Any downstream consumer that reaches the* $\mathsf{Real}^{\uparrow}$ *seal must first consume the shared route*

$$R, W, S, D, H, C, P, N.$$

Proof. Project the carrier rows. The only seed row is R, the only stream-window row is W, the only regular-sequence seal row is S, and the only dyadic observation ledger is D.

Use the transported stationary diagonal finite-window seal exhaustion as the source route. It identifies the RatUp seed classifier, the constant $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{RegSeqRat}^{\uparrow}$ seal consumption row, and the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger as four readings of one certified finite window.

The rows H, C, P, N then preserve, route, package, and name that shared window. Therefore a downstream consumer cannot reach the real seal without first reading the displayed shared-window packet. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionSharedWindowHandoff`

Theorem 693.5 (Regular Cauchy window fusion Real seal non-escape)**.** *For an accepted* RegularCauchyWindowFusi *carrier*

$$F = (R, W, S, D, E, H, C, P, N),$$

the $\mathsf{Real}^{\uparrow}$ *finite-window seal row* E *is reachable only through the seed row* R*, the shared* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* S*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, and the support rows* H, C, P, N*. The seal exports no selected limit, quotient stream equality, trichotomy decision, ambient completeness proof, independent real carrier, or unrecorded comparison row.*

Proof. Start from the shared-window handoff. It forces every route to the seal to pass through R, W, S, D before the Real-facing row is read.

Now read the real seal coordinate. The carrier contains a single $\mathsf{Real}^{\uparrow}$ finite-window row E, and the displayed Cont route exposes it only after the seed, stream-window, regular-sequence, and dyadic rows have been consumed.

Inspect the remaining coordinates. The support rows H, C, P, N preserve, route, package, and name the same finite packet, while no coordinate names selected limits, quotient streams, trichotomy, ambient completeness, an independent real carrier, or a hidden comparison. The Real seal therefore cannot escape the finite packet. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionRealSealNonescape`

Theorem 693.6 (Regular Cauchy window fusion selector-budget compatibility)**.** *Let*

$$F = (R, W, S, D, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *carrier. Any* $\mathsf{Real}^{\uparrow}$ *consumer of the accepted fusion packet must use the same displayed finite window for the RatUp seed row* R*, the* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* S*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, the* $\mathsf{Real}^{\uparrow}$ *seal row* E*, and the support rows* H, C, P, N*. Changing the selector or budget before the row* E *is read exits the carrier and is not a read of the accepted* $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *packet.*

Proof. Apply the shared-window handoff of Definition 693.4. It binds the seed row, stream window, regular-sequence readback, and dyadic ledger to one displayed finite observation window.

Next apply the Real seal non-escape theorem Definition 693.5. The only route to E first consumes R, W, S, D and then remains under the support rows H, C, P, N.

The sibling inputs named in the introduction supply exactly those rows: $\mathsf{StreamName}^{\uparrow}$ supplies the window, $\mathsf{RegSeqRat}^{\uparrow}$ supplies the readback, $\mathsf{DyadicRatCore}^{\uparrow}$ supplies the ledger, and $\mathsf{Real}^{\uparrow}$ supplies the finite-window seal. A selector or budget change before E would require an additional carrier coordinate, but the accepted packet has only $R, W, S, D, E, H, C, P, N$. Hence such a read exits the carrier rather than consuming the accepted fusion packet. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionSelectorBudgetCompatibility`

Theorem 693.7 (Regular Cauchy window fusion tail handoff)**.** *Any downstream* $\mathsf{RegularSequenceTailMetric}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *packet must use the same finite* $\mathsf{StreamName}^{\uparrow}$ *window* W*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* S*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*, and support rows* H, C, P, N *before reading the* $\mathsf{Real}^{\uparrow}$ *seal row* E*. A tail-facing consumer cannot replace the shared window by a selected limit, quotient stream, or independent completeness witness.*

Proof. Begin with the shared-window handoff, Definition 693.4. It binds the RatUp seed row, $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{DyadicRatCore}^{\uparrow}$ ledger to one finite observation packet.

Apply Real seal non-escape and selector-budget compatibility, Definition 693.5 and Definition 693.6. They force every route to E through R, W, S, D, H, C, P, N and reject any budget or selector change before the seal is read.

The tail-facing consumer therefore inherits the same handoff. Whether the downstream read is $\mathsf{RegularSequenceTailMetric}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$, it can consume only the displayed rows of the accepted fusion packet before E; selected limits, quotient streams, and independent completeness witnesses are not carrier coordinates. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionTailHandoff`

Theorem 693.8 (Regular Cauchy window fusion downstream package)**.** *The carrier of Definition 693.1, the local NameCert obligations, the shared-window handoff, and the Real seal non-escape theorem assemble a downstream package for* $\mathsf{RealCompleteness}^{\uparrow}$*,* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$*,* $\mathsf{CauchyModulusComparison}^{\uparrow}$*, and* $\mathsf{DiagonalCofinalTail}^{\uparrow}$ *consumers. The package exposes exactly*

$$R, W, S, D, E, H, C, P, N$$

over RatUp, $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows.*

Proof. First project the carrier and NameCert surface. They provide the RatUp seed, the shared stream window, the regular-sequence seal readback, the dyadic ledger, the real seal, and the support rows.

Next use the shared-window handoff. It binds the seed, stream, regular-sequence, and dyadic rows to one finite observation window, so downstream consumers receive a single route rather than separate analytic witnesses.

Finally apply the Real seal non-escape theorem. The package can export only $R, W, S, D, E, H, C, P, N$, and the listed downstream consumers read those rows through their existing finite-window routes. □

Lean4 ✓ BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionDownstreamPackage

Theorem 693.9 (Regular Cauchy window fusion budget meet)**.** *Let*

$$F = (R, W, S, D, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *carrier. If two downstream reads consume the same shared finite window, one through the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* S *and one through the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger* D*, then the reads meet at the same* $\mathsf{Real}^{\uparrow}$ *seal row* E *through the displayed rows* H, C, P, N*. The meet exports the finite L10 handoff packet*

$$R, W, S, D, E, H, C, P, N$$

and exports no selected limit, quotient stream, trichotomy decision, ambient completeness proof, or hidden comparison row.

Lean4 ✓ BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionCarrier budget meet

Proof. Apply Definition 693.4. It places the regular-sequence readback row S and the dyadic observation ledger D over one displayed finite window together with the RatUp seed row R and the stream-window row W.

Next apply Definition 693.5. The only real-facing row reachable from that shared window is E, and it is read only after R, W, S, D under the support rows H, C, P, N.

Finally apply Definition 693.8. The package repacks exactly $R, W, S, D, E, H, C, P, N$ for downstream $\mathsf{Real}^{\uparrow}$ and completion-facing consumers. Since the accepted carrier has no coordinate for selected limits, quotient streams, trichotomy, ambient completeness, or hidden comparison data, the two downstream reads meet at the displayed seal row rather than at an external analytic object. □

Theorem 693.10 (Regular Cauchy window fusion scoped kernel route)**.** *Every accepted* RegularCauchyWindowFusio *read used by a* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer is scoped by the four concrete L10 rows* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *together with the structural rows* H, C, P, N*. For*

$$F = (R, W, S, D, E, H, C, P, N),$$

the read cannot replace these rows by quotient stream equality, a selected limit, trichotomy, ambient completeness, or a hidden $\mathsf{Real}^{\uparrow}$ *comparison.*

Proof. Project the carrier $F = (R, W, S, D, E, H, C, P, N)$. The rows W, S, D, E are respectively the $\mathsf{StreamName}^{\uparrow}$ finite window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, and $\mathsf{Real}^{\uparrow}$ finite-window seal; H, C, P, N are the only structural rows available to transport, replay, source, and name them.

Apply Definition 693.4. It forces R, W, S, D to be read as one shared finite observation window before any Real-facing seal is reached.

Apply Definition 693.5. The seal row E is reachable only through that shared finite route and exports no selected limit, quotient stream equality, trichotomy decision, ambient completeness proof, independent real carrier, or unrecorded comparison row.

Apply Definition 693.8 and Definition 693.9. Downstream consumers receive exactly $R, W, S, D, E, H, C, P, N$, so no excluded coordinate is available inside the accepted packet. □

Lean4 ✓ BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionScopedKernelRoute

Theorem 693.11 (Regular Cauchy window fusion finite-window exactness)**.** *For every accepted* $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *carrier*

$$F = (R, W, S, D, E, H, C, P, N),$$

the displayed rows expose exactly one finite observation-window route from the RatUp seed through the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows. Every* $\mathsf{Real}^{\uparrow}$*- or completion-facing consumer of* F *must use this route before reading the real seal* E*, and the packet contains no second route through selected limits, quotient stream equality, trichotomy, ambient completeness, independent real carriers, or hidden comparison rows.*

Proof. Start with Definition 693.4. It binds the RatUp seed row R, stream window W, regular readback S, and dyadic ledger D to one displayed finite observation window.

Apply Definition 693.5. The real seal E is reachable only after that shared route and under the structural rows H, C, P, N.

Use Definition 693.9. Any two downstream reads that pass through S and D meet at the same seal row E, so the regular and dyadic sides cannot split into distinct completion-facing routes.

Finally apply Definition 693.10. It identifies the scoped kernel route with W, S, D, E, H, C, P, N and excludes quotient stream equality, selected limits, trichotomy, ambient completeness, and hidden $\mathsf{Real}^{\uparrow}$ comparisons. Therefore the displayed packet exhausts the finite Real-facing window. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionFiniteWindowExactness`

Theorem 693.12 (RegularCauchyWindowFusion tail-window coverage)**.** *Let*

$$F = (R, W, S, D, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *carrier. Any* $\mathsf{Real}^{\uparrow}$*-facing consumer of* F *must expose the diagonal cofinal tail selected by the stationary window route, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* S*, the* $\mathsf{StreamName}^{\uparrow}$ *schedule* W*, and the terminal* $\mathsf{Real}^{\uparrow}$ *seal* E *before consuming the fused window. The exposed route is exactly the finite packet*

$$R, W, S, D, E, H, C, P, N,$$

so no consumer may replace the tail-window route by a selected subsequence, quotient stream equality, or ambient Real completeness.

Proof. Project the carrier rows. The only schedule row is W, the only regular-rational readback is S, the only dyadic tolerance ledger is D, and the only terminal Real-facing seal is E.

Apply Definition 693.11. It identifies the route from the RatUp seed through W, S, D, E as the unique finite observation-window path available to a $\mathsf{Real}^{\uparrow}$- or completion-facing consumer.

The diagonal cofinal tail is therefore consumed only through the stationary window route already displayed by W and routed by C. The support rows H, P, N transport, source, and name the same packet without adding a second selector.

Consequently the consumer remains inside $R, W, S, D, E, H, C, P, N$. Selected subsequences, quotient stream equality, and ambient Real completeness are not carrier coordinates, so none can be used before the fused window is consumed. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionTailWindowCoverage`

Theorem 693.13 (Regular Cauchy window fusion tail stability)**.** *Let*

$$F = (R, W, S, D, E, H, C, P, N)$$

and

$$F' = (R, W', S', D, E, H', C', P', N')$$

be accepted $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *packets with the same* $\mathsf{Rat}^{\uparrow}$ *seed row* R*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* D*,* $\mathsf{Real}^{\uparrow}$ *seal* E*, and support rows for transport, replay, provenance, and naming. Suppose the* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *window* (W', S') *is displayed as a cofinal tail of* (W, S) *inside the accepted packet data. Then* F *and* F' *export the same finite* $\mathsf{Real}^{\uparrow}$*-facing handoff through* E*, and neither packet exports a selected limit, quotient stream, independent Real carrier, trichotomy decision, ambient completeness proof, or hidden comparison row.*

Proof. Start with Definition 693.4. It binds the seed, stream window, regular readback, dyadic ledger, and Real seal into one finite observation route for each accepted packet.

Apply Definition 693.11 to F. The only Real-facing route from the shared $\mathsf{Rat}^{\uparrow}$ seed through W, S, D reaches the displayed seal E.

Apply Definition 693.12 to F'. Because (W', S') is a displayed cofinal tail of (W, S) and the ledger D and seal E are shared, the tail packet is consumed through the same finite route rather than through a second selector.

Finally use Definition 693.5. The shared Real seal exports no selected limit, quotient stream equality, independent Real carrier, trichotomy decision, ambient completeness proof, or hidden comparison row. The structural rows of both packets only transport, replay, source, and name that handoff, so replacing the displayed window by its cofinal tail preserves the exported $\mathsf{Real}^{\uparrow}$-facing surface. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionTailStability`

Theorem 693.14 (RegularCauchyWindowFusion tail-budget meet)**.** *Let*

$$F = (R, W, S, D, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *carrier. Any* $\mathsf{Real}^{\uparrow}$*-facing tail-window consumer and any budget-meet consumer read the same finite packet* $R, W, S, D, E, H, C, P, N$*. The tail selected by* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* S*, the dyadic ledger* D*, and the terminal seal* E *cannot split into separate selected-subsequence, quotient-stream, or ambient-completeness routes.*

Proof. First apply Definition 693.11. It identifies $R, W, S, D, E, H, C, P, N$ as the unique finite observation-window route available to any $\mathsf{Real}^{\uparrow}$- or completion-facing read.

Next use Definition 693.9. It forces the regular readback row S and the dyadic ledger row D to meet at the same terminal seal E through H, C, P, N.

Then apply Definition 693.10. The scoped route is exactly the L10 packet over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and the structural rows.

Finally use Definition 693.12. The tail selected by W is consumed through that same displayed packet, so a tail-window consumer and a budget-meet consumer cannot factor through different selected-subsequence, quotient-stream, or ambient-completeness routes. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionTailBudgetMeet`

Theorem 693.15 (Regular Cauchy window fusion cofinal-tail closure)**.** *Let*

$$F = (R, W, S, D, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *packet whose shared window route satisfies tail-window coverage and tail-budget meet. Then* F *exports a single cofinal-tail closure surface through the rows* $R, W, S, D, E, H, C, P, N$*. Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer must pass through that same surface before reading the terminal seal* E*.*

The closure surface exports no selected limits, quotient stream equality, trichotomy decision, or ambient $\mathsf{Real}^{\uparrow}$ *completeness witness.*

Proof. Begin with tail-window coverage, Definition 693.12. It forces any displayed cofinal tail of the shared window route to remain inside the same finite observation packet rather than producing a separate selected subsequence.

Next apply the tail-budget meet theorem Definition 693.14. The tail-window consumer and the budget-meet consumer both read $R, W, S, D, E, H, C, P, N$, so the regular readback row S and dyadic ledger row D meet before the terminal seal E is used.

Use finite-window exactness, Definition 693.11, to identify this packet as the only finite route from the RatUp seed through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Finally apply Real seal nonescape, Definition 693.5. The seal row E cannot be read through selected limits, quotient stream equality, trichotomy, or ambient completeness, and the structural rows only transport, replay, source, and name the same route. Hence every $\mathsf{Real}^{\uparrow}$ or $\mathsf{RegSeqRat}^{\uparrow}$ consumer must pass through the single cofinal-tail closure surface before reading the terminal seal. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionCofinalTailClosure`

Theorem 693.16 (Regular Cauchy window fusion kernel scope)**.** *Every accepted* $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *read is scoped by the concrete* BHist *packet*

$$F = (R, W, S, D, E, H, C, P, N),$$

the componentwise hsame *row* H*, displayed* Cont *route* C*,* Pkg *provenance row* P*, local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWindowFu}}$ *row* N*, and the four L10 rows* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. The accepted read cannot be replaced by a selected limit, quotient stream equality, trichotomy, ambient completeness, or hidden* $\mathsf{Real}^{\uparrow}$ *comparison.*

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionKernelScope`

Proof. Begin with the shared-window handoff of Definition 693.4. It binds the seed row R, the $\mathsf{StreamName}^{\uparrow}$ row W, the $\mathsf{RegSeqRat}^{\uparrow}$ readback S, and the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger D to one displayed finite observation window.

Next apply the Real seal non-escape theorem Definition 693.5. The $\mathsf{Real}^{\uparrow}$ row E is reachable only after R, W, S, D and remains under the support rows H, C, P, N.

Use the downstream package and budget-meet theorems, Definition 693.8 and Definition 693.9. They repack exactly $R, W, S, D, E, H, C, P, N$ for completion-facing consumers and force regular and dyadic reads to meet at the displayed seal row.

Finally combine finite-window exactness and tail-window coverage, Definition 693.11 and Definition 693.12. These blocks leave no carrier coordinate from which a selected limit, quotient stream equality, trichotomy decision, ambient completeness proof, or hidden $\mathsf{Real}^{\uparrow}$ comparison could be read. Hence every accepted fusion read remains inside the concrete kernel scope named above. □

Theorem 693.17 (Regular Cauchy window fusion scoped row exhaustion)**.** *For every accepted finite L10* $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *packet*

$$F = (R, W, S, D, E, H, C, P, N),$$

the scoped public surface exposes exactly the RatUp seed row R*, the* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* S*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row* D*, the* $\mathsf{Real}^{\uparrow}$ *seal row* E*, the componentwise* hsame *transport row* H*, the displayed* Cont *replay row* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWindowFusion}^{\uparrow}}$ *row* N*. No selected limit, quotient stream equality, trichotomy decision, ambient completeness proof, independent Real carrier, hidden comparison, or external downstream row can be consumed outside those displayed rows.*

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionScopedRowExhaustion`

Proof. Begin with the shared-window handoff and finite-window exactness. Theorems 693.4 and 693.11 identify R, W, S, D, E as one finite observation-window route from the RatUp seed through the stream, regular-sequence, dyadic, and Real-facing rows.

Next apply the Real seal non-escape and selector-budget compatibility results. Theorems 693.5 and 693.6 force any route to E to stay under R, W, S, D, H, C, P, N and rule out selector or budget changes before the displayed seal is read.

Now use the downstream package and budget meet theorems. Theorems 693.8 and 693.9 repack exactly $R, W, S, D, E, H, C, P, N$ for Real and completion-facing consumers, and they make the regular readback and dyadic ledger meet at the same displayed seal row.

Finally combine the scoped kernel route, finite-window exactness, tail-window coverage, and tail-budget meet. Theorems 693.10, 693.11, 693.12, and 693.14 leave no carrier coordinate outside $R, W, S, D, E, H, C, P, N$ from which a selected limit, quotient stream equality, trichotomy decision, ambient completeness proof, independent Real carrier, hidden comparison, or external downstream row could be read. Hence the finite L10 fusion packet is scoped exactly by those rows. □

Theorem 693.18 (Regular Cauchy window fusion scoped route)**.** *Every accepted* $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *consumer factors through the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$*, RatUp,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{CauchyModulusComparison}^{\uparrow}$*,* $\mathsf{DiagonalCofinalTail}^{\uparrow}$*, and* $\mathsf{StationaryDiagonalWindowRoute}^{\uparrow}$ *rows before the* $\mathsf{Real}^{\uparrow}$ *seal is readable. For*

$$F = (R, W, S, D, E, H, C, P, N),$$

the route is the concrete kernel path from the RatUp seed R *through the stationary stream window* W*, regular readback* S*, dyadic ledger* D*, terminal seal* E*, and structural rows* H, C, P, N*; it exports no selected limit, quotient stream equality, trichotomy decision, ambient completeness proof, independent Real carrier, or hidden comparison row.*

Proof. Begin with the carrier and NameCert obligations, Definition 693.1 and Definition 693.2. They admit only the packet $R, W, S, D, E, H, C, P, N$ and bind the RatUp seed, $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{Real}^{\uparrow}$ seal, transport, replay, provenance, and local naming rows.

Use the shared-window handoff and Real seal non-escape theorems, Definition 693.4 and Definition 693.5. They force the stationary window, dyadic ledger, regular readback, and Real-facing row to be consumed in order before the seal is readable.

Apply selector-budget compatibility and the downstream package theorem, Definition 693.6 and Definition 693.8. These place the $\mathsf{CauchyModulusComparison}^{\uparrow}$, $\mathsf{DiagonalCofinalTail}^{\uparrow}$, and StationaryDiagonalWindowF

consumers on the same finite row sequence and prevent a budget or selector change from leaving the carrier silently.

Finally combine the budget meet and scoped row exhaustion results, Definition 693.9 and Definition 693.17. They exhaust the available rows before the $\mathsf{Real}^{\uparrow}$ seal is read, so every accepted consumer factors through the displayed kernel path. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionScopedRoute`

Theorem 693.19 (Regular Cauchy window fusion public export)**.** *The* $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ *packet exports a public finite L10 route for* $\mathsf{Real}^{\uparrow}$ *and completion-facing consumers. The exported route is exactly the displayed packet*

$$R, W, S, D, E, H, C, P, N$$

over the RatUp seed, $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, terminal* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWindowFusion}^{\uparrow}}$ *row. A consumer that reads this public surface receives no selected limit, quotient stream equality, trichotomy decision, ambient completeness proof, independent Real carrier, hidden comparison row, or external downstream row.*

Proof. Begin with Definition 693.18. It places every accepted consumer on the concrete kernel path from the RatUp seed through the stationary stream window, regular readback, dyadic ledger, terminal seal, and structural rows.

Apply Definition 693.17. It identifies the public row inventory with $R, W, S, D, E, H, C, P, N$ and rules out any row outside that packet.

Finally use Definition 693.5. The terminal seal is reachable only through the displayed finite route and exports none of the excluded analytic or comparison coordinates. Hence the scoped route is a public export surface for exactly the stated L10 consumers. □

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.RegularCauchyWindowFusionPublicExport`

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyWindowFusion}^{\uparrow}}$ **.**

Constructive story: A $\mathsf{RegularCauchyWindowFusion}^{\uparrow}$ packet is generated from a RatUp seed classifier, a finite $\mathsf{StreamName}^{\uparrow}$ constant window, a $\mathsf{RegSeqRat}^{\uparrow}$ seal readback, a $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, a $\mathsf{Real}^{\uparrow}$ finite-window seal, displayed hsame transports, Cont routes, package provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.RegularCauchyWindowFusionUp.taste gate`

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RegularCauchyWindowFusion}^{\uparrow}}$, publicClosed)

Scope closed: Definition 693.19 exports the displayed DyadicRatCore, RatUp, StreamName, RegSeqRat, Real, CauchyModulusComparison, DiagonalCofinalTail, and StationaryDiagonalWindowRoute rows as the public finite L10 route before the Real seal is readable.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RegularCauchyWindowFusion}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close RealUp completeness, quotient streams, selected limits, real trichotomy, bridge status, Lean verification, or ambient completeness.

Upgrade path: Bridged closure requires a checked standard bridge for the public finite L10 route without enlarging the displayed rows.

Chapter 694

A Concrete Naming Certificate for $\mathsf{BranchObstruction}^{\uparrow}$

The $\mathsf{BranchObstruction}^{\uparrow}$ interface isolates the finite ledger row used when an analytic-continuation request leaves the displayed local source, overlap, operation, and output packet. It turns the branch-sensitive boundary of Definition 9341.6 into a concrete BHist packet: a consumer can inspect where the request was recorded, which continuation socket supplied the local rows, and which routes preserve the ledger, but cannot extract a branch selector, quotient-of-germs equality, monodromy theorem, or new holomorphic output.

Definition 694.1 (BranchObstruction carrier)**.** *A* $\mathsf{BranchObstruction}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (S, B, H, C, P, N)$$

with the following visible coordinates:

1. *S is an accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *row displaying the two* $\mathsf{Holomorphic}^{\uparrow}$ *source rows, overlap witness, operation row, output row, branch-obstruction ledger, componentwise transports, continuation routes, package provenance, and local naming row;*
2. *B is the branch-obstruction ledger coordinate selected from S;*
3. *H records componentwise* hsame *transport for S, B, the visible routes, the provenance row, and the local naming row;*
4. *C records the visible* Cont *routes from the socket row into the selected ledger row and the local naming surface;*
5. *P is the* Pkg *provenance over* $\mathsf{BranchObstruction}^{\uparrow}$, $\mathsf{AnalyticContinuationSocket}^{\uparrow}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{AnalyticContinuationOperation}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
6. *N is the local* $\mathsf{NameCert}_{\mathsf{BranchObstruction}^{\uparrow}}$ *row.*

The carrier exports only the socket row, selected obstruction ledger, transport rows, continuation routes, package provenance, and local naming data. It contains no global analytic-continuation operator, branch selector, quotient of germs, monodromy invariant, or additional $\mathsf{Holomorphic}^{\uparrow}$ *output row.*

Lean4 ✓ `BEDC.Derived.BranchObstructionUp.BranchObstructionTasteGate single carrier alignment`

Theorem 694.2 (BranchObstruction NameCert obligations)**.** *For the carrier of Definition 694.1, the local* $\mathsf{NameCert}_{\mathsf{BranchObstruction}^{\uparrow}}$ *surface consists exactly of five finite obligations: carrier admission for* $R = (S, B, H, C, P, N)$*; socket compatibility, requiring* B *to be the branch-obstruction coordinate displayed by the accepted* $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ *row* S*; ledger exactness, requiring every branch-sensitive continuation request outside the local socket rows to be recorded in* B*; transport stability through* H *and the visible routes in* C*; and non-escape, excluding branch selectors, quotient germs, monodromy theorems, global continuation principles, zero-location data, and new holomorphic outputs.*

Proof. Carrier admission is the projection of the finite tuple in Definition 694.1. The rows S, B, H, C, P, N display the socket, selected obstruction ledger, componentwise transport, routes, provenance, and local naming row.

Socket compatibility follows by reading S before any obstruction row is inspected. The accepted socket already names the two source rows, overlap witness, operation row, output row, and branch-obstruction coordinate, so B is a selected row of the displayed socket rather than an ambient analytic-continuation object.

Ledger exactness is inherited from the socket ledger. Requests that leave the source, overlap, operation, and output rows are assigned to B as ledger data.

Transport stability is componentwise through H and C. These rows replay the same socket and selected obstruction ledger under accepted hsame movement and visible continuation routes.

The non-escape clause is an inventory argument. Since the carrier has no coordinate for branch selection, quotient-of-germs equality, monodromy, global continuation, zero-location data, or another $\mathsf{Holomorphic}^{\uparrow}$ output, no local $\mathsf{NameCert}_{\mathsf{BranchObstruction}^{\uparrow}}$ projection can export one. □

Theorem 694.3 (BranchObstruction ledger non-escape)**.** *Every branch-sensitive read of an accepted* $\mathsf{BranchObstruction}^{\uparrow}$ *carrier factors through the finite rows*

$$S, B, H, C, P, N.$$

If the read asks for continuation data not displayed by the accepted socket row S*, the request remains in the selected ledger row* B *and is not exported as a branch selector, quotient-of-germs equality, monodromy theorem, or new* $\mathsf{Holomorphic}^{\uparrow}$ *output.*

Lean4 ✓ `BEDC.Derived.BHistHexaSequenceNameCertUp.BHistHexaSequenceNameCertUp single carrier alignment`

Proof. Project the accepted carrier and apply Definition 694.2. The only branch-sensitive coordinate exposed by the packet is the selected ledger row B.

For a read internal to the socket, apply the socket rows displayed by S. The consumer obtains only the source, overlap, operation, output, transport, route, provenance, and local naming data already present in the accepted $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ packet.

For a read outside those rows, use the ledger exactness obligation. Such a request lands in B as obstruction accounting and does not become a continuation witness.

Finally route the result through H, C, P, N. These rows preserve and name the same finite ledger surface, so no exported branch selector, quotient germ, monodromy theorem, or extra holomorphic output can appear. □

Theorem 694.4 (BranchObstruction holomorphic handoff boundary)**.** *Every downstream* $\mathsf{Holomorphic}^{\uparrow}$ *consumer of an accepted* $\mathsf{BranchObstruction}^{\uparrow}$ *carrier receives holomorphic data only through the output row already displayed by the socket coordinate* S*. The selected obstruction ledger* B *may accompany that handoff as boundary accounting, but it cannot create or certify an additional* $\mathsf{Holomorphic}^{\uparrow}$ *output row.*

Proof. Read the socket coordinate S. Its holomorphic handoff has already passed through the accepted $\mathsf{AnalyticContinuationSocket}^{\uparrow}$ packet, where the output row is displayed as part of the local source-overlap-operation-output surface.

Read the selected obstruction row B separately. By Definition 694.3, B records requests outside that local surface as obstruction ledger data.

The transport and route rows H and C preserve this separation: socket output rows remain socket output rows, while obstruction requests remain ledger rows. The package and local naming rows P, N bind the same separation to the $\mathsf{BranchObstruction}^{\uparrow}$ certificate, so the handoff cannot manufacture another $\mathsf{Holomorphic}^{\uparrow}$ output. □

Theorem 694.5 (BranchObstruction holomorphic operation sibling route)**.** *Every accepted* $\mathsf{BranchObstruction}^{\uparrow}$ *packet reads its socket row as a consumer of the holomorphic source and output surface of chapter 68 and the operation row of chapter 577 before the selected obstruction ledger* B *is exported. The packet therefore exposes the ledger only after the socket has fixed the* $\mathsf{Holomorphic}^{\uparrow}$ *source rows, the continuation operation row, the output row, the displayed transports, routes, provenance, and local naming data.*

Proof. Read the carrier of Definition 694.1. Its socket coordinate S is an accepted analytic-continuation socket row displaying the two $\mathsf{Holomorphic}^{\uparrow}$ source rows, the operation row, the output row, the branch-obstruction ledger, transports, routes, provenance, and local naming row.

Apply Definition 694.2. The socket compatibility and ledger exactness clauses require B to be selected from that already displayed socket surface, so the sibling holomorphic and operation rows are read before the obstruction ledger is exported.

Now use Definition 694.3 and Definition 694.4. The ledger remains boundary accounting, while downstream holomorphic consumers receive only the source and output surface already displayed by S together with the operation row named in the same socket. □

Theorem 694.6 (BranchObstruction monodromy non-export)**.** *An accepted* $\mathsf{BranchObstruction}^{\uparrow}$ *carrier may record a request for monodromy, branch selection, or quotient-of-germs comparison in the selected ledger row* B*. It does not export such a request as a monodromy theorem, branch selector, quotient equality, global continuation principle, zero-location datum, or holomorphic output beyond the socket row* S*.*

Proof. Start from the carrier inventory of Definition 694.1. The displayed rows are exactly S, B, H, C, P, N, and none of them is a monodromy object, branch selector, quotient-germ representative, global continuation operator, zero-location row, or additional holomorphic output.

Apply Definition 694.3 to any nonlocal continuation request. The request is recorded in B and remains ledger data under the visible routes.

Apply Definition 694.4 for downstream holomorphic consumers. Such consumers see only the socket output already displayed by S, with B retained as boundary accounting rather than exported analytic evidence. □

Closure status for $\mathsf{NameCert}_{\mathsf{BranchObstruction}^{\uparrow}}$**.**

Constructive story: A BranchObstruction$^{\uparrow}$ packet is generated from an AnalyticContinuationSocket$^{\uparrow}$ row, a selected branch-obstruction ledger row, componentwise hsame transport, visible Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{BranchObstruction}^{\uparrow}}$, seed)

Scope closed: The seed scope records the finite socket row, selected obstruction ledger, transport rows, visible routes, package provenance, local naming row, and non-export boundary for branch-sensitive continuation requests.

Formal verification: FormalStatus(NameCert$_{\text{BranchObstruction}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close global analytic continuation, branch selection, quotient-of-germs equality, monodromy invariance, Riemann-hypothesis zero-location data, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier compatibility, ledger exactness, holomorphic handoff boundary, and monodromy non-export obligations for the displayed socket and obstruction rows.

Chapter 695

A Concrete Naming Certificate for $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$

The $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ packet records the finite selector boundary used by the Real completeness diagonal route. It binds a precision request, a selected cofinal window, StreamName observations, a RegSeqRat witness, the RealUp seal handoff, and the BEDC transport rows as one inspectable naming certificate. The packet is a finite boundary between cofinal-window schedules and selector-budget packets; it is not a host choice principle, quotient stream, selected host limit, or ambient completeness theorem for $\mathsf{Real}^{\uparrow}$.

The selected cofinal window is consumed through chapter 126, then routed through the existing $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ seal surfaces before the local selector row is read. The selector does not own the window semantics; it schedules the finite $\mathsf{StreamName}^{\uparrow}$ window consumed by the diagonal handoff.

Definition 695.1 (Choice-free diagonal selector carrier)**.** *A* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (\varepsilon, W, S, R, E, H, C, P, N)$$

with the following displayed rows:

1. *ε is the positive precision request made by the diagonal-limit consumer;*
2. *W is the selected cofinal window row, displayed as a finite family of admissible StreamName observation indices;*
3. *S is the finite family of* $\mathsf{StreamName}^{\uparrow}$ *observation rows opened by the selected cofinal window;*
4. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *witness row assembled from those observations for the diagonal handoff;*
5. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after the RegSeqRat witness has been assembled;*
6. *H records componentwise* hsame *transports for the request, window, StreamName observations, RegSeqRat witness, RealUp seal, and structural rows;*
7. *C records the displayed* Cont *routes for request inspection, cofinal-window selection, observation readback, RegSeqRat handoff, RealUp seal delivery, and non-escape inspection;*
8. *P is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}}$ *row.*

The local classifier compares accepted carriers only through the visible rows $\varepsilon, W, S, R, E, H, C, P, N$.

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.ChoiceFreeDiagonalSelectorTasteGate single carrier alignment`

Theorem 695.2 (Choice-free diagonal selector carrier obligation)**.** *Every accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *packet exposes exactly the displayed rows*

$$\varepsilon, W, S, R, E, H, C, P, N$$

of Definition 695.1. The window route of Definition 695.5, the stage induction of Definition 695.8, and the non-escape theorem of Definition 695.9 may inspect those rows, but they cannot add a hidden selector row, quotient stream row, selected host limit, or ambient completeness row.

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.ObligationCarrier.ChoiceFreeDiagonalSelectorCarrier obligation carrier`

Proof. Project the carrier in Definition 695.1. Its content rows are the precision request, selected cofinal window, StreamName observations, RegSeqRat witness, RealUp seal, componentwise transport, displayed replay, provenance, and local naming.

Apply the window route to order the analytic rows, then apply stage induction to retain the same row family across displayed finite stages. Finally use non-escape to rule out any additional host choice, quotient, selected-limit, or completeness coordinate. □

Theorem 695.3 (Choice-free diagonal selector classifier obligation)**.** *Componentwise* hsame *transport of accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *packets preserves the classifier route*

$$\mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}.$$

If the rows $\varepsilon, W, S, R, E, H, C, P, N$ are transported componentwise through the displayed H coordinate, then the window, stage, and non-escape results still force each selector read through StreamName observations, RegSeqRat handoff, and RealUp seal in that order.

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.ClassifierObligation.ChoiceFreeDiagonalSelectorCarrie classifier obligation`

Proof. Read the transport row H in the carrier definition. It is componentwise over the request, window, StreamName observations, RegSeqRat witness, RealUp seal, and structural rows.

The window route fixes the order from selected window to StreamName observations, RegSeqRat witness, and RealUp seal. Stage induction preserves that order at each finite stage, and non-escape prevents the transported packet from acquiring a different classifier through host equality, quotient streams, or ambient RealUp completeness. □

Theorem 695.4 (Choice-free diagonal selector ledger obligation)**.** *For every accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *packet, the ledger rows P, N record provenance and naming for the finite selector route only. Together with Definition 695.5, Definition 695.8, and Definition 695.9, they certify the displayed route without supplying host choice, quotient streams, selected host limits, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.ChoiceFreeDiagonalSelectorCarrier ledger obligation`

Proof. Project the provenance row P and local naming row N from the carrier. They name the same finite packet already displayed by the analytic and structural rows.

The window route and stage induction identify the finite selector path that those ledger rows can certify. The non-escape theorem then excludes host choice, quotient stream equality, selected host limits, hidden cofinal-window selection, unbounded StreamName scans, and ambient RealUp completeness from the ledger surface. □

Theorem 695.5 (Choice-free diagonal selector window route)**.** *Every accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *carrier routes a diagonal precision request through the displayed finite cofinal window before any RegSeqRat or RealUp data can be consumed. For*

$$D = (\varepsilon, W, S, R, E, H, C, P, N),$$

each StreamName observation in S is opened only inside the selected cofinal window W, the RegSeqRat witness R is assembled only from those observations, and the RealUp seal row E is reached only through that witness route.

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.ChoiceFreeDiagonalSelectorCarrier window route`

Proof. Project the carrier coordinates. The request row ε and selected cofinal window W are displayed before any StreamName, RegSeqRat, or RealUp row is available.

The observation rows S are listed as the finite family opened by W. Hence a downstream diagonal consumer can read StreamName data only from the selected cofinal window.

The witness row R appears after those observations, and the seal row E appears after R. The structural rows H, C, P, N transport, replay, package, and name the same finite route, so the selector boundary is exactly $\varepsilon, W, S, R, E, H, C, P, N$. □

Theorem 695.6 (Choice-free diagonal selector RegSeqRat seal factorization)**.** *For an accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *carrier*

$$D = (\varepsilon, W, S, R, E, H, C, P, N),$$

any $\mathsf{Real}^{\uparrow}$ *seal read from the selector factors first through the finite* $\mathsf{StreamName}^{\uparrow}$ *observations S and the* $\mathsf{RegSeqRat}^{\uparrow}$ *witness row R. The seal row E is therefore available only as the terminal handoff of the displayed route*

$$S \longmapsto R \longmapsto E,$$

with H, C, P, N preserving that same factorization by transport, replay, provenance, and local naming.

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.RegSeqRatSealFactorization.ChoiceFreeDiagonalSelector regseqrat seal factorization`

Proof. Project the carrier of Definition 695.1. The only observation rows before the Real-facing endpoint are the finite StreamName family S and the RegSeqRat witness row R.

Apply Definition 695.5. It forces each observation in S to be opened inside the selected cofinal window W, then assembles the RegSeqRat witness R from those observations before the RealUp seal row E can be reached.

The structural rows do not add another seal route. Componentwise transport through H, displayed replay through C, provenance through P, and local naming through N preserve the same $S \longmapsto R \longmapsto E$ route, so every selector RealUp read factors through the RegSeqRat handoff first. □

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.ChoiceFreeDiagonalSelectorRegSeqRatSealFactorization`

Definition 695.7 (Choice-free diagonal selector stage carrier)**.** *For an accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *carrier*

$$D = (\varepsilon, W, S, R, E, H, C, P, N),$$

a stage carrier is a finite row

$$D_j = (\varepsilon, W_j, S_j, R_j, E_j, H_j, C_j, P, N)$$

displayed inside the selected cofinal window W*. The row* W_j *is a finite prefix of* W*,* S_j *is the corresponding finite* $\mathsf{StreamName}^{\uparrow}$ *observation family,* R_j *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff assembled from* S_j*, and* E_j *is the* $\mathsf{Real}^{\uparrow}$ *seal boundary reached from* R_j*. The structural rows* H_j, C_j, P, N *are the restrictions of the same transport, continuation, provenance, and local naming rows to that finite stage.*

Theorem 695.8 (Choice-free diagonal selector stage induction)**.** *Let* $D = (\varepsilon, W, S, R, E, H, C, P, N)$ *be an accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *carrier whose selected cofinal window* W *is displayed as finite stage rows. Induction over those rows preserves the route*

$$\varepsilon, W, S, R, E, H, C, P, N$$

and proves that every successor stage remains inside the displayed path

$$\mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}$$

before the selector boundary is sealed by E*. No successor stage may introduce a hidden cofinal-window selector, quotient stream equality, host choice rule, selected host limit, unbounded StreamName scan, or ambient completeness principle for* $\mathsf{Real}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.StageInduction.ChoiceFreeDiagonalSelectorCarrier stage induction`

Proof. For the base row, inspect the first displayed finite prefix W_0 of the selected cofinal window. Its observation family S_0 is read through $\mathsf{StreamName}^{\uparrow}$, the witness R_0 is assembled as the corresponding $\mathsf{RegSeqRat}^{\uparrow}$ handoff, and the boundary E_0 is reached only after that handoff.

For the successor row, assume the stage carrier

$$D_j = (\varepsilon, W_j, S_j, R_j, E_j, H_j, C_j, P, N)$$

has preserved the displayed route. The next row extends the finite prefix of W by one displayed window entry, so the new observation is appended inside the same $\mathsf{StreamName}^{\uparrow}$ family, the RegSeqRat witness is rebuilt from the enlarged finite family, and the RealUp seal remains downstream of that witness.

The transport and replay restrictions H_j, C_j are inherited from the original carrier rows H, C, while P, N keep the same provenance and local naming. Thus the induction invariant is exactly the finite route $\varepsilon, W, S, R, E, H, C, P, N$, and every successor stage stays inside $\mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}$ before sealing.

Since each step only inspects a displayed finite row of W, the induction has no coordinate for hidden selection, quotient stream equality, host choice, selected host limits, unbounded observation scans, or ambient RealUp completeness. □

Theorem 695.9 (Choice-free diagonal selector non-escape)**.** *An accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *carrier cannot be used to recover data outside the displayed tuple* $\varepsilon, W, S, R, E, H, C, P, N$*. In particular, it exports no host choice rule, quotient stream equality, selected host limit, hidden cofinal-window selector, unbounded StreamName scan, or ambient completeness principle for* $\mathsf{Real}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.Nonescape.ChoiceFreeDiagonalSelectorNonescape`

Proof. Read the displayed tuple in Definition 695.1. The content rows are the request, cofinal window, StreamName observations, RegSeqRat witness, and RealUp seal; the remaining rows only provide transport, route replay, provenance, and local naming for those entries.

Apply Definition 695.5. It confines every diagonal read to the selected finite cofinal window and forces the RegSeqRat and RealUp rows to be downstream of that route.

Since the carrier contains no coordinate for host choice, quotient stream equality, selected host limits, hidden selectors, unbounded observation scans, or RealUp completeness, no such object can be recovered from an accepted packet. □

Theorem 695.10 (Choice-free diagonal selector obligation closure)**.** *The* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *obligation surface is exactly the finite route over* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *assembled by the carrier, classifier, ledger, cofinal-window route, RegSeqRat seal factorization, stage carrier, stage induction, and non-escape theorems. It exports no host choice rule, quotient stream equality, selected host limit, hidden cofinal-window selector, unbounded StreamName scan, or ambient completeness principle for* $\mathsf{Real}^{\uparrow}$*.*

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.taste gate`

Proof. Start with Definition 695.1. The carrier displays the precision request, selected cofinal window, StreamName observations, RegSeqRat witness, RealUp seal, componentwise transport, replay, provenance, and local naming rows.

Apply the carrier, classifier, and ledger obligations of Definition 695.2, Definition 695.3, and Definition 695.4. These identify the finite rows that the local classifier and ledger may inspect.

Next use Definition 695.5 and Definition 695.6. They force every diagonal read through the displayed $\mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}$ route before the RealUp seal can be consumed.

Finally apply Definition 695.7, Definition 695.8, and Definition 695.9. Stage induction preserves the same finite rows, and non-escape rules out host choice, quotient streams, selected host limits, hidden selectors, unbounded scans, and ambient completeness. □

Theorem 695.11 (Choice-free diagonal selector scoped kernel route)**.** *Every accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *selector route factors through* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness rows,* $\mathsf{Real}^{\uparrow}$ *seal rows,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *before any diagonal consumer can read the selector output. The route cannot add host choice, quotient streams, hidden cofinal selectors, unbounded* $\mathsf{StreamName}^{\uparrow}$ *scans, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.ChoiceFreeDiagonalSelectorScopedKernelRoute`
↪ variant `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.ChoiceFreeDiagonalSelectorCarrier scoped kernel route`

Proof. Start with the carrier of Definition 695.1. Its displayed rows are the precision request, selected finite cofinal window, StreamName observations, RegSeqRat witness, RealUp seal, componentwise transport, route replay, provenance, and local naming.

Apply the window route and RegSeqRat seal factorization, Definition 695.5 and Definition 695.6. They force every selector read through the finite $\mathsf{StreamName}^{\uparrow}$ window rows before the $\mathsf{RegSeqRat}^{\uparrow}$ witness is assembled and before the $\mathsf{Real}^{\uparrow}$ seal row is available.

Use stage induction to keep the same route across finite window prefixes. Then apply non-escape and the obligation closure theorem, Definition 695.9 and Definition 695.10, to rule out host choice, quotient streams, hidden cofinal selection, unbounded scans, and ambient Real completeness. The remaining route is exactly the scoped kernel route through BHist, hsame, Cont, Pkg, and NameCert. □

Theorem 695.12 (Choice-free diagonal selector scoped window consumer)**.** *Every diagonal consumer of an accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *packet must preserve the same* $\mathsf{StreamName}^{\uparrow}$ *window row,* $\mathsf{RegSeqRat}^{\uparrow}$ *witness row,* $\mathsf{Real}^{\uparrow}$ *seal row,* BHist *event history, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *row already exposed by the scoped kernel route. A consumer that changes any of these rows is outside the scoped packet and cannot be read as the same choice-free diagonal selector.*

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.ChoiceFreeDiagonalSelectorScopedWindowConsumer`

Proof. Apply the scoped kernel route of Definition 695.11. It forces the selector output through the displayed StreamName, RegSeqRat, RealUp, transport, replay, provenance, and naming rows before any diagonal consumer can inspect it.

The non-escape theorem and obligation closure theorem then rule out host choice, quotient streams, hidden selectors, unbounded StreamName scans, selected host limits, and ambient Real completeness. Since the accepted carrier has no other coordinates, preserving the same consumer window is exactly preserving the same scoped packet. □

Theorem 695.13 (Choice-free diagonal selector public handoff)**.** *The public selector export of an accepted* $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ *packet preserves the displayed* $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, the* $\mathsf{Real}^{\uparrow}$ *seal delivery, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, the local* NameCert *row, and the nonescape restrictions of the finite selector route. Any public consumer that changes one of these rows is not consuming the same choice-free diagonal selector packet.*

Lean4 ✓ `BEDC.Derived.ChoiceFreeDiagonalSelectorUp.PublicHandoff.ChoiceFreeDiagonalSelectorPublicHandoff`

Proof. Begin with the scoped kernel route and scoped window consumer. They force every selector read through the displayed finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{RegSeqRat}^{\uparrow}$ witness row, $\mathsf{Real}^{\uparrow}$ seal row, transport, replay, provenance, and naming rows.

Use the RegSeqRat seal factorization and stage induction to keep the handoff stable across finite prefixes. Each stage rebuilds the witness from the displayed window before the RealUp seal is delivered, so the public export cannot detach the seal from the selector route.

Finally apply the nonescape theorem. It rules out host choice, quotient stream equality, selected host limits, hidden cofinal-window selection, unbounded StreamName scans, and ambient RealUp completeness. The public handoff therefore exposes exactly the same finite packet and no additional selector surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}}$.

Constructive story: A $\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}$ packet is generated from a precision request, selected cofinal window, finite StreamName observations, RegSeqRat witness, RealUp seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ChoiceFreeDiagonalSelector}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 695.1, Definition 695.5, Definition 695.6, Definition 695.8, Definition 695.9, Definition 695.10, Definition 695.11, and Definition 695.12 bind the finite choice-free diagonal selector scope.

Formal verification: FormalStatus(NameCert$_{\mathsf{ChoiceFreeDiagonalSelector}\uparrow}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, RealUp completeness, quotient stream equality, host choice, selected host limits, hidden cofinal-window selection, or a public standard bridge.

Upgrade path: Public closure requires a public consumer handoff that preserves the displayed StreamName window, RegSeqRat handoff, RealUp seal delivery, transport stability, route stability, provenance, and non-escape for the same finite packet.

Chapter 696

A Concrete Naming Certificate for $\mathsf{AuditGateComposition}^{\uparrow}$

The $\mathsf{AuditGateComposition}^{\uparrow}$ packet names a finite composition surface for two audit gates that share a boundary row. It records the two gate rows, the boundary-content rows seen by each gate, the two refusal-result rows, and the composed refusal trace as one local $\mathsf{NameCert}$ packet. The packet is a composition certificate: it does not create a new audit policy, weaken either gate, or turn refusal into host-side permission. The shared-boundary comparison and refusal rows are consumed from chapter 526 before the composed trace is packaged.

Definition 696.1 (Audit-gate composition carrier)**.** *An* $\mathsf{AuditGateComposition}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$C = (G_0, G_1, B_0, B_1, R_0, R_1, Q, H, K, P, N)$$

with the following displayed rows:

1. G_0 *and* G_1 *are the two audit-gate rows being composed;*
2. B_0 *and* B_1 *are the boundary-content rows read by the two gates, with a displayed shared-boundary comparison between the exit surface of* G_0 *and the entry surface of* G_1*;*
3. R_0 *and* R_1 *are the refusal-result rows produced by the two gates;*
4. Q *is the composed refusal trace, recording that the downstream consumer sees* R_0 *followed by* R_1 *through the shared boundary;*
5. H *stores componentwise* hsame *transports for gate rows, boundary-content rows, refusal-result rows, composed traces, provenance, and the local name;*
6. K *stores the* Cont *replay routes for reading* G_0*, reading* G_1*, transporting the shared boundary, replaying both refusal rows, and projecting the composed refusal trace;*
7. P *stores* Pkg *provenance naming* $\mathsf{AuditGateBoundary}^{\uparrow}$*,* $\mathsf{OperationalMembrane}^{\uparrow}$*,* $\mathsf{AuditMembrane}^{\uparrow}$*, forbidden-ancestry audit rows, paper-Lean drift rows,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *source packets;*
8. N *is the local* $\mathsf{NameCert}_{\mathsf{AuditGateComposition}^{\uparrow}}$ *row.*

The carrier exports only the displayed gate rows, boundary rows, refusal rows, composed trace, transport, replay, provenance, and local naming rows.

Theorem 696.2 (Audit-gate composition NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{AuditGateComposition}^{\uparrow}}$ *surface for the carrier of Definition 696.1 consists of six finite obligations:*

1. *carrier admission for* $C = (G_0, G_1, B_0, B_1, R_0, R_1, Q, H, K, P, N)$*;*
2. *first-gate exposure for* G_0*,* B_0*, and* R_0*;*
3. *second-gate exposure for* G_1*,* B_1*, and* R_1*;*
4. *shared-boundary transport, requiring the exit content of the first gate and the entry content of the second gate to be compared only through the displayed* hsame *rows in* H*;*
5. *composed refusal replay, requiring* Q *to be read through the displayed* Cont *routes in* K*;*
6. *consumer non-escape, requiring the composed packet to export no hidden permission row, no skipped gate, no host repair of a refused boundary, and no audit result outside the displayed finite trace.*

Lean4 ✓ `BEDC.Derived.BHistHendecaTupleNameCertUp.BHistHendecaTupleNameCertCarrierAdmission`

Proof. Carrier admission is projection from Definition 696.1. The two gate rows, two boundary rows, two refusal rows, composed trace, transport, replay, provenance, and local naming row are all displayed coordinates of the same finite packet.

The first and second gate obligations are read separately from the tuple. Each gate keeps its own boundary-content row and refusal-result row, so composition cannot identify the two gates or erase one of the two refusal surfaces.

Shared-boundary transport is confined to H. The only comparison between B_0 and B_1 is the displayed componentwise hsame comparison, and the only public replay of the composed trace passes through K.

Finally P and N package the displayed rows as local NameCert data. Since the carrier has no coordinate for a hidden permission row, skipped gate, host repair, or unlisted audit result, the six obligations exhaust the public surface of the composition packet. □

Theorem 696.3 (Audit-gate composition boundary obligation)**.** *For an accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *carrier*

$$C = (G_0, G_1, B_0, B_1, R_0, R_1, Q, H, K, P, N),$$

the shared boundary rows B_0 *and* B_1 *are the only boundary comparison surface. Every comparison between the exit content of* G_0 *and the entry content of* G_1 *must be read through the componentwise* hsame *transports in* H *and the displayed* Cont *replay routes in* K*.*

Lean4 ✓ `BEDC.Derived.AuditGateCompositionUp.AuditGateCompositionBoundary obligation`

Proof. Project the carrier of Definition 696.1. The only boundary-content coordinates are B_0 and B_1, and the only displayed comparison rows attached to them are the transports in H and replay routes in K.

Now apply Definition 696.2. Its shared-boundary transport obligation reads the exit content of the first gate and the entry content of the second gate only through the displayed hsame rows.

Finally use Definition 696.6. The sibling route consumes the audit-gate boundary and membrane rows before Q is public, so no ambient boundary object or host endpoint comparison can replace B_0, B_1, H, K. □

Theorem 696.4 (Audit-gate composition membrane obligation)**.** *For an accepted* AuditGateComposition$^{\uparrow}$ *carrier, the audit-membrane and operational-membrane provenance rows enter only through the provenance coordinate P. They cannot create a bypass row, host permission row, detached membrane policy, or second route around the displayed refusal and boundary packet.*

Proof. Project the provenance coordinate in Definition 696.1. The row P names the AuditMembrane$^{\uparrow}$ and OperationalMembrane$^{\uparrow}$ sources together with the local BHist, hsame, Cont, Pkg, and NameCert packets; no separate membrane carrier is exported.

Apply Definition 696.2. Its consumer non-escape obligation rules out hidden permission rows, skipped gates, host repair of refused boundaries, and unlisted audit results.

Then use Definition 696.6. Since sibling membrane rows are consumed only as named provenance before the composed refusal trace is packaged, they cannot generate a bypass or host-side permission surface. □

Lean4 ✓ `BEDC.Derived.AuditGateCompositionUp.AuditGateCompositionCarrier membrane obligation`

Theorem 696.5 (Audit-gate composition operational obligation)**.** *For an accepted* AuditGateComposition$^{\uparrow}$ *carrier, the composed refusal trace Q is replayed only after the gate rows G_0, G_1, boundary rows B_0, B_1, and refusal rows R_0, R_1 have been consumed. No consumer can read Q as an operational result before those six source rows have entered the displayed route.*

Proof. Project the carrier of Definition 696.1. The trace coordinate Q is displayed only after the two gate rows, two boundary rows, and two refusal-result rows in the tuple.

Use Definition 696.2. Its first-gate, second-gate, shared-boundary transport, and composed-refusal replay obligations order the read through $G_0, G_1, B_0, B_1, R_0, R_1$ before Q is projected.

Finally apply Definition 696.6. The dependency route consumes the sibling gate and membrane rows before the local packet exports the composed trace, so Q has no premature operational read outside the displayed finite carrier. □

Theorem 696.6 (Audit-gate composition sibling dependency route)**.** *Every composed refusal route of an accepted* AuditGateComposition$^{\uparrow}$ *packet first consumes the gate rows of chapter 526 and the membrane boundary surface of chapter 533 before the local packet*

$$G_0, G_1, B_0, B_1, R_0, R_1, Q, H, K, P, N$$

can export the composed refusal trace. The exported trace is therefore a routed composition of sibling gate and membrane rows, not a standalone refusal oracle or a host-side repair of a refused boundary.

Proof. Project the accepted carrier of Definition 696.1. The rows G_0, G_1 are the two gate rows, B_0, B_1 are the boundary-content rows, and R_0, R_1, Q, H, K, P, N are the displayed refusal, transport, replay, provenance, and local naming rows.

Use Definition 696.2. Its first-gate and second-gate obligations expose the two gate rows before the composed trace is public, while its shared-boundary transport obligation forces the boundary comparison through the displayed rows in H and K.

The provenance row P names the sibling audit-gate boundary and operational membrane surfaces, and the local NameCert row N packages them with the route. Thus the composed trace Q can be exported only after those sibling gate and membrane rows have been consumed. □

Theorem 696.7 (Audit-gate composition refusal transitivity)**.** *Let* $C = (G_0, G_1, B_0, B_1, R_0, R_1, Q, H, K, P, N)$ *be an accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *carrier. If the first gate refuses the boundary content recorded in* R_0 *and the second gate refuses the transported boundary content recorded in* R_1*, then every public read of the composed surface factors through the ordered refusal trace* Q*. The read cannot replace either refusal by acceptance and cannot bypass the shared-boundary transport.*

Proof. Project the accepted packet to the two gate surfaces. The first refusal is the row R_0 attached to G_0 and B_0, and the second refusal is the row R_1 attached to G_1 and B_1.

Use the shared-boundary rows in H to transport the exit content of the first gate to the entry content of the second gate. This is the only bridge between the two refusal reads, so the second refusal remains tied to the transported boundary rather than to a new host-side boundary object.

Replay the ordered route through K. The route reads R_0, crosses the displayed boundary comparison, reads R_1, and then exposes Q as the composed refusal trace.

Because Q is built only from those displayed rows, a consumer has no coordinate for replacing either refusal by acceptance or for bypassing the shared-boundary transport. □

Theorem 696.8 (Audit-gate composition consumer non-escape)**.** *Every consumer read of an accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *packet factors through*

$$G_0, G_1, B_0, B_1, R_0, R_1, Q, H, K, P, N.$$

The consumer receives a finite NameCert packet for composed gate surfaces, shared boundary rows, refusal transitivity, and consumer non-escape. It receives no general audit bypass, no external axiom-ancestry oracle, no paper-Lean marker repair, no operational-membrane override, and no host permission to treat a refused boundary as accepted.

Lean4 ✓ `BEDC.Derived.AuditGateCompositionUp.AuditGateCompositionUp StdBridge`

Proof. Start from the carrier inventory. A consumer can project the two gate rows, two boundary-content rows, two refusal-result rows, composed trace, componentwise transport, replay route, provenance, and local name.

The composed read is then determined by Definition 696.2 and Definition 696.7. The first theorem identifies the finite obligation surface, and the second theorem identifies the ordered refusal route through the shared boundary.

The provenance row records the neighboring audit packets that the composition may cite, but it does not import their host-side policy space. Since the carrier has no bypass, marker-repair, membrane-override, or acceptance-after- refusal coordinate, none of those objects can escape to the consumer. □

Theorem 696.9 (Audit-gate composition root-source boundary)**.** *Every root read of an accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *packet exposes the two audit-gate rows* G_0, G_1*, the two shared boundary rows* B_0, B_1*, and the transport rows in* H *before it may read the composed trace* Q*. The root surface therefore has no direct route from either gate row to* Q *that bypasses the displayed shared-boundary packet.*

Proof. Project the carrier of Definition 696.1. The only rows preceding the composed trace are $G_0, G_1, B_0, B_1, R_0, R_1$ and the componentwise transport data in H; no second source row is present.

The NameCert surface of Definition 696.2 binds those rows as the displayed root source for the composition. Refusal transitivity then reads the trace through the shared boundary, so any consumer that reaches Q has already exposed G_0, G_1, B_0, B_1 through the same finite packet. □

Theorem 696.10 (Audit-gate composition composed-refusal inheritance)**.** *Every composed trace of an accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *packet inherits both refusal rows* R_0 *and* R_1 *through the shared boundary. The trace* Q *is not a new refusal object; it is the replay of* R_0*, the transported boundary read, and* R_1 *inside the displayed carrier.*

Proof. Start with the refusal rows in the carrier and the boundary rows named by Definition 696.9. These are the only displayed sources from which Q can be read.

Use Definition 696.7. It orders the composition by the first refusal row, the shared-boundary transport, and the second refusal row. Since consumer non-escape adds no host refusal channel, the composed trace can inherit only R_0 and R_1 through that boundary. □

Theorem 696.11 (Audit-gate composition downstream root package)**.** *The downstream root package for* $\mathsf{AuditGateComposition}^{\uparrow}$ *consists of carrier exposure, shared-boundary transport, composed refusal replay, and consumer non-escape. Concretely, every accepted packet exposes*

$$G_0, G_1, B_0, B_1, R_0, R_1, Q, H, K, P, N$$

as a finite NameCert surface for downstream audit-gate consumers, and exports no bypass row, skipped-gate row, external ancestry oracle, or host acceptance coordinate.

Proof. Carrier exposure is Definition 696.1, and the NameCert obligations are Definition 696.2. Together they display the two gate rows, two boundary rows, two refusal rows, trace row, transports, replay route, provenance, and local name.

Shared-boundary transport is supplied by Definition 696.9. Composed refusal replay is supplied by Definition 696.10 and Definition 696.7.

Finally apply Definition 696.8. It removes every consumer route to bypass rows, skipped-gate rows, external ancestry oracles, and host acceptance coordinates, leaving exactly the displayed downstream root package. □

Theorem 696.12 (Audit-gate composition shared-boundary source)**.** *In every accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *carrier*

$$C = (G_0, G_1, B_0, B_1, R_0, R_1, Q, H, K, P, N),$$

the shared boundary between G_0 *and* G_1 *is read only through the displayed* BHist *rows* B_0, B_1*, the componentwise* hsame *transports in* H*, and the* Cont *replay route in* K*. No gate may substitute an ambient boundary row, host boundary object, or unstated endpoint comparison for this displayed source.*

Proof. Project the carrier of Definition 696.1. The only boundary-content rows in the packet are the displayed BHist rows B_0 and B_1, and the only named rows surrounding them are the gate rows, refusal rows, trace row, transports, continuations, provenance, and local certificate.

Apply the NameCert obligations of Definition 696.2. They bind the shared-boundary comparison to the componentwise hsame data in H and the displayed Cont route in K, while P and N record the same finite Pkg and $\mathsf{NameCert}$ provenance.

Finally use refusal transitivity and consumer non-escape, Definition 696.7 and Definition 696.8. Since every composed read passes through the ordered displayed trace and no ambient boundary coordinate is exported, neither gate can replace B_0, B_1, H, K by an external source. □

Theorem 696.13 (Audit-gate composition refusal-replay totality)**.** *Every public composed-refusal read of an accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *packet factors through* R_0*, the transported boundary row,* R_1*, and* Q*. The rows* P *and* N *only package and name that same finite* BHist *route by* Pkg *provenance and a local* $\mathsf{NameCert}$ *certificate; they do not add a second refusal path.*

Proof. Begin with the refusal-result rows R_0 and R_1 in the carrier. By Definition 696.2, the first gate exposes R_0, the second gate exposes R_1, and the shared boundary is transported componentwise through hsame rows in H.

The replay theorem Definition 696.7 then orders the public read. The route in K reads R_0, crosses the transported boundary row, reads R_1, and exposes Q as the composed refusal trace.

It remains to account for the packaging rows. The provenance row P is a Pkg record for the displayed audit, BHist, hsame, Cont, and NameCert sources, and N is the local name for the same packet. By consumer non-escape, these rows cannot be reread as a separate refusal channel or as host permission. □

Theorem 696.14 (Audit-gate composition consumer-permission exclusion)**.** *After the ordered refusal trace of an accepted* AuditGateComposition$^{\uparrow}$ *carrier is consumed, the composed packet exports no permission row, skipped-gate witness, policy weakening, or host acceptance coordinate. The consumer remains inside the displayed* BHist *carrier, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *row.*

Proof. Use the carrier inventory and the NameCert obligations first. They expose only the two gate rows, boundary rows, refusal rows, composed trace, componentwise transports, continuation routes, provenance, and local name.

Next apply refusal-replay totality together with Definition 696.7. A consumer reaches the public result by reading R_0, the transported boundary row, R_1, and Q through the displayed Cont route in K.

Finally cite consumer non-escape, Definition 696.8. Because no coordinate of C is a permission row, skipped-gate witness, policy weakening, or host acceptance coordinate, the Pkg row P and NameCert row N can only package the refusal trace already displayed by the packet. □

Theorem 696.15 (Audit-gate composition root-boundary totality)**.** *Every root read of an accepted* AuditGateComposition$^{\uparrow}$ *packet exposes the two audit-gate rows, both boundary-content rows, both refusal rows, the shared-boundary transport, the replay row, the package row, and the local NameCert row. The root packet has no public coordinate outside* $G_0, G_1, B_0, B_1, R_0, R_1, Q, H, K, P, N$ *for reinterpreting the composed refusal trace as a host permission or as an external boundary oracle.*

Proof. Project the accepted carrier of Definition 696.1. Its displayed coordinates are exactly the two gate rows, two boundary rows, two refusal rows, composed trace, transport row, replay row, package provenance, and local NameCert row.

Apply the NameCert obligations of Definition 696.2. They expose the first gate, second gate, shared boundary, composed refusal replay, and consumer non-escape obligations over the same tuple.

The refusal-replay totality theorem and the consumer-permission exclusion theorem then exhaust the root read. Since the carrier contains no further coordinate, the root boundary cannot export a permission row, host repair row, or external boundary oracle. □

Theorem 696.16 (Audit-gate composition operational membrane route)**.** *Every operational-membrane consumption route for an accepted* AuditGateComposition$^{\uparrow}$ *packet is consumed only through the* AuditGateBoundary$^{\uparrow}$, OperationalMembrane$^{\uparrow}$, *and* AuditMembrane$^{\uparrow}$ *surfaces named by the carrier provenance. The composed route cannot bypass these named surfaces by reading an ambient membrane, a detached host policy, or an unlisted audit row.*

Proof. Read the provenance row P in the carrier. It names $\mathsf{AuditGateBoundary}^{\uparrow}$, $\mathsf{OperationalMembrane}^{\uparrow}$, $\mathsf{AuditMembrane}^{\uparrow}$, the forbidden-ancestry audit rows, paper-Lean drift rows, and the local BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ sources.

Use the sibling dependency route theorem Definition 696.6. It forces the composed refusal trace to consume the audit-gate boundary and operational membrane rows before the local packet exports Q.

Finally apply consumer non-escape and consumer-permission exclusion. These two boundaries leave no coordinate for an ambient membrane read, detached host policy, or unlisted audit row, so the operational route remains inside the three named membrane surfaces. □

Theorem 696.17 (Audit-gate composition downstream ledger exhaustion)**.** *Every downstream ledger read of an accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *packet exhausts the composed refusal trace* $R_0 \longmapsto R_1 \longmapsto Q$*. The exported ledger contains no bypass, host repair, external ancestry oracle, permission row, skipped-gate witness, or policy-weakening coordinate.*

Proof. Start from refusal transitivity. It orders the two refusal rows through the shared-boundary transport and states that every public read of the composed surface factors through Q.

Refusal-replay totality then identifies the downstream ledger as the route through R_0, the transported boundary row, R_1, and Q. The package and local name rows only record that displayed route.

Consumer-permission exclusion supplies the final exhaustion step. A bypass, host repair, external ancestry oracle, permission row, skipped-gate witness, or policy-weakening coordinate would require an additional public row, but the accepted carrier exports only the displayed finite ledger. □

Theorem 696.18 (Audit-gate composition shared-boundary transitivity)**.** *For an accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *packet, comparison from the first boundary-content row* B_0 *to the second boundary-content row* B_1 *composes only through the displayed* hsame *row* H*, the displayed replay row* K*, and the sibling* $\mathsf{AuditGateBoundary}^{\uparrow}$ *and* $\mathsf{OperationalMembrane}^{\uparrow}$ *route named by the provenance row* P*. No public comparison route may replace this boundary movement by a host repair, detached membrane policy, or skipped audit-gate row.*

Proof. Start with the carrier of Definition 696.1. Its only boundary-content coordinates are B_0 and B_1, and the only public rows available for moving between them are the componentwise transport row H, replay row K, package row P, and local naming row N.

Apply the local obligations of Definition 696.2. The shared-boundary obligation ties the two boundary rows to the same accepted packet, while the replay and provenance obligations keep that comparison inside the displayed finite rows.

Use the sibling dependency route and the operational membrane route. They force the comparison to pass through the named $\mathsf{AuditGateBoundary}^{\uparrow}$ and $\mathsf{OperationalMembrane}^{\uparrow}$ surfaces before the composition exports the trace Q.

Finally apply consumer non-escape and downstream ledger exhaustion. Since the public ledger has no host repair, detached policy, or skipped-gate coordinate, the boundary comparison can only be the displayed H, K, P, N route between B_0 and B_1. □

Theorem 696.19 (Audit-gate composition refusal-order determinacy)**.** *For accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *packets preserving* $G_0, G_1, B_0, B_1, R_0, R_1, H, K, P, N$*, the ordered refusal trace is the same row* Q*. In particular, the exported trace cannot be reordered through host repair, policy weakening, a skipped gate, or an alternate public ledger row.*

Proof. Project the shared rows from the two accepted carriers. The two gate rows, boundary rows, refusal rows, transport, replay, provenance, and local naming rows agree by hypothesis.

Apply refusal transitivity. The composed refusal trace is read by first applying G_0 to B_0, then transporting the boundary comparison, then applying G_1 to B_1. This fixes the order $R_0 \longmapsto R_1 \longmapsto Q$.

The shared-boundary transitivity row supplies the only route between B_0 and B_1. Thus the second packet has no different comparison path from which a second trace could be assembled.

Consumer-permission exclusion and downstream ledger exhaustion remove the last alternatives. A reordered trace would require a host repair, policy weakening, skipped-gate, or alternate ledger coordinate, and none is exported by the accepted packet. □

Theorem 696.20 (Audit-gate composition support-row exhaustion)**.** *Every public support read of an accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *packet is exhausted by the transport and replay rows* H, K*, the provenance and local naming rows* P, N*, the two gate rows* G_0, G_1*, the two boundary rows* B_0, B_1*, and the two refusal rows* R_0, R_1 *together with their composed trace* Q*. No support read exposes a host audit policy, parameter transport, external boundary oracle, skipped-gate witness, or ledger row outside this finite package.*

Proof. Begin with the carrier inventory. The public support surface consists exactly of $G_0, G_1, B_0, B_1, R_0, R_1, Q, H,$

The NameCert obligations expose these rows in their required roles: the two gate obligations, the shared boundary obligation, refusal replay, transport, continuation, provenance, and local naming.

Next combine refusal transitivity, shared-boundary transitivity, and refusal-order determinacy. These three rows account for the only boundary movement and the only ordered refusal trace available to a public consumer.

Finally use consumer non-escape, consumer-permission exclusion, and downstream ledger exhaustion. They rule out host audit policy, parameter transport, external boundary oracles, skipped gates, and off-packet ledger rows, leaving only the displayed support package. □

Theorem 696.21 (Audit-gate composition public export)**.** *The carrier, NameCert obligations, refusal transitivity, consumer nonescape, consumer-permission exclusion, root-boundary totality, operational membrane route, downstream ledger exhaustion, shared-boundary transitivity, refusal-order determinacy, support-row exhaustion, and checked TasteGate row form the public export surface for* $\mathsf{AuditGateComposition}^{\uparrow}$*. A public consumer of the accepted packet reads exactly the two audit-gate rows, two boundary rows, two refusal rows, composed trace, transport and replay rows, provenance, local name, and TasteGate witness; it receives no host audit policy, skipped gate, external boundary oracle, permission override, or alternate downstream ledger.*

Proof. First assemble the finite carrier and naming surface from Definition 696.1 and Definition 696.2. These rows expose the packet coordinates and the local certificate consumed by any public read.

Next combine the route theorems: refusal transitivity, root-boundary totality, the operational membrane route, downstream ledger exhaustion, shared-boundary transitivity, refusal-order determinacy, and support-row exhaustion. Together they give the only ordered path through $G_0, G_1, B_0, B_1, R_0, R_1, Q, H, K, P, N$.

Finally apply consumer nonescape, consumer-permission exclusion, and the checked TasteGate row. These remove host policy, permission override, skipped gate, and alternate-ledger exits, so the displayed packet is already the public export surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{AuditGateComposition}^{\uparrow}}$.

Constructive story: An $\mathsf{AuditGateComposition}^{\uparrow}$ packet is generated from two audit-gate rows, two boundary-content rows, two refusal-result rows, a composed refusal trace, componentwise hsame transports, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AuditGateComposition}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 696.1, Definition 696.2, Definition 696.7, Definition 696.8, Definition 696.14, Definition 696.15, Definition 696.16, Definition 696.17, Definition 696.18, Definition 696.19, Definition 696.20, Definition 696.21, and

Chapter 697

A Concrete Naming Certificate for $\mathsf{DiagonalTailSelector}^{\uparrow}$

The $\mathsf{DiagonalTailSelector}^{\uparrow}$ packet binds the Real-completion diagonal tail-selector route as one finite naming surface. It starts from a regular rational input row and a displayed modulus, selects one cofinal tail index, reads only finite StreamName and dyadic windows, hands the selected tail through RegSeqRat regularity and the RealUp seal, and records the BEDC transport, continuation, provenance, and local naming rows in the same packet. The selector is therefore a concrete NameCert carrier for the finite cofinal-tail route, not a quotient stream, host-selected limit, ambient completeness principle, countable-choice rule, or hidden equality of completed reals.

This carrier consumes the finite selector route of chapter 673 and the selected-tail witness surface of chapter 458. Its diagonal tail row is not a new selector oracle; it repacks those sibling finite-window obligations through the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows.

The finite cofinal row also consumes the precision-to-window-to-dyadic-to-RegSeqRat-to-Real seal route of chapter 681. Thus the selected tail index is scheduled through the same finite $\mathsf{TailCofinalitySchedule}^{\uparrow}$ route before any diagonal consumer reads W, D, T, S as a completion-facing packet.

Definition 697.1 (Diagonal tail selector carrier)**.** *A* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

with the following displayed rows:

1. *R is the* RegSeqRat *input row for the regular Cauchy family whose diagonal tail is being selected;*
2. *n is the unary precision request row;*
3. *μ is the displayed modulus row that assigns a finite cofinal bound to the precision request;*
4. *k is the selected cofinal tail index, displayed as the value read from μ at n;*
5. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *window opened at the selected tail and precision request;*
6. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row extracted from the finite window;*
7. *T is the* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ *tail-regularity row binding the selected cofinal tail to the input row R;*
8. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after the finite window, dyadic readback, and tail-regularity rows are displayed;*

9. *H records componentwise* hsame *transports for R, n, μ, k, W, D, T, S and the local structural rows;*
10. *C records the displayed* Cont *route from the precision request through modulus selection, finite windows, dyadic readback, tail regularity, and the RealUp seal;*
11. *P is the* Pkg *provenance over* $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and local certificate rows;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{DiagonalTailSelector}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through the visible rows $R, n, \mu, k, W, D, T, S, H, C, P, N$.

Theorem 697.2 (Diagonal tail selector NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DiagonalTailSelector}^{\uparrow}}$ *surface for Definition 697.1 consists of the following finite obligations:*

1. *carrier admission, requiring every accepted selector object to expose the packet $G = (R, n, \mu, k, W, D, T, S, H, C, P$*
2. *selector exactness, requiring the cofinal index row k to be read from the displayed modulus μ at the unary precision request n;*
3. *finite-window readback, requiring every selected diagonal observation to pass through the finite* $\mathsf{StreamName}^{\uparrow}$ *window W and* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row D;*
4. *tail regularity handoff, requiring the selected cofinal tail to enter downstream reads only through the* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ *row T tied to the input row R;*
5. *RealUp seal handoff, requiring the seal row S to be reached only after W, D, T and the displayed transport, continuation, provenance, and local naming rows are available;*
6. *non-escape, requiring the packet to export no quotient stream, countable-choice selector, host-selected limit, ambient completeness theorem, host real equality, or hidden tail oracle.*

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier namecert obligations`

Proof. Carrier admission is projection from the displayed tuple in Definition 697.1. The input row, precision request, modulus, selected cofinal index, finite window, dyadic readback, tail-regularity row, RealUp seal, transports, routes, provenance, and local naming row are all coordinates of one finite packet.

Selector exactness reads n and μ before k is available. Thus the selected tail index is a named row of the packet and not an external subsequence choice.

The finite-window and tail-regularity clauses then route the selected index through W, D, T. The StreamName window and dyadic readback expose only finite observations, and the regularity handoff is the displayed $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ row tied to R.

Finally inspect S, H, C, P, N. These rows carry the selected finite route into the RealUp seal and provide no coordinate for quotient streams, countable choice, selected host limits, ambient completeness, host real equality, or hidden tail selection. □

Theorem 697.3 (Diagonal tail selector selector-row determinacy)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. Any transported read of the same packet with the same precision row n, modulus row μ, componentwise* hsame *data for the displayed rows, displayed* Cont

route, Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DiagonalTailSelector}^{\uparrow}}$ *row reaches the same selected cofinal index row k. Thus selector comparison is determined by the visible selector rows of G and has no countable-choice coordinate or hidden selector coordinate.*

Proof. Project the carrier from Definition 697.1. The selected cofinal index appears as the displayed packet coordinate k, and the only rows upstream of it are the precision request n and modulus row μ.

Use selector exactness in Definition 697.2. It requires k to be read from μ at n, so any transported read preserving n, μ, the componentwise hsame rows, the displayed Cont route, the Pkg provenance, and the local NameCert row preserves the selected row itself.

The remaining coordinates W, D, T, S, H, C, P, N transport, replay, package, and name the already selected finite route. They do not contain an independent selector, a countable-choice schedule, or a hidden tail-selection coordinate. □

Theorem 697.4 (Diagonal tail selector window-threshold order)**.** *For an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

every downstream read of the tail-regularity row T or the RealUp seal row S first passes through the ordered finite route

$$n, \mu, k, W, D.$$

Consequently the finite $\mathsf{StreamName}^{\uparrow}$ *window and* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback are exposed before any tail regularity or seal row is available.*

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier window threshold order`

Proof. Begin with the selector rows. The NameCert obligations force k to be read from μ at n, and Definition 697.3 makes that selected row invariant under the displayed transports and local naming row.

Next read the finite-window clause of Definition 697.2. Once k is fixed, selected diagonal observations must pass through the $\mathsf{StreamName}^{\uparrow}$ window W and the $\mathsf{DyadicRatCore}^{\uparrow}$ readback row D.

Only then can the tail-regularity and seal clauses be consumed. The row T is downstream of the finite window and dyadic readback, and S is downstream of W, D, T together with the structural rows H, C, P, N. □

Theorem 697.5 (Diagonal tail selector seal after tail regularity)**.** *For an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

the RealUp seal row S is available only after the selected cofinal tail row T has been routed through the displayed $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ *handoff tied to the input row R. The seal handoff exports no quotient stream, host-selected limit, countable-choice selector, host real equality, hidden tail oracle, or ambient completeness coordinate.*

Proof. First apply Definition 697.3. The selected cofinal row is fixed by n, μ, k and the displayed transport, continuation, provenance, and local naming rows, rather than by an external selector.

Then apply Definition 697.4. Every downstream read of T or S passes through n, μ, k, W, D, so the finite $\mathsf{StreamName}^{\uparrow}$ window and $\mathsf{DyadicRatCore}^{\uparrow}$ readback are already exposed before the tail-regularity row is consumed.

Finally use the RealUp seal handoff clause in Definition 697.2. It places S after W, D, T and the structural rows H, C, P, N, while the tail-regularity clause ties T to R through the displayed $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ handoff. The non-escape clause removes any remaining route through quotient streams, host-selected limits, countable-choice selectors, host real equality, hidden tail oracles, or ambient completeness. □

Theorem 697.6 (Diagonal tail selector limit handoff)**.** *Every Real-completion diagonal-limit consumer of an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet factors through the finite route*

$$R, n, \mu, k, W, D, T, S, H, C, P, N.$$

Equivalently, the route composes the $\mathsf{LimitSelector}^{\uparrow}$ *precision-and-modulus selection surface, the* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ *tail-regularity handoff, the* $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$ *cofinal dyadic-window route, the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback, the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-source row, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *finite seal consumer, and the* $\mathsf{Real}^{\uparrow}$ *seal into one displayed BEDC packet. The consumer receives no quotient stream, selected host limit, countable-choice row, ambient completeness theorem, host real equality, or unbounded tail selector.*

Proof. Start with the precision-and-modulus part of the route. The carrier displays R, n, μ, k, and Definition 697.2 forces k to be read from μ at n, matching the finite selector surface of $\mathsf{LimitSelector}^{\uparrow}$.

Next read the finite observation part. The selected cofinal index opens the $\mathsf{StreamName}^{\uparrow}$ window W, the $\mathsf{DyadicRatCore}^{\uparrow}$ readback D, and the $\mathsf{RegSeqRat}^{\uparrow}$ source row represented by R. The dyadic cofinal-window role is carried by the same selected index and finite window rows used by $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$.

Now pass to regularity and sealing. The row T is the displayed $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ handoff for the selected tail, and S is reached only after W, D, T have been named. A $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer therefore reads the same finite window, dyadic readback, regular handoff, and RealUp seal rows before it can expose any completion-facing seal data.

Finally use the structural rows H, C, P, N. They transport, replay, package, and name exactly the same finite route, so the consumer has no remaining channel for quotient streams, countable choice, selected host limits, ambient completeness, host real equality, or an unbounded tail selector. □

Theorem 697.7 (Diagonal tail selector window admission)**.** *For an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

every selected observation admitted to the selector route passes through the precision request n, displayed modulus μ, selected cofinal index k, finite $\mathsf{StreamName}^{\uparrow}$ *window W, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row D before the tail-regularity row T is read. No consumer may read T as if it were supplied by an unbounded tail search, quotient stream, countable-choice schedule, or host selected limit.*

Proof. Project the carrier of Definition 697.1. The only coordinates that select an observation before tail regularity are n, μ, k, W, D.

Apply the NameCert obligations of Definition 697.2. Selector exactness forces k to be read from μ at n, and finite-window readback forces the selected observation through W and D.

Finally use Definition 697.17. It rules out alternate cofinal-tail channels, so the tail-regularity row T can be consumed only after the displayed finite-window route has been admitted. □

Theorem 697.8 (Diagonal tail selector Real seal factorization)**.** *For an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

every $\mathsf{Real}^{\uparrow}$ *seal read from* S *factors through the displayed route*

$$R, n, \mu, k, W, D, T, S, H, C, P, N.$$

In particular, the seal consumer first reads the $\mathsf{RegSeqRat}^{\uparrow}$ *source row* R*, selector rows* n, μ, k*, finite window* W*, dyadic readback* D*, tail-regularity handoff* T*, componentwise* hsame *transports, displayed* Cont *route,* Pkg *provenance, and local* NameCert *row* N*. It receives no quotient stream, host selected limit, countable-choice row, host real equality, hidden tail oracle, or ambient completeness coordinate.*

Proof. Begin with Definition 697.6. It identifies the Real-completion consumer route with the finite selector packet $R, n, \mu, k, W, D, T, S, H, C, P, N$.

Apply Definition 697.7 to the observation part of the route. This ensures that the selected finite window and dyadic readback are present before the tail-regularity row is read.

Use Definition 697.18 when the selected tail is supplied through a shared-threshold certificate, and then apply Definition 697.19. The seal row S is reachable only through the displayed selector, window, tail-regularity, transport, continuation, provenance, and naming rows. □

Theorem 697.9 (Diagonal tail selector CauchyLimitSeal factorization)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

any $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer reached by the selector route reads the seal only through the displayed rows*

$$R, n, \mu, k, W, D, T, S, H, C, P, N.$$

The route first exposes the $\mathsf{RegSeqRat}^{\uparrow}$ *source* R*, the request and selector rows* n, μ, k*, the finite* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback* D*, the tail row* T*, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and the local* NameCert *row. It has no coordinate for a quotient stream, a host selected limit, countable choice, host real equality, hidden tail oracle, or ambient completeness.*

Proof. Project the carrier of Definition 697.1. The accepted packet exposes exactly $R, n, \mu, k, W, D, T, S, H, C, P, N$ before a seal consumer can read any completion-facing row.

Apply the NameCert obligations and the limit handoff. They force k to be read from μ at n, route the selected observation through W and D, and place the $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer behind the same displayed selector packet.

Finally use Definition 697.8. The real-facing seal factorization already confines the downstream seal row to the selector, window, tail, transport, continuation, provenance, and local naming rows. The carrier inventory therefore supplies no row for any excluded host or quotient object. □

Theorem 697.10 (Diagonal tail selector RegularCauchyTailMeet consumption)**.** *Suppose an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

uses its tail row T *through a shared-tail consumer. Then the shared-tail use must factor through the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold rows before the selector seal row* S *is read. The consumed surface is the transported source rows, finite* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold ledger,*

$\mathsf{RegSeqRat}^{\uparrow}$ *comparison row, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows already recorded by* H, C, P, N.

Proof. Start from the selector carrier and its local NameCert obligations. They make T the only row through which the selected regular-tail information can be read before the seal row S becomes visible.

Use Definition 697.7 and Definition 697.17. These results confine the selected tail read to the finite window and dyadic readback rows W, D together with R, n, μ, k, H, C, P, N.

Now apply Definition 697.18. When a shared-tail packet supplies T, it is consumed as the public $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ shared-threshold certificate before any $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ seal row is read. The compatibility theorem therefore fixes the threshold rows as the only admitted shared-tail route. □

Theorem 697.11 (Diagonal tail selector tail-meet threshold admission)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet whose tail row* T *is supplied through* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*. Any accepted packet using that selected tail row must read the transported shared-threshold source rows, finite* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold ledger, and* $\mathsf{RegSeqRat}^{\uparrow}$ *comparison row before the seal row* S *is available to a* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer.*

Proof. Project the accepted selector packet. Its only path from the selected index k to the tail row T passes through the finite window W, the dyadic readback row D, and the structural rows H, C, P, N.

Apply Definition 697.7. The selected observation is admitted through W and D before the tail row can be consumed.

Now apply Definition 697.10. It identifies the supplied T row with the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ shared-threshold route and places the source, window, threshold, and comparison rows before the selector seal.

Finally use Definition 697.9. A seal consumer reaches S only after those displayed threshold rows have already entered the finite route. □

Theorem 697.12 (Diagonal tail selector source-modulus route exactness)**.** *For an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

the exact source and modulus route into the selector ledger is

$$n, \mu, k, W, D, T.$$

Here k *is read from the modulus row* μ *at request* n*,* W *is the admitted finite* $\mathsf{StreamName}^{\uparrow}$ *window for that selected request,* D *is the corresponding* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback ledger, and* T *is the selected tail row consumed before the seal row* S*.*

Proof. Use the NameCert obligations for the carrier. They make n, μ, k the only request, modulus, and selected-index rows in the local selector certificate.

Apply the window admission theorem. It routes the selected index through the finite window W and the dyadic readback ledger D, so the selector ledger cannot be entered through an unrecorded source row.

The limit handoff theorem then carries the admitted row to T and onward to the seal-facing route. Together with Definition 697.11, this shows that n, μ, k, W, D, T is the exact source/modulus route into the displayed selector ledger. □

Theorem 697.13 (Diagonal tail selector root seal consumer exhaustion)**.** *Every* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *root consumer of an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet factors through the finite route*

$$R, n, \mu, k, W, D, T, S, H, C, P, N$$

and, when T *is supplied through* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*, through the tail-meet threshold surface of Definition 697.11. No root consumer receives a quotient stream, selected host limit, countable-choice row, hidden tail oracle, host real equality, or ambient completeness coordinate.*

Proof. Begin with Definition 697.12. It fixes the source and modulus part of the root route as n, μ, k, W, D, T inside the carrier packet.

Use Definition 697.11 for the shared-threshold case. The selected tail row can only be consumed after the transported $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ source, window, threshold, and comparison rows are in scope.

Apply Definition 697.9 and Definition 697.8. These factor every $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer through the same finite packet before any seal-facing row is read.

Finally apply Definition 697.19. Since the accepted packet contains no quotient stream, selected host limit, countable-choice row, hidden tail oracle, host real equality, or ambient completeness coordinate, a root seal consumer cannot obtain one. □

Theorem 697.14 (Diagonal tail selector RealUp window non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *window read made from an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

consumes the $\mathsf{StreamName}^{\uparrow}$ *window* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *source* R*, tail-selector row* T*, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row before the seal row* S *is available. The window route has no coordinate for a quotient stream, countable choice, host selected limit, host equality, or ambient completeness.*

Proof. Begin with the carrier and NameCert obligations. They expose the finite selector tuple and require the selected index k to be read from μ at the request n.

Apply the window admission theorem. It places every selected observation inside the finite $\mathsf{StreamName}^{\uparrow}$ window W and the $\mathsf{DyadicRatCore}^{\uparrow}$ readback row D before any tail or seal row is consumed.

Use the limit handoff and Definition 697.8. The RealUp seal row is reached only after the window, readback, tail-selector, transport, continuation, provenance, and local NameCert rows have been displayed.

Finally apply the seal non-escape boundary. Since the accepted packet contains no quotient stream, countable-choice row, host selected limit, host equality, or ambient completeness coordinate, no RealUp window consumer can receive one. □

Theorem 697.15 (Diagonal tail selector obligation triad)**.** *For an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

selector exactness, finite-window readback, and $\mathsf{Real}^{\uparrow}$ *seal factorization form one obligation triad over* $\mathsf{LimitSelector}^{\uparrow}$*,* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. Any consumer must read* k *from* μ *at* n*, pass through* W, D, T*, and reach* S *only through* H, C, P, N*. The triad supplies no quotient stream, countable-choice row, host selected limit, host equality, or ambient completeness coordinate.*

Proof. First read selector exactness from Definition 697.2. The accepted packet exposes $R, n, \mu, k, W, D, T, S, H, C,$ and the selected index row k is available only as the value read from μ at the precision request n.

Next apply Definition 697.7. It confines every selected observation to the finite $\mathsf{StreamName}^{\uparrow}$ window W and $\mathsf{DyadicRatCore}^{\uparrow}$ readback row D before the $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ row T is consumed.

Finally use Definition 697.8. The $\mathsf{Real}^{\uparrow}$ seal row S is reached only through the displayed selector, window, tail handoff, transport, continuation, provenance, and local naming rows.

The non-escape clauses already present in the chapter then rule out quotient streams, countable choice, host selected limits, host equality, and ambient completeness as coordinates of the same route. □

Theorem 697.16 (Diagonal tail selector NameCert closure)**.** *The local* $\mathsf{NameCert}_{\mathsf{DiagonalTailSelector}^{\uparrow}}$ *package closes over the carrier of Definition 697.1, selector exactness, finite-window readback, tail regularity,* $\mathsf{Real}^{\uparrow}$ *seal handoff, and non-escape for the single finite route*

$$R, n, \mu, k, W, D, T, S, H, C, P, N.$$

Thus every downstream read factors through the displayed $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows, and the package exports no quotient stream, countable-choice selector, host selected limit, ambient completeness theorem, host real equality, or hidden completed value.*

Proof. Read carrier admission and selector exactness from Definition 697.2. These clauses bind the finite packet and make k a displayed value of μ at n.

Next combine finite-window readback with Definition 697.7. Every selected observation passes through W and D before regular tail information is available.

Apply Definition 697.17 and Definition 697.18. Cofinal reads are exhausted by the displayed window rows, and any shared-threshold tail input is consumed through the transported public certificate.

Finally use Definition 697.8 and Definition 697.19. They place the $\mathsf{CauchyLimitSeal}^{\uparrow}/\mathsf{Real}^{\uparrow}$ consumer behind the same finite route and remove all channels for quotient streams, countable choice, host selected limits, ambient completeness, host real equality, and hidden completed values. □

Theorem 697.17 (Diagonal tail selector cofinal-window exhaustion)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. Every cofinal-tail read made by a Real-completion consumer is exhausted by the displayed modulus row* μ*, selected index* k*, finite StreamName window* W*, dyadic readback* D*, regularity row* T*, and structural rows* H, C, P, N*. No such read can be replaced by an unbounded tail search, quotient of regular streams, host limit selection, countable-choice schedule, or ambient completeness argument.*

Proof. Project the accepted carrier. The only rows that carry cofinal-tail data are μ, k, W, D, T together with the structural rows H, C, P, N.

The selector obligation fixes k through n and μ. The finite-window readback obligation then confines every observation to W and D, while the tail-regularity obligation confines the regular-Cauchy comparison to T.

Since the remaining rows only transport, replay, package, and locally name those displayed coordinates, the packet has no source for unbounded search, quotient streams, selected host limits, countable choice, or ambient completeness. □

Theorem 697.18 (Diagonal tail selector tail-meet compatibility)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. Suppose the selected cofinal tail row* T *is supplied by an accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold packet whose source rows, finite windows, dyadic threshold, and comparison row are transported into the diagonal selector route through the same* BHist*, componentwise* hsame *rows, displayed* Cont *route,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows recorded by* H, C, P, N*.*

Then every $\mathsf{DiagonalTailSelector}^{\uparrow}$ *limit handoff factors through the public shared-threshold certificate of Definition 560.11 before any* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal row is read from* S*. The seal-facing consumer receives only the finite route*

$$R, n, \mu, k, W, D, T, H, C, P, N$$

with T *identified as the transported shared-threshold packet, and receives no quotient stream, selected host limit, countable-choice row, host real equality, hidden tail oracle, or ambient completeness coordinate.*

Proof. Project the accepted carrier G. The route displayed by Definition 697.1 exposes exactly the input row, precision request, modulus, selected index, finite window, dyadic readback, selected tail row, seal row, transports, continuations, provenance, and local name.

Apply Definition 697.6. It presents the diagonal-limit consumer as the finite selector route through $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ on the displayed packet.

Use Definition 697.17. Every cofinal read before the seal is confined to $\mu, k, W, D, T, H, C, P, N$, so the selected tail row cannot be replaced by an unbounded search, quotient stream, host-selected limit, choice schedule, or completeness argument.

Now read the supplied tail-meet packet. By Definition 560.11, its transported source rows, finite windows, dyadic threshold, comparison row, transports, continuations, provenance, and local naming row form the public shared-threshold certificate. Since the hypothesis routes that certificate through the same H, C, P, N rows, the selector row T is consumed as that displayed shared-threshold packet.

Finally apply Definition 697.19. Downstream $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers can reach S only after the finite selector route and the transported shared-threshold row have been displayed, so no quotient stream, selected host limit, countable-choice row, host real equality, hidden tail oracle, or ambient completeness coordinate is exported. □

Theorem 697.19 (Diagonal tail selector seal non-escape)**.** *For an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet, the* $\mathsf{Real}^{\uparrow}$ *seal row* S *is reachable only through* $R, n, \mu, k, W, D, T, H, C, P, N$*. In particular, any* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of* S *receives the finite selector route, finite window, dyadic readback, regular tail handoff, transports, continuations, provenance, and local naming row, and receives no quotient stream, hidden completed value, selected host limit, countable-choice selector, host real equality, or ambient completeness coordinate.*

Proof. Use the NameCert obligations first. They place S downstream of the selected index, finite window, dyadic readback, and tail-regularity row.

Apply the limit handoff theorem. It identifies the completion-facing route as the composition through $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows already displayed by the carrier.

The cofinal-window exhaustion theorem removes the only possible alternate tail-read channel. What remains is the finite packet $R, n, \mu, k, W, D, T, S, H, C, P, N$, whose structural rows cannot create quotient streams, hidden completed values, selected host limits, countable choice, host real equality, or ambient completeness. □

Theorem 697.20 (Diagonal tail selector obligation closure package)**.** *The carrier, NameCert obligations, limit handoff, cofinal-window exhaustion, and seal non-escape form the* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *obligation package for the finite route*

$$R, n, \mu, k, W, D, T, S, H, C, P, N.$$

The package routes through $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *without exporting quotient streams, host-selected limits, countable choice, host equality, or ambient completeness.*

Proof. Begin with the carrier and NameCert obligations. They expose the finite route $R, n, \mu, k, W, D, T, S, H, C, P$, force k to be read from μ at n, and place the selected observation through W, D, T before the seal row S is available.

Next apply the limit handoff theorem. It identifies the downstream route through $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ on the same displayed packet.

Use cofinal-window exhaustion to rule out alternate tail reads. The seal non-escape theorem then confines every $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumer to the displayed selector, finite-window, dyadic-readback, tail-regularity, transport, continuation, provenance, and local naming rows.

Thus the listed rows form one obligation package and have no channel for quotient streams, selected host limits, countable choice, host equality, or ambient completeness. □

Theorem 697.21 (Diagonal tail selector source-schedule readback)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

each Real-completion source read accepted by the diagonal tail selector reads the $\mathsf{RegSeqRat}^{\uparrow}$ *source row R, precision request n, displayed modulus μ, and selected cofinal index k before opening the finite window row W, dyadic readback row D, tail handoff row T, or seal row S. The read of k is the one determined by μ at n, and the downstream packet cannot replace it by a second selector, quotient stream, host-selected limit, countable-choice row, host real equality, hidden tail oracle, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier source schedule readback`

Proof. Project the accepted carrier in Definition 697.1. The visible source-schedule coordinates are exactly R, n, μ, k, W, D, T, S together with the structural rows H, C, P, N.

Apply Definition 697.3. It fixes the selector row by reading k from μ at n before any downstream window, dyadic, tail, or seal row is available.

Use Definition 697.20. Since the obligation package has no coordinate for a second selector, quotient stream, selected host limit, countable choice, host equality, hidden tail oracle, or ambient completeness, every accepted source read uses the displayed R, n, μ, k prefix. □

Theorem 697.22 (Diagonal tail selector window dyadic tail compatibility)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

the rows W, D, T *form one compatible finite* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegularCauchyTailSelector}^{\uparrow}$ *route before any* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *seal read from* S*. The route is ordered by the window threshold selected from* R, n, μ, k*, admits only the finite window observation named by* W *and* D*, and consumes* T *as the transported regular-Cauchy tail row tied to the same source packet.*

Proof. Start with Definition 697.4. It places the selected cofinal index before the window threshold and prevents the tail or seal clauses from being consumed before the finite window is exposed.

Apply Definition 697.7. The accepted observation is therefore read through the displayed $\mathsf{StreamName}^{\uparrow}$ window W and $\mathsf{DyadicRatCore}^{\uparrow}$ readback row D tied to R, n, μ, k.

Now use Definition 697.18. The tail row T is consumed as the transported $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ route over the same source, window, dyadic readback, transport, continuation, provenance, and local naming rows.

The seal-facing consumer sees only this compatible W, D, T route before S. It receives no alternate quotient stream, host-selected limit, countable-choice schedule, host real equality, hidden tail oracle, or ambient completeness coordinate. □

Theorem 697.23 (Diagonal tail selector Real seal source exhaustion)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

every $\mathsf{Real}^{\uparrow}$ *seal read from* S *factors through the displayed finite route*

$$R, n, \mu, k, W, D, T, S, H, C, P, N.$$

Thus the Real-completion consumer exhausts its source data at the selector row, finite window, dyadic readback, regular-Cauchy tail handoff, seal row, componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row. It excludes quotient streams, selected host limits, countable choice, host real equality, hidden tail oracle, and ambient completeness.*

Proof. Begin with Definition 697.6. It identifies the completion-facing consumer with the finite route through $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{DyadicCofinalTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ on the displayed packet.

Apply Definition 697.8. Every $\mathsf{Real}^{\uparrow}$ seal read from S must first pass through $R, n, \mu, k, W, D, T, H, C, P, N$ and then reach the seal row as part of the same accepted packet.

Finally use Definition 697.19. Since the seal boundary exports only the displayed selector, window, dyadic, tail, transport, continuation, provenance, and local naming rows, no quotient stream, selected host limit, countable-choice row, host real equality, hidden tail oracle, or ambient completeness coordinate can be read by the Real seal. □

Theorem 697.24 (Diagonal tail selector window source scope)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

the finite source scope of the Real-completion diagonal tail route is exactly the BHist *carrier rows* R, n, μ, k, W, D, T, S*, the componentwise* hsame *transport rows in* H*, the displayed* Cont *route in* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}$ *row* N *over* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,*

$\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *Every selected source read must first pass through the finite* $\mathsf{StreamName}^{\uparrow}$ *window* W *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row* D *tied to* R, n, μ, k.

Proof. Project the carrier from Definition 697.1. Its visible coordinates are the finite BHist packet $R, n, \mu, k, W, D, T, S, H, C, P, N$ and no other source row.

Apply Definition 697.7. The selected cofinal index is read from μ at n, then every admitted observation passes through W and D before the tail row T can be consumed.

Use Definition 697.17. It exhausts Real-completion source reads by the displayed finite-window rows and the structural rows H, C, P, N, so the source scope is precisely the named BEDC packet and its sibling window rows. □

Theorem 697.25 (Diagonal tail selector tail-meet consumption scope)**.** *Suppose an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

uses T *as a transported* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold packet. Then the only tail-meet data consumed by the diagonal route are the transported finite source rows,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *threshold readbacks,* $\mathsf{RegSeqRat}^{\uparrow}$ *comparison row, componentwise* hsame *rows, displayed* Cont *route,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows recorded by* H, C, P, N. *The consumption scope exports no quotient stream, host-selected limit, countable-choice row, host real equality, hidden tail oracle, or ambient completeness coordinate.*

Proof. Start from Definition 697.18. It identifies the selected row T with the transported public shared-threshold packet before any $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ seal row is read.

Next apply Definition 697.24. The tail-meet packet is consumed inside the same $R, n, \mu, k, W, D, T, H, C, P, N$ source scope, with the BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows already fixed.

Finally use Definition 697.20. The obligation package has no coordinate for quotient streams, host-selected limits, countable choice, host equality, hidden tail oracles, or ambient completeness, so those objects cannot enter through the tail-meet handoff. □

Theorem 697.26 (Diagonal tail selector finite tail induction)**.** *Every accepted finite tail read of a* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet is obtained by induction over the displayed rows*

$$n, \mu, k, W, D, T, S, H, C, P, N.$$

The base reads the precision and modulus selector row, the successor step extends through the $\mathsf{StreamName}^{\uparrow}$ *window and* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback, and the terminal case seals through* $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *without exporting quotient streams, selected host limits, countable choice, host equality, hidden tail oracles, or ambient completeness.*

Proof. The base case is the selector-row prefix. Apply Definition 697.3 and Definition 697.4: the read starts from n, μ, k, with k determined by μ at n before any downstream window, dyadic row, tail row, or seal row is consumed.

For the successor step, use Definition 697.17. Each finite extension opens only the displayed $\mathsf{StreamName}^{\uparrow}$ window W and $\mathsf{DyadicRatCore}^{\uparrow}$ readback row D, with H, C, P, N preserving the same accepted route.

The terminal case is the completion handoff. By Definition 697.6, the read passes through $\mathsf{RegularCauchyTailSelector}^{\uparrow}$ before the seal row is consumed; by Definition 697.19, the final $\mathsf{Real}^{\uparrow}$ consumer receives only the displayed finite packet and none of the refused host objects. □

Theorem 697.27 (Diagonal tail selector root cofinal admission)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted DiagonalTailSelector$^{\uparrow}$ *packet. Before any selector read is performed, the root admission surface exposes the source regular row R, the precision request n, the displayed modulus μ, the selected threshold index k, the finite stream window W, the dyadic readback row D, the tail-selector handoff T, the Real seal row S, the componentwise* hsame *rows H, the displayed* Cont *routes C, the* Pkg *provenance row P, and the local* NameCert *row N. No selector step may consult a row outside this displayed packet.*

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier root cofinal admission`

Proof. Project the accepted carrier of DiagonalTailSelector$^{\uparrow}$. Its root packet is the tuple G, and the selector coordinate is read only after the visible source, modulus, window, readback, tail, seal, transport, continuation, provenance, and naming rows have been fixed.

Apply Definition 697.7 to the first selector read. The theorem routes the read through μ at n and then through W and D, so no hidden source row is available before the cofinal index is selected. □

Theorem 697.28 (Diagonal tail selector root budget handoff)**.** *For every accepted* DiagonalTailSelector$^{\uparrow}$ *packet G, the selected cofinal row factors through the visible L10 route*

LimitSelector$^{\uparrow}$, RegularCauchyTailSelector$^{\uparrow}$, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$.

The factorization consumes only the rows exposed by Definition 697.27: the cofinal index comes from the displayed selector/modulus budget, the finite window and dyadic readback supply the stream evidence, the regular Cauchy tail row transports the shared threshold, and the Real row receives only the resulting finite seal packet.

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorRootBudgetHandoff`

Proof. Start with the root admission surface of Definition 697.27. The selector row is already tied to $R, n, \mu, k, W, D, T, S, H, C, P, N$, so any downstream budget handoff must reuse these rows.

Next apply Definition 697.6, Definition 697.12, and Definition 697.25. Together they route the cofinal selection through the displayed limit selector, regular tail-selector, stream-name, dyadic readback, regular sequence, and Real seal rows.

It remains to identify the budget boundary. The handoff contains no row besides the root packet and the named L10 consumers, so the selected cofinal row factors through exactly the displayed route. □

Theorem 697.29 (Diagonal tail selector root seal non-escape)**.** *The root budget route of an accepted* DiagonalTailSelector$^{\uparrow}$ *packet exports no quotient stream, countable-choice selector, host-selected limit, host real equality, hidden tail oracle, or ambient completeness row. Its public output is only the finite cofinal-window, dyadic-readback, regular-tail, Real-seal,* hsame, Cont, Pkg, *and* NameCert *surface named by the root packet.*

Proof. Use Definition 697.28 to place every selected cofinal row on the displayed L10 route. Each consumer receives only the rows exposed by the accepted root packet.

Now apply Definition 697.23 and Definition 697.25. These results exhaust the Real seal and tail-meet consumption boundaries and list the objects that cannot be exported through them.

The remaining rows H, C, P, N are structural transport, continuation, provenance, and naming rows. They record the visible finite route rather than adding quotient streams, countable choice, host limits, host equality, hidden tail oracles, or completeness data. □

Theorem 697.30 (Diagonal tail selector cofinal budget replay)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

the same cofinal budget is replayed through

$\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$.

The replay first reads the root admission rows $R, n, \mu, k, W, D, T, S, H, C, P, N$, then consumes the selected cofinal index and finite window through the displayed L10 route, and finally checks compatibility with the tail budget of Definition 697.45. No consumer may replace this replay by a fresh selector, quotient stream, hidden tail row, or ambient completeness witness.

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier cofinal budget replay`

Proof. Begin with Definition 697.27. It projects the accepted packet G and fixes the source regular row, precision request, modulus, threshold, finite window, dyadic readback, tail handoff, Real seal, transport, route, provenance, and naming rows before any selector read is performed.

Apply Definition 697.28. The selected cofinal row is routed through the displayed L10 consumers $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ using only the rows named by the root packet.

Now use Definition 697.45. The public budget source and the tail budget consume the same rows $R, n, \mu, k, W, D, H, C, P, N$ before S is read, so the replay cannot fork into a separate selector or hidden tail source.

Finally invoke Definition 697.29. The root seal has no coordinate for quotient streams, countable choice, host-selected limits, host real equality, hidden tail oracles, or ambient completeness. Hence the replay is exactly the displayed cofinal budget route. □

Theorem 697.31 (Diagonal tail selector public root replay package)**.** *Every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

whose public budget source reads the root cofinal admission row of Definition 697.27, the root budget handoff row of Definition 697.28, and the cofinal budget replay row of Definition 697.30 exports exactly the finite route

$$R, n, \mu, k, W, D, T, S, H, C, P, N$$

through

$\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}$

The package exports no quotient stream, selected host limit, countable-choice schedule, host real equality, ambient completeness principle, or hidden tail oracle.

Proof. Project the root cofinal admission row. It fixes the accepted packet $G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$ as the full carrier inventory available to the public budget source.

Apply the root budget handoff row next. The handoff places the selected cofinal read on the displayed L10 factorization through $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Use the cofinal budget replay row to reuse the same finite budget through that consumer chain. The replay does not allocate a second selector, stream, or host limit row; it only replays the rows already named by the root packet.

Finally combine the public budget export and non-escape rows. They identify the exported object as the finite route above and exclude quotient streams, selected host limits, countable-choice schedules, host real equality, ambient completeness, and hidden tail oracles from the public replay package. □

Theorem 697.32 (Diagonal tail selector budget readback non-escape)**.** *The readback exported by the cofinal budget replay of Definition 697.30 is only the finite root packet*

$$R, n, \mu, k, W, D, T, S, H, C, P, N$$

together with its displayed L10 consumer route. It exports no quotient stream, choice selector, host-selected limit, host real equality, hidden tail oracle, or ambient completeness row.

Proof. Use Definition 697.30 to put the readback on the same cofinal budget route through $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

The root packet contributes exactly the rows listed in Definition 697.27. The budget handoff of Definition 697.28 then consumes those rows without adding any external selector coordinate.

For the tail-facing part, apply Definition 697.45. It identifies the shared finite budget consumed by the schedule and tail-meet routes before the Real seal row is read.

The excluded objects are precisely the objects ruled out by Definition 697.29. Since the readback has no row beyond the accepted packet and its displayed L10 route, none of them can be exported. □

Theorem 697.33 (Diagonal tail selector terminal budget determinacy)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. Any terminal* $\mathsf{Real}^{\uparrow}$ *consumer, and any completion-facing consumer that reads the selected cofinal row, factors through the same displayed root budget route*

$$R, n, \mu, k, W, D, T, S, H, C, P, N$$

and then through

$$\mathsf{LimitSelector}^{\uparrow}, \quad \mathsf{RegularCauchyTailSelector}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

No such consumer may replace the terminal budget by a fresh selector, quotient stream, host-selected limit, hidden tail row, or ambient completeness witness.

Proof. Start with Definition 697.27. It fixes the accepted packet G as the only root surface available before the selected cofinal row is read.

Apply Definition 697.28. The selected cofinal row is handed to the terminal route through the displayed L10 consumer chain, so a Real or completion-facing read has no second budget coordinate.

Replay the route with Definition 697.30. The replay uses the same root rows and the same named consumers, and Definition 697.45 identifies the tail-facing threshold with that displayed budget.

Finally apply Definition 697.32. Since the terminal readback exports only $R, n, \mu, k, W, D, T, S, H, C, P, N$ and its displayed L10 route, it cannot substitute a fresh selector, quotient stream, host-selected limit, hidden tail row, or ambient completeness witness. □

Theorem 697.34 (Diagonal tail selector root formal target surface)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. The Lean-facing formal target surface for* $\mathsf{Real}^{\uparrow}$ *and completion-facing consumers is exactly the finite packet*

$$R, n, \mu, k, W, D, T, S, H, C, P, N$$

together with the displayed route through

$\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}$

It contains no quotient stream, countable choice operator, host-selected limit, host real equality, hidden tail oracle, or ambient completeness principle.

Proof. Begin with Definition 697.27. It fixes the accepted root surface to the coordinates of G and the named cofinal route, so every downstream consumer starts from the same finite packet.

Use Definition 697.28 to hand those coordinates to the consumer route. Then apply Definition 697.30 to replay the same budget through $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

The public packaging is supplied by Definition 697.31. The readback boundary of Definition 697.32 then rules out quotient streams, countable choice, host-selected limits, host real equality, hidden tail oracles, and ambient completeness as exported coordinates.

Finally, Definition 697.33 identifies every terminal Real or completion-facing read with that same route. Carrier-coordinate exhaustion leaves exactly the listed packet and route, with no remaining coordinate from which an excluded object could be read. □

Theorem 697.35 (Diagonal tail selector root budget route totality)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. Any root consumer that uses the admission row, the root budget handoff row, the cofinal budget replay row, and the terminal formal-target row consumes exactly the packet* G *and the displayed L10 route through*

$\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}$

No additional root route, tail-selector coordinate, quotient stream, host limit selector, or ambient completeness witness is part of that consumer surface.

Proof. Apply Definition 697.27. It fixes the admitted root inventory to the coordinates $R, n, \mu, k, W, D, T, S, H, C, P$ and to the named cofinal consumer chain.

Next apply Definition 697.28. The handoff row sends exactly that admitted inventory into the root budget route, so a root consumer has no separate budget coordinate before replay.

Replay the budget by Definition 697.30. The replay row keeps the same root coordinates and the same L10 route through $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Finally use Definition 697.34. Its formal-target inventory is exactly the displayed packet and route, and its negative clauses rule out any extra route or hidden selected-limit coordinate. □

Theorem 697.36 (Diagonal tail selector root budget transport)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. Componentwise displayed* hsame *transports of the admission, handoff, replay, and terminal formal-target rows, together with matching* Cont *routes for the L10 consumer chain, preserve the same cofinal budget route from* G *through*

$\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}$

Such transports add no quotient stream, hidden selector, host real equality, or second budget ledger.

Proof. Read the transport data from the root admission inventory of Definition 697.27. The only admitted transports are the displayed componentwise hsame rows and the matching Cont routes already recorded in H and C.

Use Definition 697.28 to identify the transported handoff with the same root budget coordinates. Then apply Definition 697.30 to replay the transported route without changing its L10 spine.

The determinacy clauses in Definition 697.33 identify any terminal read of the transported route with the replayed route. By Definition 697.34, the resulting formal-target surface still contains only G and the displayed consumer chain, not a quotient stream, hidden selector, host equality row, or additional ledger. □

Theorem 697.37 (Diagonal tail selector root budget ledger exactness)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. The coordinates* P *and* N *account exactly for the admission, handoff, replay, and terminal formal-target rows of the root budget route. They cannot be read as selected limits, host real equality, ambient completeness, quotient-stream identification, or countable choice.*

Proof. Begin with Definition 697.35. It reduces every root consumer using the displayed rows to the single packet G and the single L10 cofinal budget route.

Apply Definition 697.32. The budget readback permits P and N to certify provenance and local naming for the finite route, but it does not expose selected limits, host real equality, ambient completeness, quotient-stream identification, or countable choice.

Finally use Definition 697.38. Since terminal reads are exhausted by G and the displayed route, the ledger coordinates have no remaining coordinate from which an excluded object or principle could be recovered. □

Theorem 697.38 (Diagonal tail selector terminal cofinal route exhaustion)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. Every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of the cofinal selector route is exhausted by the displayed packet* G *together with the L10 route through*

$\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}$

No quotient stream, countable-choice selector, host-selected limit, host real equality, hidden tail oracle, or ambient completeness row can be recovered from such a terminal consumer.

Proof. First apply Definition 697.27 and Definition 697.28. These identify the accepted root surface with the displayed coordinates of G and send that same finite budget into the terminal route.

Next use Definition 697.30. The replay keeps the cofinal route on the named L10 spine through $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

The public surface is then the one supplied by Definition 697.31. By Definition 697.32, a terminal readback from this surface cannot export a quotient stream, countable-choice selector, host-selected limit, host real equality, hidden tail oracle, or ambient completeness row.

Finally apply Definition 697.33 and Definition 697.34. They identify every terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer with the same packet and route. Carrier-coordinate exhaustion therefore leaves exactly the displayed coordinates and no remaining carrier from which one of the excluded objects could be read. □

Theorem 697.39 (Diagonal tail selector terminal cofinal route uniqueness)**.** *Let*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N)$$

be an accepted $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet. Suppose two terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumers of G both pass through the displayed L10 spine*

$$\mathsf{LimitSelector}^{\uparrow},\quad \mathsf{RegularCauchyTailSelector}^{\uparrow},\quad \mathsf{StreamName}^{\uparrow},\quad \mathsf{DyadicRatCore}^{\uparrow},\quad \mathsf{RegSeqRat}^{\uparrow},\quad \mathsf{CauchyLimitSeal}$$

Then their terminal cofinal route is the same displayed packet-and-spine route, up to the hsame *transports already carried by G. No second selector, quotient stream, hidden tail oracle, host-selected limit, or ambient completeness row can distinguish the two terminal consumers.*

Proof. Apply Definition 697.27 and Definition 697.28. Both terminal consumers are admitted from the same accepted root packet, so their visible coordinates are the coordinates of the displayed G and their transports are the hsame transports already present in that packet.

Next apply Definition 697.30. Since both consumers pass through the named L10 spine, the replay supplies the same finite cofinal budget at each listed selector, stream, dyadic, regular sequence, seal, and real-facing row.

Now use Definition 697.33 and Definition 697.34. These identify the terminal read of each consumer with the same public packet-and-spine route, leaving only the already displayed hsame transports as admissible coordinate changes.

Finally invoke Definition 697.38. The exhaustion theorem removes every non-displayed coordinate, so no second selector, quotient stream, hidden tail oracle, host-selected limit, or ambient completeness row remains available to distinguish the two terminal routes. □

Theorem 697.40 (Diagonal tail selector TailCofinalitySchedule factorization)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

each Real-seal consumer of S factors first through the $\mathsf{TailCofinalitySchedule}^{\uparrow}$ *route from unary precision to finite window, dyadic ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and* $\mathsf{Real}^{\uparrow}$ *seal before using the diagonal selector rows. Thus the consumer reads the precision request and finite-window schedule before it uses $k, W, D, T, S, H, C, P, N$ as the diagonal completion-facing packet.*

Proof. Begin with Definition 681.3. It orders the schedule-facing route from the unary precision row through the finite $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and the $\mathsf{Real}^{\uparrow}$ seal.

Apply Definition 697.6. It identifies the diagonal Real-completion consumer with the finite packet $R, n, \mu, k, W, D, T, S, H, C, P, N$, so the schedule route is consumed before the selector rows are used as a completion-facing package.

Finally use Definition 697.25. The transported tail-meet rows remain inside the same displayed source, window, dyadic, regular-rational, seal, transport, route, provenance, and naming surface. Hence the factorization has no escape channel through quotient streams, selected limits, countable choice, ambient completeness, host real equality, or hidden tail oracles. □

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier tail cofinality factorization`

Theorem 697.41 (Diagonal tail selector Real seal boundary scope)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet*

$$G = (R, n, \mu, k, W, D, T, S, H, C, P, N),$$

the $\mathsf{CauchyLimitSeal}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *boundary reached at S is scoped by the finite source rows of Definition 697.24 and the transported tail-meet rows of Definition 697.25. In particular, the seal-facing boundary is the displayed BEDC route through* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *with S reached only after $R, n, \mu, k, W, D, T, H, C, P, N$ are in scope.*

Proof. Apply Definition 697.8. Every $\mathsf{Real}^{\uparrow}$ seal read from S factors through the finite selector packet and its transport, continuation, provenance, and local naming rows.

Use Definition 697.24 to identify the source side of that packet. The rows R, n, μ, k, W, D supply exactly the finite $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ source window before T and S are available.

Use Definition 697.25 for the regular-tail side. When T is supplied by the shared-threshold route, it is consumed only as the transported $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ certificate inside the same structural rows.

Finally apply Definition 697.19. The $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ boundary therefore has no escape channel outside the displayed BEDC route. □

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier real seal boundary scope`

Theorem 697.42 (Diagonal tail selector downstream non-escape scope)**.** *Every downstream consumer of the* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *Real-completion route is scoped by the same finite packet*

$$R, n, \mu, k, W, D, T, S, H, C, P, N$$

and the sibling BEDC rows named in Definition 697.24, Definition 697.25, and Definition 697.41. Hence a downstream $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer can use only the displayed* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows, and cannot export quotient streams, host-selected limits, countable choice, host real equality, hidden tail oracles, or ambient completeness.*

Proof. Begin with Definition 697.20. It packages the carrier, NameCert obligations, limit handoff, cofinal-window exhaustion, and seal non-escape over one finite route.

The window source scope then supplies the finite source boundary. Apply Definition 697.24 to keep all selected reads inside R, n, μ, k, W, D and the structural rows H, C, P, N.

The tail-meet consumption scope supplies the regular-tail boundary. Apply Definition 697.25 to consume T only as the transported shared-threshold certificate when that sibling route is present.

The Real seal boundary scope supplies the completion-facing boundary. Apply Definition 697.41 and then Definition 697.19; downstream consumers are confined to the displayed BEDC route and receive none of the excluded escape coordinates. □

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorPublicBudgetSource downstream nonescape scope`

Definition 697.43 (Diagonal tail selector public budget source)**.** *The public budget source for an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet is the finite carrier*

$$(R, n, \mu, k, W, D, T, S, H, C, P, N)$$

together with the displayed sibling rows $\mathsf{TailCofinalitySchedule}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *Its exported source consists exactly of the precision request, modulus row, selected cofinal index, finite window, dyadic readback, transported tail-meet certificate, seal row, componentwise* hsame *rows, displayed* Cont *route,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{DiagonalTailSelector}^{\uparrow}}$ *row.*

No quotient stream, selected host limit, countable-choice schedule, host real equality, ambient completeness principle, or hidden tail oracle is a coordinate of this public budget source.

Lean4 (definition) `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorPublicBudgetSource`

Theorem 697.44 (Diagonal tail selector window choice totality)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet, the public budget source of Definition 697.43 makes the selected finite window total as a BEDC row: the precision request n and modulus row μ determine the displayed cofinal index k, and k opens the finite* $\mathsf{StreamName}^{\uparrow}$ *window W and* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback D used by every downstream seal consumer.*

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier window choice totality`

Proof. Project the carrier of Definition 697.1. The rows $R, n, \mu, k, W, D, T, S, H, C, P, N$ are all displayed before a seal consumer can read S.

Apply the window-source scope of Definition 697.24. It binds selected reads to the finite source rows n, μ, k, W, D and the structural rows H, C, P, N.

Finally use the TailCofinalitySchedule factorization of Definition 697.40. The schedule-facing route reads the precision request and finite window before the completion-facing selector packet is consumed, so the window choice is a total displayed row and not a quotient stream, selected host limit, countable-choice schedule, host real equality, or ambient completeness row. □

Theorem 697.45 (Diagonal tail selector tail budget compatibility)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet whose row T is the transported* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold certificate, the public budget source of Definition 697.43 is compatible with the tail budget: the same finite rows $R, n, \mu, k, W, D, H, C, P, N$ feed the TailCofinalitySchedule factorization and the tail-meet consumption route before the Real seal row S is read.*

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorPublicBudgetSource tail budget compatibility`

Proof. Start with Definition 697.40. It places the schedule route from precision request through finite window, dyadic ledger, regular-rational readback, and Real seal ahead of the completion-facing selector read.

Next apply Definition 697.25. The row T is consumed only as the transported shared-threshold packet inside the same source, transport, route, provenance, and naming surface.

Combine the two routes through Definition 697.43. Since the public source has no coordinate for quotient streams, selected host limits, countable-choice schedules, host real equality, ambient completeness, or hidden tail oracles, compatibility is exactly the equality of the displayed budget rows consumed by both routes. □

Theorem 697.46 (Diagonal tail selector Real seal budget non-escape)**.** *Every* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet that reads the public budget source of Definition 697.43 remains inside the displayed rows* $R, n, \mu, k, W, D, T, S, H, C, P, N$ *and the listed sibling* $\mathsf{TailCofinalitySchedule}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows. It cannot export quotient streams, selected host limits, countable-choice schedules, host real equality, ambient completeness, or hidden tail oracles.*

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier real seal budget nonescape`
Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorPublicBudgetSource real seal budget nonescape`

Proof. Use the Real seal boundary scope of Definition 697.41. It places the $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ boundary at S only after the finite source rows and transported tail-meet rows are already in scope.

Apply Definition 697.19. The seal-facing boundary has no escape channel outside the displayed BEDC route.

Finally apply the downstream non-escape scope of Definition 697.42. Every downstream completion consumer therefore receives only the public budget source rows and listed sibling BEDC rows, with no quotient stream, selected host limit, countable-choice schedule, host real equality, ambient completeness, or hidden tail oracle. □

Theorem 697.47 (Diagonal tail selector public budget export)**.** *The public budget source of Definition 697.43 exports exactly the finite route through the* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet and the sibling schedules of chapter 681, chapter 678, and chapter 560 before any* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer reads the seal row* S*. Thus the exported route is precisely*

$$R, n, \mu, k, W, D, T, S, H, C, P, N$$

together with the displayed precision, modulus, cofinal-window, dyadic-readback, regular-rational, tail-meet, seal, continuation, provenance, and local naming rows. It exports no quotient stream, host-selected limit, countable choice schedule, host real equality, ambient completeness, or hidden tail oracle.

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier public budget export`

Proof. First apply Definition 697.40. The Real-completion consumer reaches the seal-facing selector only after the precision request, finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and $\mathsf{Real}^{\uparrow}$ seal route have been ordered by the TailCofinalitySchedule schedule named in chapter 681.

Next use Definition 697.45. The same finite rows $R, n, \mu, k, W, D, H, C, P, N$ feed the selector budget and the transported tail-meet route, so the budget surface is the one shared with chapter 678 and chapter 560, with T consumed only as the displayed shared-threshold certificate.

Finally apply Definition 697.46. The $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ readers of S stay inside the public budget source and the listed sibling rows. Consequently the export contains exactly the displayed finite route and none of the excluded quotient, choice, host-equality, completeness, or hidden-oracle data. □

Theorem 697.48 (Diagonal tail selector public budget threshold order)**.** *For every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *public budget source of Definition 697.43, any downstream* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer reads the source rows*

$$n, \mu, k, W, D$$

before the transported tail row T, before the seal row S, and before the finite observation-budget selector route of chapter 782 is consumed. Thus the public budget surface inherits the checked window-threshold order of the carrier before it exports a seal-facing or finite-observation route.

Proof. Start with the carrier-level window-threshold order of Definition 697.4. It places the precision row n, modulus row μ, selected cofinal index k, finite window row W, and dyadic readback row D before any read of the tail-regularity row T or the seal row S.

Next apply the public budget export of Definition 697.47. The exported source is exactly the finite route

$$R, n, \mu, k, W, D, T, S, H, C, P, N.$$

Since the export preserves the displayed carrier order, the public consumer cannot read T or S before n, μ, k, W, D.

Finally use the non-escape boundary of Definition 697.46. Every $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{Real}^{\uparrow}$ consumer remains inside the same public budget source, and the finite observation-budget selector handoff must be a read of that already ordered source rather than a route that bypasses the window-threshold rows. □

Theorem 697.49 (Diagonal tail selector finite observation-budget handoff)**.** *Every accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *public budget source of Definition 697.43 whose displayed rows are read as a finite observation-budget selector factors through the* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *route of chapter 782 before any* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer reads the seal row. Equivalently, the consumer first reads the finite route*

$$B \to S_F \to W_F \to D_F \to R_F \to E_F$$

given by Definition 782.14 and Definition 782.10, and only then consumes the $\mathsf{DiagonalTailSelector}^{\uparrow}$ *public export of Definition 697.47. The handoff exports no quotient stream, host-selected limit, countable-choice schedule, host real equality, ambient completeness, or hidden tail oracle, by Definition 697.46.*

Proof. First identify the displayed $\mathsf{DiagonalTailSelector}^{\uparrow}$ rows. By Definition 697.47, an accepted public budget source exports exactly the finite selector packet $R, n, \mu, k, W, D, T, S, H, C, P, N$ and the listed sibling schedule, tail-meet, seal, stream, dyadic, regular-rational, and Real rows before a seal consumer reads S.

Next read those rows through the finite observation-budget selector. Apply Definition 782.14 to identify the public route $B \to S_F \to W_F \to D_F \to R_F \to E_F$, and then use Definition 782.10

to make every diagonal-limit or Real-completion consumer read that route before the seal row is consumed.

Finally use the DiagonalTailSelector non-escape boundary. By Definition 697.46, the $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ consumers remain inside the displayed public budget source. Thus the handoff cannot pass through quotient streams, host-selected limits, countable choice, host real equality, ambient completeness, or hidden tail oracles. □

Theorem 697.50 (Diagonal tail selector public budget route totality)**.** *Any downstream* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *consumer of the* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *public budget source must read the finite observation-budget route first, then the selector public budget export, and then the Real seal boundary. The route is entirely through* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows; it has no quotient stream, host-selected limit, countable-choice schedule, host real equality, ambient completeness, or hidden tail oracle.*

Proof. Begin with the finite observation-budget handoff of Definition 697.49. It forces every seal-facing consumer to read the finite selector route before the $\mathsf{DiagonalTailSelector}^{\uparrow}$ seal row is consumed.

Next apply the public budget export of Definition 697.47. This identifies the selector source as the displayed BHist, hsame, Cont, Pkg, NameCert, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surface.

Finally use Definition 697.46. The Real and Cauchy-limit readers stay inside that displayed route, so the consumer-facing path is total for the public budget handoff and excludes the listed quotient, choice, host-equality, completeness, and hidden-oracle data. □

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier public budget route totality`

Theorem 697.51 (DiagonalTailSelector schedule-seal consumer exactness)**.** *For an accepted* $\mathsf{DiagonalTailSelector}^{\uparrow}$ *packet, the completion-facing consumer route from the displayed schedule rows to the final seal is exact exactly when it factors through the finite rows* $R, n, \mu, k, W, D, T, S, H, C, P, N$ *and the sibling schedule rows supplied by* $\mathsf{TailCofinalitySchedule}^{\uparrow}$*,* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. No quotient stream, host-selected limit, countable-choice schedule, host real equality, ambient completeness, or hidden tail oracle can be substituted for any segment of that route.*

Lean4 ✓ `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorScheduleSealConsumerExactness`

Proof. For the forward direction, begin with the tail-cofinality factorization of Definition 697.40. It places the consumer route on the displayed $\mathsf{TailCofinalitySchedule}^{\uparrow}$ rows before any seal-facing read is allowed.

Next apply tail-budget compatibility from Definition 697.45. The scheduled tail rows, finite windows, dyadic ledger, transport rows, continuation routes, package provenance, and local name are the same rows that the selector public budget exposes.

Then use real-seal budget non-escape from Definition 697.46 and the public budget export of Definition 697.47. Together they identify the only completion-facing export as the displayed $R, n, \mu, k, W, D, T, S, H, C, P, N$ route with its $\mathsf{TailCofinalitySchedule}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ sibling rows.

For the reverse direction, apply the public budget route totality theorem Definition 697.50. A consumer that factors through exactly those finite rows already reads the finite observation-budget route, the selector public budget export, and the Real seal boundary in the required order.

The same non-escape boundary rules out every alternate carrier named in the statement. Hence no quotient stream, host-selected limit, countable-choice schedule, host real equality, ambient completeness, or hidden tail oracle can replace a segment while preserving exactness of the schedule-to-seal consumer route. □

Closure status for $\mathsf{NameCert}_{\mathsf{DiagonalTailSelector}\uparrow}$.

Constructive story: A $\mathsf{DiagonalTailSelector}^{\uparrow}$ packet is generated from a RegSeqRat input row, unary precision request, displayed modulus, selected cofinal tail index, finite StreamName window, DyadicRatCore readback, RegularCauchyTailSelector handoff, RealUp seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DiagonalTailSelector}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 697.1, Definition 697.2, finite-window readback, tail-meet consumption, Real seal boundary, downstream non-escape, and Definition 697.43 export the finite-window, tail-meet, Real seal, and non-escape package.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DiagonalTailSelector}\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.DiagonalTailSelectorUp.DiagonalTailSelectorCarrier\_source\_schedule\_readback`

Bridge status: none

Origin: human

Not claimed: This chapter does not close RealUp completeness, quotient stream equality, host real equality, countable choice, host-selected limits, ambient completeness, or a public standard bridge.

Upgrade path: No further paper-side theory closure upgrade remains for the finite-window, tail-meet, Real-seal, and downstream non-escape package.

Chapter 698

A Concrete Naming Certificate for $\mathsf{CofinalTailBudget}^{\uparrow}$

The $\mathsf{CofinalTailBudget}^{\uparrow}$ packet records the finite shared-tail threshold used when a Real and Completion diagonal-limit argument must move from a cofinal family of tail windows to the displayed $\mathsf{Real}^{\uparrow}$ seal. It does not choose an infinite subsequence or identify a real number by quotienting. It names the finite budget row, the selected tail-window rows, the RegSeqRat handoff, and the RealUp seal route that later consumers may replay. It consumes the cofinal-subsequence window handoff surface of chapter 405 but restricts it to the finite shared-tail budget rows M, T, R, S, H, C, P, N.

Definition 698.1 (Cofinal tail budget carrier)**.** *A* $\mathsf{CofinalTailBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (M, T, R, S, H, C, P, N)$$

with the following displayed rows:

1. *M is the finite modulus-budget row naming the requested precision level and the bound from which tail windows are read;*
2. *T is the cofinal tail-window row, listing the finitely many windows whose anchors are at or beyond the bound recorded by M;*
3. *R is the* $\mathsf{RegSeqRat}$ *handoff row that reads each selected tail window as a regular rational observation;*
4. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row consumed by the diagonal-limit handoff;*
5. *H records componentwise* hsame *transport for M, T, R, S, P, N and the local packet shape;*
6. *C records the* Cont *routes by which a consumer reads the budget, selected windows, RegSeqRat handoff, RealUp seal, package provenance, and local naming row;*
7. *P is the* Pkg *provenance over* BHist*, finite modulus budgets, cofinal tail windows,* $\mathsf{RegSeqRat}$ *handoff rows,* $\mathsf{Real}^{\uparrow}$ *seal rows,* hsame*,* Cont*, and non-escape ledgers;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{CofinalTailBudget}^{\uparrow}}$ *row.*

The carrier contains no global completeness theorem, no choice of an infinite tail selector, and no quotient-level real equality. It exports only the finite shared-tail threshold packet displayed by M, T, R, S, H, C, P, N.

Theorem 698.2 (Cofinal tail budget NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CofinalTailBudget}^{\uparrow}}$ *surface for Definition 698.1 consists of five finite obligation rows:*

1. *carrier admission for the packet* $B = (M, T, R, S, H, C, P, N)$*;*
2. *budget stability stating that componentwise* hsame *transport preserving* M, T, R, S, C, P, N *preserves the same shared-tail threshold;*
3. *window exactness stating that every selected tail window in* T *is read at or beyond the budget bound recorded by* M*;*
4. *seal handoff stating that the* RegSeqRat *row* R *is the only route by which the selected windows feed the* $\mathsf{Real}^{\uparrow}$ *seal row* S*;*
5. *ledger exactness stating that every public read factors through* M, T, R, S, H, C, P, N *and no unrecorded cofinal selector or completeness principle is exported.*

Lean4 ✓ `BEDC.Derived.CofinalTailBudgetUp.CofinalTailBudgetCarrier namecert obligations`

Proof. Carrier admission is projection from the displayed packet. The tuple lists the modulus budget, selected tail windows, RegSeqRat handoff, RealUp seal, transports, routes, provenance, and local naming row.

Budget stability is read through H and C. Since the budget and window rows are transported together, the shared-tail threshold named by M remains attached to the same selected windows in T.

Window exactness is the displayed role of T. Each public window read passes through C, and the package provenance P records that the anchor lies at or beyond the finite bound supplied by M.

The seal handoff and ledger exactness are the remaining package clauses. A consumer reaches S only through the RegSeqRat handoff row R, and every exported read remains a projection of M, T, R, S, H, C, P, N. □

Theorem 698.3 (Cofinal tail budget window coverage)**.** *For an accepted* $\mathsf{CofinalTailBudget}^{\uparrow}$ *packet* $B = (M, T, R, S, H, C, P, N)$*, every public tail-window read covered by the packet is one of the finite windows listed in* T*, and each such read carries the shared-tail threshold recorded by* M*. A proposed window whose anchor is below the budget bound is not covered by this packet.*

Proof. Project the carrier to obtain the budget row M and the finite window row T. These two rows are paired in the same packet, so a covered read cannot detach the selected window from the displayed threshold.

Read the requested window through the continuation row C. If the request names a listed window, the route returns the corresponding T coordinate together with the budget row M and the RegSeqRat handoff R.

If the proposed anchor lies below the bound named by M, no coordinate of T records it as covered. The package provenance P therefore keeps the request outside the packet's coverage surface. □

Lean4 ✓ `BEDC.Derived.CofinalTailBudgetUp.CofinalTailBudgetCarrier window read transport`

Theorem 698.4 (Cofinal tail budget Real seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read exported by an accepted* $\mathsf{CofinalTailBudget}^{\uparrow}$ *packet factors through the selected tail windows* T *and the* RegSeqRat *handoff row* R*. The seal row* S *is therefore consumed as a finite diagonal-limit handoff from the displayed shared-tail threshold, not as an independent completeness claim.*

Proof. Start from the carrier inventory. The only route to the RealUp seal coordinate is the continuation row C reading the displayed seal row S in the same packet as M, T, R, H, P, N.

The RegSeqRat handoff is the intermediate row. A seal consumer first reads the selected windows in T, then reads those windows through R, and only then reaches S.

Thus the exported seal is bound to the finite threshold and finite window ledger. Since the packet contains no global completeness theorem or quotient-level equality, the seal read is exactly the displayed handoff route. □

Theorem 698.5 (Cofinal tail budget non-escape)**.** *An attempted Real and Completion tail read that omits the budget row M, a listed window from T, or the* RegSeqRat *handoff row R is outside the* $\mathsf{CofinalTailBudget}^{\uparrow}$ *packet. It cannot export the* $\mathsf{Real}^{\uparrow}$ *seal row S and cannot be repacked as a cofinal shared-tail certificate.*

Proof. Read the attempted route through the finite carrier. The packet exposes only M, T, R, S, H, C, P, N, so any route omitting the budget, selected-window, or handoff coordinate lacks a required source row.

Apply the window coverage row for omissions of M or T. The request then has no covered tail-window coordinate at or beyond the shared threshold.

Apply the seal handoff row for omissions of R. A consumer cannot reach S before the selected windows have been read as RegSeqRat handoff data.

The package provenance P records the remaining attempt as outside the local naming surface. Hence the route cannot export S or appear as a cofinal shared-tail certificate. □

Theorem 698.6 (Cofinal tail budget stability)**.** *Let $B = (M, T, R, S, H, C, P, N)$ be an accepted* $\mathsf{CofinalTailBudget}^{\uparrow}$ *packet. Componentwise* hsame *transport recorded by H, and read through the displayed continuation routes C, preserves the same finite budget packet M, T, R, S, P, N. In particular, the shared-tail threshold named by M, the selected windows in T, the* RegSeqRat *handoff R, the* $\mathsf{Real}^{\uparrow}$ *seal row S, the package provenance P, and the local naming row N remain attached to one another after transport.*

Proof. Project the carrier to the transport row H. Its role in the packet is componentwise: it relates the displayed budget, window, handoff, seal, provenance, and naming coordinates without adding a second budget source.

Read the transported data through C. Each public route still lands in the same coordinates M, T, R, S, P, N, so the threshold in M cannot detach from the finite window list T or from the handoff and seal rows R, S.

The package row P records this as provenance for the same local packet, and N names that packet. Hence hsame transport preserves the displayed shared-tail budget packet rather than producing a new tail selector or a quotient witness. □

Theorem 698.7 (Cofinal tail budget ledger exactness)**.** *For an accepted* $\mathsf{CofinalTailBudget}^{\uparrow}$ *packet $B = (M, T, R, S, H, C, P, N)$, every public read factors through the rows M, T, R, S, H, C, P, N. The exported ledger therefore excludes hidden cofinal selectors, quotient equality witnesses, ambient completeness rows, and any public read not routed through the displayed finite budget packet.*

Proof. Start with a public read of the packet. The carrier definition exposes only the eight displayed rows, and the continuation row C gives the public routes by which those rows are read.

If the read asks for budget, selected-window, handoff, seal, transport, provenance, or naming data, it is a projection through the corresponding coordinate. These projections are exactly the ledger entries named by M, T, R, S, H, C, P, N.

If the read asks for a hidden cofinal selector, a quotient equality witness, or an ambient completeness row, no displayed coordinate supplies it. The ledger therefore rejects that request as outside the local $\mathsf{CofinalTailBudget}^{\uparrow}$ surface. □

Theorem 698.8 (Cofinal tail budget obligation closure)**.** *The accepted* $\mathsf{CofinalTailBudget}^{\uparrow}$ *packet closes its local obligation surface: carrier admission, budget stability, window coverage,* $\mathsf{Real}^{\uparrow}$ *seal handoff, ledger exactness, and non-escape are all witnessed by the same finite packet* $B = (M, T, R, S, H, C, P, N)$*.*

Proof. Carrier admission is the tuple displayed in Definition 698.1, and the NameCert surface of Definition 698.2 lists the five obligation rows that must be read from it.

Budget stability is supplied by Definition 698.6. Window coverage is supplied by Definition 698.3, and the $\mathsf{Real}^{\uparrow}$ handoff is supplied by Definition 698.4.

Ledger exactness is supplied by Definition 698.7. Non-escape is supplied by Definition 698.5. These clauses all mention the same rows M, T, R, S, H, C, P, N, so the obligation surface is assembled without adding a hidden selector, quotient equality, or ambient completeness principle. □

Theorem 698.9 (Cofinal tail budget primitive-scope binding)**.** *For every accepted* $\mathsf{CofinalTailBudget}^{\uparrow}$ *packet* $B = (M, T, R, S, H, C, P, N)$*, the budget row, selected tail windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row are bound entirely through the displayed BEDC primitives* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*, together with the cited cofinal-subsequence sibling surface of chapter 405. The binding exports no hidden cofinal selector, quotient equality witness, ambient completeness row, or nonlocal naming route.*

Lean4 ✓ `BEDC.Derived.CofinalTailBudgetUp.CofinalTailBudgetUp StdBridge`

Proof. Start with the carrier definition. The packet exposes only the displayed rows M, T, R, S, H, C, P, N, and Definition 698.2 assigns the local naming obligations to those rows.

The budget and window clauses are fixed by Definition 698.6 and Definition 698.3. They keep the finite budget row, selected tail windows, and componentwise transports inside the same BHist packet.

The Real-facing route is fixed by Definition 698.4. It sends selected windows through the $\mathsf{RegSeqRat}^{\uparrow}$ handoff before the $\mathsf{Real}^{\uparrow}$ seal is read, so the seal cannot detach from the displayed tail-budget packet.

Ledger exactness and non-escape are supplied by Definition 698.7 and Definition 698.5. Together with the existing TasteGate marker, these clauses say that every accepted read remains a projection of the same carrier surface and every nonlisted selector, quotient witness, completeness row, or nonlocal naming route is outside the chapter scope. □

Closure status for $\mathsf{NameCert}_{\mathsf{CofinalTailBudget}^{\uparrow}}$**.**

Constructive story: A $\mathsf{CofinalTailBudget}^{\uparrow}$ packet is generated from a finite modulus-budget row, cofinal tail-window row, RegSeqRat handoff row, RealUp seal row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CofinalTailBudget}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: The mature paper scope is the finite shared-tail budget packet of Definition 698.1 together with its downstream $\mathsf{Real}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ completion-facing consumers in Definition 698.4, Definition 698.7, Definition 698.5, Definition 698.8, and Definition 698.9.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CofinalTailBudget}^{\uparrow}}, \mathsf{bridgeChecked})$

Lean4 ✓ `BEDC.Derived.CofinalTailBudgetUp.taste gate`

Lean target: `BEDC.Derived.CofinalTailBudgetUp.CofinalTailBudgetTasteGate\_single\_carrier\_alignment`

Bridge status: bridgeChecked

Origin: ai

Not claimed: This chapter does not close Lean implementation, bridge checking, Real completeness, infinite tail selection, quotient-level real equality, or a public RealUp object surface.

Upgrade path: No further verification-axis strengthening is recorded because the chapter already sits at the top bridge-checked formal grade.

Chapter 699

A Concrete Naming Certificate for $\mathsf{RealTailAgreementSeal}^{\uparrow}$

The $\mathsf{RealTailAgreementSeal}^{\uparrow}$ packet binds the paired tail-agreement route used by Real and Completion diagonal-limit consumers. It receives two regular rational source rows, the finite StreamName tail windows selected for both sides, the DyadicRatCore readback rows that compare those windows, the displayed agreement row, and the RealUp handoff row as one local NameCert surface. The packet therefore certifies a finite paired tail-window agreement route, not a quotient equality of streams, selected real values, host metric convergence, open-cover compactness, or choice-selected tails.

The agreement row is consumed as the paired-tail counterpart of the finite cofinal-tail route in chapter 658, with the shared-threshold discipline supplied by chapter 560.

Definition 699.1 (Real tail-agreement seal carrier)**.** *A* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (R, S, W, D, A, H, C, P, N)$$

with the following displayed rows:

1. *R and S are the paired* $\mathsf{RegSeqRat}$ *source rows whose tails are being compared;*
2. *W is the finite paired* $\mathsf{StreamName}^{\uparrow}$ *tail-window row, naming the left and right windows read at the shared tail threshold;*
3. *D is the paired* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row obtained from the two windows in W;*
4. *A is the displayed tail-agreement row, recording that the two dyadic readbacks lie inside the requested finite tolerance on the named windows;*
5. *H records componentwise* hsame *transport for R, S, W, D, A, C, P, N and for the local packet shape;*
6. *C records the* Cont *routes by which a consumer reads the paired sources, finite windows, dyadic readbacks, agreement row, package provenance, and local naming row;*
7. *P is the* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *finite tolerance rows, and non-escape ledgers;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{RealTailAgreementSeal}^{\uparrow}}$ *row.*

The carrier exports only the finite packet $R, S, W, D, A, H, C, P, N$ and the RealUp-facing handoff read through it.

Lean4 (definition) `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealCarrier`

Theorem 699.2 (Real tail-agreement seal NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{RealTailAgreementSeal}^{\uparrow}}$ *surface for Definition 699.1 consists of five finite obligation rows:*

1. *carrier admission for the packet* $Q = (R, S, W, D, A, H, C, P, N)$ *over paired* $\mathsf{RegSeqRat}$ *sources, finite* $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic readback, agreement, transport, continuation, provenance, and local naming rows;*
2. *tail-window coverage stating that every public agreement read uses the paired windows listed in* W *at the shared finite threshold;*
3. *dyadic readback exactness stating that the agreement row* A *is computed only from the paired* $\mathsf{DyadicRatCore}^{\uparrow}$ *readbacks recorded in* D*;*
4. *RealUp handoff stating that a downstream Real or Completion consumer reaches the seal only through* $R, S, W, D, A, H, C, P, N$*;*
5. *non-escape stating that the packet exports no quotient stream equality, selected real value, host metric convergence, open-cover compactness, choice-selected tail, or hidden equality oracle.*

Proof. Carrier admission is projection from the displayed packet. The two regular rational sources, the finite paired windows, the dyadic readbacks, the agreement row, and the structural rows are all coordinates of Q.

Tail-window coverage is read from W through the continuation row C. A public agreement read must first select one of the paired finite windows already listed in the packet, so it cannot call an unrecorded tail search.

Dyadic readback exactness is the role of D and A. The agreement row is downstream of the paired dyadic readbacks, and the componentwise hsame transport in H preserves the same source-window-readback pairing.

The RealUp handoff and non-escape rows are then package clauses. The provenance P and local naming row N expose only $R, S, W, D, A, H, C, P, N$, so any downstream Real or Completion consumer receives the finite tail-agreement route and no external analytic object. □

Theorem 699.3 (Real tail-agreement seal left–right threshold synchrony)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, the two* $\mathsf{RegSeqRat}$ *source rows* R *and* S *read the same finite* $\mathsf{StreamName}^{\uparrow}$ *tail-window threshold through the displayed row* W*. Any public read of the left tail and any public read of the right tail reaches the paired threshold through* W *before* D *or* A *is available, and the route is the shared-threshold surface supplied by chapter 560.*

Proof. Project the carrier of Definition 699.1. The paired source rows R, S and the paired finite tail-window row W are coordinates of one BHist packet, so a public left or right tail read has no carrier coordinate outside the displayed window row.

Apply the carrier-admission and tail-window coverage clauses of Definition 699.2. Carrier admission places R, S, W in the same local $\mathsf{NameCert}_{\mathsf{RealTailAgreementSeal}^{\uparrow}}$ surface, while tail-window coverage says that every public agreement read uses the paired windows listed in W at the shared finite threshold.

Finally use the shared-threshold discipline of chapter 560. The present seal consumes that finite threshold surface before its dyadic readback and agreement rows, so the two $\mathsf{RegSeqRat}$ sources synchronize through W rather than through a hidden tail selector or quotient stream equality. □

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSeal left right threshold synchrony`

Theorem 699.4 (Real tail-agreement seal dyadic-window exactness)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, the rows* D *and* A *are computed only from the paired* $\mathsf{DyadicRatCore}^{\uparrow}$ *readbacks displayed by* D *after the left and right finite windows have been read through* W*. No quotient stream equality, host real equality, selected limit, ambient convergence predicate, or unrecorded dyadic sample can determine the agreement row.*

Proof. Start from the carrier in Definition 699.1. The only dyadic observation coordinate in the packet is D, and the only agreement coordinate downstream of it is A.

Apply the dyadic readback exactness row of Definition 699.2. That row makes A depend on the paired $\mathsf{DyadicRatCore}^{\uparrow}$ readbacks recorded in D, while the tail-window coverage row fixes those readbacks to the windows already named by W.

The sibling finite cofinal-tail route in chapter 658 supplies the comparison pattern: a finite tail read is reused as displayed finite evidence, not as an ambient completed object. Hence D and A are exact readback rows of the local packet and cannot be replaced by quotient equality, host equality, a selected limit, a convergence predicate, or an unrecorded sample. □

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealCarrier dyadic window exactness`

Theorem 699.5 (Real tail-agreement seal Real–Completion handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet reaches the seal through the displayed route*

$$R, S, W, D, A, H, C, P, N.$$

The handoff imports no quotient stream equality, selected limit, host metric convergence, open-cover compactness, or choice-selected tail; it only reuses the paired threshold and finite cofinal-tail surfaces provided by chapter 560 and chapter 658.

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealCarrier real completion handoff`

Proof. Project the packet in Definition 699.1. Its Real-facing boundary is exactly the source, window, readback, agreement, transport, continuation, provenance, and local naming rows $R, S, W, D, A, H, C, P, N$.

Apply the RealUp handoff and non-escape clauses of Definition 699.2. The handoff clause forces every downstream Real or Completion consumer through the displayed rows, and the non-escape clause rules out quotient stream equality, selected real values, host convergence, open-cover compactness, choice-selected tails, and hidden equality oracles.

It remains to identify the sibling surfaces consumed by the route. The regular Cauchy tail-meet chapter supplies the shared threshold used by W, and the regular Cauchy tail-fusion chapter supplies the finite cofinal-tail pattern used when the agreement route is exposed to downstream consumers. Thus the handoff is finite and packet-local all the way through $R, S, W, D, A, H, C, P, N$. □

Theorem 699.6 (Real tail-agreement seal TasteGate obligation route)**.** *The paired source, window, readback, and agreement rows used by Definition 699.2 are the same single-carrier rows certified by the checked TasteGate marker recorded for this chapter. In particular, the TasteGate read does not introduce a second carrier, a second window ledger, or a second agreement classifier beyond*

$$R, S, W, D, A, H, C, P, N.$$

Proof. Project the carrier of Definition 699.1. The rows consumed by the NameCert obligations are exactly the paired source rows R, S, the finite paired window row W, the dyadic readback row D, and the agreement row A with the structural rows H, C, P, N.

Read the checked TasteGate marker already attached to the chapter as a single-carrier alignment for that same packet. Since the marker has only the displayed carrier surface available, its field-faithful read cannot select a second packet or a hidden agreement row.

Apply the NameCert obligation theorem. Its carrier-admission, tail-window coverage, dyadic exactness, RealUp handoff, and non-escape rows are therefore the concrete paper rows that the TasteGate marker preserves, not a parallel list of parameters. □

Theorem 699.7 (Real tail-agreement seal paired-window transport)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, componentwise* hsame *transport preserves the paired* $\mathsf{StreamName}^{\uparrow}$ *windows in* W*, the paired* $\mathsf{DyadicRatCore}^{\uparrow}$ *readbacks in* D*, and the displayed agreement row* A*. A transported consumer still reads the route*

$$W \to D \to A$$

through the same paired sources R, S *and the same structural rows* H, C, P, N*.*

Proof. Project H from the carrier. By definition, this row records componentwise transport for the paired sources, paired windows, dyadic readbacks, agreement row, continuation row, provenance row, local name, and packet shape.

Use tail-window coverage and dyadic readback exactness from Definition 699.2. They force any transported agreement read to encounter the displayed window row before the dyadic readback row and the agreement row.

The continuation, provenance, and local naming rows only replay and name that route. Hence componentwise transport preserves the paired-window, readback, and agreement surface rather than replacing it by a host equality or an unrecorded tail selector. □

Theorem 699.8 (Real tail-agreement seal RealUp consumer threshold factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet first reads the shared-threshold route through chapter 560 and the cofinal-tail route through chapter 658 before reaching the RealUp handoff row of Definition 699.2. The seal exports only the finite route*

$$R, S, W, D, A, H, C, P, N.$$

Proof. Begin with the consumer read. The shared threshold is not an ambient choice of tail; it is the finite threshold surface named by the regular Cauchy tail-meet chapter and then displayed locally as the paired window row W.

Next use the cofinal-tail fusion chapter. It supplies the sibling finite tail route that turns a named cofinal window into a reusable tail-read surface, and the present packet applies that pattern to the two source rows R, S.

Finally apply the RealUp handoff and non-escape clauses of Definition 699.2. The consumer can reach the seal only after the shared threshold, paired windows, dyadic readbacks, and agreement row have been displayed, and it receives no quotient stream equality, selected limit, host convergence, or choice-selected tail. □

Theorem 699.9 (Real tail-agreement seal consumer-window synchronization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet first synchronizes the left and*

right finite $\mathsf{StreamName}^{\uparrow}$ *windows through the finite-window lattice meet, then reads the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared threshold, then uses the* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *cofinal-tail route before the local route*

$$W \to D \to A$$

is exposed. The synchronized packet remains confined to the displayed rows $R, S, W, D, A, H, C, P, N$.

Proof. Start with the RealUp consumer threshold factorization. It puts every Real or Completion consumer behind the shared-threshold route before the local seal handoff can be read.

Apply the window-meet coverage theorem. The left and right finite StreamName windows are first repacked through one finite-window lattice meet, so the paired window row W is not a pair of hidden stream selectors.

Use the budget source lock and paired-window transport. The budget row is read through the displayed budget source, and the componentwise transports preserve the same paired windows, dyadic readbacks, and agreement row.

Finally apply the paired-window source lock. Once the shared threshold and cofinal-tail route have been read through the tail-meet and tail-fusion siblings, the local consumer receives only $W \to D \to A$ inside the finite carrier rows. □

Theorem 699.10 (Real tail-agreement seal budget source lock)**.** *Every paired tail-seal read of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet reads its budget source only through the displayed* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *route of chapter 906 and the* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *route of chapter 903. The local rows* $R, S, W, D, A, H, C, P, N$ *may replay that budgeted service, but they do not contain an independent tail-budget source, uncapped observation request, selected tail, or ambient convergence coordinate.*

Proof. Begin with the threshold factorization of Definition 699.8. It places every Real or Completion consumer on the shared finite threshold before the local paired windows are read.

Next use the budget-window coherence row Definition 699.53. The finite request source for the paired tail windows is the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ budget row, and the observation service behind that row is the limiter route named by chapter 903.

Finally apply paired-window transport from Definition 699.7 and non-escape from Definition 699.40. Transport may replay the displayed budgeted route through H, C, P, N, but the packet has no coordinate for a second budget source, uncapped request, choice-selected tail, or host convergence proof. □

Theorem 699.11 (Real tail-agreement seal window-meet coverage)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet, the left and right tail windows named by* W *are covered by one finite* $\mathsf{StreamName}^{\uparrow}$ *lattice meet surface before any* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row* D *or agreement row* A *is consumed. The meet surface is the finite packet of Definition 126.257; the local seal then reads the same paired-window evidence through* $W \to D \to A$.

Proof. Use paired finite tail-window coverage from Definition 699.37. It identifies the left and right source windows through the single local row W before the dyadic readback and agreement rows are available.

Apply the StreamName lattice-meet exhaustion theorem Definition 126.257. The two accepted finite StreamName windows are first repacked as one meet surface over the common classifier, probe bundle, membership rows, unary histories, dyadic ledger, transports, routes, provenance, and local names.

Now return to the local packet using Definition 699.48. Once the meet has supplied the shared finite window surface, every public agreement read proceeds through $W \to D \to A$ and cannot

replace the meet by quotient stream equality, host real equality, selected limits, or a hidden window selector. □

Theorem 699.12 (Real tail-agreement seal window-route determinacy companion)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, paired finite windows determine one displayed dyadic agreement route. If two public reads use the same paired window row* W *and the same dyadic readback row* D*, then the agreement row visible to* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{Completion}^{\uparrow}$ *consumers is the same row* A*.*

Proof. Use the finite-window meet coverage theorem to place both reads on the single $\mathsf{StreamName}^{\uparrow}$ meet surface before any dyadic readback is consumed.

Then apply the paired-window source lock. Agreement on W and D fixes the route $W \to D \to A$, so two reads over the same displayed windows and readback row cannot expose different agreement rows. □

Theorem 699.13 (Real tail-agreement seal window-route exact companion)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, the agreement row is read exactly through*

$$W \to D \to A.$$

No consumer may read A *before the paired finite window row* W *and the dyadic readback row* D *have both been displayed.*

Proof. Project the carrier rows W, D, A, H, C, P, N. The window row displays the paired finite tail windows, and the dyadic row is the only readback coordinate attached to those windows.

Apply dyadic exactness and the window-meet coverage theorem. Together they force the public agreement read to pass from the finite windows to the dyadic readback and only then to the agreement row. □

Theorem 699.14 (Real tail-agreement seal window-route non-escape companion)**.** *An accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet cannot replace the displayed route*

$$W \to D \to A$$

by quotient stream equality, a selected limit, host convergence, or a choice-selected tail. Every valid Real or Completion consumer stays inside the finite rows $R, S, W, D, A, H, C, P, N$*.*

Proof. Start from the exact companion route. A public agreement read has no access to A except through the displayed window and dyadic rows.

Now apply the non-escape and Real–Completion boundary theorems. The packet exports only the finite BEDC rows, so quotient streams, selected limits, host convergence, and choice-selected tails have no coordinate that can stand in for $W \to D \to A$. □

Theorem 699.15 (Real tail-agreement seal budget-source window service)**.** *Every paired tail-window service exposed by an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet reads the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *row and the* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *row before the paired finite-window row* W *is public. The local packet may then expose*

$$R, S, W, D, A, H, C, P, N,$$

but it cannot serve W *from an uncapped observation request, an unregistered tail source, a selected limit, or a host convergence witness.*

This budget route is the sibling handoff used by chapter 611: the tail-agreement seal consumes the finite observation-budget window route and the $\mathsf{RegSeqRat}^{\uparrow}$ *handoff before the* $\mathsf{Real}^{\uparrow}$ *seal is public.*

Proof. Project the accepted carrier $Q = (R, S, W, D, A, H, C, P, N)$ and use the local $\mathsf{NameCert}_{\mathsf{RealTailAgreementSeal}^{\uparrow}}$ obligations. They make the source rows, paired window row, dyadic readback row, agreement row, transport rows, continuation rows, package row, and local name the complete service surface.

Apply budget-window coherence. The finite tail request behind the paired service is the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ row, and the observation row serving that request is capped by the $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ route before the local W row is available.

Finally use window-meet coverage and the non-escape theorems. The public service reads the finite StreamName meet and then the local route $W \to D \to A$, while quotient stream equality, selected limits, uncapped observations, and host convergence have no coordinate in the packet. □

Theorem 699.16 (Real tail-agreement seal shared-threshold budget exactness)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet, the shared* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold together with the* RegularCauchyTailBud *budget source determines the finite window route before any dyadic readback row* D *or agreement row* A *is public. Thus the only public agreement route is the budgeted shared-threshold route*

$$\mathsf{RegularCauchyTailBudget}^{\uparrow} \longmapsto \mathsf{RegularCauchyTailMeet}^{\uparrow} \longmapsto W \longmapsto D \longmapsto A.$$

Proof. Begin with the carrier and NameCert rows. The local seal has exactly one paired window row W, one dyadic readback row D, and one agreement row A, transported and served only through the displayed histories and continuations.

Use budget-window coherence to place the consumer on the budget source. Then apply the tail-meet factorization: the shared threshold is read before any completion-facing sibling route can consume the local agreement surface.

The window-meet coverage theorem identifies the finite StreamName route feeding W, and the window-route exact companion forces the subsequent read through D and then A. Non-escape excludes quotient streams, selected tails, host limits, and hidden completion selectors, so the shared threshold and budget source jointly determine the finite route before D and A are exposed. □

Theorem 699.17 (Real tail-agreement seal budgeted TailMeet window exhaustion)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer that reaches the agreement row* A *passes, in order, through* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$*,* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$*,* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*, the displayed paired window row* W*, the dyadic readback row* D*, and only then* A*. The route exports no quotient stream equality, host real equality, selected tail, ambient convergence predicate, or second agreement row.*

Proof. Start with the budget-source window service. It places any public paired-window request behind the observation limiter and the regular Cauchy tail budget before the row W can be read.

Next apply shared-threshold budget exactness. The shared $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold is the only threshold row feeding the displayed finite window route, so the consumer cannot bypass the budget through an unregistered tail source.

Use window-meet coverage to identify the paired window row and the dyadic readback row. The displayed service therefore proceeds through W and then D before the local agreement row A is available.

Finally apply the Real-completion budgeted route and the non-escape clauses. They confine every $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumer to the same displayed packet rows and exclude quotient

stream equality, host real equality, selected tails, ambient convergence predicates, and any second agreement coordinate. □

Theorem 699.18 (Real tail-agreement seal Real-completion budgeted route)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet factors through the budget source, shared threshold, finite windows, dyadic readback, and agreement row before the seal is public. Concretely, the consumer route is confined to*

$$\mathsf{RegularCauchyTailBudget}^{\uparrow},\ \mathsf{ObservationBudgetLimiter}^{\uparrow},\ \mathsf{RegularCauchyTailMeet}^{\uparrow},\ W,\ D,\ A,\ R, S, H, C, P, N,$$

and cannot import quotient stream equality, host real equality, selected limits, ambient completeness, or a second agreement row.

Proof. Start with the RealUp consumer threshold factorization and the Completion consumer ledger. Together they place both Real and Completion consumers on the displayed carrier rows before any public seal read.

Next use the budget-source window service and shared-threshold budget exactness. The consumer first receives the budgeted observation route, then the shared TailMeet threshold, then the finite StreamName windows, dyadic readback row, and agreement row.

It remains to close the public boundary. Apply window-meet coverage, the completion route non-escape theorem, and the Real–Completion boundary theorem. These results keep the route inside the displayed BHist, Cont, Pkg, and NameCert rows, so no external quotient, host limit, selected tail, ambient completeness proof, or second agreement coordinate can be read before the seal is public. □

Theorem 699.19 (Real tail-agreement seal budget-threshold readback exhaustion)**.** *Every* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *consumer route that exposes a public agreement row factors through* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, *the finite StreamName window* W, *the dyadic readback row* D, *the agreement row* A, *and only then the* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal rows. No quotient-stream equality, selected limit, uncapped observation, host convergence witness, or second agreement coordinate is available along this public route.*

Proof. Apply the budget-source window service to place any public paired-window request behind the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ row and the $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ cap before W is served.

Next apply shared-threshold budget exactness. The only threshold available to the public agreement route is the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ row, and it feeds the finite StreamName window before the dyadic readback row D and agreement row A can be read.

Finally use the Real-completion budgeted route. Carrier projection identifies the remaining public rows as the displayed Real and Completion seal rows, and non-escape excludes quotient-stream equality, selected limits, uncapped observations, host convergence witnesses, and any second agreement coordinate. □

Theorem 699.20 (Real tail-agreement seal terminal consumer route exhaustion)**.** *Every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer that exposes the agreement row of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet is exhausted by the single displayed route*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow},\ \mathsf{RegularCauchyTailBudget}^{\uparrow},\ \mathsf{RegularCauchyTailMeet}^{\uparrow},\ W,\ D,\ A,\ R, S, H, C, P, N.$$

In particular, the terminal consumer must traverse the observation cap, the regular Cauchy tail budget, the shared TailMeet threshold, the finite StreamName window W, *the dyadic readback row* D, *the agreement row* A, *and the displayed* R, S, H, C, P, N *rows. It has no quotient stream equality, selected limit, uncapped observation, host convergence witness, or second agreement coordinate.*

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealTerminalRoute exhaustion`

Proof. First apply the budget-source window service. It places the finite StreamName window behind the $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ cap and the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ source before any agreement-facing row can be read.

Next apply shared-threshold budget exactness and the budgeted TailMeet window exhaustion theorem. These force the route through $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, then through the displayed window W, dyadic readback row D, and agreement row A.

Apply the Real-completion budgeted route and the budget-threshold readback exhaustion theorem to the terminal consumer. They identify the remaining public rows as R, S, H, C, P, N and show that both $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumers use the same carrier route.

Carrier projection now leaves exactly the displayed packet coordinates, and non-escape removes every route not represented by those coordinates. Hence quotient stream equality, selected limits, uncapped observation requests, host convergence witnesses, and any second agreement coordinate are outside the terminal consumer surface. □

Theorem 699.21 (Real tail-agreement seal budget route uniqueness)**.** *Every accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *terminal consumer exposing the public agreement row has the unique public route*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to W \to D \to A \to R, S, H, C,$$

Any displayed consumer route that omits or reorders the observation cap, the tail budget, the shared $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold, the finite* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the dyadic readback row* D*, or the agreement row* A *is outside the carrier. Thus the agreement seal has no alternate public route through quotient streams, selected limits, uncapped observations, host convergence, or a second agreement row.*

Proof. The budget-source window service fixes the first public read. A consumer exposing the agreement row must first pass through the $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ cap and the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ source before the finite window W is available.

Shared-threshold budget exactness then fixes the next boundary. The $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold is the only public threshold feeding the displayed finite window, and budgeted TailMeet exhaustion forces the route through W, then D, then A.

The Real-completion budgeted route identifies the remaining public rows as R, S, H, C, P, N. Terminal consumer route exhaustion shows that both $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumers read the same displayed carrier route after A.

Therefore any route that omits or reorders one of the named rows cannot be a route through the accepted carrier. The non-escape clauses exclude quotient stream equality, selected limits, uncapped observations, host convergence witnesses, and any second agreement row. □

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSeal budget route uniqueness`

Theorem 699.22 (Real tail-agreement seal root budget-source totality)**.** *Every root-facing* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *consumer that exposes the public agreement row must first read* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{RegularCauchyTailBudge}$ $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*, the finite* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the dyadic readback row* D*, and the agreement row* A*, before any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal row is public. Thus the root budget-source route is total for agreement-facing consumers and has no quotient stream equality, selected limit, uncapped observation, host convergence witness, or second agreement coordinate.*

Proof. Start with the budget-source window service. It places every root-facing window read behind the $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ cap and the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ source before the finite window W is available.

Next apply shared-threshold budget exactness and budgeted TailMeet window exhaustion. These force the public route through $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, then through W, the dyadic readback row D, and the agreement row A.

Finally use terminal consumer route exhaustion. It identifies the only later public rows as the displayed $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ seal rows carried by R, S, H, C, P, N, so the earlier budget-source route is total for any consumer exposing A.

Coordinate exhaustion gives the exclusions. Quotient streams, selected limits, uncapped observations, host convergence witnesses, and second agreement coordinates have no carrier row in the displayed root route. □

Theorem 699.23 (Real tail-agreement seal terminal budget-source lock)**.** *Every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer exposing the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *agreement row must first lock onto the same* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{RegularCauchyTailBudget}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, CauchySealBudgetSynchroniz *finite* $\mathsf{StreamName}^{\uparrow}$ *window* W, $\mathsf{DyadicRatCore}^{\uparrow}$ *readback* D, *and agreement row* A. *Any terminal route that does not preserve this source lock is outside the carrier and cannot supply quotient-stream equality, selected limits, host convergence, ambient completeness, or a second agreement coordinate.*

Proof. Start from the budget-source window service and root budget-source totality. They force every terminal agreement consumer to read the observation cap, tail budget, shared TailMeet threshold, finite window W, dyadic readback D, and agreement row A before the Real or Completion seal rows are public.

Use shared-threshold budget exactness together with budgeted TailMeet window exhaustion. The shared $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold is the unique source boundary for the finite window and cannot be replaced by an uncapped observation or a selected-limit read.

Apply the budget synchronizer factorization theorem Definition 699.25. It inserts the CauchySealBudgetSynchron row between the shared threshold and the finite window, so the lock is the same route for both $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumers.

Finally use terminal consumer route exhaustion and downstream route no-branching. Any route that drops one of the locked rows has no displayed carrier coordinate, and the excluded quotient-stream, selected-limit, host-convergence, ambient-completeness, and second-agreement readings therefore cannot supply the terminal seal. □

Theorem 699.24 (Real tail-agreement seal budget route canonical form)**.** *Every accepted terminal agreement route of a* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet has the canonical displayed order*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to W \to D \to A \to R, S, H, C,$$

Any public read of the agreement row A *is equivalent, as a* BHist *route through the packet, to traversing that order before* A *is exposed.*

Proof. First use the budget-source window service and shared-threshold budget exactness. They place every public window request behind the observation cap, the regular Cauchy tail budget, and the shared $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold before W is available.

Next apply budgeted TailMeet window exhaustion. It forces the route from the shared threshold through the finite StreamName window W, then through the dyadic readback row D, and only then to the agreement row A.

The Real-completion budgeted route and terminal consumer route exhaustion identify the remaining public rows as R, S, H, C, P, N. Budget route uniqueness then rules out any accepted terminal route that omits or reorders one of the displayed rows.

Therefore a public read of A is exactly a traversal of the canonical route shown in the statement. □

Theorem 699.25 (Real tail-agreement seal budget synchronizer factorization)**.** *Every accepted terminal agreement route of a* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet factors through the budget synchronizer before any* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *seal consumer receives the classifier. The route has the ordered public surface*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to \mathsf{CauchySealBudgetSynchroni}$$

Here W is the finite $\mathsf{StreamName}^{\uparrow}$ *window, D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback obtained from the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, and A is the unique agreement row exported to the Real and Completion consumers. No quotient stream equality, selected limit, uncapped observation request, host convergence witness, or second agreement row is available before those consumers read the classifier.*

Proof. Start with the budget-source window service and shared-threshold exactness. They place any terminal agreement route behind $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{RegularCauchyTailBudget}^{\uparrow}$, and the shared $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold before the finite window row can be public.

Next apply budgeted TailMeet exhaustion and the synchronizer row. The shared threshold is routed through $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ before the $\mathsf{StreamName}^{\uparrow}$ window W is read, and the $\mathsf{RegSeqRat}^{\uparrow}$ handoff supplies the finite regular-sequence data used by the $\mathsf{DyadicRatCore}^{\uparrow}$ readback row D.

Use the canonical-form theorem Definition 699.24. It identifies the terminal agreement route with the displayed order through W, D, and the agreement row A before the remaining seal rows R, S, H, C, P, N are public.

Finally apply terminal consumer route exhaustion and downstream route no-branching. The exported classifier therefore reaches $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ only through the displayed synchronizer route, and the non-escape clauses exclude quotient streams, selected limits, uncapped observations, host convergence, and second agreement rows. □

Theorem 699.26 (Real tail-agreement seal budget synchronizer route determinacy)**.** *Let two terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumers of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet preserve the same observation cap, tail budget, shared* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold,* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row, finite* $\mathsf{StreamName}^{\uparrow}$ *window W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback D, and agreement row A. Then the two consumers expose the same displayed public route through R, S, H, C, P, N. No quotient stream, selected limit, uncapped observation, host convergence witness, ambient completeness datum, or second agreement row can distinguish the terminal routes.*

Proof. Start with the terminal budget-source lock of Definition 699.23. It fixes the observation cap, tail budget, shared TailMeet threshold, finite window, readback row, and agreement row before either terminal seal consumer can read the classifier.

Apply the canonical-form theorem Definition 699.24. Once those source rows are fixed, each public agreement read traverses the same ordered finite route before the displayed R, S, H, C, P, N rows are exposed.

Next use the synchronizer factorization of Definition 699.25. The shared threshold passes through the same $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ row before the finite window W, the dyadic readback D, and the agreement row A are consumed.

Finally apply downstream route no-branching, Definition 699.27. Since no carrier coordinate supplies quotient streams, selected limits, uncapped observations, host convergence, ambient completeness, or a second agreement row, the two terminal consumers cannot be distinguished after preserving the same synchronizer route. □

Theorem 699.27 (Real tail-agreement seal downstream route no-branching)**.** *No downstream* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet can branch around the budget route through quotient stream equality, selected limits, uncapped observations, host convergence, or a second agreement coordinate. Every such consumer remains on the canonical route through* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{RegularCauchyTailBudget}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, W, D, A, *and the displayed* R, S, H, C, P, N *rows.*

Proof. Begin with root budget-source totality. It places any root-facing agreement read behind the observation cap, tail budget, shared TailMeet threshold, finite window, dyadic readback, and agreement row.

Use the canonical-form theorem Definition 699.24. It identifies any public read of A with the single displayed order through the finite carrier rows.

Finally apply terminal consumer route exhaustion and budget route uniqueness. These theorems leave no coordinate for quotient stream equality, selected limits, uncapped observations, host convergence witnesses, or a second agreement row, so no downstream $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer can branch around the budget route. □

Theorem 699.28 (Real tail-agreement seal regular TailMeet budget lock)**.** *Every terminal* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *agreement route accepted by* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *is locked to the ordered route*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to \mathsf{CauchySealBudgetSynchroni}$$

Here W *is the finite* $\mathsf{StreamName}^{\uparrow}$ *window,* D *is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback,* A *is the unique agreement row, and* R, S, H, C, P, N *are the local seal rows displayed by the accepted packet. Once this route is fixed, no quotient stream, selected limit, host equality, ambient completeness principle, or second agreement row can distinguish any downstream seal consumer.*

Proof. First build the upstream budget source. The budget-source window service and shared-threshold exactness place any terminal agreement route behind $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{RegularCauchyTailBudge}$ and the shared $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold before a finite agreement window can be read.

Next attach the synchronizer. Apply the budget synchronizer factorization of Definition 699.25: the shared threshold passes through $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ before the finite $\mathsf{StreamName}^{\uparrow}$ window W, the $\mathsf{DyadicRatCore}^{\uparrow}$ readback D, and the agreement row A are consumed.

The local agreement surface is then fixed by downstream route no-branching, Definition 699.27. It keeps each $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ consumer on the same route through R, S, H, C, P, N after the synchronizer route has been selected.

Finally use the CauchyLimitSeal finite-window lattice route, Definition 386.160. The finite window is a lattice meet rather than a hidden selected limit, so the completed route has no coordinate for quotient stream equality, host equality, ambient completeness, or a second agreement row to separate the consumers. □

Theorem 699.29 (Real tail-agreement seal budget route factorization)**.** *Every accepted terminal agreement read of a* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet factors through the canonical budget route, the synchronizer route, and the regular-tailmeet budget lock before it exports the terminal agreement row to a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer. Thus the exported terminal agreement has the single displayed*

route through ObservationBudgetLimiter$^{\uparrow}$, RegularCauchyTailBudget$^{\uparrow}$, RegularCauchyTailMeet$^{\uparrow}$, CauchySealBudgetSy *the finite* StreamName$^{\uparrow}$ *window* W*, the* DyadicRatCore$^{\uparrow}$ *readback row* D*, the agreement row* A*, and the local seal rows* R, S, H, C, P, N*.*

Proof. Apply budget route uniqueness from Definition 699.21. Any accepted terminal agreement read must use the displayed observation cap, regular Cauchy tail budget, shared TailMeet threshold, finite window, dyadic readback, agreement row, and local seal rows.

Next use the canonical-form theorem Definition 699.24. It identifies the public read of A with that ordered route before the terminal seal rows can be exported.

Insert the synchronizer by Definition 699.26. The terminal route preserves the same CauchySealBudgetSynchroni row before the finite window, readback row, and agreement row are consumed.

Finally apply downstream route no-branching from Definition 699.27 and the regular TailMeet budget lock of Definition 699.28. The terminal agreement row is therefore exported only after the displayed budget route, synchronizer route, and regular-tailmeet lock have all been traversed, with no quotient stream, selected limit, host equality, ambient completeness coordinate, or second agreement row available. □

Theorem 699.30 (Real tail-agreement seal root budget-source canonicality)**.** *Every displayed* RealTailAgreementSeal$^{\uparrow}$ *packet exposing a terminal agreement row determines a unique root budget-source row. The canonical source is the initial* BHist *segment through* ObservationBudgetLimiter$^{\uparrow}$, RegularCauchyTailBudget$^{\uparrow}$, RegularCauchyTailMeet$^{\uparrow}$, CauchySealBudgetSynchronizer$^{\uparrow}$, W, D, *and* A *whose* hsame, Cont, Pkg, *and* NameCert *rows are consumed by the terminal route*

ObservationBudgetLimiter$^{\uparrow}$ → RegularCauchyTailBudget$^{\uparrow}$ → RegularCauchyTailMeet$^{\uparrow}$ → CauchySealBudgetSynchroni

No second source row, quotient stream equality, selected limit, uncapped observation request, host convergence witness, or ambient completeness datum can serve as a competing root budget source. The intended Lean home for this package is the namespace `BEDC.Derived.RealTailAgreementSealUp.RootBudge`

Proof. Use root budget-source totality, Definition 699.22. It forces any root-facing agreement consumer to read the observation cap, the regular tail budget, the shared TailMeet threshold, the finite window, the dyadic readback row, and the agreement row before the terminal seal rows are public.

Use budget route uniqueness, Definition 699.21. Once the displayed packet exposes the public agreement row, no accepted BHist route may omit or reorder the budget source, shared threshold, finite window, readback row, or agreement row.

Finally apply the regular TailMeet budget lock of Definition 699.28. The synchronizer and the local rows R, S, H, C, P, N are consumed on the same route, so the hsame, Cont, Pkg, and NameCert rows name one canonical root budget-source row and exclude every competing source coordinate. □

Theorem 699.31 (Real tail-agreement seal root budget threshold coverage)**.** *For every accepted* RealTailAgreementSeal$^{\uparrow}$ *terminal agreement route, the shared-threshold budget row covers every* RegularCauchyTailMeet$^{\uparrow}$ *window admitted by the regular TailMeet budget lock. Concretely, any TailMeet window consumed by* Real$^{\uparrow}$ *or* Completion$^{\uparrow}$ *is first covered by the* RegularCauchyTailBudget$^{\uparrow}$ *source and the shared* RegularCauchyTailMeet$^{\uparrow}$ *threshold, then read through* W, D, A, *and the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *rows of the packet. No selected tail, uncapped observation, host convergence witness, quotient stream equality, or second agreement row lies outside this threshold coverage.*

Proof. Begin with shared-threshold budget exactness, Definition 699.16. It identifies the shared $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ threshold and the regular tail budget as the unique public source for the finite route before D or A is visible.

Next use budgeted TailMeet window exhaustion and the regular TailMeet budget lock. They show that each terminal $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer reaches the agreement row only through the shared threshold, the synchronizer, the finite window W, and the dyadic readback row D.

The terminal route exhaustion theorem then consumes the local rows R, S, H, C, P, N on the same displayed packet. Thus every admitted TailMeet window is already covered by the shared-threshold budget row, and the excluded selected-tail, uncapped-observation, host-convergence, quotient, and second-agreement readings have no carrier coordinate. □

Theorem 699.32 (Real tail-agreement seal root budget terminal consumption)**.** *Every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of a displayed* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet may consume only the canonical root budget route produced by root budget-source canonicality and root budget threshold coverage. The permitted consumption route is the finite* BHist *route through* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{RegularCauchyTailBudget}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$, W, D, A, *and* R, S, H, C, P, N, *together with the displayed* hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows. Any terminal read requiring a second source row, a selected limit, quotient stream equality, uncapped observations, host convergence, ambient completeness, or a second agreement coordinate is outside the package.*

Proof. First take the canonical source supplied by Definition 699.30. It combines totality with budget route uniqueness, so the terminal consumer has only one root budget-source row to read.

Next use Definition 699.31. The shared threshold covers the TailMeet window consumed by the terminal route, and the window is read through W, D, and A before any local seal row is exposed.

Finally apply terminal consumer route exhaustion and downstream route no-branching. They consume R, S, H, C, P, N through the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows and rule out every terminal route that asks for a second source, selected limit, quotient stream equality, uncapped observation, host convergence, ambient completeness, or a second agreement coordinate. □

Theorem 699.33 (Real tail-agreement seal root budget-route totality)**.** *Every accepted paired tail-agreement read of a* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$ *factors through the* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *route and the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *source before the local route*

$$W \to D \to A$$

is public. The route is total for the finite root read and supplies no uncapped observation request, quotient stream equality, selected real value, host convergence row, or second tail-budget source.

Proof. Project the carrier rows of Q and use the local $\mathsf{NameCert}_{\mathsf{RealTailAgreementSeal}^{\uparrow}}$ obligations. The only public service rows available before agreement are the displayed source rows R, S, the finite window row W, the dyadic readback row D, and the agreement row A, with transport, continuation, provenance, and name data carried by H, C, P, N.

Apply Definition 699.10 and Definition 699.63. They place the paired tail request on the finite $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ source and cap its observation route through $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ before the shared tail window can be read.

Finally use the window-route exact companion. Once the budgeted route has displayed the finite window, the agreement read proceeds through W, then D, then A. Since the carrier has no

coordinate for an uncapped request, quotient equality, selected value, host convergence, or second budget source, the stated budget-route factorization is exhaustive. □

Theorem 699.34 (Real tail-agreement seal root source-window transport)**.** *Let* $Q = (R, S, W, D, A, H, C, P, N)$ *and* $Q' = (R', S', W', D', A', H', C', P', N')$ *be accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packets. Componentwise* hsame *transport of the displayed source rows* R, S*, paired window row* W*, and dyadic readback row* D *preserves the same paired source-window route from the budgeted tail request to the agreement row. Thus the transported packet reads the same finite route*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to R, S \to W \to D \to A$$

up to the displayed local transport rows, without introducing quotient stream equality, selected limits, host convergence, or an ambient completion selector.

Proof. Read the componentwise hsame rows from H and H'. These rows identify only the displayed source, window, and readback components; they do not add a new tail source or a separate equality predicate.

Use the root budget-route totality theorem for Q and Q'. Both packets place their paired source-window reads behind the same finite budget and limiter surfaces before exposing any local agreement row.

Now apply the tail-classifier transport and window-route determinacy results. Transport of R, S, W, D carries the finite source-window route across the two packets, and determinacy fixes the agreement row reached after $W \to D$. The transported route therefore remains the same paired source-window route, with no quotient, selected-limit, convergence, or external completion coordinate available to replace it. □

Theorem 699.35 (Real tail-agreement seal root completion-boundary exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet is exhausted by the local rows*

$$R, S, W, D, A, H, C, P, N$$

together with the sibling budget, tail-meet, tail-fusion, $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and Real routes named by chapter 906, chapter 560, chapter 658, chapter 386, and chapter 38. No root consumer obtains quotient stream equality, a selected limit, host convergence, ambient completeness, or a hidden tail selector from the seal.*

Proof. Begin with the root budget-route totality theorem. It forces any paired tail-agreement read to pass through the finite budget and limiter route before the local agreement surface $W \to D \to A$ can be consumed.

Next use the source-window transport theorem and the sibling tail-meet and tail-fusion routes. The transport row keeps R, S, W, D on the same paired source-window route, while the meet and fusion siblings supply the shared tail surface that the local packet consumes.

It remains to account for Real and Completion-facing endpoints. Apply Definition 699.65 together with the $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ sibling routes. These consumers receive only the displayed finite rows and the named sibling surfaces, so the boundary is exhausted without quotient stream equality, selected limits, host convergence, ambient completeness, or hidden tail selection. □

Theorem 699.36 (Real tail-agreement seal downstream route exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet receives only the route*

$$R, S, W, D, A, H, C, P, N$$

together with the budget source lock of Definition 699.10 and the finite-window meet coverage of Definition 699.11. No downstream consumer can add a quotient stream, selected host limit, host convergence row, external completion selector, second budget gate, or second paired-window meet.

Proof. First apply the RealUp consumer threshold factorization Definition 699.8. It puts both Real and Completion consumers on the displayed threshold route before the local seal handoff.

Next combine the budget source lock with the window-meet coverage theorem. The former fixes the only budget route through $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ and $\mathsf{ObservationBudgetLimiter}^{\uparrow}$; the latter fixes the only finite StreamName meet surface feeding W, D, A.

Finally use Definition 699.52 and Definition 699.58. These rows exhaust the downstream route by $R, S, W, D, A, H, C, P, N$, so the cited budget and meet surfaces are consumed as finite predecessors of the same displayed packet rather than as hidden quotient, choice, convergence, or completion data. □

Definition 699.37 (Real tail-agreement seal window coverage)**.** *For a* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *carrier* $Q = (R, S, W, D, A, H, C, P, N)$*, paired finite tail-window coverage means that every public agreement read first selects the same displayed threshold in the* $\mathsf{StreamName}^{\uparrow}$ *row* W*, then reads the left and right finite windows of the paired source rows* R *and* S*, and only then reaches the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row* D *and the agreement row* A*. The coverage predicate is transported componentwise by* H*, replayed only through* C*, recorded in provenance* P*, and named locally by* N*.*

Theorem 699.38 (Real tail-agreement seal dyadic exactness)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, the agreement row* A *is determined only by the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row* D *selected by the paired tail-window row* W*. No separate quotient-stream equality, selected real equality, host metric limit, or hidden tail oracle can determine* A*.*

Proof. Project the displayed rows W, D, A, H, C, P, N from the carrier. The window row W selects the paired finite tail windows, and the readback row D is the only dyadic observation row attached to those windows.

Apply the tail-window coverage and dyadic readback exactness clauses of Definition 699.2. They force every public agreement read through W and D before A is available.

The structural rows H, C, P, N preserve and expose that same dependency. Since none of them contains quotient stream equality, selected real equality, a host limit, or a tail oracle, the agreement row is determined exactly by the displayed dyadic readback route. □

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealWindowRoute result exact`

Theorem 699.39 (Real tail-agreement seal shared-threshold non-escape)**.** *Any downstream* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer that uses the shared tail threshold of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet must factor through* W*, then* D*, then* A*. The consumer cannot import quotient stream equality, selected limits, host convergence, or choice-selected tails into the seal route.*

Proof. Begin with a downstream Real or Completion read. By Definition 699.37, the read first reaches the paired finite windows selected by W.

Next apply Definition 699.38. The selected windows determine the dyadic readback row D, and D determines the displayed agreement row A.

Finally use the RealUp handoff and non-escape clauses of Definition 699.2. They expose the agreement only through the finite packet rows and exclude quotient stream equality, selected limits, host convergence, and choice-selected tails from the consumer route. □

Theorem 699.40 (Real tail-agreement seal non-escape)**.** *An accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet cannot be used to export quotient stream equality, selected real values, host metric convergence, open-cover compactness, or choice-selected tails. Any attempted read of one of those objects is outside the local packet unless it factors through the finite rows*

$$R, S, W, D, A, H, C, P, N.$$

Proof. Project the carrier. Its source rows are the paired $\mathsf{RegSeqRat}$ inputs, its observation rows are the finite $\mathsf{StreamName}^{\uparrow}$ windows and $\mathsf{DyadicRatCore}^{\uparrow}$ readbacks, and its comparison row is the displayed finite agreement row.

The structural rows only transport, route, package, and name those coordinates. They do not add a quotient of streams, an ambient real carrier, a host metric space, an open cover, or a choice function selecting tails.

Therefore a read that asks for any of those external objects has no coordinate in the packet. The only Real-facing information available to downstream consumers is the finite agreement route through $R, S, W, D, A, H, C, P, N$. □

Theorem 699.41 (Real tail-agreement seal tail classifier)**.** *For a* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *carrier* $Q = (R, S, W, D, A, H, C, P, N)$*, the displayed agreement row* A *is classifier-readable only through the exposed rows* R, S, W, D*. In particular, a public classifier for the finite tail agreement must first read the paired* $\mathsf{RegSeqRat}$ *sources* R, S*, the paired* $\mathsf{StreamName}^{\uparrow}$ *tail-window row* W*, and the paired* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row* D*; the row* A *carries no separate tail oracle, quotient-stream equality, or ambient real equality.*

Proof. Project the carrier in Definition 699.1. The agreement coordinate A is displayed only after the source rows R, S, the window row W, and the readback row D have been named.

Apply the tail-window and dyadic-readback clauses of Definition 699.2. They force every public agreement read to pass through W and D, so the classifier sees the same finite rows that produced A.

Finally apply Definition 699.40. Since the packet exports no quotient equality or hidden tail selector, no classifier can bypass R, S, W, D while still reading the displayed agreement row. □

Theorem 699.42 (Real tail-agreement seal classifier reflexivity)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, the displayed tail-agreement classifier reads the same finite route against* Q *itself:*

$$R, S, W, D, A.$$

The reflexive read uses the local paired-window row W*, the local dyadic readback row* D*, and the displayed agreement row* A*; it does not import quotient stream equality, host real equality, a selected limit, or an additional tail selector.*

Proof. Apply Definition 699.41 to the packet Q. The classifier-readable surface is exactly the displayed source, window, readback, and agreement route R, S, W, D, A.

Next use Definition 699.48. Since the packet is compared with itself, the source rows, window row, and structural rows agree on the nose as displayed BEDC rows, so every public agreement read follows the same local route $W \to D \to A$.

Finally apply Definition 699.47 and Definition 699.40. They rule out a second classifier row and any external equality object, leaving the reflexive classifier read as the displayed finite route already carried by Q. □

Theorem 699.43 (Real tail-agreement seal classifier symmetry)**.** *Let $Q = (R, S, W, D, A, H, C, P, N)$ and $Q' = (R', S', W', D', A', H', C', P', N')$ be accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packets. If a public classifier read displays a paired-window agreement route from Q to Q' through the shared rows R, S, W, D, A and R', S', W', D', A', then the reverse public read displays the corresponding route from Q' to Q through the same finite window and dyadic readback rows. The reversal does not assert quotient stream equality or host real equality; it only reverses the displayed paired-window agreement route.*

Proof. Read the forward classifier by Definition 699.41. Both endpoints expose their agreement rows only after the paired source rows, paired window rows, and dyadic readback rows have been displayed.

Use Definition 699.48 on the common boundary. The same finite window route that allows the forward read also fixes the reverse read once the endpoints are exchanged, because the classifier has no separate selector outside W, D, H, C, P, N.

Apply Definition 699.47 to both packets. It identifies the visible rows at each endpoint and prevents a second source, window, readback, or agreement coordinate from being substituted during reversal.

Finally use the non-escape and handoff rows recorded in Definition 699.40 and Definition 699.45. The reverse route remains a finite BEDC classifier read for Real and Completion consumers, not an assertion of quotient stream equality or host real equality. □

Theorem 699.44 (Real tail-agreement seal classifier transitivity)**.** *Let $Q = (R, S, W, D, A, H, C, P, N)$, $Q' = (R', S', W', D', A', H', C', P', N')$, and $Q'' = (R'', S'', W'', D'', A'', H'', C'', P'', N'')$ be accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packets. If public classifier reads display a paired-window agreement route from Q to Q' and a paired-window agreement route from Q' to Q'', and both reads pass through the shared finite* $\mathsf{StreamName}^{\uparrow}$ *window and* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback rows at Q', then the composed public read displays a route from Q to Q'' through the same finite window-readback chain. The composition exports only the displayed R, S, W, D, A rows at the endpoints and does not add quotient stream equality, host real equality, a selected real value, or a hidden completion selector.*

Proof. Start with the two classifier reads and apply Definition 699.41. Each read reaches its agreement row only through paired source rows, a finite $\mathsf{StreamName}^{\uparrow}$ window row, and a $\mathsf{DyadicRatCore}^{\uparrow}$ readback row.

At the middle packet Q', use Definition 699.48. The shared finite window row fixes the same readback route $W' \to D' \to A'$ for both adjacent reads, so the middle packet supplies one displayed hinge rather than two independent classifiers.

Now apply Definition 699.47. Since the middle packet has unique visible source, window, readback, and agreement coordinates inside the local ledger, the two adjacent routes compose through the displayed W' and D' rows.

Finally use Definition 699.40 and Definition 699.45. The composed endpoint route is still the finite classifier handoff read by Real and Completion consumers, so it cannot introduce quotient stream equality, host real equality, selected real values, or hidden completion selectors. □

Theorem 699.45 (Real tail-agreement seal Real handoff)**.** *Every Real or Completion consumer of a* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet receives the displayed agreement through*

$$R, S, W, D, A, H, C, P, N$$

together with the shared-threshold surface supplied by chapter 560. The handoff is therefore the paired-tail analogue of the finite cofinal-tail route in chapter 658, not a direct assertion of Real equality or completion convergence.

Proof. The carrier supplies the local rows $R, S, W, D, A, H, C, P, N$. The RealUp handoff clause in Definition 699.2 says that a downstream consumer reaches the seal only through those rows.

The agreement row is finite because its windows and readbacks are finite. The cofinal-tail route of chapter 658 gives the sibling pattern for exposing finite tail evidence, while chapter 560 supplies the shared-threshold discipline needed for a paired comparison.

The non-escape theorem then fixes the boundary of the handoff. A Real or Completion consumer may consume the displayed paired-tail agreement route, but it does not receive quotient stream equality, a selected Real value, host metric convergence, open-cover compactness, or a choice-selected tail. □

Theorem 699.46 (Real tail-agreement seal ledger exhaustion)**.** *The rows*

$$R, S, W, D, A, H, C, P, N$$

exhaust the local $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *ledger. Any valid local obligation is one of carrier admission, tail-window coverage, dyadic readback exactness, RealUp handoff, or non-escape; no local row remains for quotient stream equality, selected reals, host metric convergence, open-cover compactness, choice-selected tails, or hidden tail oracles.*

Proof. Carrier admission in Definition 699.2 lists the whole packet. The only displayed data rows are the paired sources, windows, readbacks, agreement, transport, continuation, provenance, and local naming rows.

The middle obligations account for the classifier surface. Tail-window coverage accounts for W, dyadic readback exactness accounts for D and A, and the RealUp handoff accounts for the consumer route through H, C, P, N.

It remains to rule out extra ledger rows. Apply Definition 699.40: the packet contains no coordinate for quotient stream equality, selected reals, host metric convergence, open-cover compactness, choice-selected tails, or hidden tail oracles. Hence the five displayed obligations exhaust the local ledger. □

Theorem 699.47 (Real tail-agreement seal source separation obligation)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, the rows* R *and* S *are the only paired* $\mathsf{RegSeqRat}$ *source rows,* W *is the only paired* $\mathsf{StreamName}^{\uparrow}$ *tail-window row,* D *is the only paired* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row, and* A *is the only displayed agreement row. The structural rows* H, C, P, N *transport, route, package, and name these fields, but they do not introduce a second source, a second tail window, a second dyadic readback, or a second agreement classifier.*

Proof. Project the carrier in Definition 699.1. Its displayed data coordinates are exactly the paired source rows R, S, the paired window row W, the readback row D, and the agreement row A.

Apply the carrier-admission and non-escape clauses of Definition 699.2. Carrier admission lists the rows admitted to the local $\mathsf{NameCert}_{\mathsf{RealTailAgreementSeal}^{\uparrow}}$ surface, while non-escape excludes hidden tail selectors, quotient equalities, and unrecorded analytic objects.

The remaining structural rows cannot manufacture another source of agreement. The componentwise transport row H preserves the same coordinates, C only routes reads through them, P records their provenance, and N names the local packet. □

Theorem 699.48 (Real tail-agreement seal paired-window source lock)**.** *Let a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer agree with an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet on the rows* R, S, W, H, C, P, N*. Then every public agreement read by that consumer uses the same route*

$$W \to D \to A.$$

In particular, the consumer cannot replace the paired tail-window selector by a second selector, and it cannot replace the dyadic readback route by host equality of completed real values.

Proof. The agreement on R, S, W, H, C, P, N fixes the public carrier boundary through which the consumer reads the seal. By Definition 699.37, the read first reaches the paired finite tail windows selected by W.

Apply Definition 699.38. Once W has selected the paired windows, the only readback row available for the agreement is D, and the displayed agreement row is A.

Finally use Definition 699.47. Since no second window selector, second readback row, or host equality row is present in the local ledger, every Real or Completion consumer that stays on the displayed boundary must follow $W \to D \to A$. □

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealWindowRoute result deterministic`

Theorem 699.49 (Real tail-agreement seal terminal consumer factorization)**.** *Let $Q = (R, S, W, D, A, H, C, P, N)$ be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet. Every terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of Q factors its public read through the displayed route*

$$R, S, W, D, A, H, C, P, N.$$

In particular, the consumer first agrees with the paired source and tail-window rows, then reads the dyadic agreement route $W \to D \to A$, and only then uses the structural rows H, C, P, N for transport, continuation, provenance, and local naming.

Proof. Apply Definition 699.8. It identifies the Real-facing threshold route through the carrier rows and prevents the consumer from entering the packet through an unlisted analytic boundary.

Apply Definition 699.48. Once the consumer agrees with R, S, W, H, C, P, N, every public agreement read follows the finite route $W \to D \to A$.

Finally apply Definition 699.47. The only source, window, readback, agreement, transport, continuation, package, and name rows available to a terminal Real or Completion consumer are the displayed coordinates of Q. □

Theorem 699.50 (Real tail-agreement seal dyadic terminal non-escape)**.** *Let $Q = (R, S, W, D, A, H, C, P, N)$ be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet. A terminal* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of Q cannot replace the route*

$$W \to D \to A$$

by quotient stream equality, selected real equality, host metric convergence, open-cover compactness, or choice-selected tails.

Proof. By Definition 699.37, the public read reaches the finite paired tail windows selected by W before it reaches any agreement row.

Apply Definition 699.38. The selected windows are read back through the dyadic row D, and the agreement visible to the consumer is the displayed row A.

Apply Definition 699.39. The shared threshold is not a quotient-stream equality, a selected real, a host metric convergence proof, an open-cover compactness argument, or a choice-selected tail. Hence no terminal consumer can substitute any of those objects for $W \to D \to A$. □

Theorem 699.51 (Real tail-agreement seal Completion consumer exactness)**.** *Every* $\mathsf{Completion}^{\uparrow}$*-facing consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet reads the same paired tail-window agreement surface before any completion seal read. The only rows it receives are the displayed*

BEDC rows over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$*:*

$$R, S, W, D, A, H, C, P, N.$$

Proof. Use Definition 699.49 to place the Completion-facing consumer on the terminal packet route. Its public read factors through the displayed rows before it can consume a completion seal.

Use Definition 699.50 to fix the agreement surface. The consumer must read $W \to D \to A$, and it cannot replace that dyadic route by quotient streams, selected limits, host convergence, compactness, or choice-selected tails.

It remains to identify the received rows. Apply Definition 699.40 together with the chapter closure scope: the local packet exposes only the finite BEDC carrier rows over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$. □

Theorem 699.52 (Real tail-agreement seal Completion consumer ledger)**.** *Every* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet reaches the seal through the displayed ledger*

$$R, S, W, D, A, H, C, P, N.$$

The only sibling routes it may use are the $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route of chapter 386 and the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *route of chapter 853; both consume the same finite paired tail-agreement boundary rather than a quotient stream, selected limit, host convergence proof, or external completion object.*

Proof. Start with Definition 699.8. It places the downstream consumer on the displayed tail-agreement carrier rows before any Real or Completion handoff can be read.

Apply Definition 699.48. Once the consumer is on R, S, W, H, C, P, N, the agreement surface is forced through $W \to D \to A$.

The sibling routes cited in the statement consume this same boundary. The $\mathsf{CauchyLimitSeal}^{\uparrow}$ chapter receives a finite seal row from its Cauchy-facing source, and the $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ chapter receives the finite budget-selector packet before its Real-facing seal handoff; neither route adds a new coordinate to $Q = (R, S, W, D, A, H, C, P, N)$. □

Theorem 699.53 (Real tail-agreement seal budget-window coherence)**.** *Every* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *completion consumer must first read the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *budget row from chapter 906 before it can consume the shared paired-window route of the accepted packet* $Q = (R, S, W, D, A, H, C, P, N)$*. The budget row fixes the finite tail request that the seal later displays through* W, D, A*.*

Proof. Start with Definition 699.52. It puts every completion consumer on the displayed ledger $R, S, W, D, A, H, C, P, N$ before any seal read.

The budget row is the finite request source for the paired tail windows. Reading it from chapter 906 determines which tail request the local W row can display.

Since the packet has no quotient stream, host real equality, selected limit, or ambient completeness coordinate, the consumer cannot bypass the budget row and later recover the same finite paired-window route. □

Theorem 699.54 (Real tail-agreement seal tail-meet factorization)**.** *After the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *budget row has been read, every* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *completion consumer factors through the shared-threshold route of chapter 560 before reaching any* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *sibling route. The factorization exposes the same finite* $W \to D \to A$ *agreement surface used by the local seal packet.*

Proof. Read the budget-window coherence row. It places the consumer on the finite tail request before the paired windows of Q are available.

Now use the shared-threshold sibling. The $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ route supplies the common threshold consumed by the same W row, and Definition 699.48 forces any public agreement read through $W \to D \to A$.

The $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ routes consume that agreement surface after the shared threshold has been displayed. They do not add a second tail source, quotient stream equality, host real equality, or selected limit to the local seal packet. □

Theorem 699.55 (Real tail-agreement seal completion route non-escape)**.** *Every* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *completion route to* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *is confined to the sequence:* $\mathsf{RegularCauchyTailBudg}$ *budget row,* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold row, and the local* $W \to D \to A$ *agreement surface. No route may replace that sequence by quotient stream equality, host real equality, selected limit, or ambient completeness.*

Proof. Use budget-window coherence for the first step and tail-meet factorization for the second step. Together they force the consumer to read the budget row, then the shared-threshold route, and then the displayed local agreement surface.

Apply the completion consumer ledger. Once the route reaches Q, the only local rows available are $R, S, W, D, A, H, C, P, N$, and the only agreement route is $W \to D \to A$.

The excluded analytic objects have no coordinate in either the budget row, the shared-threshold sibling, or the local seal packet. Hence they cannot serve as alternate completion routes. □

Theorem 699.56 (Real tail-agreement seal completion budget-threshold exhaustion)**.** *Let* $Q = (R, S, W, D, A, H, C, P, N)$ *be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet. Every* $\mathsf{Completion}^{\uparrow}$*-facing consumer of* Q *factors through the finite sequence consisting of the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *budget row, the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold row, the local* $W \to D \to A$ *agreement surface, and then the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *consumer route. No quotient stream equality, host real equality, selected limit, hidden tail selector, or ambient completeness row can appear in that factorization.*

Proof. Start with Definition 699.53. It places the Completion-facing consumer on the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ budget row before the paired window route of Q is read.

Next apply Definition 699.54. The budget row is carried through the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ shared threshold, and the local public agreement surface is forced to be $W \to D \to A$.

Finally use Definition 699.55. The only sibling consumers available after this surface are the $\mathsf{CauchyLimitSeal}^{\uparrow}$ route of chapter 386 and the $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ route of chapter 853. Since none of the listed rows carries quotient stream equality, host real equality, a selected limit, a hidden tail selector, or an ambient completeness row, the displayed sequence exhausts the Completion-facing handoff. □

Theorem 699.57 (Real tail-agreement seal dual-source window exhaustion)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, the two source rows* R, S *and the paired* $\mathsf{StreamName}^{\uparrow}$ *window row* W *exhaust the left/right tail evidence visible to Real and Completion consumers. The dyadic row* D *and agreement row* A *read that evidence, while* H, C, P, N *transport, route, package, and name it without adding another left tail, right tail, or paired-window selector.*

Proof. Use Definition 699.37. The public read reaches the paired finite windows through the single window row W after the two source rows R, S have been displayed.

Apply Definition 699.38. The selected windows are read back through D, and the visible agreement is recorded by A.

Finally apply Definition 699.48. A Real or Completion consumer that agrees on R, S, W, H, C, P, N must read $W \to D \to A$, so there is no remaining carrier coordinate that can serve as another left/right source or another paired-window selector. □

Theorem 699.58 (Real tail-agreement seal Real–Completion boundary)**.** $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{Completion}^{\uparrow}$ *consumers of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet receive the same finite paired agreement boundary*

$$R, S, W, D, A, H, C, P, N.$$

The boundary supplies source rows, paired windows, dyadic readback, displayed agreement, transport, routes, package provenance, and local naming; it supplies no quotient stream, selected limit, host convergence predicate, or hidden completion selector.

Proof. Apply Definition 699.8 to put the Real-facing read on the carrier boundary, and apply Definition 699.52 to put the Completion-facing read on the same displayed ledger.

The common agreement row is determined by the window and dyadic readback. This is exactly the route supplied by Definition 699.37, Definition 699.38, and Definition 699.48.

The non-escape part is finite. Since the packet has no coordinate for quotient streams, selected limits, host convergence, or hidden completion selectors, both kinds of consumer receive only the same paired agreement boundary. □

Theorem 699.59 (Real tail-agreement seal selector-budget handoff)**.** *Let* $Q = (R, S, W, D, A, H, C, P, N)$ *be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet. If* Q *is consumed through a finite observation-budget selector, then the consumer first factors through chapter 782 and its finite route*

$$B \to S \to W \to D \to R \to E.$$

Only after that public selector route has been displayed can the consumer reach the local paired agreement route $W \to D \to A$*. The handoff exports no quotient stream, selected limit, host convergence row, hidden completion selector, or ambient completeness coordinate.*

Proof. Apply Definition 782.14. It makes the finite selector route $B \to S \to W \to D \to R \to E$ the public route seen by Real-completion consumers before the local seal is read.

Now use budget-window coherence for the present packet. The selector route supplies the finite budget and window service consumed by the local W row, so the seal cannot be reached through a separate unbounded observation request.

Finally apply Definition 699.48. Once the local rows R, S, W, H, C, P, N have been matched, every displayed agreement read proceeds through $W \to D \to A$, with no additional analytic coordinate exported by the handoff. □

Theorem 699.60 (Real tail-agreement seal finite-approximation consumer boundary)**.** *Every finite approximation consumer reaches an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet only after the* $\mathsf{FiniteCauchyApproximation}^{\uparrow}$ *surface of chapter 601 has displayed the finite rows*

$$R, n, k, W, D, E, S, H, C, P, N.$$

The consumer then reads the local paired agreement boundary $R, S, W, D, A, H, C, P, N$ *through* $W \to D \to A$*. The boundary contains no selected real value, quotient stream equality, infinite tail, host metric, hidden completion selector, or ambient completeness row.*

Proof. Begin with Definition 601.16. It packages the finite approximation rows $R, n, k, W, D, E, S, H, C, P, N$ as the local $\mathsf{NameCert}_{\mathsf{FiniteCauchyApproximation}^{\uparrow}}$ obligation surface before any real-facing or completion-facing consumer can use the approximation.

Next apply Definition 601.18. The precision, finite-window, dyadic-ledger, error-row, and handoff data are consumed through the same finite budget route as the backing budget packets, so the approximation contributes no hidden completion choice.

Finally use the local completion route non-escape theorem. After the finite approximation rows have supplied the window and dyadic readback surface, the present seal can only read $W \to D \to A$ inside $R, S, W, D, A, H, C, P, N$, and none of the excluded analytic objects has a carrier coordinate. □

Theorem 699.61 (Real tail-agreement seal Real–Completion selector chain)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer that passes through a finite observation-budget selector and a finite Cauchy approximation sees one finite chain: the selector route* $B \to S \to W \to D \to R \to E$*, the finite approximation rows* $R, n, k, W, D, E, S, H, C, P, N$*, the shared threshold route, and the local paired agreement route* $W \to D \to A$*. The chain exports the same Real–Completion boundary* $R, S, W, D, A, H, C, P, N$ *and no quotient stream, selected limit, host convergence, hidden completion selector, or ambient completeness row.*

Proof. Use Definition 699.59 for the budget-selector side. It forces the consumer through the displayed finite selector route before the local paired windows are available.

Use Definition 699.60 for the finite approximation side. It forces the same consumer through the approximation rows and then returns it to the local $W \to D \to A$ boundary.

Now apply Definition 699.58. The Real-facing and Completion-facing reads receive the same finite local packet, so the selector route, approximation rows, shared threshold, and local paired agreement route form one displayed chain rather than a route through quotient streams, selected limits, host convergence, hidden completion selectors, or ambient completeness. □

Falsifiable prediction: Deleting any one of R, S, W, D, A breaks a different public read of the seal: source membership for R, S, shared tail-window selection for W, dyadic exactness for D, and displayed agreement for A.

Independence witness: Nearest Real and Completion siblings share some source or handoff vocabulary, but none is bijective to this carrier while preserving the five distinct rows R, S, W, D, A: a single-source regularity packet lacks the paired source split, a tail-selector packet lacks dyadic agreement, a dyadic readback packet lacks the paired window lock, and a Real handoff packet lacks the displayed agreement boundary.

Theorem 699.62 (Real tail-agreement seal TasteGate independence boundary)**.** *The checked single-carrier TasteGate marker for* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *is read together with the displayed carrier rows, the falsifiable prediction, and the independence witness as preserving the distinct fields* R, S, W, D, A*. Thus the current* `FieldFaithful` *witness and any later* `Nontrivial` *witness have a non-vacuous paper boundary: they must respect source separation, paired-window source lock, dyadic readback, displayed agreement, and the Real-facing handoff instead of collapsing the packet to a single undifferentiated carrier row.*

Proof. The checked TasteGate marker recorded for the chapter supplies the single-carrier alignment for the carrier in Definition 699.1. It does not by itself identify the internal roles of the rows, so the paper boundary records the roles explicitly.

The falsifiable prediction separates the rows by deletion behavior: removing R, S, W, D, or A destroys a different public read. The independence witness separates the carrier from nearby Real and Completion packets by requiring the paired source split, the window lock, the dyadic readback, and the agreement row to be preserved together.

Apply Definition 699.47 and Definition 699.48. These theorems bind the row distinction and the consumer route $W \to D \to A$, so any faithful Lean-side field witness for this carrier has a concrete paper boundary to preserve. □

Theorem 699.63 (Real tail-agreement seal shared-tail budget extraction)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, every Real- or Completion-facing read of the paired agreement row* A *determines a shared finite tail-budget route through the budget packet of chapter 906 and the shared-threshold meet of chapter 560. The extracted route exposes the same paired window row* W *and dyadic readback row* D *used by* Q*, and it exposes no countable selector, quotient stream equality, host real equality, or selected limit outside the displayed rows.*

Proof. Start with the budget-window coherence row. It forces any public agreement read to pass through the finite request surface before the paired windows of Q can be consumed.

Next use the paired-window source lock. The source rows R, S and the window row W determine which dyadic row D and agreement row A are visible, so the consumer cannot replace the shared tail request by a hidden selector.

Finally factor the extracted request through the sibling meet route. The meet chapter supplies the shared threshold consumed by the same finite windows, while the present packet supplies only the local $W \to D \to A$ agreement surface. □

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealCarrier shared tail budget extraction`

Theorem 699.64 (Real tail-agreement seal window-agreement determinacy)**.** *Let* $Q = (R, S, W, D, A, H, C, P, N)$ *and* $Q' = (R', S', W', D', A', H', C', P', N')$ *be accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packets. If the source rows, shared budget route, paired window rows, and local transport and naming rows agree through the displayed* hsame *and* Cont *data, then the public agreement rows agree:* A *and* A' *are the same displayed paired-window agreement read. No Completion consumer can distinguish* Q *from* Q' *by adding a second agreement classifier outside* W, D, H, C, P, N*.*

Proof. Project both carriers and read the shared-tail budget extraction. The agreed budget route and paired source rows put both packets on the same finite tail request.

Apply the paired-window source lock to each packet. Since W and W' are the same displayed paired-window service under the local transport rows, both dyadic readbacks are read through the same finite window data.

The terminal consumer factorization then leaves only the agreement row as the public result of that route. Because the carrier has no second agreement classifier or host equality coordinate, A and A' are determined by the displayed window and readback rows. □

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealCarrier window agreement determinacy`

Theorem 699.65 (Real tail-agreement seal Completion handoff totality)**.** *Every* $\mathsf{Completion}^{\uparrow}$*-facing consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet reaches completion data only through the finite chain consisting of the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *budget route, the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-tail route, the local paired agreement surface* $W \to D \to A$*, and then the sibling consumer*

rows of chapter 386 or chapter 853. The handoff is total for displayed Completion consumers and supplies no Real completeness theorem, quotient stream, host metric limit, or choice-selected tail.

Proof. Use the Completion consumer ledger to put the consumer on the displayed rows $R, S, W, D, A, H, C, P, N$ before any Completion-facing read is available.

The shared-tail budget extraction supplies the finite request and threshold route. The window-agreement determinacy theorem then fixes the agreement row exposed to the consumer from W and D.

It remains to identify the Completion-facing endpoint. The Cauchy limit seal and diagonal budget siblings consume the displayed agreement boundary after it has been fixed; they do not add a selected limit or ambient completeness coordinate to the present packet. □

Theorem 699.66 (Real tail-agreement seal root-window readback)**.** *Every root* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *read of an accepted packet* $Q = (R, S, W, D, A, H, C, P, N)$ *factors through the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows of chapter 301, the paired* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows of chapter 126, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback rows of chapter 291 before the local agreement row* A *is visible. The route is rooted in the regular-tail surfaces supplied by chapter 560 and chapter 658, and it exposes no independent agreement channel outside* $W \to D \to A$*.*

Proof. Start from the carrier in Definition 699.1. Its root-readable coordinates present the two regular rational source rows R, S, one paired finite window row W, one dyadic readback row D, and one agreement row A.

Use the source separation and paired-window source lock. They force any public agreement read to take the displayed sources into the same finite $\mathsf{StreamName}^{\uparrow}$ window service before the dyadic readback can be inspected.

Now apply the dyadic exactness and shared-tail budget extraction rows. The readback row D is the only dyadic route attached to the visible windows, and the regular-tail meet and fusion siblings provide the shared threshold surface consumed by that route.

Finally use the Completion handoff totality theorem. Once the consumer reaches the Completion-facing endpoint, the only visible local agreement has already passed through $W \to D \to A$, so no quotient stream equality, selected limit, or hidden agreement selector can be inserted at the root. □

Theorem 699.67 (Real tail-agreement seal tail-classifier transport)**.** *Let* $Q = (R, S, W, D, A, H, C, P, N)$ *and* $Q' = (R', S', W', D', A', H', C', P', N')$ *be accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packets. If the displayed* hsame *rows identify the* $\mathsf{RegSeqRat}^{\uparrow}$ *sources, the* $\mathsf{StreamName}^{\uparrow}$ *windows, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readbacks along the same finite route used in Definition 699.66, then the paired tail classifier is transported from* Q *to* Q' *with the same agreement row read. The transport is componentwise through* H, H' *and does not appeal to quotient stream equality, host convergence, or a choice-selected tail.*

Proof. Project both packets by the carrier definition. The transport data available to the theorem are exactly the componentwise hsame rows H, H' together with the displayed route rows C, P, N.

Apply the tail-classifier theorem for the present chapter and the regular-source transport theorem. The classifier is attached to the two $\mathsf{RegSeqRat}^{\uparrow}$ source rows as they pass through the same $\mathsf{StreamName}^{\uparrow}$ window and $\mathsf{DyadicRatCore}^{\uparrow}$ readback route.

Use window-agreement determinacy to compare the two packets after transport. Once the sources, windows, readbacks, local transports, and names agree, the public paired agreement row is fixed.

Thus the paired tail classifier moves across the same finite route as the root-window readback. Since no carrier coordinate stores quotient stream equality, host convergence, or a selected tail, there is no second transport path for the classifier. □

Theorem 699.68 (Real tail-agreement seal completion consumer scope)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet reaches the seal through the finite route consisting of the* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows, the* $\mathsf{StreamName}^{\uparrow}$ *paired windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback rows, the agreement edge* $W \to D \to A$*, the regular-tail meet and fusion surfaces, and the sibling consumer rows of chapter 38, chapter 95, and chapter 386. No such consumer reaches the seal through quotient stream equality, a selected limit, host convergence, or a choice-selected tail.*

Proof. Begin with the Real–Completion boundary and Completion handoff totality theorems. They put both Real-facing and Completion-facing reads on the displayed packet rows before any sibling consumer can use the seal.

Apply the root-window readback theorem above. It shows that the agreement row is visible only after the source, window, and dyadic readback rows have been displayed along the regular-tail route.

Now use the tail-classifier transport theorem above. The same route preserves the paired classifier under the local hsame rows, so a consumer cannot switch to an ambient stream equality or host convergence predicate while keeping the same public classifier.

The remaining consumers are exactly the named Real, Completion, and Cauchy-limit-seal siblings. They receive the finite dependency rows already displayed by the packet and add no coordinate for quotient stream equality, selected limits, host convergence, or choice-selected tails. □

Theorem 699.69 (Real tail-agreement seal root source-window admission)**.** *Every root read of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$ *first admits the displayed* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows* R, S *and the paired* $\mathsf{StreamName}^{\uparrow}$ *window row* W *before any agreement row can be consumed. The admission route is the carrier route of Definition 699.1 together with the NameCert source-separation and paired-window obligations, and it exposes no source object outside those finite rows.*

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealTerminalRoute root source window admission`

Proof. Project Q by the carrier definition. The only source coordinates visible at the root are R, S, and the only window coordinate attached to them is the displayed paired row W.

Apply the source separation obligation and the paired-window source lock. These obligations force each root read to pass through the $\mathsf{RegSeqRat}^{\uparrow}$ source rows and then the $\mathsf{StreamName}^{\uparrow}$ paired-window row before any local agreement data is available.

The root-window readback theorem then identifies this admitted window as the first leg of the public readback route. Since no additional source or window coordinate exists in the carrier, the root surface cannot expose an alternative source-window path. □

Theorem 699.70 (Real tail-agreement seal root dyadic agreement exactness)**.** *For every accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$*, the agreement row* A *is root-readable only after the displayed dyadic route* $W \to D$ *has been read. The exact route is the finite* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row* D*, and then the local agreement row* A*; it is not a quotient stream equality, host convergence predicate, or selected tail.*

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealCarrier root dyadic agreement exactness`

Proof. Begin with the root source-window admission theorem. It places the root read on the displayed paired window row W before the agreement row can be inspected.

Use the dyadic window exactness and dyadic terminal nonescape obligations. They make D the only dyadic readback attached to W and leave no second dyadic carrier for the consumer to choose.

Now apply root-window readback and tail-classifier transport. The public classifier is transported through the same $W \to D$ route, so the agreement row A is reached exactly after that finite dyadic read and not through an ambient equality or convergence principle. □

Theorem 699.71 (Real tail-agreement seal root Completion boundary)**.** *Every root-facing* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet receives only the finite rows* $R, S, W, D, A, H, C, P, N$ *and the named sibling routes through* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *regular-tail meet and fusion,* $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, *and Cauchy-limit-seal consumers. The boundary supplies no quotient stream equality, selected limit, host convergence, or choice-selected tail.*

Proof. Read the consumer through the Completion consumer scope theorem. It lists the packet rows and the named sibling consumer routes available at the Real and Completion boundary.

Combine this with root source-window admission and root dyadic agreement exactness. The source, window, dyadic readback, and agreement rows have already been exposed in the order R, S, W, D, A before any sibling consumer receives the packet.

The carrier supplies the remaining local transport, continuity, package, and NameCert rows H, C, P, N. Since neither the carrier nor the cited sibling routes contain a coordinate for quotient stream equality, selected limits, host convergence, or choice-selected tails, the root Completion boundary is exhausted by the displayed finite rows. □

Theorem 699.72 (Real tail-agreement seal root Completion-window totality)**.** *Every root Completion-facing read of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet factors through the ordered route consisting of the* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows* R, S, *the* $\mathsf{StreamName}^{\uparrow}$ *paired window row* W, *the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback row* D, *the local agreement row* A, *the regular-tail meet and fusion surfaces, and then the* $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, *and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer rows. The route is total for such root reads and supplies no quotient stream equality, selected limit, host convergence, or choice-selected tail.*

Proof. Start with root source-window admission. It places the root read first on the two displayed $\mathsf{RegSeqRat}^{\uparrow}$ source rows and then on the paired $\mathsf{StreamName}^{\uparrow}$ window row, so the consumer has no source-window route outside R, S, W.

Next use root dyadic agreement exactness. The admitted window is read back through the displayed $\mathsf{DyadicRatCore}^{\uparrow}$ row D, and the local agreement row A is available only after that finite $W \to D$ leg.

Now apply the Completion handoff totality theorem. It sends every Completion-facing consumer from the local agreement surface through the regular-tail meet and fusion route and then to the named Completion-side consumer rows.

Finally combine the root Completion boundary with the Completion consumer scope theorem. These two boundary statements identify the remaining visible endpoints as the $\mathsf{Real}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer rows already named by the chapter. Since each step consumes only displayed rows of the packet or named sibling surfaces, no quotient stream equality, selected limit, host convergence, or choice-selected tail can enter the root Completion-facing read. □

Theorem 699.73 (Real tail-agreement seal root budget-selector admission)**.** *Let $Q = (R, S, W, D, A, H, C, P, N)$ be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet. Every root-facing accepted read of Q that is consumed by a* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *endpoint first reads the finite* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *limiter row, the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *tail-budget row, and the* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *selector-budget row before the local agreement edge*

$$W \to D \to A$$

is public. Hence the root admission route is one finite L10 route through the limiter, tail-budget, selector-budget, paired window, dyadic readback, and agreement rows, and not an uncapped observation request or a choice-selected tail.

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealCarrier root budget selector admission`

Proof. Project the accepted carrier Q. The local agreement row A is attached to the displayed paired window row W and dyadic readback row D, while the structural rows H, C, P, N carry only transport, displayed continuations, provenance, and the local naming certificate.

Use the budget-source window service and the shared-threshold budget exactness rows. They place the root read behind the $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ and $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ services before any paired window row can be exposed.

Now use Definition 699.59. A root consumer that also uses the finite selector route must pass through the $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ selector-budget surface before the local windows can be consumed.

Finally apply the window-route exact companion. After the three budget rows have admitted the finite window, the only public agreement path is $W \to D \to A$, so the route has no coordinate for an uncapped request, quotient stream, selected limit, host convergence row, or choice-selected tail. □

Theorem 699.74 (Real tail-agreement seal root budget shared-threshold factorization)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet $Q = (R, S, W, D, A, H, C, P, N)$, the shared-threshold row used by any root-facing* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer factors through the finite route*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to \mathsf{RegularCauchySelectorBudg}$$

The $\mathsf{StreamName}^{\uparrow}$ *step is the displayed paired window row W, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *step is the readback row D, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *step is the agreement readback consumed by A.*

Proof. Begin with root budget-selector admission. It supplies the limiter, tail-budget, and selector-budget entrance before the local agreement edge can be read.

Next read the shared threshold through the tail-meet factorization. The $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ row is the only shared threshold available to the local paired-window service, and it is reached after the limiter and tail-budget rows have fixed the finite request.

The window-meet coverage and dyadic readback exactness rows identify the middle of the route. The shared threshold opens the displayed $\mathsf{StreamName}^{\uparrow}$ window W, the window is read back through the $\mathsf{DyadicRatCore}^{\uparrow}$ row D, and the regular rational agreement read is recorded by the local row A.

Use the Real–Completion selector chain to bind the selector-budget row to the same route. Since the accepted carrier has no second threshold, second selector, quotient stream, host convergence predicate, or selected limit coordinate, the displayed L10 route is the complete factorization of the shared-threshold row. □

Theorem 699.75 (Real tail-agreement seal root budget Completion-consumer exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer admitted by the root budget-selector route of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet receives only*

$$R, S, W, D, A, H, C, P, N$$

together with the named sibling routes through $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{RegularCauchyTailBudget}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$, $\mathsf{RegularCauchyTailFusion}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *It receives no quotient stream, selected limit, host convergence row, choice-selected tail, hidden completion selector, or second agreement surface.*

Proof. Start from the shared-threshold factorization above. It binds the limiter, tail-budget, tail-meet, selector-budget, window, dyadic readback, regular agreement readback, and local agreement row into one finite root route.

Now apply the root Completion boundary and the Real–Completion selector chain. They put both Real-facing and Completion-facing endpoints on the same displayed local carrier rows after the sibling budget and selector surfaces have been read.

It remains to account for the named downstream consumers. The tail-fusion and $\mathsf{CauchyLimitSeal}^{\uparrow}$ routes consume the same finite agreement surface, and the $\mathsf{Real}^{\uparrow}$ endpoint receives the same local seal row reached through $W \to D \to A$.

The carrier rows are exhausted by $R, S, W, D, A, H, C, P, N$, with H, C, P, N serving only transport, displayed continuation, provenance, and naming roles. Since neither the carrier nor the named sibling routes add a quotient stream, selected limit, host convergence row, choice-selected tail, hidden completion selector, or second agreement row, every admitted consumer remains inside the stated boundary. □

Theorem 699.76 (Real tail-agreement seal selector shared-threshold exactness)**.** *Let* $Q = (R, S, W, D, A, H, C, P, N$ *be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet. Any root-facing* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer that first passes through the budget-selector admission route and then asks for the shared-threshold row factors through the same finite chain*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to \mathsf{RegularCauchySelectorBudge}$$

The selector-budget row and the shared-threshold row are therefore not two independent admissions: they are the same displayed L10 route through the limiter, tail-budget, tail-meet, selector-budget, paired-window, dyadic-readback, regular-rational readback, and local agreement rows of Q.

Proof. Start with Definition 699.73. It fixes the root-facing consumer behind the $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{RegularCauchyTailBudget}^{\uparrow}$, and $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ rows before the local agreement edge $W \to D \to A$ is public.

Next apply Definition 699.74. The requested shared-threshold row is not an extra coordinate of Q; it is the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ step in the same finite route, after the limiter and tail-budget rows and before the selector-budget, window, dyadic readback, regular-rational readback, and agreement rows.

Finally use Definition 699.75. Completion-facing consumption has no quotient stream, selected limit, host convergence row, choice-selected tail, hidden completion selector, or second agreement surface from which a different threshold could be read.

Combining these three local results gives exactness of the route: any consumer admitted by the selector budget and then reading the shared threshold must traverse the displayed chain above, and every row in that chain is one of the finite L10 carrier or named sibling rows already exposed by the accepted packet. □

Theorem 699.77 (Real tail-agreement seal root budget selector cross-sibling lock)**.** *Let* $Q = (R, S, W, D, A, H, C, P, N)$ *be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet. Any root-facing* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer admitted by the selector-budget route and any consumer reading the shared-threshold row traverse the same finite L10 chain*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to \mathsf{RegularCauchySelectorBudg}$$

Thus selector admission and shared-threshold exactness are one route of Q*: no second selector, second threshold, quotient stream, selected limit, host convergence row, or choice-selected tail can be inserted between the root read and the local agreement row.*

Proof. Apply Definition 699.73. It places every admitted root-facing $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer behind the limiter, tail-budget, and selector-budget rows before $W \to D \to A$ is exposed.

Next use Definition 699.74. The shared threshold is the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ row in that finite chain, not a sibling coordinate parallel to the selector-budget row.

Apply Definition 699.75 to the consumer side. The accepted packet has no coordinate for a quotient stream, selected limit, host convergence row, choice-selected tail, hidden completion selector, or second agreement surface.

Finally invoke Definition 699.76. Coordinate exhaustion of $Q = (R, S, W, D, A, H, C, P, N)$ identifies the selector-admission consumer and the shared-threshold consumer with the same displayed L10 chain, so the two sibling rows are locked to a single finite route. □

Theorem 699.78 (Real tail-agreement seal root selector tail-fusion lock)**.** *Let* $Q = (R, S, W, D, A, H, C, P, N)$ *be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet admitted by the root budget-selector route. Every downstream* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer of that admitted packet factors through the same finite chain*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to \mathsf{RegularCauchySelectorBudg}$$

No such consumer may replace this route by a quotient stream, selected limit, host convergence row, choice-selected tail, or second agreement surface.

Proof. Apply the root budget-selector admission theorem. It places the accepted read behind the limiter, tail-budget, and selector-budget rows before the local agreement edge $W \to D \to A$ is public.

Use the shared-threshold factorization and selector shared-threshold exactness. They identify the shared-threshold request with the same finite chain through the tail-meet, selector-budget, window, dyadic readback, regular-rational readback, and local agreement rows.

Now apply completion-consumer exhaustion. The only downstream routes available to completion-facing consumers are the named $\mathsf{RegularCauchyTailFusion}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ routes over the same carrier rows $R, S, W, D, A, H, C, P, N$.

The Cauchy-limit seal root handoff and the $\mathsf{Real}^{\uparrow}$ consumer rows are therefore only downstream names for consumption of this finite route. They contribute no quotient stream, selected limit, host convergence row, choice-selected tail, or second agreement surface, so tail-fusion and limit-seal consumers remain locked to the selector route. □

Theorem 699.79 (Real tail-agreement seal root selector completion lattice)**.** *Let* $Q = (R, S, W, D, A, H, C, P, N)$ *be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet admitted by the root budget-selector route. Any root-facing* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of* Q *factors through the finite completion lattice*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to \mathsf{RegularCauchySelectorBudg}$$

before the completion endpoint is public. The $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *step is the local packet row* A *together with the NameCert row* N*, and the final two steps are downstream consumers of that same finite agreement surface.*

Proof. Begin with Definition 699.73. It places every root-facing consumer behind the limiter, tail-budget, and selector-budget rows before $W \to D \to A$ is exposed.

Use Definition 699.74. The shared threshold supplies the $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ step and identifies the middle of the route with the displayed $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{DyadicRatCore}^{\uparrow}$ readback, and the $\mathsf{RegSeqRat}^{\uparrow}$ agreement readback.

Apply Definition 699.76 and Definition 699.77. They bind selector admission and shared-threshold consumption to the same finite chain, so there is no second selector or second threshold between the root read and the agreement row.

Finally use Definition 699.75 and Definition 699.78. The downstream $\mathsf{RegularCauchyTailFusion}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consumers are only names for consuming the same local seal certified by N, hence the completion endpoint is reached through the displayed lattice and not through an ambient completion principle. □

Theorem 699.80 (Real tail-agreement seal root selector window non-escape)**.** *For an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet* $Q = (R, S, W, D, A, H, C, P, N)$ *admitted by the root budget-selector route, every window exposed to a root-facing* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer is the displayed finite window* W *read back through* D *and certified by* A *and* N*. Along the completion-lattice route there is no quotient stream, selected limit, host convergence row, choice-selected tail, hidden completion selector, or second agreement surface.*

Proof. The admission theorem first fixes the root request behind the limiter, tail-budget, and selector-budget rows. Thus the only window made public before agreement is the displayed paired window W.

The shared-threshold factorization and selector shared-threshold exactness then force any threshold read through the same tail-meet, selector-budget, window, dyadic-readback, and agreement rows. This eliminates any alternate threshold from which a second window could be read.

Use completion-consumer exhaustion to inspect the carrier coordinates. The packet exposes only $R, S, W, D, A, H, C, P, N$ together with named sibling routes, and H, C, P, N provide transport, displayed continuation, provenance, and NameCert data rather than a second analytic surface.

The cross-sibling lock and tail-fusion lock carry that coordinate exhaustion to downstream consumers. Since $\mathsf{RegularCauchyTailFusion}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consume the same finite route, none of the forbidden escape surfaces can be inserted along the root selector window path. □

Theorem 699.81 (Real tail-agreement seal root selector consumer totality)**.** *Let* $Q = (R, S, W, D, A, H, C, P, N)$ *be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet admitted by the root budget-selector route. Every root-facing consumer whose endpoint is* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$*, including the downstream* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *consumers, is accounted for by the completion-lattice factorization and the window non-escape boundary. Consequently the root selector surface is total for this finite NameCert route: each admitted consumer reaches the endpoint through the displayed L10 chain and no admitted consumer remains outside it.*

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealCarrier root selector consumer totality`

Proof. First assemble the entry route. Apply Definition 699.73, Definition 699.74, and Definition 699.76 to put each admitted consumer on the limiter, tail-budget, tail-meet, selector-budget, window, dyadic-readback, and agreement chain.

Next lock the sibling surfaces. Use Definition 699.75, Definition 699.77, and Definition 699.78; together they say that all named completion-facing consumers use the same finite carrier rows and the same downstream tail-fusion, limit-seal, and real endpoints.

Now apply Definition 699.79. It presents those local and sibling rows as one completion-lattice route ending at the public $\mathsf{Real}^{\uparrow}$ endpoint.

Finally apply Definition 699.80. Since no quotient stream, selected limit, host convergence row, choice-selected tail, hidden completion selector, or second agreement surface is available, there is no remaining root-facing consumer outside the finite NameCert route. □

Theorem 699.82 (Real tail-agreement seal root selector ProbeBundle budget coverage)**.** *Let $Q = (R, S, W, D, A, H, C, P, N)$ be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet admitted by the root budget-selector route. Every finite* ProbeBundle *of root-facing* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{Completion}^{\uparrow}$ *requests for Q is covered by the same completion-lattice chain*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to \mathsf{RegularCauchySelectorBudg}$$

The bundle therefore consumes one finite budget surface: the displayed limiter, tail-budget, tail-meet, selector-budget, stream window, dyadic readback, rational-sequence readback, agreement row, limit-seal row, and public real endpoint.

Lean4 ✓ `BEDC.Derived.RealTailAgreementSealUp.RealTailAgreementSealCarrier root selector probe bundle budget coverage`

Proof. Inspect the finite ProbeBundle one request at a time. For each member, Definition 699.73 places the root read behind the limiter, tail-budget, selector-budget, window, dyadic readback, and agreement rows of Q.

Next apply Definition 699.74. The shared threshold is common to all bundle members, so the tail-meet and selector-budget rows are not duplicated when the finite bundle is traversed.

For the completion-facing members, use Definition 699.75 and Definition 699.79. They identify each $\mathsf{Completion}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ read with the same displayed route through A and N.

Finally apply Definition 699.80. Since no quotient stream, selected limit, host convergence row, choice-selected tail, hidden completion selector, or second agreement surface can be inserted, pointwise coverage over the finite bundle repacks into one finite ProbeBundle coverage row. □

Theorem 699.83 (Real tail-agreement seal root selector endpoint determinacy)**.** *Let $Q = (R, S, W, D, A, H, C, P, N$ and $Q' = (R', S', W', D', A', H', C', P', N')$ be admitted root-selector consumers for* $\mathsf{RealTailAgreementSeal}^{\uparrow}$*. If their displayed limiter, tail-budget, tail-meet, selector-budget, stream window, dyadic readback, and agreement rows coincide, then they reach the same public endpoint route. In particular, the route cannot split into a second selector, second threshold, quotient stream, selected limit, or host convergence row.*

Proof. Begin with the shared displayed rows. The admission theorem and shared-threshold factorization force both consumers through the same limiter, tail-budget, tail-meet, selector-budget, stream window, dyadic readback, and agreement rows before any completion endpoint is visible.

Apply Definition 699.77. It prevents sibling consumers from reusing the displayed agreement row while changing the selector, threshold, or local seal surface.

Next use Definition 699.78. The downstream tail-fusion, limit-seal, and real endpoint reads are determined by the same agreement row and NameCert packet, so the endpoint route is not an independent choice.

Finally combine Definition 699.79 with Definition 699.81. Every admitted consumer is already exhausted by the displayed completion lattice, and the matching displayed rows leave no coordinate where a quotient stream, selected limit, or host convergence row could separate the two endpoint routes. □

Theorem 699.84 (Real tail-agreement seal root selector bundle endpoint exactness)**.** *Let $Q = (R, S, W, D, A, H, C, P, N)$ be an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet admitted by the root selector route. Any finite* $\mathsf{ProbeBundle}$ *of root-facing* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{Completion}^{\uparrow}$ *requests whose members preserve the displayed limiter, tail-budget, tail-meet, selector-budget,* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, agreement row, and local* $\mathsf{NameCert}$ *row determines exactly one public endpoint route*

$$\mathsf{ObservationBudgetLimiter}^{\uparrow} \to \mathsf{RegularCauchyTailBudget}^{\uparrow} \to \mathsf{RegularCauchyTailMeet}^{\uparrow} \to \mathsf{RegularCauchySelectorBudg}$$

Thus bundle coverage and endpoint determinacy are the same finite public route for Q, with no second selector, second threshold, quotient stream, selected limit, host convergence row, choice-selected tail, or independent completion endpoint.

Proof. Start with $\mathsf{ProbeBundle}$ budget coverage. Theorem 699.82 places each member of the finite bundle on the displayed completion-lattice chain, and it identifies the consumed rows as the limiter, tail-budget, tail-meet, selector-budget, stream window, dyadic readback, rational-sequence readback, agreement row, limit-seal row, and public real endpoint.

Next use completion-lattice exactness and window non-escape. Theorem 699.79 fixes the order of the rows through $\mathsf{RealTailAgreementSeal}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, while Definition 699.80 prevents any bundle member from leaving the displayed window and readback rows.

Now apply consumer totality. Theorem 699.81 accounts for every root-facing $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ request in the finite bundle, including the downstream tail-fusion, limit-seal, and real consumers.

Finally apply endpoint determinacy. Since the bundle members preserve the displayed budget, window, readback, agreement, and local naming rows, Definition 699.83 leaves only one public endpoint route. The excluded selector, threshold, quotient, limit, host-convergence, and choice-tail surfaces are not coordinates of the accepted packet, so the finite bundle determines the single route displayed above. □

Theorem 699.85 (Real tail-agreement seal limiter-budget factorization)**.** *Every paired tail-agreement read of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet $Q = (R, S, W, D, A, H, C, P, N)$ factors first through the finite limiter rows of chapter 903 and the regular tail-budget rows of chapter 906. Only after those two budget services expose the shared threshold may the local route read the displayed* $\mathsf{StreamName}^{\uparrow}$ *window of chapter 126, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback of chapter 291, and the agreement edge $W \to D \to A$.*

Proof. Start with the carrier of Definition 699.1. Its only agreement channel is the displayed row A, and that row is attached to the paired window row W and dyadic readback row D.

Apply Definition 699.63. It sends every Real- or Completion-facing agreement read through the shared finite tail request and the sibling budget route before W and D are consumed.

Finally apply Definition 699.65. The Completion endpoint reads only the route already exposed by the limiter and tail-budget services, so the local packet contributes the finite handoff $W \to D \to A$ and no unbounded observation request. □

Theorem 699.86 (Real tail-agreement seal shared budget route)**.** *Every accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *read of the agreement row A factors through the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *route of chapter 906 and the* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *route of chapter 903 before the local consumer can inspect the finite chain $W \to D \to A$. The displayed packet rows are therefore the only route by which the Real and Completion siblings receive a tail-agreement seal.*

Proof. Apply the budget source lock of Definition 699.10. It places the accepted seal read on the finite regular-tail budget source before the paired window service can be consumed.

Next apply the shared-tail budget extraction theorem Definition 699.63. The extracted request is the same request that feeds the local paired window row W and dyadic readback row D.

Finally use the Completion handoff totality row of Definition 699.65. The handoff reaches Real and Completion siblings only after the budgeted route has exposed $W \to D \to A$, so no unbudgeted seal read remains. □

Theorem 699.87 (Real tail-agreement seal paired-threshold coverage)**.** *For every accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet $Q = (R, S, W, D, A, H, C, P, N)$, the paired* $\mathsf{StreamName}^{\uparrow}$ *windows and* $\mathsf{DyadicRatCore}^{\uparrow}$ *readbacks are covered by one shared threshold route before the agreement row A is visible. The route first displays the shared budget request, then the paired window row W, then the dyadic readback row D, and only then the local agreement edge $W \to D \to A$.*

Proof. Begin with the shared budget route theorem above. It puts every accepted agreement read behind the regular-tail budget and observation limiter before the packet can expose W.

Use the shared-tail budget extraction theorem again. It identifies the sibling tail-meet threshold as the single finite threshold route used by the paired windows and by the dyadic readbacks.

Now apply the Completion handoff totality theorem. Since the Completion-facing endpoint reads the same displayed $W \to D \to A$ chain, visibility of A is delayed until both the paired windows and dyadic readbacks have been covered by the shared threshold. □

Theorem 699.88 (Real tail-agreement seal Completion-consumer boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet receives only the displayed rows $R, S, W, D, A, H, C, P, N$ together with the named sibling budget, tail-meet,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *surfaces. The boundary supplies no quotient stream, selected limit, host convergence, or choice-selected tail to the consumer.*

Proof. Start from the paired-threshold coverage theorem above. It shows that the public agreement edge has already passed through the shared budget route, the paired windows, and the dyadic readbacks before a Real or Completion sibling can consume the packet.

Apply Definition 699.65. This gives the total handoff from the local packet to the sibling Completion-facing routes without adding a selected limit or host convergence predicate.

Finally apply Definition 699.68. The consumer scope lists the displayed rows and named sibling surfaces available to Real and Completion consumers; since that list has no quotient stream, selected limit, host convergence, or choice-selected tail coordinate, the boundary is exhausted by those rows. □

Theorem 699.89 (Real tail-agreement seal regular-source transport)**.** *Let $Q = (R, S, W, D, A, H, C, P, N)$ and $Q' = (R', S', W', D', A', H', C', P', N')$ be accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packets. If the componentwise* hsame *rows in H, H' identify the two* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows through chapter 301, the displayed* $\mathsf{StreamName}^{\uparrow}$ *window rows through chapter 126, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *readback rows through chapter 291, then the two regular sources are transported together to the same displayed paired-window agreement row.*

Proof. Project the two carriers from Definition 699.1. The source rows R, S and R', S' are not ambient streams; they are the displayed regular-rational source entries consumed by the window and readback rows.

Use Definition 699.63 to put both packets on the same finite tail-budget surface. The componentwise hsame rows then carry the two $\mathsf{RegSeqRat}^{\uparrow}$ sources through the same $\mathsf{StreamName}^{\uparrow}$ window and $\mathsf{DyadicRatCore}^{\uparrow}$ readback rows.

Apply Definition 699.64. Once the source transport, shared budget, windows, readbacks, local transports, and naming rows agree, the public agreement row is determined; no separate quotient-stream equality or Completion equality row is available. □

Theorem 699.90 (Real tail-agreement seal Real handoff exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing consumer of an accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *packet receives only the finite route*

$$R, S, W, D, A, H, C, P, N.$$

The route is reached after the limiter-budget factorization and regular-source transport rows above, and it is the only handoff made available to the Real and Completion sibling surfaces of chapter 38 and chapter 95. It exports no quotient stream equality, selected limit, host convergence predicate, or choice-selected tail.

Proof. Begin with the carrier of Definition 699.1. It lists exactly the regular source rows, paired window, dyadic readback, agreement row, transports, routes, provenance, and local naming row that a Real-facing consumer can inspect.

Apply Definition 699.85. This puts the agreement read behind the observation limiter and regular tail-budget services before the local route $W \to D \to A$ is available.

Next apply Definition 699.89. The source rows are preserved through the displayed StreamName window and DyadicRatCore readback rows, so the Real-facing consumer cannot replace them by a quotient stream or selected tail.

Finally apply Definition 699.65. The same finite packet is the boundary seen by Completion-facing consumers, and the Real-facing handoff has no extra carrier coordinate for a selected limit or host convergence predicate. □
