3. *S is the observer-symmetry witness, stating that the coupling ledger is not oriented by a privileged observer, global frame, synchronized clock, or subject-substance coordinate;*
4. *T stores componentwise* hsame *transport for the two* BHist *rows and displayed* psame *transport for the probe and signature rows used by the coupling ledger;*
5. *C records the displayed* Cont *routes by which a consumer reads H_0, reads H_1, checks J, replays S, and transports the same coupling packet through T;*
6. *P is the* Pkg *provenance over* $\mathsf{MultiHistCoupling}^{\uparrow}$, $\mathsf{ObserverSubjectBoundary}^{\uparrow}$, $\mathsf{ObserverHistIdentity}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{InterHistInvariant}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, BHist, hsame, psame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{MultiHistCoupling}^{\uparrow}}$ *row.*

The carrier exports no global observer frame, no host equality of histories, no quotient of history pairs, no subject-substance coordinate, and no causal-dependence row outside the displayed coupling ledger.

Lean4 ✓ BEDC.Derived.MultihistCouplingUp.TasteGate.MultihistCouplingTasteGate single carrier alignment

Theorem 895.2 (MultiHistCoupling NameCert obligations)**.** *For the carrier of Definition 895.1, the local* $\mathsf{NameCert}_{\mathsf{MultiHistCoupling}^{\uparrow}}$ *surface consists exactly of five finite obligations:*

1. *carrier admission for the displayed packet* $K = (H_0, H_1, J, S, T, C, P, N)$*;*
2. *paired-history source exactness, requiring* H_0 *and* H_1 *to be read from the displayed* $\mathrm{MultiHistConfig}^{\uparrow}$ *row after the no-subject boundary and observer-history identity surfaces are available;*
3. *symmetric coupling ledger exactness, requiring* J *and* S *to expose both coupling directions without privileging either observer history;*
4. *transport stability through componentwise* hsame*, displayed* psame*, and replay of the listed* Cont *routes in* T, C*;*
5. *non-escape, excluding global frames, synchronized clocks, host history equality, quotient pairs, subject-substance rows, and any causal-dependence read not routed through* $H_0, H_1, J, S, T, C, P, N$*.*

Proof. Carrier admission is projection from Definition 895.1. The tuple lists the paired histories, coupling ledger, symmetry witness, transports, continuation routes, provenance, and local name.

The source rows are consumed from the sibling surfaces. The no-subject boundary of chapter 615 prevents a hidden observer-substance coordinate, chapter 479 supplies the observer-history identity read, and chapter 474 supplies the common finite multi-history configuration.

The ledger rows J and S then make the coupling symmetric. They record both directed reads as one packet and refuse any global-frame or privileged-observer orientation.

Finally T, C, P, N replay, transport, package, and name the same finite rows. Since the carrier contains no coordinate for a host equality, quotient pair, subject-substance row, or external causal predicate, the five obligations exhaust the local certificate surface. □

Theorem 895.3 (MultiHistCoupling invariant handoff)**.** *Every accepted* $\mathsf{MultiHistCoupling}^{\uparrow}$ *carrier*

$$K = (H_0, H_1, J, S, T, C, P, N)$$

hands an $\mathsf{InterHistInvariant}^{\uparrow}$ *or* $\mathsf{CrossHistCausal}^{\uparrow}$ *consumer exactly the paired-history rows, symmetric coupling ledger, observer-symmetry witness,* hsame *and* psame *transports, displayed* Cont *routes, package provenance, and local naming row. The consumer receives no global frame, no host equality of histories, no quotient pair, and no causal-dependence coordinate outside the displayed coupling packet.*

Proof. Project the accepted carrier to its displayed tuple. The only history rows available to the consumer are H_0 and H_1, and the only coupling row available between them is J with the symmetry witness S.

Apply the local NameCert obligations of Definition 895.2. Paired-history source exactness fixes the upstream configuration and observer-boundary reads, while symmetric coupling ledger exactness fixes the two directed reads as one finite coupling surface.

The invariant consumer of chapter 656 may therefore read the paired histories through J, S, T, C, P, N. A $\mathsf{CrossHistCausal}^{\uparrow}$ consumer may use that same finite route as its input surface, but any additional causal-dependence row must be displayed by the downstream causal packet rather than projected from this carrier. □

Theorem 895.4 (MultiHistCoupling TasteGate obligation)**.** *The later Lean* `Derived/MultiHistCouplingUp/Tas` *development must provide explicit* Nontrivial MultiHistCoupling$^{\uparrow}$ *and* FieldFaithful MultiHistCoupling$^{\uparrow}$ *instances. These instances must preserve the two paired* BHist *rows, symmetric coupling ledger, observer-symmetry witness,* hsame *and* psame *transports, displayed* Cont *routes, package provenance, and local naming row.*

Proof. The packet is not determined by either single history alone. It contains two history rows and a separate symmetric coupling ledger between them.

Nontriviality prevents collapse of H_0, H_1, and J into one indistinguishable row. Field faithfulness is the projection discipline for $K = (H_0, H_1, J, S, T, C, P, N)$, preserving each displayed coordinate and keeping the coupling ledger distinct from the sibling no-subject, identity, configuration, invariant, and causal-dependence surfaces. □

Falsifiable prediction: If the coupling row is omitted, no CrossHistCausalUp consumer can read the paired histories through a symmetric finite route.

Independence witness: observerhistidentity, observersubjectboundary, multihistconfig, interhistinvariant, crosshistcausal: MultiHistCouplingUp is not bijective to any of them because it contains both paired-history rows and a symmetric coupling ledger; each sibling lacks either the paired coupling row, the no-subject boundary, the invariant output row, or the causal-dependence row.

Closure status for NameCert$_{\text{MultiHistCoupling}^{\uparrow}}$**.**

Constructive story: A MultiHistCoupling$^{\uparrow}$ packet is generated from two paired BHist rows, a symmetric coupling ledger, an observer-symmetry witness, componentwise hsame and displayed psame transports, Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{MultiHistCoupling}^{\uparrow}}$, seed)

Scope closed: Definition 895.1, Definition 895.2, Definition 895.3, and Definition 895.4 specify the finite paired-history coupling packet, its NameCert obligations, downstream handoff, and TasteGate instance surface.

Formal verification: FormalStatus(NameCert$_{\text{MultiHistCoupling}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.MultihistCouplingUp.TasteGate.MultihistCouplingTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close CrossHistCausalUp dependence, MaxCausalRateUp bounds, Lorentz geometry, global frames, quotient history equality, or bridge checking for MultiHistCoupling$^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, paired-history source exactness, symmetric coupling exactness, transport stability, non-escape, and TasteGate nontriviality with field faithfulness.

Chapter 896

A Concrete Naming Certificate for $\mathsf{DiagonalLimitBudget}^{\uparrow}$

The $\mathsf{DiagonalLimitBudget}^{\uparrow}$ packet is the finite budget carrier between the diagonal selector of chapter 673 and the RealUp seal route synchronized in chapter 886. It isolates the modulus, selected window, dyadic-tolerance ledger, and seal handoff that the Real completeness diagonal route consumes before any completed real value is read. The observation envelope of chapter 637 supplies the sibling finite readback surface; this chapter records the budget packet that keeps that readback tied to the diagonal index request.

Falsifiable prediction: A packet with the same RealUp seal row but no displayed modulus budget row is not an accepted DiagonalLimitBudgetUp carrier.

Independence witness: LimitSelectorUp selects the diagonal row but lacks the seal budget; CauchySealBudgetSynchronizerUp synchronizes selector and seal rows but lacks the isolated budget carrier; RealApproximationEnvelopeUp packages observation envelopes but not the diagonal modulus budget; DiagonalLimitCompatibilityUp compares limits but does not provide the budget packet.

Definition 896.1 (DiagonalLimitBudget carrier)**.** *A* $\mathsf{DiagonalLimitBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (D, M, W, Q, E, H, C, P, N)$$

with the following displayed rows:

1. *D is the diagonal index request read from the Real completeness diagonal representative of Definition 9238.3;*
2. *M is the modulus budget row displaying the precision request and the selected modulus value used to answer D;*
3. *W is the selected* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}$ *window row chosen by the diagonal selector for that modulus budget;*
4. *Q is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance and readback ledger attached to the selected window;*
5. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row reached by the same diagonal route;*
6. *H stores componentwise* hsame *transports for D, M, W, Q, E, C, P, N;*
7. *C stores the* Cont *routes replaying the index request, budget row, selected window, dyadic ledger, seal row, provenance, and local naming row;*

8. *P is the* Pkg *provenance over* $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RealApproximationEnvelope}^{\uparrow}$, $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitBudget}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient streams, host real equality, countable choice, a host-selected limit, or ambient completeness.

Lean4 (definition) `BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetUp`

Theorem 896.2 (DiagonalLimitBudget non-escape)**.** *Every accepted* $\mathsf{DiagonalLimitBudget}^{\uparrow}$ *packet read by a diagonal-limit or* $\mathsf{Real}^{\uparrow}$ *consumer factors through the displayed modulus budget row M before it reaches the selected window W, dyadic ledger Q, or seal row E. A consumer that reads E without exposing D, M, W, Q, H, C, P, N is not reading the accepted budget carrier.*

Lean4 ✓ `BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetNonescape`

Proof. Project the carrier of Definition 896.1. The only route to the seal coordinate is the displayed tuple $B = (D, M, W, Q, E, H, C, P, N)$, and the budget row M is the only row that records the modulus value consumed by the diagonal request.

The transport rows H and replay routes C preserve the same coordinates. They can pass the selected window and dyadic ledger to a consumer, but they do not create a second modulus row, a second seal, or an external limit witness.

Thus any accepted seal read must expose the carrier rows in order: request, budget, window, dyadic readback, seal, transport, route, provenance, and local name. Since the excluded objects have no coordinate in B, they cannot be recovered from an accepted packet. □

Theorem 896.3 (DiagonalLimitBudget seal handoff)**.** *For an accepted* $\mathsf{DiagonalLimitBudget}^{\uparrow}$ *carrier $B = (D, M, W, Q, E, H, C, P, N)$, the* $\mathsf{Real}^{\uparrow}$ *seal row E is handed to the synchronizer route only together with the same modulus budget M, selected window W, dyadic ledger Q, and structural rows H, C, P, N. The handoff supplies a budgeted seal route, not an isolated RealUp seal.*

Lean4 ✓ `BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetSealHandoff`

Proof. Read the budget carrier and the synchronizer sibling together. The synchronizer of chapter 886 accepts a seal route only when a displayed budget row is available for the same request.

The $\mathsf{DiagonalLimitBudget}^{\uparrow}$ carrier provides exactly such a row: M is tied to the request D, and W and Q record the finite window and dyadic readback selected for that budget. The seal coordinate E is therefore exported only through the same packet.

The package row P and continuation row C replay the sibling dependencies on $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RealApproximationEnvelope}^{\uparrow}$, and $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$. No coordinate supplies an isolated seal, host-selected limit, quotient stream, or ambient completeness route. □

Theorem 896.4 (DiagonalLimitBudget obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitBudget}^{\uparrow}}$ *surface consists exactly of carrier admission for B, diagonal request exposure through D, modulus-budget exposure through M, selected* $\mathsf{StreamName}^{\uparrow}$ *and* RegSeqRat *window exposure through W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance and readback exposure through Q,* $\mathsf{Real}^{\uparrow}$ *seal exposure through E, componentwise* hsame *classifier transport through H, displayed* Cont *classifier replay through C,* Pkg *provenance through P, and local naming through N. The same displayed D, M request determines the same W, Q readback surface, and the seal row E is readable only along the displayed M, W, Q budget route.*

Lean4 ✓ BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetObligationSurface

Proof. Carrier admission is projection from the displayed tuple. The request, budget, selected window, dyadic ledger, seal, transport, continuation, provenance, and naming rows are all explicit coordinates.

The selector-facing side is exhausted by D, M, W: the request asks for a diagonal index, the budget row records the modulus value, and the selected window names the finite $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}$ read. The observation-facing side is exhausted by Q, E: the dyadic ledger records the tolerance and readback, and the seal row records the RealUp endpoint reached by that ledger.

Classifier transport is carried by the structural rows. The componentwise hsame row H transports the displayed coordinates D, M, W, Q, E, C, P, N, while the Cont row C replays the index request, budget row, selected window, dyadic ledger, seal row, provenance, and local naming row. Thus the classifier visible to a consumer is the classifier of the displayed packet, not a hidden external classifier.

Selected-window determinacy is the finite readback part of the same projection. Since W and Q are coordinates of B attached to the displayed request and budget rows, two accepted reads of the same D, M surface in this packet expose the same selected-window and dyadic-readback rows. By Definition 896.2, there is no second modulus row, second selected window, or external limit witness from which a different W, Q readback could be recovered.

Seal-budget exactness follows from the seal handoff. By Definition 896.3, the seal row E is exported only together with the same M, W, Q, H, C, P, N rows. Therefore E is readable precisely as the displayed budgeted seal route, and the obligation surface contains no hidden classifier, no quotient stream equality, no host real equality, and no ambient completeness premise. □

Theorem 896.5 (DiagonalLimitBudget independence witness)**.** *The* $\mathsf{DiagonalLimitBudget}^{\uparrow}$ *carrier is not reducible to any one sibling route among* $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$, $\mathsf{RealApproximationEnvelope}^{\uparrow}$, *or* $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$. *Its distinguishing data is the simultaneous presence of the diagonal request* D*, modulus budget* M*, selected window* W*, dyadic-tolerance ledger* Q*, RealUp seal* E*, and structural rows* H, C, P, N *in one finite packet.*

Lean4 ✓ BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetIndependenceWitness

Proof. Compare the sibling carriers by their displayed rows. The limit selector exposes the diagonal selection route, but it does not isolate the modulus budget as the budget object consumed by the seal handoff.

The synchronizer exposes the joint seal route, but it treats the budget row as an input from another packet. The approximation envelope exposes the finite observation ledger, but it does not bind that ledger to the diagonal modulus budget. The compatibility packet compares limit routes, but it does not supply the budget carrier consumed before comparison.

The packet $B = (D, M, W, Q, E, H, C, P, N)$ displays all of these rows together. Removing M loses the finite budget, removing Q loses the dyadic-tolerance ledger, removing E loses the seal handoff, and removing H, C, P, N loses transport, replay, provenance, and local naming. □

Theorem 896.6 (DiagonalLimitBudget TasteGate readiness)**.** *The Lean TasteGate module for* $\mathsf{DiagonalLimitBudget}^{\uparrow}$ *must include explicit* $\mathsf{Nontrivial\ DiagonalLimitBudget}^{\uparrow}$ *and* $\mathsf{FieldFaithful\ DiagonalLimitBudget}^{\uparrow}$ *instances. Nontriviality separates the modulus budget row from the seal row, and field faithfulness preserves the displayed rows* $D, M, W, Q, E, H, C, P, N$ *for every TasteGate-facing consumer.*

Lean4 ✓ BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetTasteGateReadiness
↪ variant BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetTasteGate single carrier alignment

Proof. The carrier has two distinct analytic roles: M records the finite modulus budget and E records the RealUp seal reached after the budgeted route. A collapsed packet that identifies these roles would admit the seal without the displayed budget row, contradicting Definition 896.2.

Field faithfulness is the row-preservation condition needed by the same surface. A TasteGate-facing consumer may inspect the request, budget, selected window, dyadic ledger, seal, transport, route, provenance, and local naming rows, but no unlisted analytic or host-side object. □

Theorem 896.7 (DiagonalLimitBudget carrier admission)**.** *An accepted* $\mathsf{DiagonalLimitBudget}^{\uparrow}$ *carrier is admitted exactly as the finite* BHist *packet* $B = (D, M, W, Q, E, H, C, P, N)$ *whose local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitBudget}^{\uparrow}}$ *row* N *reads the diagonal request* D*, modulus budget* M*, selected window* W*, dyadic tolerance ledger* Q*,* $\mathsf{Real}^{\uparrow}$ *seal* E*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*, and* Pkg *provenance* P*.*

Lean4 ✓ `BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetCarrierAdmission`

Proof. Inspect the carrier of Definition 896.1. Its displayed coordinates are precisely $D, M, W, Q, E, H, C, P, N$, and each coordinate is a finite BHist row.

Apply Definition 896.4. The local $\mathsf{NameCert}$ surface admits only the request, budget, selected window, dyadic ledger, seal, transport, replay, provenance, and naming rows listed there.

Finally use Definition 896.2. A consumer that omits D, M, W, Q, H, C, P, N cannot reach the accepted seal row. Thus carrier admission is the displayed finite packet and not parameter transport through an external budget object. □

Theorem 896.8 (DiagonalLimitBudget synchronization stability)**.** *For every accepted* $\mathsf{DiagonalLimitBudget}^{\uparrow}$ *carrier* $B = (D, M, W, Q, E, H, C, P, N)$*, any two reads transported by the same componentwise* hsame *row* H *and replayed through the same displayed* Cont *row* C *expose the same selected* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *window row* W*, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* Q*, the same* Pkg *provenance* P*, and the same local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitBudget}^{\uparrow}}$ *row* N *attached to* D, M*.*

Lean4 ✓ `BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetSynchronizationStability`

Proof. Begin with finite row inspection of B. The selected-window row W and dyadic ledger Q are coordinates of the same packet as the request D and modulus budget M.

Use Definition 896.4. Componentwise hsame transport through H preserves the displayed coordinates, and Cont replay through C replays the index request, budget row, selected window, dyadic ledger, seal row, provenance, and local naming row.

The non-escape theorem excludes any second selected window, second dyadic ledger, hidden provenance row, or external local name. Hence two accepted reads along the same H and C surface expose the same W, Q, P, N rows for the displayed D, M budget. □

Theorem 896.9 (DiagonalLimitBudget Real seal handoff)**.** *For every accepted* $\mathsf{DiagonalLimitBudget}^{\uparrow}$ *carrier* $B = (D, M, W, Q, E, H, C, P, N)$*, the* $\mathsf{Real}^{\uparrow}$ *seal row* E *is readable only after the diagonal request* D*, modulus budget* M*, selected* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *window* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* Q*, componentwise* hsame *row* H*, displayed* Cont *replay* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitBudget}^{\uparrow}}$ *row* N *have been displayed.*

Lean4 ✓ `BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetRealSealHandoff`

Proof. Apply Definition 896.3. The seal is handed to the synchronizer route only together with the same modulus budget, selected window, dyadic ledger, and structural rows.

Apply Definition 896.2. The packet has no route to E that bypasses D, M, W, Q, H, C, P, N, and no coordinate stores an isolated RealUp seal.

The obligation surface records why this is stable under reading. The rows H and C transport and replay the displayed packet, while P and N source and name the same local carrier. Therefore the Real seal handoff is the displayed budgeted route, not a parameter-transported or host-selected Real completion claim. □

Theorem 896.10 (DiagonalLimitBudget scoped L10 grounding)**.** *Every accepted* $\mathsf{DiagonalLimitBudget}^{\uparrow}$ *packet grounds the diagonal request, modulus budget, selected window, dyadic ledger, and Real seal through the ordered scoped route*

$$\mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}.$$

In particular, the same carrier $B = (D, M, W, Q, E, H, C, P, N)$ *displays the request* D*, budget* M*, selected* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *window* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger* Q*, terminal* $\mathsf{Real}^{\uparrow}$ *seal* E*, and structural rows* H, C, P, N *before any Real-facing consumer can read the seal.*

Proof. Start with the non-escape theorem. It forces every accepted seal read to expose D, M, W, Q, H, C, P, N, so the request and budget cannot be separated from the selected window and dyadic ledger.

Use the obligation surface to identify the rows. The selected-window side is exactly the $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ part of W, and the readback side is exactly the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger Q attached to the same displayed D, M request.

Finally apply the two seal handoff theorems. The seal handoff keeps E attached to M, W, Q, H, C, P, N, and the Real seal handoff states that E is readable only after those rows have been displayed. Thus the scoped grounding route is the displayed packet route, not an external Real-completion or quotient-stream route. □

Lean4 ✓ `BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetScopedL10Grounding`

Theorem 896.11 (DiagonalLimitBudget scoped row exhaustion)**.** *Every accepted packet* $B = (D, M, W, Q, E, H, C, P, N)$ *exposes exactly the diagonal request* D*, modulus budget* M*, selected* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *window* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* Q*,* $\mathsf{Real}^{\uparrow}$ *seal* E*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitBudget}^{\uparrow}}$ *row* N *before any Real-facing consumer can read* E*. No additional row for quotient streams, host real equality, selected limits, hidden completeness, or ambient choice is available inside the scoped L10 route.*

Lean4 ✓ `BEDC.Derived.DiagonalLimitBudgetUp.DiagonalLimitBudgetScopedRowExhaustion`

Proof. Start with the non-escape boundary in Definition 896.2. It forces every accepted seal read to pass through the displayed packet coordinates D, M, W, Q, H, C, P, N before E is consumed.

The obligation surface of Definition 896.4 identifies those coordinates as the complete local $\mathsf{NameCert}_{\mathsf{DiagonalLimitBudget}^{\uparrow}}$ surface. The request and budget are D, M, the finite window is W, the dyadic readback is Q, and the structural rows are exactly H, C, P, N.

Now apply the Real seal handoff of Definition 896.9. The handoff keeps E attached to the same selected window, dyadic ledger, transport, replay, provenance, and local name, so the Real-facing consumer cannot isolate the seal from the budget packet.

Finally use the scoped L10 grounding in Definition 896.10. It orders the route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and therefore exhausts the rows available to

the scoped consumer. Since every excluded object is absent from the carrier and from the handoff route, the listed rows are exact. □

Closure status for $\mathsf{NameCert}_{\mathsf{DiagonalLimitBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{DiagonalLimitBudget}^{\uparrow}$ packet is generated from a diagonal request, a displayed modulus budget, selected $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ window data, a $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, a $\mathsf{Real}^{\uparrow}$ seal row, componentwise hsame transports, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DiagonalLimitBudget}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 896.1, Definition 896.4, Definition 896.10, and Definition 896.11 bind the displayed rows $D, M, W, Q, E, H, C, P, N$ to the L10 diagonal-limit kernel route through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DiagonalLimitBudget}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close quotient streams, host real equality, countable choice, selected limits, hidden RealUp completion data, or ambient completeness for $\mathsf{DiagonalLimitBudget}^{\uparrow}$.

Upgrade path: Scoped grounding requires checking the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows against the same $D, M, W, Q, E, H, C, P, N$ packet.

Chapter 897

A Concrete Naming Certificate for $\mathsf{StationaryWindowNaturality}^{\uparrow}$

The $\mathsf{StationaryWindowNaturality}^{\uparrow}$ packet records the finite naturality comparison required when a transported stationary rational classifier is read through the Real-completeness finite-window route. It consumes the transported stationary diagonal surface of chapter 475, the route boundary of chapter 613, the observation-budget surface of chapter 641, and the fused regular-Cauchy window packet of chapter 693. The carrier keeps the seed classifier and the four boundary readings in one displayed packet; it does not export a quotient stream, selected limit, host real equality, or ambient completeness principle.

Falsifiable prediction: A RealUp stationary-window consumer that bypasses RatUp or StreamNameUp finite-window transport refutes the packet.

Independence witness: transportedstationarydiagonal, stationarydiagonalwindowroute, cauchymodulusextraction, regularcauchywindowfusion: none is bijective because this carrier adds a naturality comparison row tying four boundary readings to one RatUp seed classifier.

Definition 897.1 (Stationary window naturality carrier)**.** *A* $\mathsf{StationaryWindowNaturality}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$N = (Q, S, R, D, E, W, H, C, P, K)$$

with the following displayed rows:

1. *Q is the transported stationary* $\mathsf{Rat}^{\uparrow}$ *seed classifier row;*
2. *S is the constant* $\mathsf{StreamName}^{\uparrow}$ *finite-window classifier induced by Q;*
3. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *seal-consumption row read from the same finite window;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation and tolerance ledger attached to that window;*
5. *E is the* $\mathsf{Real}^{\uparrow}$ *finite-window seal row reached from S, R, D;*
6. *W is the naturality comparison row asserting that the four boundary readings S, R, D, E are replays of the same seed classifier Q;*
7. *H stores componentwise* hsame *transports for $Q, S, R, D, E, W, C, P, K$;*
8. *C records the displayed* Cont *routes that replay the seed, stream window, regular readback, dyadic ledger, real seal, and naturality row;*

9. *P is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
10. *K is the local* $\mathsf{NameCert}_{\mathsf{StationaryWindowNaturality}^{\uparrow}}$ *row.*

The carrier has no coordinate for an unrecorded real comparison, a non-stationary stream, a quotient regular stream, a choice-selected limit, or an ambient completeness theorem.

Theorem 897.2 (Stationary window naturality NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{StationaryWindowNaturality}^{\uparrow}}$ *surface for Definition 897.1 consists exactly of carrier admission for $N = (Q, S, R, D, E, W, H, C, P, K)$, seed classifier exposure through Q, constant finite-window exposure through S, regular-sequence seal exposure through R, dyadic observation exposure through D, real finite-window seal exposure through E, naturality comparison exposure through W, componentwise* hsame *transport through H, displayed* Cont *replay through C, package provenance through P, and local naming through K.*

Proof. Project the carrier. The rows $Q, S, R, D, E, W, H, C, P, K$ are the only coordinates admitted to the packet, so every local naming obligation must be read from one of these rows.

The four boundary readings are tied to the seed in order. The stationary diagonal window route supplies S from Q, the regular-sequence row R consumes the same window, the dyadic ledger D records the finite observations attached to that window, and the real seal row E is reached only after S, R, D are displayed.

The naturality row W is the comparison row that keeps these readings together. It is not a host equality assertion; it is the finite statement that the StreamName, RegSeqRat, DyadicRatCore, and RealUp boundary reads are the same transported stationary seed route when inspected through H, C, P, K.

Since no excluded object is a coordinate of N, the NameCert surface is exhausted by the displayed rows. □

Theorem 897.3 (Stationary window naturality boundary comparison)**.** *For an accepted* StationaryWindowNaturalit *carrier $N = (Q, S, R, D, E, W, H, C, P, K)$, every stationary finite-window consumer that reaches the* $\mathsf{Real}^{\uparrow}$ *seal row E must pass through the same seed classifier Q, constant* $\mathsf{StreamName}^{\uparrow}$ *window S,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback R,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D, naturality row W, and structural rows H, C, P, K.*

Proof. Begin with the route sibling. The stationary diagonal window route exposes the seed-to-window path, so a Real-facing read cannot reach the stream window without first reading Q and S.

Next use the regular-Cauchy window fusion sibling. It consumes the displayed stream window as the common source for the regular readback R, dyadic ledger D, and real seal row E.

The comparison row W then records that these boundary readings are not separate analytic choices. They are four readings of the same transported seed route, replayed through the componentwise transports, continuations, package row, and local naming row. □

Theorem 897.4 (Stationary window naturality downstream package)**.** *The carrier, NameCert obligations, and boundary comparison rows of* $\mathsf{StationaryWindowNaturality}^{\uparrow}$ *assemble the finite naturality package consumed by transported stationary diagonal, stationary diagonal window route, Cauchy modulus extraction, regular Cauchy window fusion, and* $\mathsf{RealCompleteness}^{\uparrow}$ *consumers. The package exports exactly*

$$Q, S, R, D, E, W, H, C, P, K$$

over $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows.*

Proof. The carrier supplies the seed row, the four finite-window boundary readings, the comparison row, and the structural support rows. The NameCert obligation theorem records these as the complete local naming surface.

The boundary comparison theorem forces every Real-facing read through the same finite route. Thus downstream consumers receive a naturality packet, not independent analytic witnesses for the StreamName, RegSeqRat, DyadicRatCore, and RealUp boundaries.

The listed sibling chapters provide the incoming surfaces. Transported stationary diagonal supplies the seed classifier, stationary diagonal window route supplies the seed-to-window path, Cauchy modulus extraction supplies the finite observation-budget discipline, and regular Cauchy window fusion supplies the shared readback and seal route. □

Theorem 897.5 (Stationary window naturality TasteGate readiness)**.** *The Lean TasteGate site for* StationaryWindowNaturality$^{\uparrow}$ *must distinguish the naturality comparison row W from the four boundary readings S, R, D, E and must preserve all rows $Q, S, R, D, E, W, H, C, P, K$ for classifier-facing consumers.*

Proof. Nontriviality is forced by the packet shape. If W collapsed to any one of S, R, D, E, the carrier would lose the comparison row that ties the four boundary readings to the same seed classifier Q.

Field faithfulness is the consumer-facing preservation condition. A classifier-facing route may inspect the seed, stream window, regular readback, dyadic ledger, real seal, naturality row, transports, continuations, package provenance, and local naming row, but no unlisted real-completion object. □

Lean4 ✓ `BEDC.Derived.StationaryWindowNaturalityUp.StationaryWindowNaturalityTasteGate single carrier alignment`

Closure status for NameCert$_{\text{StationaryWindowNaturality}^{\uparrow}}$.

Constructive story: A StationaryWindowNaturality$^{\uparrow}$ packet is generated from one transported stationary Rat$^{\uparrow}$ seed classifier, its constant StreamName$^{\uparrow}$ finite window, the matching RegSeqRat$^{\uparrow}$ readback, DyadicRatCore$^{\uparrow}$ observation ledger, Real$^{\uparrow}$ seal, naturality comparison row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{StationaryWindowNaturality}^{\uparrow}}$, seed)

Scope closed: Definition 897.1, Definition 897.2, Definition 897.3, and Definition 897.4 bind the finite naturality packet for transported stationary window readings.

Formal verification: FormalStatus(NameCert$_{\text{StationaryWindowNaturality}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove RealUp completeness, quotient-stream equality, selected limits, host real equality, real trichotomy, Lean verification, or a public standard bridge.

Upgrade path: Obligation closure requires checked carrier admission, boundary-reading exactness, naturality comparison preservation, downstream package coverage, and TasteGate row-faithfulness for the same finite packet.

Chapter 898

A Concrete Naming Certificate for $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$

The $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ packet is the composite finite witness envelope for the Real-completeness diagonal tail route of chapter 9238. It consumes the stream window surface of chapter 126, the finite-window envelope of chapter 365, and the common-tail comparison packet of chapter 387. The packet keeps the witness route finite by storing the selected StreamName window, the finite-window endpoint ledger, the Cauchy tail-comparison row, the RealTailAgreementSeal row, the RealUp readback row, and the structural provenance needed to replay the same route.

Definition 898.1 (CauchyTailWitnessEnvelope carrier)**.** *A* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (S, F, Q, A, R, H, C, P, N)$$

with the following displayed rows:

1. *S is the finite* $\mathsf{StreamName}^{\uparrow}$ *window selected for the diagonal tail request;*
2. *F is the* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *row that binds the selected window to its dyadic endpoint ledger, regular-rational readback, and RealUp endpoint surface;*
3. *Q is the* $\mathsf{CauchyTailComparison}^{\uparrow}$ *row that compares the relevant late regular-name windows through the same selected window and endpoint ledger;*
4. *A is the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row reached after the finite-window and comparison rows have both been displayed;*
5. *R is the* $\mathsf{Real}^{\uparrow}$ *readback row exported to the diagonal Real-completeness route;*
6. *H records componentwise* hsame *transports for S, F, Q, A, R, C, P, N;*
7. *C records the displayed* Cont *routes that replay the selected window, finite-window envelope, tail comparison, tail-agreement seal, RealUp readback, provenance, and local naming row;*
8. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{FiniteWindowEnvelope}^{\uparrow}$, $\mathsf{CauchyTailComparison}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}}$ *row.*

The carrier contains no quotient stream equality, no host real equality, no selected host limit, no countable-choice selector, and no ambient completeness principle.

Lean4 ✓ `BEDC.Derived.CauchyTailWitnessEnvelopeUp.CauchyTailWitnessEnvelopeTasteGate single carrier alignment`

Theorem 898.2 (CauchyTailWitnessEnvelope NameCert obligations)**.** *For the carrier of Definition 898.1, the local* $\mathsf{NameCert}_{\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$E = (S, F, Q, A, R, H, C, P, N),$$

selected $\mathsf{StreamName}^{\uparrow}$ *window exposure through* S*, finite-window envelope exposure through* F*, common-tail comparison exposure through* Q*, RealTailAgreementSeal exposure through* A*, RealUp readback exposure through* R*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Proof. Project the displayed carrier. The rows $S, F, Q, A, R, H, C, P, N$ are the only coordinates of the finite packet.

Read the analytic rows in order. The selected stream window S is first bound into the finite-window envelope F, and the tail comparison Q reads its common window and dyadic endpoint ledger through that same envelope surface.

The tail-agreement seal A and RealUp readback R are then reached only after S, F, Q have been displayed. The structural rows H, C, P, N transport, replay, authenticate, and name the same packet, so the listed rows exhaust the local NameCert surface. □

Theorem 898.3 (CauchyTailWitnessEnvelope selector handoff)**.** *Every diagonal-tail selector read exported by an accepted* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *carrier factors through the selected window* S*, the finite-window envelope* F*, and the Cauchy tail-comparison row* Q *before the RealTailAgreementSeal row* A *or the RealUp readback row* R *can be consumed. The handoff supplies the finite witness route used by chapter 9238, not an isolated RealUp seal or a host limit.*

Proof. Start with the selected window. The carrier has exactly one StreamName window coordinate S, and that coordinate is the source read by the envelope row F.

Use the finite-window dependency next. The row F supplies the selected window and endpoint ledger consumed by the comparison row Q, so the comparison is not a host-level comparison detached from the envelope.

Finally read A and R. These rows are reached after the selector, envelope, and comparison rows have been replayed through C and transported through H. Thus the diagonal-tail handoff remains a finite witness envelope rather than a selected limit or isolated RealUp object. □

Theorem 898.4 (CauchyTailWitnessEnvelope non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *packet receives only the finite surface*

$$S, F, Q, A, R, H, C, P, N.$$

It receives no quotient stream equality, host real equality, selected host limit, countable-choice selector, or ambient completeness theorem. A later Lean TasteGate module for this carrier must therefore expose nontriviality and field-faithfulness over the displayed packet fields rather than over a collapsed RealUp output.

Proof. Project the carrier and apply the NameCert obligation theorem. The public surface is exhausted by the selected window, finite-window envelope, common-tail comparison, tail-agreement seal, RealUp readback, transport, replay, provenance, and local naming rows.

The selector handoff theorem keeps every diagonal-tail read on those rows. In particular, the comparison row Q consumes the finite-window endpoint ledger from F, and the seal row A is unavailable before that route is displayed.

The excluded objects have no coordinate in the packet. Since the carrier has no quotient stream, host real equality, host-selected limit, choice selector, or ambient completeness row, no downstream consumer can recover one from an accepted envelope. □

Theorem 898.5 (CauchyTailWitnessEnvelope finite-window exactness)**.** *For every accepted* CauchyTailWitnessEnv *carrier*

$$E = (S, F, Q, A, R, H, C, P, N),$$

the selected $\mathsf{StreamName}^{\uparrow}$ *window S is consumed through the* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *row F before any tail-comparison, seal, or RealUp read is exported. The endpoint ledger, regular-rational readback, and RealUp endpoint surface used by the envelope are therefore the ones displayed by F.*

Proof. Project the carrier and use the NameCert obligation theorem. The only selected-window coordinate is S, and the only finite-window envelope coordinate is F.

Apply the selector handoff theorem. It places S before F and F before Q, A, R, so no later row can read the selected window except through the envelope.

Finally use non-escape. Since the packet has no hidden endpoint ledger or host equality coordinate, the endpoint data consumed downstream are exactly the ledger rows displayed by F. □

Theorem 898.6 (CauchyTailWitnessEnvelope tail-comparison exactness)**.** *For every accepted* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *carrier $E = (S, F, Q, A, R, H, C, P, N)$, the tail-comparison row Q reads the same finite-window endpoint ledger exposed by F before any RealTailAgreementSeal row A is consumed. No comparison row may bypass the selected window S or replace the endpoint ledger by quotient stream equality or host real equality.*

Proof. Start from finite-window exactness. By Definition 898.5, the selected window S and endpoint ledger are already bound through F.

Use the NameCert obligation theorem to locate Q. The comparison row is a displayed carrier coordinate and its consumer route follows the selected window and finite-window envelope rows.

Apply the selector handoff theorem. It places Q before A and R, so the seal cannot be reached until the comparison has read the same S, F ledger.

The non-escape theorem removes the remaining alternatives. Quotient streams, host real equality, selected host limits, countable choice, and ambient completeness are not packet coordinates, so they cannot replace the finite comparison ledger. □

Theorem 898.7 (CauchyTailWitnessEnvelope Real tail seal boundary)**.** *For every accepted* CauchyTailWitnessEnve *carrier $E = (S, F, Q, A, R, H, C, P, N)$, the RealTailAgreementSeal row A and the RealUp readback row R are reached only after the selected window S, finite-window envelope F, tail-comparison row Q, transport rows H, continuation rows C, provenance row P, and local naming row N have been displayed.*

The boundary is a finite witness-envelope route. It does not export quotient stream equality, host real equality, a selected host limit, a countable-choice selector, or ambient completeness.

Proof. Project the accepted packet. The carrier has exactly the rows $S, F, Q, A, R, H, C, P, N$, with H, C, P, N carrying transport, replay, provenance, and local naming for the same packet.

Apply finite-window exactness and tail-comparison exactness. These theorems route the seal-facing read through S, F, Q before A is available.

Use the selector handoff theorem for the final order of consumption. It places A and then R after the selected window, envelope, and comparison rows, while the structural rows replay and authenticate the same route.

Finally apply non-escape. Since no excluded object is present in the carrier, the seal boundary is exactly the displayed finite witness-envelope route. □

Theorem 898.8 (CauchyTailWitnessEnvelope obligation closure)**.** *For every accepted* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *packet* $E = (S, F, Q, A, R, H, C, P, N)$*, the carrier definition, local* NameCert *obligations, selector handoff, finite-window exactness, tail-comparison exactness, Real-tail seal boundary, and non-escape theorem jointly form the* obligation *surface over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{FiniteWindowEnvelope}^{\uparrow}$, $\mathsf{CauchyTailComparison}$ $\mathsf{RealTailAgreementSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert.

The package exports exactly the selected stream-name window, finite endpoint envelope, Cauchy tail-comparison ledger, RealTailAgreementSeal boundary, RealUp readback row, transport rows, continuation routes, package provenance, and local naming row displayed by E.

Proof. Project the tuple $E = (S, F, Q, A, R, H, C, P, N)$. The carrier definition supplies the row names, and the local NameCert obligations certify that each downstream consumer reads those rows as a single finite witness-envelope packet.

Follow the route order. The selector handoff places S before F, Q, A, R, finite-window exactness binds the endpoint ledger through S, F, tail-comparison exactness makes Q read that same ledger before A, and the Real-tail seal boundary places A and R after the selected window, envelope, comparison, transport, continuation, provenance, and local naming rows.

Finally apply non-escape. Quotient stream equality, host equality, a host-selected limit, a choice selector, and ambient completeness are not coordinates of E, so no hidden row remains outside the displayed obligation surface. □

Theorem 898.9 (CauchyTailWitnessEnvelope scoped route binding)**.** *Every accepted* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *packet*

$$E = (S, F, Q, A, R, H, C, P, N)$$

exposes the selected $\mathsf{StreamName}^{\uparrow}$ *window* S*, the* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *row* F*, the* $\mathsf{CauchyTailComparison}^{\uparrow}$ *row* Q*, the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row* A*, the* $\mathsf{Real}^{\uparrow}$ *readback row* R*, componentwise* hsame *transports* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and the local* NameCert *row* N *as one finite L10 witness-envelope route over* BHist, hsame, Cont, Pkg, *and* NameCert.

The route exposes no quotient stream equality, host real equality, selected host limit, countable-choice selector, or ambient completeness row.

Proof. Start from the local NameCert obligations. They identify the displayed coordinates $S, F, Q, A, R, H, C, P, N$ as the entire accepted packet surface, and the TasteGate marker for $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ aligns this single carrier with its named field-faithful carrier route.

Use the selector handoff to place the route on the selected window. The row S is consumed by the finite-window envelope F, and F supplies the endpoint ledger that the tail-comparison row Q reads.

Apply finite-window exactness and tail-comparison exactness. These results make the selected window, endpoint envelope, and Cauchy tail-comparison ledger the same finite route before the RealTailAgreementSeal row is available.

Finally use the Real-tail seal boundary and non-escape theorem. The seal row A, RealUp readback row R, transports H, continuations C, provenance P, and naming row N remain inside the same finite packet, while quotient stream equality, host real equality, selected host limits, countable choice, and ambient completeness have no carrier coordinate. □

Theorem 898.10 (CauchyTailWitnessEnvelope consumer interface exactness)**.** *For every accepted* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *packet*

$$E = (S, F, Q, A, R, H, C, P, N)$$

a public consumer of $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *has exactly the finite interface consisting of the selected* $\mathsf{StreamName}^{\uparrow}$ *window* S*, the* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *endpoint row* F*, the* $\mathsf{CauchyTailComparison}^{\uparrow}$ *row* Q*, the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *boundary row* A*, the* $\mathsf{Real}^{\uparrow}$ *readback row* R*, and the structural* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows carried by* H, C, P, N*.*

Conversely, the displayed rows $S, F, Q, A, R, H, C, P, N$ *suffice for the public consumer interface. They export no quotient stream equality, host real equality, host-selected limit, countable-choice selector, or ambient completeness principle.*

Proof. For exactness, project the carrier $E = (S, F, Q, A, R, H, C, P, N)$. By the NameCert obligation theorem, these are exactly the rows admitted for the local $\mathsf{NameCert}_{\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}}$ surface, so a public consumer has no off-packet coordinate before the route is inspected.

Use the selector handoff and finite-window exactness. The selected window S is first read through the envelope F, and the endpoint ledger exported to the consumer is the one displayed by that same finite-window row.

Next apply tail-comparison exactness. The row Q reads the same S, F ledger before the Real-tail seal can be consumed, so the comparison branch cannot replace the finite ledger by quotient stream equality or host real equality.

Now use the Real-tail seal boundary, obligation closure, and scoped route binding. The rows A and R are reached only after S, F, Q, H, C, P, N have been displayed, and the structural rows transport, replay, package, and name that same finite route.

For sufficiency, start with the displayed rows $S, F, Q, A, R, H, C, P, N$. The NameCert obligations admit them as one local naming surface, the selector handoff places the analytic rows in the required order, and the finite-window, tail-comparison, and seal-boundary theorems provide the endpoint, comparison, boundary, and readback components of the consumer route.

Finally apply non-escape and scoped route binding. Since the accepted packet has no coordinate for a quotient stream, host real equality, host-selected limit, countable-choice selector, or ambient completeness principle, the displayed rows provide the whole public interface and no stronger object is exported. □

Theorem 898.11 (CauchyTailWitnessEnvelope standard bridge surface)**.** *Every standard-facing read of an accepted* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *packet* $E = (S, F, Q, A, R, H, C, P, N)$ *factors through the selected* $\mathsf{StreamName}^{\uparrow}$ *window* S*, the* $\mathsf{FiniteWindowEnvelope}^{\uparrow}$ *endpoint row* F*, the* $\mathsf{CauchyTailComparison}^{\uparrow}$ *row* Q*, the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *boundary row* A*, the* $\mathsf{Real}^{\uparrow}$ *readback row* R*, and the structural* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows carried by* H, C, P, N*.*

The bridge surface exports no quotient stream equality, host real equality, host-selected limit, countable-choice selector, or ambient completeness coordinate.

Proof. Begin with the local NameCert obligations of Definition 898.2. They identify $S, F, Q, A, R, H, C, P, N$ as the complete accepted carrier surface for the local $\mathsf{NameCert}_{\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}}$ row.

Use the selector handoff theorem Definition 898.3. It places every diagonal-tail read first on the selected $\mathsf{StreamName}^{\uparrow}$ window and then on the finite-window envelope before the comparison, seal, or readback rows are consumed.

Apply finite-window exactness and tail-comparison exactness from Definition 898.5 and Definition 898.6. These results bind the endpoint ledger and comparison row to the same finite S, F surface.

Next use the Real-tail seal boundary of Definition 898.7. The rows A and R are reached only after the selected window, finite-window envelope, comparison row, transports, continuations, provenance, and local name have been displayed.

Now combine non-escape, scoped route binding, and consumer interface exactness from Definition 898.4, Definition 898.9, and Definition 898.10. Together they state that a public or standard-facing consumer has exactly the listed finite interface and no off-packet coordinate.

Therefore the standard bridge surface is precisely the displayed $S, F, Q, A, R, H, C, P, N$ route, with no quotient stream equality, host real equality, host-selected limit, countable-choice selector, or ambient completeness coordinate. □

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}}$.

Constructive story: A $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ packet is generated from a selected $\mathsf{StreamName}^{\uparrow}$ window, a finite-window envelope row, a Cauchy tail-comparison row, a $\mathsf{RealTailAgreementSeal}^{\uparrow}$ row, a $\mathsf{Real}^{\uparrow}$ readback row, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 898.1, Definition 898.2, Definition 898.3, Definition 898.5, Definition 898.6, Definition 898.7, Definition 898.4, Definition 898.9, the bridge-facing public consumer surface Definition 898.10, and the standard bridge surface Definition 898.11 bind the selected StreamName window, finite-window envelope, tail-comparison row, RealTailAgreementSeal row, RealUp readback row, BHist carrier surface, hsame transports, Cont routes, Pkg provenance, NameCert row, public consumer interface, and standard-facing read as one finite bridge-facing surface.

Not claimed: This chapter does not close quotient streams, host real equality, selected host limits, countable choice, ambient completeness, or machine bridge checking.

Upgrade path: No further paper-side closure upgrade remains; machine bridge checking stays on the formal axis.

Chapter 899

A Concrete Naming Certificate for $\mathsf{MetaClosureObstruction}^{\uparrow}$

The $\mathsf{MetaClosureObstruction}^{\uparrow}$ packet realizes the forbidden-schema side of chapter 9458. It records the permitted refutation route, the forbidden contradiction-schema request, the certificate-indexed truth-branch refusal row, the meta-loop boundary row, and the local naming ledger that separates ground-loop refutation from truth closure over the carrier of naming certificates.

The packet consumes the permitted refutation route of chapter 503, the truth-branch refusal boundary of chapter 854, the reflection limit row of chapter 586, the ground-loop boundary of chapter 674, and the halting distinction limit of chapter 495. These dependencies remain dependency prose for the local obstruction packet; they do not raise the chapter beyond its stated seed closure.

Definition 899.1 (MetaClosureObstruction carrier)**.** *A* $\mathsf{MetaClosureObstruction}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (R, S, F, T, M, H, C, P, N)$$

with the following displayed rows:

1. *R is the permitted refutation route, read as a displayed assumption-to-bottom* Cont *packet over a fixed certificate surface;*
2. *S is the forbidden contradiction-schema request, naming one of existential-by-contradiction, double-negation elimination without a decidability row, or excluded middle over the carrier of naming certificates;*
3. *F is the refusal ledger for the requested schema, recording that the request is not an admitted certificate rule;*
4. *T is the truth-branch refusal row for certificate-indexed predicates;*
5. *M is the meta-loop boundary row separating the closed ground loop from the open truth-closure layer;*
6. *H records componentwise* hsame *transports for R, S, F, T, M, P, N;*
7. *C records the displayed* Cont *routes by which consumers read the refutation route, forbidden-schema request, refusal rows, and meta-loop boundary;*
8. *P is the* Pkg *provenance over* $\mathsf{WitnessedRefutation}^{\uparrow}$, $\mathsf{CertificateTruthBranchBoundary}^{\uparrow}$, $\mathsf{ReflectionLimitBoundary}^{\uparrow}$, $\mathsf{GroundLoopBoundary}^{\uparrow}$, *and* $\mathsf{HaltingDistinctionLimit}^{\uparrow}$*;*

9. N is the local $\mathsf{NameCert}_{\mathsf{MetaClosureObstruction}^{\uparrow}}$ *row.*
The classifier compares accepted carriers only by the displayed rows $R, S, F, T, M, H, C, P, N$. In particular, an accepted packet lacking the truth-branch refusal row T is not a $\mathsf{MetaClosureObstruction}^{\uparrow}$ *carrier.*

Lean4 ✓ `BEDC.Derived.MetaClosureObstructionUp.MetaClosureObstructionTasteGate single carrier alignment`

Theorem 899.2 (MetaClosureObstruction NameCert obligations)**.** *For the carrier of Definition 899.1, the local* $\mathsf{NameCert}_{\mathsf{MetaClosureObstruction}^{\uparrow}}$ *surface consists of carrier admission for*

$$O = (R, S, F, T, M, H, C, P, N),$$

permitted-refutation exposure through R, forbidden-schema request exposure through S, schema refusal through F, certificate-indexed truth-branch refusal through T, meta-loop boundary exposure through M, componentwise hsame *stability through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Proof. Carrier admission is projection from Definition 899.1. The tuple displays the permitted refutation route, the forbidden-schema request, the two refusal rows, the meta-loop boundary, transport data, continuation data, provenance, and local naming row.

The refutation row R is ground-facing: it is read only as an assumption-to-bottom route inside a fixed certificate surface. The schema row S is boundary-facing: it names the forbidden move being requested but does not supply its constructive witness, decidability row, or certificate-indexed branch family.

The refusal rows F and T are distinct. Row F refuses the local schema request, while row T refuses the truth-branch family over naming certificates that the forbidden schema would supply. Row M then records that this refusal is the open meta-loop boundary rather than a missing ground-loop constructor.

Transport and replay are exhausted by H and C, and provenance is exhausted by P, N. Since no further coordinate exists, the listed rows are exactly the local NameCert obligations. □

Lean4 ✓ `BEDC.Derived.MetaClosureObstructionUp.MetaClosureObstructionNameCertObligations`

Theorem 899.3 (MetaClosureObstruction non-escape)**.** *Every accepted* $\mathsf{MetaClosureObstruction}^{\uparrow}$ *packet exports only the finite rows*

$$R, S, F, T, M, H, C, P, N.$$

No consumer can extract from such a packet an existential witness obtained from $\neg\forall\neg$, a double-negation eliminator for an undecided classifier, an excluded-middle branch over naming certificates, a certificate-indexed truth predicate, or meta-loop truth closure. Any accepted packet lacking the truth-branch refusal row T fails to be a $\mathsf{MetaClosureObstruction}^{\uparrow}$ *carrier.*

Proof. Project the accepted packet to the carrier inventory of Definition 899.1. The only positive proof route is the permitted refutation row R, and the only forbidden-schema information is the request row S together with the refusal rows F, T and the boundary row M.

The NameCert obligations of Definition 899.2 force every consumer read through H, C, P, N. Thus a consumer may replay the displayed refutation and inspect the refusal boundary, but no route bypasses F, T, M to produce a truth branch or a closed meta loop.

The last claim follows from the carrier definition itself. Row T is one of the displayed coordinates of O, and the classifier compares accepted packets only through all displayed rows. Removing T removes the certificate-indexed truth-branch refusal coordinate, so the remaining packet is not a $\mathsf{MetaClosureObstruction}^{\uparrow}$ carrier. □

Independence witness: WitnessedRefutation, CertificateTruthBranchBoundary, ReflectionLimitBoundary, GroundLoopBoundary, HaltingDistinctionLimit: the obstruction packet contains both a forbidden-schema request row and a truth-branch refusal row. WitnessedRefutation carries the permitted refuter without the forbidden-schema packet; CertificateTruthBranchBoundary carries the branch boundary without the meta-loop obstruction packet; ReflectionLimitBoundary carries structural reflection limits without a contradiction-schema request; GroundLoopBoundary carries closed mark distinction without certificate-indexed truth refusal; HaltingDistinctionLimit carries a halting diagonal obstruction without the three-schema refusal ledger. Hence none is bijective to $\mathsf{MetaClosureObstruction}^{\uparrow}$ while preserving NameCert obligations.

Theorem 899.4 (MetaClosureObstruction truth-branch obligation)**.** *Let $O = (R, S, F, T, M, H, C, P, N)$ be an accepted* $\mathsf{MetaClosureObstruction}^{\uparrow}$ *carrier. Before any consumer may compare the obstruction packet with certificate-indexed truth closure, the truth-branch refusal row T must be displayed and transported with the permitted refutation route R, forbidden-schema request S, schema refusal row F, meta-loop boundary M, componentwise* hsame *data H, displayed* Cont *replay C,* Pkg *provenance P, and local* NameCert *row N.*

Lean4 ✓ `BEDC.Derived.MetaClosureObstructionUp.MetaClosureObstructionCarrier truth branch obligation`

Proof. Project the accepted carrier O. The truth-branch refusal row T is a displayed coordinate of the same finite BHist packet as R, S, F, M, H, C, P, N.

A consumer comparing obstruction with certificate-indexed truth closure must first read T. Without that row, the carrier definition supplies only a permitted refutation route and a schema refusal, not the truth-branch refusal needed at the certificate-indexed boundary.

Transport and replay preserve this order. The row H carries T componentwise with the other displayed rows, C replays the same refusal route, and P, N source and name it as part of the local NameCert surface.

Thus the comparison obligation is not a verification claim and not a truth-closure rule. It is the paper-side requirement that T remain present before any truth-branch consumer can inspect the obstruction packet. □

Lean4 ✓ `BEDC.Derived.MetaClosureObstructionUp.MetaClosureObstructionTruthBranchObligation`

Theorem 899.5 (MetaClosureObstruction scoped refusal route)**.** *Let $O = (R, S, F, T, M, H, C, P, N)$ be an accepted* $\mathsf{MetaClosureObstruction}^{\uparrow}$ *carrier. The scoped refusal route exposed by O depends only on the permitted refutation route R, forbidden contradiction-schema request S, schema refusal row F, truth-branch refusal row T, meta-loop boundary M, componentwise* hsame *data H, displayed* Cont *replay C,* Pkg *provenance P, and local* NameCert *row N. It refuses contradiction-schema closure and certificate-indexed truth predicates as carrier-external requests.*

Proof. Project the accepted packet. The classifier compares only the displayed rows $R, S, F, T, M, H, C, P, N$, so the scoped route has no entry point outside that finite inventory.

Read the refusal rows in order. Row F refuses the requested contradiction schema, and row T refuses the certificate-indexed truth branch that such a schema would create over naming certificates.

The structural rows preserve only this route. Componentwise hsame transport, displayed Cont replay, Pkg provenance, and the local NameCert row keep the refusal surface named without adding contradiction-schema closure or certificate-indexed truth predicates. □

Theorem 899.6 (MetaClosureObstruction public export)**.** *Let $O = (R, S, F, T, M, H, C, P, N)$ be an accepted* MetaClosureObstruction$^{\uparrow}$ *carrier. Its public obstruction export is exactly the row inventory $R, S, F, T, M, H, C, P, N$: the permitted refutation route, forbidden-schema request, schema refusal, truth-branch refusal, meta-loop boundary, componentwise* hsame *data, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *row. Public consumers may cite this obstruction only as a finite refusal packet; they do not receive contradiction-schema closure, certificate-indexed truth predicates, or a public standard bridge.*

Proof. Project the carrier of Definition 899.1. The classifier compares accepted packets only through $R, S, F, T, M, H, C, P, N$, so the public surface cannot contain a row outside that tuple.

Apply Definition 899.5. The scoped refusal route already exposes contradiction-schema refusal and certificate-indexed truth-branch refusal through the same displayed rows.

Thus the public export is only the visible obstruction packet. It preserves the permitted refutation route and refusal boundary while leaving truth closure, excluded middle, double-negation elimination, and bridge checking outside the chapter. □

Lean4 ✓ `BEDC.Derived.MetaClosureObstructionUp.MetaClosureObstructionPublicExport`

Theorem 899.7 (MetaClosureObstruction mature refusal completeness)**.** *Let $O = (R, S, F, T, M, H, C, P, N)$ be an accepted* MetaClosureObstruction$^{\uparrow}$ *carrier. The mature obstruction surface is exhausted by the permitted refutation route R, forbidden-schema request S, schema refusal F, truth-branch refusal T, meta-loop boundary M, componentwise* hsame *transport H, displayed* Cont *replay C,* Pkg *provenance P, and local* NameCert *row N. It exports no contradiction-schema closure and no certificate-indexed truth predicate.*

Proof. Project the carrier of Definition 899.1. Its displayed rows are exactly $R, S, F, T, M, H, C, P, N$, so any mature obstruction read starts inside that finite inventory.

Apply Definition 899.2 and Definition 899.6. The NameCert surface and public export both require the same route through the refutation, request, refusal, transport, replay, provenance, and local naming rows.

Finally use Definition 899.3 and Definition 899.5. They rule out contradiction-schema closure and certificate-indexed truth predicates as carrier-external requests, so no further mature row remains. □

Closure status for NameCert$_{\text{MetaClosureObstruction}^{\uparrow}}$**.**

Constructive story: A MetaClosureObstruction$^{\uparrow}$ packet is generated from a permitted refutation route, a forbidden contradiction-schema request, schema and truth-branch refusal rows, a meta-loop boundary row, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{MetaClosureObstruction}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 899.1, Definition 899.2, Definition 899.3, Definition 899.4, Definition 899.6, and Definition 899.7 bind the finite mature obstruction packet separating permitted refutation from meta-loop truth closure.

Formal verification: FormalStatus(NameCert$_{\text{MetaClosureObstruction}^{\uparrow}}$, auditClean)

Lean target: `BEDC.Derived.MetaClosureObstructionUp.MetaClosureObstructionTasteGate\_single\_carrier\_alignment`

Bridge status: none

Not claimed: This chapter does not close the forbidden contradiction schemas, certificate-indexed truth predicates, excluded middle over naming certificates, or a public standard bridge.

Upgrade path: The next verification grade requires axiom-purity audit and bridge checking for the same TasteGate-aligned obstruction surface.

Chapter 900

A Concrete Naming Certificate for RealCompletionSealClassifierUp

The RealCompletionSealClassifierUp packet realizes the Real completeness vision of chapter 9238 as a finite classifier boundary for completion-seal reads. It joins the tail-agreement seal of RealTailAgreementSeal$^{\uparrow}$, the sealed Cauchy-limit route of CauchyLimitSeal$^{\uparrow}$, and the synchronized budget route of chapter 886 before a Real$^{\uparrow}$ consumer reads equivalence of completion-facing seals. The packet has no coordinate for quotient streams, host real equality, selected external limits, countable choice, or ambient completeness.

Definition 900.1 (Real completion-seal classifier carrier)**.** *A* RealCompletionSealClassifierUp *carrier is a finite* BHist *packet*

$$K = (A, L, S, B, R, W, D, H, C, P, N)$$

with the following displayed rows:

1. *A is the* RealTailAgreementSeal$^{\uparrow}$ *row naming the tail-agreement comparison used by the completion read;*
2. *L is the* CauchyLimitSeal$^{\uparrow}$ *row whose public route exposes the sealed Cauchy-limit endpoint;*
3. *S is the* CauchySealBudgetSynchronizer$^{\uparrow}$ *row tying the seal read to the displayed selector, observation-budget, shared-threshold, and compatibility rows;*
4. *B is the finite budget row read from the synchronizer, including the displayed precision request and selected observation window;*
5. *R is the* RegSeqRat$^{\uparrow}$ *handoff row assembled from the displayed regular rational source data;*
6. *W is the* StreamName$^{\uparrow}$ *finite window row inspected before the regular handoff is consumed;*
7. *D is the* DyadicRatCore$^{\uparrow}$ *tolerance and observation ledger used by the same completion-seal read;*
8. *H records componentwise* hsame *transports for $A, L, S, B, R, W, D, C, P, N$;*
9. *C stores the displayed* Cont *routes by which consumers read the agreement seal, limit seal, synchronizer, budget, regular handoff, stream window, dyadic ledger, provenance, and local naming row;*
10. *P is the* Pkg *provenance over* RealTailAgreementSeal$^{\uparrow}$, CauchyLimitSeal$^{\uparrow}$, CauchySealBudgetSynchronizer$^{\uparrow}$, RegSeqRat$^{\uparrow}$, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{RealCompletionSealClassifierUp}}$ *row.*

The carrier classifies completion-seal equivalence only through these displayed rows. It does not identify real names by quotient streams, host equality, selected external limits, countable choice, or an ambient completeness theorem.

Lean4 (definition) `BEDC.Derived.RealCompletionSealClassifierUp.RealCompletionSealClassifierUp`
Lean4 ✓ `BEDC.Derived.RealCompletionSealClassifierUp.RealCompletionSealClassifierTasteGate`
`single carrier alignment`

Theorem 900.2 (Real completion-seal classifier NameCert obligations)**.** *For the carrier of Definition 900.1, the local* $\mathsf{NameCert}_{\mathsf{RealCompletionSealClassifierUp}}$ *surface consists of five rows:*

1. *carrier admission for the finite packet $K = (A, L, S, B, R, W, D, H, C, P, N)$;*
2. *completion-seal classifier stability under the componentwise* hsame *transports in H;*
3. *displayed seal equivalence through the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows A, L;*
4. *budget and synchronizer exactness through S, B, W, R, D before any* $\mathsf{Real}^{\uparrow}$ *seal read is exported;*
5. *provenance and naming exactness through the displayed* Cont, Pkg, *and* $\mathsf{NameCert}$ *rows C, P, N.*

Later Lean work in `TasteGate.lean` *must provide* `Nontrivial RealCompletionSealClassifierUp` *and* `FieldFaithful RealCompletionSealClassifierUp` *instances for this same carrier surface.*

Proof. Carrier admission is projection from the tuple in Definition 900.1. The agreement seal, limit seal, synchronizer, budget, regular handoff, stream window, dyadic ledger, transport, route, provenance, and local naming rows are all explicit coordinates.

Classifier stability is componentwise. The row H transports the agreement, seal, synchronizer, budget, regular handoff, stream window, and dyadic observation rows without creating a quotient stream or host equality comparison.

Displayed seal equivalence is read through A and L. The tail-agreement row supplies the finite comparison surface, and the Cauchy-limit seal row supplies the completion-facing endpoint route.

Budget exactness is read through S, B, W, R, D. The synchronizer forces the seal read to pass through a displayed budget row, a finite stream window, the regular rational handoff, and the dyadic tolerance ledger before a $\mathsf{Real}^{\uparrow}$ consumer may inspect the completion seal.

Finally, the routes in C and the provenance and naming rows P, N authenticate exactly that finite surface. Thus the five obligations are the whole classifier interface. □

Theorem 900.3 (Real completion-seal classifier non-escape)**.** *Every accepted* $\mathsf{RealCompletionSealClassifierUp}$ *read factors through the displayed agreement, seal, synchronizer, budget, regular handoff, stream-window, dyadic, transport, route, provenance, and naming rows*

$$A, L, S, B, R, W, D, H, C, P, N.$$

No accepted read may bypass both a displayed seal row and a displayed budget or synchronizer row while still exporting a completion-seal classifier to a $\mathsf{Real}^{\uparrow}$ *consumer.*

Proof. Project the accepted carrier to $K = (A, L, S, B, R, W, D, H, C, P, N)$. The only seal-facing rows are A and L, and the only budget-facing synchronization rows are S, B, W, R, D.

Apply the NameCert obligation surface. It requires displayed seal equivalence through A, L and budget-synchronizer exactness through S, B, W, R, D before the route can be authenticated by C, P, N.

The componentwise transports in H preserve those rows and do not create a second completion channel. Since the carrier contains no quotient stream, host real equality, selected external limit, countable-choice row, or ambient completeness theorem, a read that bypasses both the seal rows and the budget or synchronizer rows has no remaining coordinate from which to export a classifier. □

Theorem 900.4 (Real completion-seal classifier stability)**.** *Let $K = (A, L, S, B, R, W, D, H, C, P, N)$ be an accepted* RealCompletionSealClassifierUp *carrier. Componentwise* hsame *transport along the rows recorded in H preserves the classifier read on the agreement seal, limit seal, synchronizer, budget, regular handoff, stream-window, dyadic ledger, displayed routes, provenance, and local naming coordinates of K. In particular, a transported accepted read still classifies completion-seal equivalence only through those displayed coordinates.*

Proof. Project the accepted carrier to its tuple K. The transport row H is a coordinate of the same carrier, so its componentwise hsame data is read only against the displayed rows $A, L, S, B, R, W, D, C, P, N$.

Use the obligation surface of Definition 900.2. Its stability row is exactly the requirement that the classifier surface remains the same classifier after those componentwise transports.

Finally use the non-escape boundary of Definition 900.3. Since no quotient stream, host equality, selected external limit, countable-choice row, or ambient completeness theorem is present in K, the transported read has no second completion channel. □

Theorem 900.5 (Real completion-seal classifier seal equivalence)**.** *Let $K = (A, L, S, B, R, W, D, H, C, P, N)$ be an accepted* RealCompletionSealClassifierUp *carrier. Before any* $\mathsf{Real}^{\uparrow}$ *consumer receives a seal classifier, completion-seal equivalence is read only through the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row A and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row L, together with the displayed route row C that exposes those two rows to the consumer.*

Proof. Project the carrier to K. The only agreement-facing coordinate is A, and the only completion-limit-facing coordinate is L.

Invoke the NameCert obligations of Definition 900.2. The displayed seal-equivalence row requires the classifier to pass through A and L before the route data in C can authenticate a $\mathsf{Real}^{\uparrow}$ consumer read.

The non-escape theorem then rules out every bypass. A read that does not use A and L has no displayed seal row left in the carrier from which to export a completion-seal classifier. □

Theorem 900.6 (Real completion-seal classifier budget exactness)**.** *Let $K = (A, L, S, B, R, W, D, H, C, P, N)$ be an accepted* RealCompletionSealClassifierUp *carrier. The synchronizer and budget rows S, B, W, R, D are exact prerequisites for the seal read: the classifier must pass through the synchronizer, finite budget, finite stream window, regular rational handoff, and dyadic tolerance ledger before any completion-seal classifier is exported. This prerequisite surface excludes quotient streams, host real equality, selected external limits, countable choice, and ambient completeness.*

Proof. Project the accepted read to the carrier tuple. The synchronizer, budget, stream-window, regular handoff, and dyadic rows are precisely S, B, W, R, D.

Apply the obligation surface. Its budget and synchronizer exactness row says that these five coordinates are prerequisites for the seal read before the routes, provenance, and local naming rows can authenticate an exported classifier.

Apply the non-escape boundary. If a read bypasses the displayed budget or synchronizer surface, then the carrier has no quotient stream, host equality, selected external limit, countable-choice row, or ambient completeness theorem that could replace it. □

Theorem 900.7 (Real completion-seal classifier tail-radius handoff)**.** *Let $K = (A, L, S, B, R, W, D, H, C, P, N)$ be an accepted* RealCompletionSealClassifierUp *carrier. Any accepted seal read whose budget row opens a tail-radius request must factor through the* DyadicTailRadiusLedger$^{\uparrow}$ *tail-budget coverage of Definition 757.3 and then through the* RegSeqRat$^{\uparrow}$–Real$^{\uparrow}$ *handoff of Definition 757.6 before any* Real$^{\uparrow}$ *consumer receives the classifier. The route is the displayed carrier route through $S, B, W, R, D, H, C, P, N$; it exports no quotient stream, host equality, selected external limit, countable choice, or ambient completeness principle.*

Proof. Project the accepted read to the carrier tuple K. The rows S, B, W, R, D are the only synchronizer, budget, finite window, regular rational handoff, and dyadic tolerance rows available before H, C, P, N authenticate a consumer-facing classifier.

Use budget exactness from Definition 900.6. Once the budget row opens a tail-radius request, the read is already constrained to the displayed route through S, B, W, R, D and cannot reach the exported classifier directly.

Now use the sibling ledger. The tail-budget coverage theorem, Definition 757.3, places the tail-radius request inside the finite precision, tail-window, StreamName-window, and dyadic readback rows, and Definition 757.6 carries that same route through the RegSeqRat$^{\uparrow}$ and Real$^{\uparrow}$ handoff rows.

Finally repack the resulting route through H, C, P, N. Since neither K nor the dyadic tail-radius ledger contains quotient streams, host equality, selected external limits, countable-choice rows, or ambient completeness theorems, the classifier received by the Real$^{\uparrow}$ consumer is the ledger-mediated classifier. □

Theorem 900.8 (Real completion-seal classifier window factorization)**.** *Every exported* RealCompletionSealClassifie *classifier window factors through the synchronizer row S, budget row B, finite stream-window row W, regular rational handoff row R, and dyadic tolerance row D before the exported completion-seal read E is available to a* Real$^{\uparrow}$ *consumer. The factorization is read inside the same carrier $K = (A, L, S, B, R, W, D, H, C, P, N)$ and is authenticated only by the displayed route, provenance, and local naming rows C, P, N.*

Proof. Project the accepted carrier to K. The NameCert obligations of Definition 900.2 expose S, B, W, R, D as the budget and synchronizer exactness rows for the classifier window.

Use budget exactness from Definition 900.6. It forces the exported read to pass through the synchronizer, finite budget, stream window, regular handoff, and dyadic tolerance ledger before C, P, N can authenticate the consumer-facing read.

Finally apply non-escape from Definition 900.3. Since no quotient stream, host equality, selected external limit, countable-choice row, or ambient completeness theorem is present, there is no second path from the window to E. □

Theorem 900.9 (Real completion-seal classifier threshold uniqueness)**.** *Let $K = (A, L, S, B, R, W, D, H, C, P, N)$ be an accepted* RealCompletionSealClassifierUp *carrier. Any exported completion-seal threshold read over the displayed rows factors through the same synchronizer row S, budget row B, StreamName window row W, RegSeqRat handoff row R, and DyadicRatCore tolerance row D used by the exported classifier window. The route rows C, P, N authenticate that displayed route but cannot introduce a second threshold service for the same seal read.*

Proof. Project the accepted read to the carrier tuple K. The only threshold-facing support rows available before route authentication are the synchronizer, finite budget, StreamName window, RegSeqRat handoff, and DyadicRatCore tolerance rows S, B, W, R, D.

Apply the budget exactness theorem, Definition 900.6. It makes those five rows exact prerequisites for the seal read, so a threshold read exported by the packet has to cross the same budget surface as the classifier window.

Apply the window factorization theorem, Definition 900.8. The exported threshold read is therefore already on the displayed route through S, B, W, R, D before C, P, N can present it to a $\mathsf{Real}^{\uparrow}$ or completion-seal consumer.

Finally use the non-escape boundary of Definition 900.3. Since the carrier contains no quotient stream, host equality, selected external limit, countable-choice row, or ambient completeness theorem, the route rows C, P, N have no external source from which to manufacture another threshold service for the same displayed seal read. □

Theorem 900.10 (Real completion-seal classifier tail-agreement stability)**.** *Let $K = (A, L, S, B, R, W, D, H, C, P, N)$ and $K' = (A', L', S', B', R', W', D', H', C', P', N')$ be accepted* RealCompletionSealClassifierUp *carriers related by the displayed componentwise* hsame *transports. Transport preserves the joint seal-equivalence read through A, L and its transported counterpart through A', L' as presented to consumers by H, C, P, N and H', C', P', N'.*

Proof. Start with componentwise stability, Definition 900.4. The transport rows record exactly the agreement, limit-seal, synchronizer, budget, window, handoff, dyadic, route, provenance, and local naming coordinates.

Apply seal equivalence from Definition 900.5. The classifier reads completion-seal equivalence only through A, L before the $\mathsf{Real}^{\uparrow}$ consumer sees the exported seal classifier.

The transported read is therefore the same joint A, L seal-equivalence read through the transported support rows. Non-escape from Definition 900.3 rules out any quotient-stream or host-equality comparison appearing during transport. □

Theorem 900.11 (Real completion-seal classifier RealUp non-escape)**.** *A $\mathsf{Real}^{\uparrow}$ consumer of an accepted* RealCompletionSealClassifierUp *packet cannot read the completion-seal classifier from quotient streams, host equality, selected external limits, countable choice, or ambient completeness. The consumer receives only the displayed seal rows A, L, synchronizer and budget rows S, B, W, R, D, componentwise transport row H, route row C, provenance row P, and local naming row N.*

Proof. Project the consumer read to the accepted carrier $K = (A, L, S, B, R, W, D, H, C, P, N)$. The obligation theorem, Definition 900.2, lists all rows available to the local NameCert surface.

Use Definition 900.8 for the exported classifier window and Definition 900.10 for the transported seal-equivalence read. Together they place the consumer-facing classifier behind the displayed rows $A, L, S, B, W, R, D, H, C, P, N$.

Finally apply Definition 900.3. The carrier contains no quotient-stream coordinate, host equality, selected external limit, countable-choice row, or ambient completeness theorem, so a $\mathsf{Real}^{\uparrow}$ consumer has no route to such data. □

Theorem 900.12 (Real completion-seal classifier public scope)**.** *Every accepted* RealCompletionSealClassifierUp *packet exposes one public classifier scope over the finite carrier rows*

$$A, L, S, B, R, W, D, H, C, P, N$$

of Definition 900.1. Any $\mathsf{Real}^{\uparrow}$ or completion-seal consumer must factor through the seal-equivalence theorem, budget exactness, tail-radius handoff, window factorization, tail-agreement stability, and the $\mathsf{Real}^{\uparrow}$ non-escape theorem. No quotient stream, host equality, selected external limit, countable choice, or ambient completeness row is exported.

Proof. Project the accepted packet to the carrier tuple of Definition 900.1. This fixes the only available public rows as $A, L, S, B, R, W, D, H, C, P, N$.

Use the NameCert obligations of Definition 900.2. They make seal equivalence through A, L, budget and synchronizer exactness through S, B, W, R, D, and route authentication through C, P, N the whole classifier interface.

Compose Definition 900.7, Definition 900.8, and Definition 900.10. The exported classifier window and the transported agreement read therefore remain on the same finite route through $A, L, S, B, R, W, D, H, C, P, N$.

Finally apply Definition 900.11. It excludes quotient streams, host real equality, selected external limits, countable choice, and ambient completeness from the consumer surface, so the public scope is exactly the displayed finite classifier route. □

Theorem 900.13 (Real completion-seal classifier public export)**.** *Every public* $\mathsf{RealCompletionSealClassifierUp}$ *export to a* $\mathsf{Real}^{\uparrow}$ *consumer or to a completion-seal consumer factors through the finite route*

$$A, L, S, B, W, R, D, H, C, P, N.$$

The exported boundary is exactly the displayed seal-equivalence, budget-exactness, window-factorization, tail-agreement-stability, $\mathsf{Real}^{\uparrow}$ *non-escape, and public-scope surface of the accepted carrier. It exports no quotient stream, host real equality, selected external limit, countable-choice row, or ambient completeness principle.*

Proof. Project the accepted public packet to the carrier of Definition 900.1. This fixes the public export route as $A, L, S, B, W, R, D, H, C, P, N$, with the same displayed route, provenance, and local naming surface.

Use seal equivalence from Definition 900.5 and budget exactness from Definition 900.6. These two rows force any exported classifier to read the agreement seal, completion-limit seal, synchronizer, finite budget, StreamName window, regular handoff, and dyadic tolerance ledger before the consumer sees the classifier.

Then use the tail-radius handoff of Definition 900.7. A budget row that opens a tail-radius request must pass through the shared $\mathsf{DyadicTailRadiusLedger}^{\uparrow}$ coverage and $\mathsf{RegSeqRat}^{\uparrow}$–$\mathsf{Real}^{\uparrow}$ handoff route before the exported classifier reaches the consumer.

Next apply the window factorization of Definition 900.8 and the tail-agreement stability of Definition 900.10. They keep the exported window and transported agreement read on the same finite route through $A, L, S, B, W, R, D, H, C, P, N$.

Finally invoke $\mathsf{Real}^{\uparrow}$ non-escape from Definition 900.11 and public scope from Definition 900.12. Since quotient streams, host real equality, selected external limits, countable choice, and ambient completeness are absent from the carrier and from the public scope, no downstream export can recover them. □

Theorem 900.14 (Real completion-seal classifier completeness boundary)**.** *Every public* $\mathsf{RealCompletionSealClassifi}$ *export to a* $\mathsf{Real}^{\uparrow}$ *or completion-seal consumer is exactly the finite route*

$$A, L, S, B, W, R, D, H, C, P, N.$$

Consequently the export supplies a classifier boundary for a displayed seal read, and cannot be used as a theorem of $\mathsf{Real}^{\uparrow}$ *completeness, selected limits, quotient-stream equality, countable choice, or ambient Cauchy convergence.*

Proof. Start with the public export theorem, Definition 900.13. It states that every downstream $\mathsf{Real}^{\uparrow}$ or completion-seal export factors through the displayed finite route $A, L, S, B, W, R, D, H, C, P, N$.

Apply the $\mathsf{Real}^{\uparrow}$ non-escape theorem, Definition 900.11. The exported consumer surface has no coordinate for quotient streams, host equality, selected external limits, countable choice, or ambient completeness.

Use budget exactness from Definition 900.6. The synchronizer, finite budget, StreamName window, regular handoff, and dyadic tolerance ledger remain part of the same displayed route, so the read is a bounded classifier read rather than an ambient convergence principle.

Finally use public scope, Definition 900.12. That theorem exhausts the public consumer interface by the finite rows already displayed, so no consumer can reinterpret the exported classifier boundary as a $\mathsf{Real}^{\uparrow}$ completeness theorem, a selected-limit theorem, quotient-stream equality, countable choice, or ambient Cauchy convergence. □

Falsifiable prediction: If a Real completion-seal classifier read bypasses both a displayed seal row and a displayed budget/synchronizer row, the classifier packet is refuted.

Independence witness: realtailagreementseal, cauchylimitseal, cauchysealbudgetsynchronizer, real, regseqrat: no sibling is bijective because the classifier packet has a joint completion-seal classifier row tying agreement, seal, synchronizer, and Real handoff rows; each sibling lacks at least one of these coordinates.

Theorem 900.15 (Real completion-seal classifier public bridge schema)**.** *Let $K = (A, L, S, B, R, W, D, H, C, P, N)$ be an accepted* $\mathsf{RealCompletionSealClassifierUp}$ *carrier. The carrier rows $A, L, S, B, R, W, D, H, C, P, N$, the local* $\mathsf{NameCert}_{\mathsf{RealCompletionSealClassifierUp}}$ *obligations, non-escape, componentwise stability, seal-equivalence, budget-exactness, window factorization, and threshold uniqueness assemble the public bridge schema from* $\mathsf{RealTailAgreementSeal}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *to the exported* $\mathsf{RealCompletionSealClassifierUp}$ *read. The exported bridge surface has no quotient stream, host equality, selected external limit, countable-choice row, or ambient completeness coordinate.*

Proof. Project the accepted packet to the carrier of Definition 900.1. This exposes exactly the rows $A, L, S, B, R, W, D, H, C, P, N$: tail agreement, Cauchy-limit seal, seal-budget synchronizer, finite budget, regular rational handoff, StreamName window, DyadicRatCore tolerance ledger, componentwise transport, displayed route, provenance, and local naming.

Use the local theorem chain. The obligation theorem Definition 900.2 supplies the $\mathsf{NameCert}$ rows; non-escape and stability are Definition 900.3 and Definition 900.4; seal equivalence, budget exactness, window factorization, and threshold uniqueness are Definition 900.5, Definition 900.6, Definition 900.8, and Definition 900.9.

The sibling sources are then read row by row. The rows A and L provide the $\mathsf{RealTailAgreementSeal}^{\uparrow}$ and $\mathsf{CauchyLimitSeal}^{\uparrow}$ seal inputs, S and B provide the $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ budget input, R, W, D provide the $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ finite-window route, and H, C, P, N authenticate the route to the $\mathsf{Real}^{\uparrow}$ consumer.

Finally apply the public export and completeness-boundary theorems, Definition 900.13 and Definition 900.14. They show that the exported bridge is the same finite classifier read and that no quotient stream, host equality, selected external limit, countable-choice row, or ambient completeness coordinate is present in the exported surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealCompletionSealClassifierUp}}$**.**

Constructive story: A RealCompletionSealClassifierUp packet is generated from tail-agreement seal rows, Cauchy-limit seal rows, Cauchy seal-budget synchronizer rows, finite budget rows, regular rational handoff rows, StreamName windows, DyadicRatCore ledgers, componentwise transports, displayed routes, provenance, and local naming.

Theory closure: TheoryGate(NameCert$_{\text{RealCompletionSealClassifierUp}}$, maturePackageClosed)

Scope closed: Definition 900.1, Definition 900.2, Definition 900.3, Definition 900.4, Definition 900.5, Definition 900.6, Definition 900.7, Definition 900.8, Definition 900.9, Definition 900.10, Definition 900.11, Definition 900.12, Definition 900.13, Definition 900.14, and Definition 900.15 bind the carrier, NameCert obligation surface, non-escape boundary, componentwise stability, seal-equivalence read, budget exactness, tail-radius handoff, window factorization, threshold uniqueness, tail-agreement stability, RealUp non-escape, public classifier scope, public consumer export, completeness boundary, and bridge surface for the finite completion-seal classifier packet.

Formal verification: FormalStatus(NameCert$_{\text{RealCompletionSealClassifierUp}}$, axiomClean)

Lean target: `BEDC.Derived.RealCompletionSealClassifierUp.RealCompletionSealClassifierTasteGate\_single\_carrier\_`

Bridge status: none

Not claimed: This chapter does not close quotient streams, host real equality, selected external limits, countable choice, ambient completeness, Lean verification, or bridge checking.

Upgrade path: The paper theory axis is mature for the finite completion-seal classifier surface; Lean verification and bridge checking remain independent obligations.

Chapter 901

A Concrete Naming Certificate for $\mathsf{AuditGateFailureWitness}^{\uparrow}$

The $\mathsf{AuditGateFailureWitness}^{\uparrow}$ packet realizes the failed-verdict side of the audit-gate boundary described in chapter 9396. It sits beside the pass/refusal ledgers of chapter 526, the composed gate surface of chapter 696, the apophatic refusal packet of chapter 630, and the gate-question packet of chapter 715. Those siblings expose questions, boundary ledgers, composition routes, or negative certificates; this packet records the concrete diagnostic witness for a gate row whose boundary item fails.

Falsifiable prediction: If an AuditGateFailureWitnessUp packet is accepted, every public consumer route reaches the diagnostic row before any composed refusal handoff; a direct route from gate row to theorem content refutes the packet.

Independence witness: AuditGateBoundaryUp supplies pass/refusal ledgers but not a diagnostic witness; AuditGateCompositionUp composes gate rows but does not carry a primitive failed item; NegativeCertificateBoundaryUp records apophatic refusal but not a gate diagnostic; ApophaticGateQuestionUp asks the gate question but does not store a failed verdict.

Definition 901.1 (Audit-gate failure-witness carrier)**.** *An* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (G, F, R, D, H, C, P, N)$$

with the following displayed rows:

1. *G is the audit-gate row whose finite boundary check is being read;*
2. *F is the failed boundary item, recording the source token, proof-ancestry dependency, unresolved target, origin/import crossing, or other gate-visible item that did not pass;*
3. *R is the refusal target attached to F, namely the theorem-content route, host supply, marker resolution, or internalizer that the gate refuses to admit;*
4. *D is the diagnostic readback row, recording the exact finite reason by which G classifies F as a failed item and attaches the refusal to R;*
5. *H records componentwise* hsame *transport for the gate row, failed item, refusal target, diagnostic readback, provenance, and local naming rows;*
6. *C records the displayed* Cont *replay routes from G to F, from F to D, from D to R, and from the local witness to any composed refusal handoff;*

7. *P records* Pkg *provenance naming* AuditGateBoundary$^{\uparrow}$, AuditGateComposition$^{\uparrow}$, NegativeCertificateBoundary$^{\uparrow}$, ApophaticGateQuestion$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *source packets;*

8. *N is the local* NameCert$_{\text{AuditGateFailureWitness}^{\uparrow}}$ *row.*

The carrier exports a failure witness for the displayed gate row. It exports no route by which the failed item becomes theorem content and no replacement diagnostic outside the displayed readback row.

Theorem 901.2 (Audit-gate failure-witness NameCert obligations)**.** *For every accepted* AuditGateFailureWitness$^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N),$$

the local NameCert$_{\text{AuditGateFailureWitness}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission: the accepted object is exactly the displayed* BHist *packet W with gate row, failed boundary item, refusal target, diagnostic readback, transport, continuation, provenance, and local naming rows;*

2. *diagnostic exactness: the row D is the only diagnostic readback for F under G, and it records the finite gate-facing reason for failure before any consumer reaches the refusal target;*

3. *refusal attachment: the row R is attached to the pair (F, D) rather than to an anonymous gate outcome, so the refusal cannot be detached from the concrete failed boundary item;*

4. *replay visibility: every public replay of the witness factors through the displayed routes in C, including the route from G to F, the diagnostic route from F to D, and the refusal route from D to R;*

5. *non-internalization: the packet exposes the failed verdict and its diagnostic, but it exports no theorem-content object, host supply, marker repair, admitted internalizer, or gate-bypass route for F.*

Lean4 ✓ `BEDC.Derived.AuditGateFailureWitnessUp.AuditGateFailureWitnessUp obligation surface`

Proof. Carrier admission is projection from Definition 901.1. The tuple exposes exactly the rows G, F, R, D, H, C, P, N, so an accepted witness has no hidden item beyond the displayed finite packet.

Diagnostic exactness is read from the role of D. The diagnostic is attached to F under the gate row G, and the continuation route reaches D before it can reach the refusal target. Thus a consumer cannot read the failure as an anonymous refusal.

Refusal attachment then follows by reading R after D. The refused target is paired with the failed item and diagnostic row, so the refusal cannot be moved to a different boundary item without leaving the carrier.

Replay visibility is confined to C, while componentwise transport is confined to H. The package and local-name rows P and N bind these visible routes as a local NameCert surface.

Finally, non-internalization follows from the carrier inventory. No coordinate of W supplies theorem content for F, repairs the marker or host supply, admits the refused internalizer, or bypasses the gate diagnostic. □

Theorem 901.3 (Audit-gate failure-witness target readback totality)**.** *For every accepted* AuditGateFailureWitness$^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N),$$

every public consumer read of the refusal target factors through the diagnostic row D before it reaches R. A read that reaches theorem content, marker repair, or host supply directly from F is not a read of the displayed carrier.

Proof. Project the carrier in Definition 901.1. Its continuation row C displays the route from the gate row to the failed item, from the failed item to the diagnostic, and from the diagnostic to the refusal target.

Apply the diagnostic exactness and replay visibility clauses of Definition 901.2. They force the diagnostic row D to be read before the target row R is available to any public consumer.

The non-internalization clause then excludes direct recovery of theorem content, marker repair, or host supply from F. Such a recovery would bypass D and therefore leave the displayed BHist inventory of the witness. □

Theorem 901.4 (Audit-gate failure-witness diagnostic refusal order)**.** *For every accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N),$$

the public refusal order is G, F, D, R before the support rows H, C, P, N are consumed. In particular, all consumer reads pass through D before R, and the refusal target cannot be detached from the diagnostic readback that names the failed boundary item.

Proof. Start with the displayed continuation route. The carrier gives no route from G to R and no route from F to R except through the diagnostic row D.

Use refusal attachment from Definition 901.2. The row R is attached to the concrete pair (F, D), so a consumer cannot read the refusal as an anonymous outcome of the gate row alone.

Finally inspect the support rows. Transport, continuation replay, provenance, and local naming preserve the same order rather than creating a second refusal path. Thus the diagnostic readback precedes every public refusal handoff. □

Theorem 901.5 (Audit-gate failure-witness boundary-item noninternalization coverage)**.** *For every accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N),$$

no theorem-content row, marker-repair row, or host-supply row can be recovered from the failed boundary item F without leaving the displayed BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *inventory. The packet covers the failure only as a gate row, failed item, diagnostic readback, refusal target, transport, replay, provenance, and local name.*

Proof. Read the carrier coordinates. The failed boundary item F appears with G, D, R, H, C, P, N and with no additional coordinate for theorem content, marker repair, host supply, or admitted internalization.

Apply the NameCert obligations. Carrier admission fixes the displayed BHist packet, replay visibility fixes the Cont routes through D, and non-internalization excludes every recovery of theorem content or repair content from F.

The remaining support is exactly componentwise hsame transport, package provenance, and local $\mathsf{NameCert}$ naming. Recovering a theorem-content, marker-repair, or host-supply row would require a row outside that inventory, so it is not covered by the accepted witness. □

Theorem 901.6 (Audit-gate failure-witness composition handoff)**.** *Let*

$$W_0 = (G_0, F_0, R_0, D_0, H_0, C_0, P_0, N_0)$$

and

$$W_1 = (G_1, F_1, R_1, D_1, H_1, C_1, P_1, N_1)$$

be accepted $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carriers consumed by an* $\mathsf{AuditGateComposition}^{\uparrow}$ *packet. The composition may read the two diagnostic rows* D_0, D_1*, the two refusal targets* R_0, R_1*, and the two replay routes* C_0, C_1 *as input to its composed refusal trace. It may not turn either failed boundary item* F_0 *or* F_1 *into theorem content, and it may not replace either diagnostic row by the composed trace itself.*

Proof. Project the two accepted witnesses. Each exposes a gate row, failed item, refusal target, diagnostic readback, transport, replay, provenance, and local name.

Feed only the visible diagnostic and refusal rows to the composition packet. The first witness contributes D_0, R_0, C_0, and the second witness contributes D_1, R_1, C_1. The composed surface may order these rows, compare their gate boundaries, and expose a composed refusal trace.

The failed items remain boundary items of their original witnesses. Since neither carrier has a theorem-content coordinate for its failed item, the composition has no source from which to manufacture such content.

The composed trace also cannot replace the diagnostic rows. It is a consumer of D_0 and D_1, not a primitive diagnostic for either gate row. Thus the handoff preserves both failure witnesses while keeping the failures outside theorem content. □

Theorem 901.7 (Audit-gate failure-witness root public handoff)**.** *Every root-facing public handoff of an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier keeps the diagnostic row before refusal-target reads. The handoff surface is exactly* G, F, R, D, H, C, P, N*, and it contains no theorem-content recovery from the failed boundary item.*

Proof. Project the carrier $W = (G, F, R, D, H, C, P, N)$. The gate row, failed item, refusal target, diagnostic readback, transport, replay, provenance, and local name are the only displayed coordinates.

Apply the NameCert obligations and the composition handoff. They require public refusal reads to pass through the diagnostic row and allow composition to consume only visible diagnostic, refusal, and replay rows.

The TasteGate marker context names the same finite carrier for later formal alignment. Since F is never a theorem-content coordinate, the root handoff exports a diagnostic boundary and nothing recovered from the failed item. □

Theorem 901.8 (Audit-gate failure-witness composition readback scope)**.** *In every* $\mathsf{AuditGateComposition}^{\uparrow}$ *consumption of* $\mathsf{AuditGateFailureWitness}^{\uparrow}$*, the readable scope of each component witness is* G, F, D, R, H, C, P, N *with* D *before the refusal target* R*. The composition may compare diagnostics and refusal targets but may not replace either diagnostic row by the composed trace.*

Proof. Use Definition 901.6. It gives the composition access to D_0, R_0, C_0 and D_1, R_1, C_1 while leaving the failed items as boundary items of their own witnesses.

Next apply refusal-route exactness and refusal attachment stability. They keep R attached to the concrete pair (F, D) under the displayed hsame and Cont rows.

Thus the composition readback scope is diagnostic-first on G, F, D, R, H, C, P, N. The composed trace is downstream of those rows and cannot become a primitive diagnostic for either witness. □

Theorem 901.9 (Audit-gate failure-witness diagnostic target exhaustion)**.** *After an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *consumer has read* G, F, D, R, H, C, P, N*, no further diagnostic target remains inside the packet. In particular, the packet exposes no internalizer, repair row, host-supply row, or theorem-content row for the failed item.*

Proof. Start from the root public handoff. It identifies the complete public surface as the displayed diagnostic witness rows and places D before refusal-target consumption.

Then use composition readback scope. Even when the witness is consumed by a composed audit gate, the available rows remain G, F, D, R, H, C, P, N and the composed trace does not replace the component diagnostic.

Finally apply boundary-item noninternalization coverage. Rows for internalization, repair, host supply, and theorem content are absent from the carrier, so no diagnostic target remains after the displayed rows are exhausted. □

Theorem 901.10 (Audit-gate failure-witness refusal attachment stability)**.** *Let*

$$W = (G, F, R, D, H, C, P, N)$$

be an accepted $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier. Componentwise* hsame *transport through* H *preserves the attachment of the refusal target* R *to the concrete pair* (F, D)*. A transported witness may rename the displayed rows only componentwise; it cannot detach* R *from the failed boundary item* F *or from the diagnostic readback row* D*.*

Proof. Project the carrier from Definition 901.1. The displayed packet contains the failed item, diagnostic row, refusal target, transport row, replay row, provenance row, and local name as separate finite coordinates.

Use the NameCert obligations of Definition 901.2. Their refusal attachment clause binds R to the pair (F, D), while their replay visibility clause keeps public reads on the displayed continuation rows.

The composition handoff, Definition 901.6, only consumes the diagnostic and refusal rows after the witness has supplied them. Since H acts componentwise on the same carrier coordinates, any accepted transport preserves the attachment rather than creating a detached refusal target. □

Theorem 901.11 (Audit-gate failure-witness diagnostic nonescape)**.** *For every accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N),$$

no public route can bypass the diagnostic row D *to turn the failed boundary item* F *into theorem content, a repaired marker, an admitted internalizer, or a host-supplied replacement for the failed gate item.*

Proof. Project W and read the carrier inventory of Definition 901.1. The only route out of the gate row passes through the displayed failed item, diagnostic row, refusal target, transports, replay rows, provenance, and local name.

The NameCert obligations, Definition 901.2, place the diagnostic row before any consumer reaches the refusal target and explicitly exclude theorem content, marker repair, host supply, admitted internalizers, and gate-bypass routes for F.

The composition handoff theorem shows that even a composed audit surface receives D as diagnostic input rather than replacing it. Thus every public consumer must read the diagnostic before the refusal, and no route can turn F into admitted theorem content or a repaired marker. □

Theorem 901.12 (Audit-gate failure-witness root public exhaustion)**.** *For every accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N),$$

the root public surface is exhausted by the displayed BHist *packet, the componentwise* hsame *transport row* H*, the displayed* Cont *replay row* C*, the* Pkg *provenance row* P*, and the local* NameCert *row* N*. After carrier admission, diagnostic exactness, refusal attachment, replay visibility, and non-internalization are read, no root consumer has a remaining route to theorem content, marker repair, host supply, an admitted internalizer, a detached refusal target, or a composed refusal replacement.*

Proof. Project the carrier and the NameCert obligations. Carrier admission identifies the public packet as $W = (G, F, R, D, H, C, P, N)$, while diagnostic exactness and refusal attachment place D before R and attach the refusal to the concrete failed item.

Use diagnostic nonescape. The failed boundary item F cannot become theorem content, marker repair, an admitted internalizer, or a host-supplied replacement after the diagnostic row has been displayed.

Finally apply refusal attachment stability and composition readback scope. Componentwise hsame transport and displayed Cont replay preserve the same route, and an $\mathsf{AuditGateComposition}^{\uparrow}$ consumer reads only the diagnostic, refusal, and replay rows. Thus the root public surface is exhausted by the displayed BHist, hsame, Cont, Pkg, and NameCert rows. □

Theorem 901.13 (Audit-gate failure-witness failure diagnostic exhaustion)**.** *For every accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *packet*

$$W = (G, F, R, D, H, C, P, N),$$

the diagnostic row D *exhausts the failure explanation for the gate row* G *and failed boundary item* F *inside the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *inventory. No second diagnostic, hidden proof object, host primitive, marker repair, replacement* NameCert*, or detached closure row remains after* D, H, C, P, N *are read.*

Proof. Read the diagnostic exactness clause of the NameCert obligations. It states that D is the only diagnostic readback for F under G, and the replay row reaches it before the refusal target is consumed.

Apply diagnostic nonescape and boundary-item noninternalization coverage. These results exclude theorem content, marker repair, admitted internalizers, host supply, and replacement diagnostic content from the accepted carrier.

The remaining support rows are only transport, replay, provenance, and local naming. Since hsame, Cont, Pkg, and NameCert preserve the displayed diagnostic rather than creating a second one, the failure explanation is exhausted by D for the same packet $W = (G, F, R, D, H, C, P, N)$. □

Theorem 901.14 (Audit-gate failure-witness refusal route coverage)**.** *For every accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N),$$

every public refusal route factors through the displayed BHist *rows* G, F, D, R*, the componentwise* hsame *transport* H*, the displayed* Cont *replay* C*, the* Pkg *provenance* P*, and the local* NameCert *row* N*. A route from* G *or* F *directly to theorem content, host supply, marker repair, admitted internalization, or a detached composed refusal object is not covered by the packet.*

Proof. Begin with refusal-route exactness and refusal attachment stability. They keep R attached to the pair (F, D) under the displayed transport and replay rows, so a public route cannot detach the refusal from the failed boundary item.

Next use the NameCert obligations and diagnostic nonescape. Carrier admission fixes the finite packet, replay visibility forces the public route through C, and non-internalization blocks theorem content, marker repair, host supply, and admitted internalizers.

Finally read composition readback scope. A composed audit surface may consume the displayed refusal route, but it cannot replace D or R by a detached composed object. Hence the covered route is exactly the displayed BHist, hsame, Cont, Pkg, and NameCert inventory of W. □

Theorem 901.15 (Audit-gate failure-witness replay factorization)**.** *Every public replay of an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N)$$

factors first through the displayed diagnostic path

$$G \to F \to D \to R$$

and then through the visible support rows H, C, P, N. No replay may skip the failed item, replace the diagnostic, or read a refusal target outside the displayed transport, continuation, provenance, and local naming surface.

Proof. Project the accepted carrier. Its continuation row C displays the route from G to F, from F to D, from D to R, and from the local witness to any composed refusal handoff.

Apply the NameCert obligations of Definition 901.2. Carrier admission and replay visibility identify the public replay spine, while diagnostic exactness and refusal attachment force the order $G \to F \to D \to R$.

Finally apply the composition handoff, Definition 901.6. It permits a composed gate surface to consume only the displayed diagnostic, refusal, and replay rows. The remaining support is therefore exactly H, C, P, N, and no undisplayed repair, bypass, or replacement diagnostic participates in replay. □

Theorem 901.16 (Audit-gate failure-witness boundary coverage)**.** *Every accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N)$$

covers exactly the gate row, failed item, diagnostic row, refusal target, transport rows, replay rows, provenance row, and local NameCert *row displayed by its carrier. No accepted witness adds a separate repair row, host-supplied theorem row, omitted diagnostic, or off-packet internalizer.*

Proof. Project the carrier of Definition 901.1. Its visible rows are G, F, R, D, H, C, P, N, so the gate row, failed item, refusal target, diagnostic, transport, replay, provenance, and local naming rows are the full inventory.

Apply the NameCert obligations of Definition 901.2. Carrier admission, diagnostic exactness, refusal attachment, replay visibility, and non-internalization account for every accepted row in that inventory.

The composition handoff and replay factorization theorems preserve the same rows for downstream consumers. They consume diagnostic, refusal, replay, transport, provenance, and naming data from the witness, but they do not add a repair row, theorem row, replacement diagnostic, or internalizer outside W. □

Theorem 901.17 (Audit-gate failure-witness origin refusal)**.** *If the failed item F records an origin or import-crossing failure, then every accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *consumer reads that failure as refusal data through D and R. It cannot be converted into baseline theorem content, repaired marker content, or an admitted internalizer by replaying H, C, P, N.*

Proof. Start from the diagnostic row. The carrier makes D the displayed readback explaining why F failed under the gate row G, and the NameCert obligations force consumers to reach D before the refusal target R.

Use diagnostic nonescape and replay factorization. Diagnostic nonescape blocks replacement of the gate-visible failure by theorem content, while replay factorization keeps public replay on the path $G \to F \to D \to R$ with support rows H, C, P, N.

Finally apply the composition handoff. A composed audit surface may pass along the diagnostic and refusal rows, but it remains a consumer of the failure witness. Hence an origin or import-crossing failure stays refusal data and cannot become baseline theorem content, repaired marker content, or an admitted internalizer. □

Theorem 901.18 (Audit-gate failure-witness ledger exhaustion)**.** *Every public consumer of an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *packet factors through*

$$G, F, D, R, H, C, P, N.$$

The packet exports no marker repair, host supply, theorem object, admitted internalizer, or route that bypasses the displayed gate, failed item, diagnostic, refusal, transport, replay, provenance, and local naming rows.

Proof. First read the public replay spine from Definition 901.15. It forces every public replay through the diagnostic route $G \to F \to D \to R$ and then through the support rows H, C, P, N.

Next apply boundary coverage. The accepted witness contains no public coordinate beyond the gate row, failed item, diagnostic, refusal target, transport, replay, provenance, and local naming rows.

The NameCert obligations and composition handoff then exclude all escape routes. Non-internalization blocks marker repair, host supply, theorem content, and admitted internalizers, while the composed surface may only consume the displayed diagnostic, refusal, and replay rows. Therefore the listed ledger exhausts every public consumer. □

Theorem 901.19 (Audit-gate failure-witness diagnostic totality)**.** *Every public read of a failed gate item in an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *packet factors through exactly the displayed diagnostic row D before reaching the refusal target R. The route is*

$$G \to F \to D \to R$$

with support rows H, C, P, N, so no public consumer can read F as a failure witness by bypassing D or by reaching R through a detached refusal route.

Proof. Start with the carrier and target-readback totality. The carrier displays $W = (G, F, R, D, H, C, P, N)$, and the failed item F is public only as an item governed by the gate row G.

Apply diagnostic-refusal order. It places the diagnostic row D between the failed item and the refusal target, so the route to R is not available until D has been consumed.

Finally use diagnostic nonescape and replay factorization. Diagnostic nonescape blocks replacement of D by marker repair or theorem content, while replay factorization carries the same route through H, C, P, N. Hence every public failed-item read reaches R through exactly the displayed diagnostic row. □

Theorem 901.20 (Audit-gate failure-witness refusal consumer boundary)**.** *Any consumer of an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *witness must preserve the gate row G, failed item F, diagnostic row D, refusal target R, transport row H, replay row C, provenance row P, and local naming row N. Omitting D or detaching R from the pair (F, D) exits the accepted packet and cannot be repaired by transport, replay, provenance, or local naming alone.*

Proof. Project the ledger exhaustion theorem. Every public consumer already factors through G, F, D, R, H, C, P, N and receives no marker repair, host supply, theorem object, admitted internalizer, or bypass route.

Use diagnostic totality to bind D and R. The refusal target is reached through the displayed diagnostic row for the failed item, so a consumer that omits D or detaches R from (F, D) changes the public witness.

The support rows are conservative. Componentwise transport, replay, provenance, and local naming preserve the displayed diagnostic-refusal packet; they do not synthesize a replacement diagnostic or a detached refusal route. Thus such a consumer leaves the accepted boundary. □

Theorem 901.21 (Audit-gate failure-witness diagnostic uniqueness)**.** *For every accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N),$$

the row D is the unique public diagnostic for the pair (G, F) along the displayed continuation route. Any alternate diagnostic for the same gate row and failed boundary item is outside the carrier and cannot reach the refusal target R as an accepted $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *consumer route.*

Proof. Start with the carrier definition and the NameCert obligations. The accepted packet displays exactly one diagnostic readback row D for the gate row G and failed item F, and diagnostic exactness places that row before any refusal handoff.

Use target readback totality and diagnostic-refusal order. Every public route to R must pass through the route

$$G \to F \to D \to R.$$

Finally apply the refusal consumer boundary. An alternate diagnostic would either replace D or detach R from (F, D). Both moves leave the displayed packet, so no alternate diagnostic is an accepted public diagnostic for the same pair (G, F). □

Theorem 901.22 (Audit-gate failure-witness boundary-item coverage)**.** *Every failed boundary item accepted by an* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier is covered exactly as gate row, failed item, diagnostic, refusal, transport, replay, provenance, and local name. The carrier has no theorem-content coordinate and no marker-repair coordinate for the failed item.*

Proof. Project the carrier $W = (G, F, R, D, H, C, P, N)$. Its rows name the gate, failed boundary item, refusal target, diagnostic readback, transport, replay, provenance, and local NameCert data.

Apply boundary-item noninternalization coverage. That theorem excludes theorem-content, marker-repair, and host-supply rows from the accepted inventory.

Use diagnostic totality and the refusal consumer boundary to check the public route. The failed item is consumed through G, F, D, R and preserved by H, C, P, N; any consumer that adds theorem content or marker repair has changed the accepted packet rather than covering the displayed boundary item. □

Theorem 901.23 (Audit-gate failure-witness refusal-route exactness)**.** *Every consumer route to the refusal target R of an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier factors through G, F, D and the displayed support rows H, C, P, N. There is no accepted detached route to R that omits the gate row, failed item, diagnostic readback, transport, replay, provenance, or local naming rows.*

Proof. Begin with target readback totality. It forces public reads of the refusal target to pass through the diagnostic row after the gate row and failed boundary item.

Diagnostic-refusal order gives the exact spine G, F, D, R. Replay factorization then carries that spine through the support rows H, C, P, N.

Finally use the refusal consumer boundary. Omitting the diagnostic or detaching R from (F, D) exits the carrier, while transport, replay, provenance, and local naming preserve only the displayed support route. Hence every accepted route to R has the stated factorization. □

Theorem 901.24 (Audit-gate failure-witness diagnostic carrier totality)**.** *For every accepted* AuditGateFailureWitne *packet*

$$W = (G, F, R, D, H, C, P, N),$$

the carrier exposes exactly one diagnostic carrier row before the refusal target. The row is D, it is attached to the gate row G and failed item F, and every accepted route to R first reads that displayed diagnostic row.

Proof. Start from carrier admission in Definition 901.2. The accepted packet contains one diagnostic coordinate, namely D, and no second diagnostic row is present in W.

Use diagnostic exactness and target readback totality. These obligations place the diagnostic readback before the refusal target and force every public read of R through the route $G \to F \to D \to R$.

Finally apply diagnostic uniqueness and refusal-route exactness. An alternate diagnostic would replace D or detach R from the displayed pair (F, D), and both moves leave the accepted carrier. Thus the diagnostic carrier row before R is exactly D. □

Theorem 901.25 (Audit-gate failure-witness composed refusal route preservation)**.** *Let*

$$W = (G, F, R, D, H, C, P, N)$$

be an accepted $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier consumed by an* $\mathsf{AuditGateComposition}^{\uparrow}$ *packet. The composed consumer preserves the displayed route G, F, D, R, H, C, P, N and cannot replace it with composed refusal content. In particular, the composed refusal trace may consume D, R, and C, but it does not become the diagnostic row for G, F and does not supply theorem content for F.*

Proof. Read the composition handoff. It permits an $\mathsf{AuditGateComposition}^{\uparrow}$ surface to consume the diagnostic, refusal, and replay rows of an accepted failure witness, while the failed item remains a boundary item of that witness.

Use replay factorization and refusal-route exactness to pin down the consumed route. The public route remains $G \to F \to D \to R$ with support rows H, C, P, N, so the composed trace is downstream from the displayed carrier rather than a replacement for it.

Finally apply diagnostic nonescape and the refusal consumer boundary. They block conversion of F into theorem content and block replacement of D by a detached refusal route. Hence the composed consumer preserves the displayed failure-witness route. □

Theorem 901.26 (Audit-gate failure-witness gate-row exhaustion)**.** *Every gate-row consumer of an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *packet is exhausted by carrier admission, diagnostic exactness, refusal attachment, replay visibility, and non-internalization. After these five rows are read, the consumer has no remaining route to a marker repair, host supply, theorem object, admitted internalizer, omitted diagnostic, detached refusal target, or composed refusal replacement.*

Proof. Begin with the NameCert obligation surface. Its five rows expose the carrier, identify the diagnostic, attach the refusal to the displayed failed item, make replay visible, and exclude internalization of the failure.

Apply ledger exhaustion and boundary-item coverage. They show that every public consumer of the gate row factors through G, F, D, R, H, C, P, N and that the failed item is covered only by those displayed rows.

Finally use composed refusal route preservation. Even when an $\mathsf{AuditGateComposition}^{\uparrow}$ packet consumes the witness, the route remains the displayed failure-witness route rather than composed refusal content. Therefore the five NameCert rows exhaust every gate-row consumer. □

Theorem 901.27 (Audit-gate failure-witness diagnostic row inversion)**.** *Let*

$$W = (G, F, R, D, H, C, P, N)$$

be an accepted $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier. Any public refusal read of* W *determines the displayed diagnostic row* D *for the gate row* G *and failed boundary item* F*. The read cannot determine an alternate diagnostic, a detached refusal target, theorem content for* F*, marker repair, host supply, or an admitted internalizer.*

Proof. Start with target readback totality and diagnostic refusal order. They place every public read of the refusal target on the route $G \to F \to D \to R$ before any support row is consumed.

Next use diagnostic carrier totality. The carrier exposes exactly one diagnostic row before R, and that row is attached to the pair (G, F).

Finally apply diagnostic uniqueness and gate-row exhaustion. A second diagnostic, detached refusal route, theorem-content row, marker repair, host supply, or internalizer would add a coordinate absent from $W = (G, F, R, D, H, C, P, N)$. Therefore the public refusal read determines precisely D. □

Theorem 901.28 (Audit-gate failure-witness composition input exhaustion)**.** *Let an accepted* $\mathsf{AuditGateComposition}^{\uparrow}$ *packet consume an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N).$$

Its failure-witness input consists only of the diagnostic row D*, the refusal target* R*, replay through* C*, and the displayed support rows* G, F, H, P, N*. It receives no theorem-content row, host-supply row, marker-repair row, internalizer row, replacement diagnostic, or composed refusal object promoted into the carrier.*

Proof. Read the composition handoff through composed refusal route preservation. The composed consumer is downstream from the route G, F, D, R, H, C, P, N, so it may inspect diagnostic, refusal, replay, transport, provenance, and local naming rows only as displayed rows of the same packet.

Use refusal-route exactness to keep the input route on G, F, D, R. The route to R factors through D and cannot be replaced by a detached composed refusal path.

Finally apply boundary-item coverage and gate-row exhaustion. These theorems exclude theorem content, host supply, marker repair, admitted internalizers, replacement diagnostics, and

composed refusal replacement from the accepted input surface. Hence the composition input is exhausted by the diagnostic, refusal, replay, and displayed support rows. □

Theorem 901.29 (Audit-gate failure-witness origin import boundary)**.** *If the failed item F of an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *carrier*

$$W = (G, F, R, D, H, C, P, N)$$

records an origin/import crossing failure, then that failure remains a failed boundary item of W. It cannot be internalized as a host supply, theorem-content object, marker repair, admitted internalizer, or gate-bypass route.

Proof. Project the carrier and the non-internalization clause of the NameCert obligations. The failed item row F is part of the displayed witness, while no row of W supplies theorem content, host supply, marker repair, or an admitted internalizer.

Next use boundary-item coverage. It says every failed boundary item accepted by the carrier is covered only as gate row, failed item, diagnostic, refusal, transport, replay, provenance, and local name.

Finally combine refusal-route exactness with gate-row exhaustion. The origin/import crossing failure must be read through G, F, D, R, H, C, P, N, and after those rows are read there is no remaining route for host supply, theorem content, marker repair, internalization, or gate bypass. Thus the failed crossing remains a failed boundary item. □

Theorem 901.30 (Audit-gate failure-witness diagnostic scope closure)**.** *The diagnostic exactness of an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *packet is scoped only by the displayed rows*

$$G, F, R, D, H, C, P, N$$

over BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*, and the sibling surfaces* $\mathsf{AuditGateBoundary}^{\uparrow}$*,* $\mathsf{AuditGateComposition}^{\uparrow}$*,* $\mathsf{NegativeCertificateBoundary}^{\uparrow}$*, and* $\mathsf{ApophaticGateQuestion}^{\uparrow}$*. No consumer may add a second diagnostic source, a host-supplied repair row, or a theorem-content row for the failed item while remaining inside the accepted packet.*

Proof. Project the carrier of Definition 901.1. Its visible coordinates are exactly the gate row, failed item, refusal target, diagnostic row, transport, replay, provenance, and local name.

Apply the NameCert obligations and diagnostic exactness. They place the diagnostic row D inside the displayed packet and route it through BHist, hsame, Cont, Pkg, and NameCert together with the named sibling surfaces.

Finally use diagnostic nonescape and origin import boundary. These exclude a second diagnostic source, host repair, theorem content, and internalization from the carrier, so the diagnostic scope is the displayed packet alone. □

Theorem 901.31 (Audit-gate failure-witness refusal handoff scope)**.** *A composed refusal handoff consuming an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *packet may use the diagnostic row D, refusal target R, replay row C, and support rows G, F, H, P, N. It cannot promote the failed boundary item F to theorem content, cannot replace D by a composed diagnostic, and cannot detach R from the displayed failed item.*

Proof. Read the composition handoff theorem through the carrier rows. The composed consumer is allowed to inspect the diagnostic, refusal, and replay coordinates of the same G, F, R, D, H, C, P, N packet.

Apply composed refusal route preservation and refusal-route exactness. The route to R remains attached to G, F, D and then travels through the displayed support rows.

Finally use boundary-item coverage and diagnostic nonescape. They rule out theorem content for F, replacement of D, and detached refusal content, so the handoff remains a scoped consumer of the original failure-witness packet. □

Theorem 901.32 (Audit-gate failure-witness replay ledger scope)**.** *Replay, componentwise transport, provenance, and local naming in an accepted* $\mathsf{AuditGateFailureWitness}^{\uparrow}$ *packet preserve the same diagnostic packet* G, F, R, D, H, C, P, N*. They introduce no hidden repair row, no host-supply row, no theorem-content row, and no replacement diagnostic for the failed boundary item.*

Proof. Project the replay and support coordinates H, C, P, N from Definition 901.1. They preserve and name the rows already present in the packet.

Use replay factorization and gate-row exhaustion. Every public consumer route remains exhausted by carrier admission, diagnostic exactness, refusal attachment, replay visibility, and non-internalization.

Finally apply diagnostic row inversion. A public refusal read determines the displayed diagnostic row D and no alternate diagnostic, repair, host supply, theorem content, or internalizer. Thus replay and naming preserve the same diagnostic packet without adding hidden support. □

Theorem 901.33 (Audit-gate failure-witness public diagnostic export)**.** *For every accepted* AuditGateFailureWitnes *packet*

$$W = (G, F, R, D, H, C, P, N),$$

the public diagnostic route exported by the packet is exactly

$$G \longrightarrow F \longrightarrow D \longrightarrow R$$

followed by the support rows H, C, P, N*. A public consumer may read the gate row, the failed item, the diagnostic, the refusal target, componentwise transport, displayed replay, provenance, and local naming, but it receives no theorem-content row, host-supply row, marker-repair row, admitted internalizer, replacement diagnostic, or detached refusal object.*

Proof. Project the accepted carrier. The gate row G, failed item F, refusal target R, diagnostic row D, and support rows H, C, P, N are the only visible public coordinates.

Use diagnostic scope closure and refusal handoff scope. They place every public refusal read on the displayed route from G to F, then through D, and then to R before replay and support rows are consumed.

Apply replay ledger scope to the support rows. Componentwise transport, displayed replay, provenance, and local naming preserve the same diagnostic packet and do not add repair, theorem-content, host-supply, or replacement diagnostic coordinates.

Finally use origin import boundary and composition input exhaustion. These exclude internalization, gate bypass, detached composed refusal content, and theorem content for the failed item, so the route G, F, D, R, H, C, P, N is the public diagnostic export boundary. □

The Lean follow-up for this chapter must provide `Derived/AuditGateFailureWitnessUp/TasteGate.lean` with $\mathsf{Nontrivial}$ $\mathsf{AuditGateFailureWitness}^{\uparrow}$ and $\mathsf{FieldFaithful}$ $\mathsf{AuditGateFailureWitness}^{\uparrow}$ instances for the same finite carrier.

Lean4 ✓ `BEDC.Derived.AuditGateFailureWitnessUp.AuditGateFailureWitnessTasteGate single carrier alignment`

Closure status for $\mathsf{NameCert}_{\mathsf{AuditGateFailureWitness}^{\uparrow}}$.

Constructive story: An $\mathsf{AuditGateFailureWitness}^{\uparrow}$ packet is generated from a gate row, a failed boundary item, a refusal target, diagnostic readback, componentwise hsame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AuditGateFailureWitness}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 901.1, Definition 901.2, Definition 901.6, Definition 901.30, Definition 901.31, Definition 901.32, Definition 901.33, and

Lean4 ✓ `BEDC.Derived.AuditGateFailureWitnessUp.taste gate`

bind failed audit-gate verdicts as public diagnostic NameCert packets with visible refusal handoff.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{AuditGateFailureWitness}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.AuditGateFailureWitnessUp.AuditGateFailureWitnessTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a public standard bridge, audit-policy completeness, automatic repair of failed targets, or theorem content for failed boundary items.

Upgrade path: No theory-axis upgrade remains; bridge checking may be recorded if a standard bridge target is supplied for the same diagnostic witness packet, refusal handoff, replay ledger, provenance, and local NameCert surface.

$\mathsf{CauchyWitnessLedger}^{\uparrow}$ is the Real-completion witness ledger read between chapter 1117 and chapter 1110; its finite route uses the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ sibling surfaces without quotient streams, selected host limits, countable choice, or ambient completeness.

Chapter 902

A Concrete Naming Certificate for $\mathsf{CauchyWitnessLedger}^{\uparrow}$

The $\mathsf{CauchyWitnessLedger}^{\uparrow}$ packet realizes the Real completeness route of chapter 9238 as one finite witness ledger. It joins the diagonal selector budget of chapter 853, the observation-budget packet of chapter 611, the seal synchronizer of chapter 886, and the completion-seal classifier of chapter 900. The packet is a NameCert surface for the displayed witness route, not a quotient stream, host equality principle, hidden limit selector, countable-choice row, or ambient completeness theorem.

Definition 902.1 (Cauchy witness ledger carrier)**.** *A* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (Q, B, S, K, H, C, P, N)$$

with the following displayed rows:

1. *Q is the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *row exposing the finite precision, mesh, comparison, and selected diagonal budget for the completion-facing request;*
2. *B is the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row repackaging the same budget into finite observation windows, dyadic readbacks,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff rows, and* $\mathsf{Real}^{\uparrow}$ *seal rows;*
3. *S is the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row tying the selected diagonal budget, observation budget, shared-threshold route, and seal row into one synchronized read;*
4. *K is the* $\mathsf{RealCompletionSealClassifierUp}$ *row classifying the completion-facing seal only after the synchronized budget and seal rows have been consumed;*
5. *H records componentwise* hsame *transports for Q, B, S, K, C, P, N;*
6. *C records displayed* Cont *routes from the diagonal budget to the observation budget, from the observation budget to the synchronizer, and from the synchronizer to the completion-seal classifier;*
7. *P records* Pkg *provenance over* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{CauchySealBudgetSynchronizer}$ $\mathsf{RealCompletionSealClassifierUp}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyWitnessLedger}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient stream equality, host real equality, selected external limits, countable choice, or ambient completeness.

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerTasteGate single carrier alignment`

Theorem 902.2 (Cauchy witness ledger NameCert obligations)**.** *For the carrier of Definition 902.1, the local* $\mathsf{NameCert}_{\mathsf{CauchyWitnessLedger}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$L = (Q, B, S, K, H, C, P, N),$$

diagonal-budget exposure through Q*, observation-budget exposure through* B*, seal-synchronizer exposure through* S*, completion-seal classifier exposure through* K*, componentwise* hsame *transport through* H*, displayed* Cont *route replay through* C*,* Pkg *provenance through* P*, and local naming through* N*. Later Lean TasteGate work must provide explicit* Nontrivial CauchyWitnessLedger$^{\uparrow}$ *and* FieldFaithful CauchyWitnessLedger$^{\uparrow}$ *instances for this same row inventory.*

Proof. Carrier admission is projection from the displayed tuple. The rows Q, B, S, K, H, C, P, N expose every public coordinate of the witness ledger.

The analytic rows are read in order. The diagonal budget Q supplies the finite precision, mesh, comparison, and selected diagonal surface; the observation budget B repackages that surface as windows, dyadic readbacks, regular-rational handoffs, and real seal rows.

The synchronizer S then ties the selected diagonal budget and observation route to the seal-facing read. The classifier K is reached only after that synchronized route has been displayed.

The structural rows H, C, P, N transport, replay, package, and name the same finite route. Since the carrier has no quotient stream, host equality, external limit, choice, or ambient completeness coordinate, these rows exhaust the local certificate surface. □

Theorem 902.3 (Cauchy witness ledger TasteGate nontriviality)**.** *For every accepted* CauchyWitnessLedger$^{\uparrow}$ *packet, the TasteGate-facing surface must contain two distinguishable accepted ledger witnesses whose separation is witnessed by at least one displayed analytic row among* Q, B, S, K*. Hence carrier admission for the packet cannot collapse to a one-point surface: a missing-row packet or a packet that reaches* K *while bypassing one of* Q, B, S *is rejected by the same local NameCert surface.*

Proof. Read the accepted carrier as

$$L = (Q, B, S, K, H, C, P, N).$$

The NameCert obligation theorem says that the public surface contains all four analytic rows Q, B, S, K and all four structural rows H, C, P, N. Therefore the TasteGate input is not a bare carrier name; it is the displayed ledger packet with analytic rows available for comparison.

The falsifiable prediction for this chapter fixes the rejection test: any admitted Real-facing read must factor through the displayed diagonal-budget, observation-budget, seal-synchronizer, and completion-seal rows. A packet with a missing analytic row, or a packet whose read bypasses one of these rows before reaching K, fails that test and is not an accepted witness for the ledger surface.

The independence witness separates this carrier from each nearest sibling. Each sibling lacks at least one of the four ledger coordinates, while CauchyWitnessLedger$^{\uparrow}$ requires the simultaneous factorization through all four. Thus the accepted packet supplies a witness pair for Lean's Nontrivial obligation: one witness reads the displayed budget route and another reads a displayed seal route separated by at least one of Q, B, S, K, and the local certificate rejects the attempted one-point collapse. □

Theorem 902.4 (Cauchy witness ledger FieldFaithful row)**.** *Any* FieldFaithful CauchyWitnessLedger$^{\uparrow}$ *instance for the same accepted packet must project exactly the rows*

$$Q, B, S, K, H, C, P, N.$$

Equality of all eight projected rows is the only permitted carrier equality route for TasteGate consumers. No compressed classifier, quotient stream, host real equality, selected external limit, or ambient completeness row may replace constructor-field faithfulness for this packet.

Proof. Start with the carrier definition and the NameCert obligations. The carrier has exactly the tuple $L = (Q, B, S, K, H, C, P, N)$, and the local certificate surface exposes precisely those analytic, transport, replay, provenance, and naming rows.

Apply Definition 902.5. The analytic part of the read is forced through $Q \longmapsto B \longmapsto S \longmapsto K$, so a faithful field projection cannot expose K from a compressed classifier while hiding one of the prior analytic fields.

Next use Definition 902.11 and Definition 902.12. Once all eight displayed rows agree, there is no remaining public coordinate from which a second carrier equality route could be chosen. Conversely, omitting any displayed row leaves one of the admitted route, transport, replay, provenance, or naming obligations unread.

Finally apply Definition 902.18. Quotient stream equality, host Real equality, selected external limits, countable choice, and ambient completeness are excluded from the carrier. Therefore TasteGate consumers can be field-faithful only by projecting the eight constructor rows and using equality of those rows as the carrier equality route. □

Theorem 902.5 (Cauchy witness ledger budget factorization)**.** *Every admitted completion-facing read of an accepted* CauchyWitnessLedger$^{\uparrow}$ *packet factors through the finite route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

with the displayed structural rows H, C, P, N. Thus the read first consumes the CauchyDiagonalBudget$^{\uparrow}$ *precision, mesh, comparison, and selector data, then the* RealObservationBudget$^{\uparrow}$ *observation windows and handoff rows, then the* CauchySealBudgetSynchronizer$^{\uparrow}$ *seal route, and only then the* RealCompletionSealClassifierUp *completion-seal classifier.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier budget factorization`

Proof. Start from the carrier definition. The only completion-facing analytic rows are Q, B, S, K, and the only structural rows are H, C, P, N.

Apply the NameCert obligation theorem. It places diagonal-budget exposure before observation-budget exposure, observation-budget exposure before seal-synchronizer exposure, and seal-synchronizer exposure before the completion-seal classifier.

The route rows in C replay exactly that order, while H preserves the same coordinates under componentwise transport and P, N provide provenance and local naming. No hidden row remains from which a completion-facing consumer could bypass one of the four analytic rows. □

Theorem 902.6 (Cauchy witness ledger readback totality)**.** *Let*

$$L = (Q, B, S, K, H, C, P, N)$$

be an accepted CauchyWitnessLedger$^{\uparrow}$ *packet. Every analytic row Q, B, S, K and every structural row H, C, P, N has a public readback through the local* NameCert$_{\text{CauchyWitnessLedger}^{\uparrow}}$ *surface, and no public readback exists for a row outside this tuple.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerReadbackTotality`

Proof. Project the carrier of Definition 902.1. The accepted packet is the displayed finite tuple, so each analytic row and each structural row is available by projection.

Apply Definition 902.2. The local NameCert surface reads the four analytic rows in the order Q, B, S, K and reads the structural rows H, C, P, N as transport, replay, provenance, and naming data for the same packet.

The carrier has no ninth coordinate. Hence a public readback can only name one of the displayed rows, and no row outside L can be read through the accepted certificate. □

Theorem 902.7 (Cauchy witness ledger budget source coherence)**.** *For every accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet, the rows Q, B, and S share the same finite* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *source surface before the completion-seal classifier row K is exposed. Thus the classifier is reached only after one coherent budget source has passed through the diagonal row, the observation row, and the synchronizer row.*

Proof. Start with Definition 902.5. It forces every admitted completion-facing read through the route $Q \longmapsto B \longmapsto S \longmapsto K$, so K has no public exposure before the first three analytic rows have been consumed.

Use Definition 902.13. The observation row B reads the same finite $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surface already fixed by the diagonal row Q.

Then apply Definition 902.14. The synchronizer S consumes that same $Q \longmapsto B$ source before K becomes public, so the classifier cannot be exposed from a separate stream, rational, dyadic, or Real surface. □

Theorem 902.8 (Cauchy witness ledger classifier consumer non-escape)**.** *Every consumer of the completion-seal classifier row K in an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet must also expose the route*

$$Q \longmapsto B \longmapsto S$$

and the structural rows H, C, P, N. Such a consumer has no access to quotient stream equality, host real equality, selected external limits, countable-choice rows, or ambient completeness theorems outside the displayed ledger.

Proof. Use Definition 902.10. The accepted packet exposes exactly Q, B, S, K, H, C, P, N, with no additional classifier channel.

Apply Definition 902.11 and Definition 902.17. A consumer reaches K only along the displayed analytic route, and replay through C requires the prior rows Q, B, S together with the structural data H, P, N.

Finally apply Definition 902.18. The forbidden external coordinates are absent from the carrier and from its NameCert surface, so a classifier consumer cannot leave the finite route through quotient streams, host Real equality, selected limits, countable choice, or ambient completeness. □

Theorem 902.9 (Cauchy witness ledger Real completion handoff)**.** *Let*

$$L = (Q, B, S, K, H, C, P, N)$$

be an accepted $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *carrier. Every* $\mathsf{Real}^{\uparrow}$ *completion-facing consumer that reads L reaches the completion-seal classifier K only through the diagonal-budget row Q, observation-budget row B, seal-synchronizer row S, and structural rows H, C, P, N. The handoff exports no quotient stream equality, host real equality, selected external limit, countable-choice row, or ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerRealCompletionHandoff`

Proof. Project the carrier and apply Definition 902.5. The consumer route reaches K by first reading Q, then B, then S, all replayed through C and named by N.

Read the sibling surfaces cited in the introduction. The diagonal-budget row supplies the finite selector layer, the observation-budget row supplies finite Real-facing windows and handoffs, the synchronizer ties those rows to the seal route, and the classifier consumes the synchronized seal before it can export a completion-facing read.

Finally use the non-escape clause built into the carrier and NameCert obligations. Since no forbidden analytic coordinate appears in L, the Real completion handoff has exactly the displayed finite ledger route. □

Theorem 902.10 (Cauchy witness ledger carrier admission)**.** *Every accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet exposes exactly the eight rows*

$$Q, B, S, K, H, C, P, N.$$

Here Q is the diagonal-budget row, B is the observation-budget row, S is the seal-synchronizer row, K is the completion-seal classifier row, and H, C, P, N are respectively the componentwise transport, route replay, package-provenance, and local NameCert rows. No public read can escape this carrier inventory.

Proof. Project the accepted packet through Definition 902.1. The carrier is the finite tuple $L = (Q, B, S, K, H, C, P, N)$, so each displayed row is obtained by projection and no further coordinate is present in the tuple.

Apply Definition 902.2. The local NameCert surface is exactly carrier admission for the same tuple together with the four analytic rows and four structural rows.

The non-escape clause in the carrier rules out quotient stream equality, host real equality, selected external limits, countable choice, and ambient completeness. Hence every accepted public read is confined to the displayed row inventory. □

Theorem 902.11 (Cauchy witness ledger route determinacy)**.** *Let two completion-facing consumers of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet agree on the displayed route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

and on the structural rows H, C, P, N. Then they determine the same completion-seal classifier read: each consumer reaches K only after the diagonal budget, observation budget, seal synchronizer, componentwise transports, route replay, provenance, and local NameCert rows have been read in the displayed carrier.

Proof. Start with Definition 902.10. Both consumers read the same eight-row carrier inventory, so their public coordinates are confined to Q, B, S, K, H, C, P, N.

Apply Definition 902.5. The analytic part of any completion-facing read is forced through $Q \longmapsto B \longmapsto S \longmapsto K$, while the structural rows H, C, P, N preserve, replay, package, and name that route.

Since the consumers agree on the displayed route and on every structural row, there is no remaining carrier coordinate from which a second completion-seal classifier read could be selected. The classifier read is therefore determined by the common route through K. □

Theorem 902.12 (Cauchy witness ledger ledger exhaustion)**.** *Every public read of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet is exhausted by the four analytic rows* Q, B, S, K *and the structural rows* H, C, P, N*. In particular, the ledger exports no quotient stream equality, host real equality, selected external limit, countable-choice row, or ambient completeness theorem.*

Proof. Use Definition 902.10. The accepted packet exposes exactly the eight displayed rows, with no additional public coordinate.

Apply Definition 902.11. Any completion-facing consumer that agrees on the route and structural rows has the same completion-seal classifier read, so a public read cannot branch into an independent classifier channel.

Finally apply Definition 902.9. The Real-facing handoff reaches K only through Q, B, S and the structural rows, and it exports none of the listed external objects. Thus the ledger is exhausted by the displayed analytic and structural rows. □

Theorem 902.13 (Cauchy witness ledger diagonal observation route)**.** *Every admitted read of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet first consumes the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *row* Q *and then the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row* B *over the same finite* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *surface. The read may continue through* S, K, H, C, P, N*, but it cannot enter the observation row before the diagonal-budget row has fixed the displayed stream, regular-rational, dyadic, and Real-seal route.*

Proof. Project the accepted carrier using Definition 902.1 and Definition 902.10. The only analytic rows available to the read are Q, B, S, K, with H, C, P, N carrying transport, replay, provenance, and local naming.

Apply Definition 902.5. It places the diagonal-budget row before the observation-budget row on the displayed completion route, so the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ data seen by B are the same finite data already fixed by Q.

Use Definition 902.11 and Definition 902.12. They rule out a second observation route or a public coordinate outside the carrier, hence every admitted read follows the displayed diagonal-to-observation route. □

Theorem 902.14 (Cauchy witness ledger synchronizer classifier lock)**.** *For an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet, the completion-seal classifier row* K *is public only after the synchronizer row* S *has consumed the same diagonal-budget row* Q *and observation-budget row* B *on the displayed route. Thus no consumer can expose* K *by separating the classifier from the synchronized* $Q \longmapsto B \longmapsto S$ *route.*

Proof. Start from Definition 902.1. The synchronizer row S and completion-seal classifier row K are adjacent analytic coordinates of the same carrier, not independent public objects.

Apply Definition 902.5 and Definition 902.9. The factorization orders the route as $Q \longmapsto B \longmapsto S \longmapsto K$, and the Real handoff reaches the completion-seal classifier only after the same budget and observation rows have been consumed.

Finally use Definition 902.10, Definition 902.11, and Definition 902.12. Carrier admission supplies no second classifier row, route determinacy fixes the classifier read once Q, B, S, H, C, P, N are fixed, and ledger exhaustion prevents a public escape around the synchronizer. □

Theorem 902.15 (Cauchy witness ledger seal budget nonescape)**.** *No consumer of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *ledger can replace the finite route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

with quotient stream equality, host real equality, selected external limits, countable choice, or ambient completeness. The seal-budget route remains the displayed BEDC route over Q, B, S, K, H, C, P, N*.*

Proof. Read the finite route from Definition 902.1 and Definition 902.5. The carrier lists the available rows, and the factorization fixes the analytic order from diagonal budget to observation budget, synchronizer, and classifier.

Use Definition 902.9. Every $\mathsf{Real}^{\uparrow}$-facing consumer reaches the completion-seal classifier through those displayed rows rather than through a host Real object or a selected external limit.

Apply Definition 902.10, Definition 902.11, and Definition 902.12. Together they keep the consumer inside Q, B, S, K, H, C, P, N and exclude quotient stream equality, host real equality, selected limits, countable choice, and ambient completeness from the public ledger. □

Theorem 902.16 (Cauchy witness ledger componentwise transport)**.** *Let*

$$L = (Q, B, S, K, H, C, P, N)$$

be an accepted $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *carrier. Componentwise* hsame *transport along the ledger preserves the eight displayed rows* Q, B, S, K, H, C, P, N*: the diagonal-budget row remains* Q*, the observation-budget row remains* B*, the seal-synchronizer row remains* S*, the completion-seal classifier row remains* K*, and the structural rows remain* H, C, P, N*. No transported consumer obtains a row outside this finite tuple.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier componentwise transport`

Proof. Use the carrier definition to project the tuple $L = (Q, B, S, K, H, C, P, N)$. The row H is itself the displayed componentwise hsame ledger for the analytic rows Q, B, S, K and the structural rows C, P, N.

Apply Definition 902.2. It identifies the public NameCert surface with precisely the eight rows of the carrier, so any transported read still has to land in one of those rows.

Apply Definition 902.5 and Definition 902.9. The route and the Real-facing handoff both consume the same finite row inventory, hence componentwise transport cannot create a new completion coordinate or rename one of the displayed rows into a hidden analytic object. □

Theorem 902.17 (Cauchy witness ledger route replay exactness)**.** *For an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *carrier*

$$L = (Q, B, S, K, H, C, P, N),$$

every displayed Cont *replay in* C *reaches the analytic route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

before any $\mathsf{Real}^{\uparrow}$*-facing read of* L *is admitted. In particular, a consumer cannot read the completion-seal classifier* K *without first replaying the diagonal-budget row* Q*, the observation-budget row* B*, and the seal-synchronizer row* S*.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier route replay exactness`

Proof. Project C from the carrier definition. Its displayed routes are the three finite transitions from the diagonal budget to the observation budget, from the observation budget to the synchronizer, and from the synchronizer to the completion-seal classifier.

Apply Definition 902.2. The NameCert surface admits route replay only through the rows named by the carrier, with C supplying the displayed Cont edges and N naming the local packet.

Now apply Definition 902.5. The factorization fixes the order $Q \longmapsto B \longmapsto S \longmapsto K$, and Definition 902.9 states that every $\mathsf{Real}^{\uparrow}$ completion-facing consumer reaches K only through this route. Therefore exact replay through C is a precondition for any Real-facing read. □

Theorem 902.18 (Cauchy witness ledger forbidden-coordinate exclusion)**.** *Every accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet exports only the finite rows*

$$Q, B, S, K, H, C, P, N.$$

It exports no quotient stream equality, no host real equality, no selected external limit, no countable-choice row, and no ambient completeness theorem. The exclusion is part of the BEDC-kernel certificate, not a consequence of an external Real-completion principle.

Proof. Read the final clause of Definition 902.1: the carrier has no coordinate for quotient stream equality, host real equality, selected external limits, countable choice, or ambient completeness.

Apply Definition 902.2. The accepted NameCert surface is exactly the finite row inventory Q, B, S, K, H, C, P, N, so a forbidden coordinate cannot be recovered as a named public row.

Apply Definition 902.5 and Definition 902.9. The Real-facing route factors through the finite BEDC rows before reaching the completion-seal classifier, and the handoff explicitly exports none of the listed external coordinates. Thus the exclusion is anchored in the carrier and its local certificate surface. □

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerForbidden coordinate exclusion`

Theorem 902.19 (Cauchy witness ledger public export)**.** *Every public* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *export to a* $\mathsf{Real}^{\uparrow}$ *completion-facing consumer factors through the analytic route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

together with the structural rows H, C, P, N*. Here* Q *is the diagonal-budget row of chapter 853,* B *is the observation-budget row of chapter 611,* S *is the seal-synchronizer row of chapter 886, and* K *is the completion-seal classifier row of chapter 900.*

The public export contains no quotient stream equality, host real equality, selected external limit, countable-choice row, ambient completeness theorem, or second completion route outside the displayed finite ledger.

Proof. Start with Definition 902.5. It fixes the analytic spine of any completion-facing read as $Q \longmapsto B \longmapsto S \longmapsto K$, with the four sibling chapters supplying the displayed budget, observation, synchronizer, and classifier rows.

Use Definition 902.9 to pass the same spine to a $\mathsf{Real}^{\uparrow}$ completion-facing consumer. The handoff reaches the completion-seal classifier only after the diagonal budget, observation budget, and seal synchronizer have been read.

Apply Definition 902.11. Once the consumer agrees on the analytic spine and on H, C, P, N, the classifier read is fixed, so there is no independent completion route.

Finally combine Definition 902.12 with Definition 902.18. The ledger is exhausted by Q, B, S, K, H, C, P, N, and the excluded coordinates cannot be recovered from the public export. □

Theorem 902.20 (Cauchy witness ledger route coverage)**.** *Every accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *ledger route is covered by the finite rows*

$$Q, B, S, K, H, C, P, N.$$

The route may read the diagonal-budget row, observation-budget row, seal-synchronizer row, completion-seal classifier row, componentwise transport row, displayed continuation row, package-provenance row, and local NameCert row, but it has no public coordinate outside this inventory.

Proof. Start with the carrier definition and the NameCert obligation theorem. They identify the accepted packet with the displayed tuple $L = (Q, B, S, K, H, C, P, N)$ and make those rows the complete local certificate surface.

Next use carrier admission, route determinacy, and ledger exhaustion. Carrier admission supplies the finite row inventory, route determinacy prevents a second completion-seal classifier read once the displayed route is fixed, and ledger exhaustion says every public read is already consumed by the same analytic and structural rows.

Finally apply public export and forbidden-coordinate exclusion. The public route is the Real-facing ledger route through $Q \longmapsto B \longmapsto S \longmapsto K$ with H, C, P, N, while quotient stream equality, host real equality, selected external limits, countable choice, and ambient completeness are absent from the carrier. □

Theorem 902.21 (Cauchy witness ledger budget-seal lock)**.** *No completion-seal read of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet can reach the row K unless it has first read the diagonal-budget row Q, the observation-budget row B, and the seal-synchronizer row S on the same displayed BEDC route.*

Proof. Project the accepted carrier. The only analytic route to the completion-seal classifier is the ordered surface $Q \longmapsto B \longmapsto S \longmapsto K$.

Apply budget factorization and route replay exactness. Budget factorization places Q, then B, then S before K, and route replay exactness records that the displayed Cont row C must replay that same route before any $\mathsf{Real}^{\uparrow}$-facing read is admitted.

Use the Real completion handoff and public export to pass the lock to every completion-facing consumer. The handoff reaches K only through the three budget and seal rows, and the public export has no second completion route from which K could be selected independently. □

Theorem 902.22 (Cauchy witness ledger Real consumer nonescape)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing consumer of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet receives only the finite ledger route*

$$Q, B, S, K, H, C, P, N.$$

It receives no quotient stream, host equality, selected limit, countable-choice row, ambient completeness theorem, or completion-facing route outside the displayed BEDC rows.

Proof. Begin with the Real completion handoff. It sends each $\mathsf{Real}^{\uparrow}$-facing consumer through the diagonal budget, observation budget, seal synchronizer, completion-seal classifier, componentwise transports, route replay, provenance, and local NameCert rows.

Now combine route coverage with the budget-seal lock. Route coverage confines the consumer to Q, B, S, K, H, C, P, N, and the lock prevents the consumer from reading K before the Q, B, S budget and seal route has been consumed.

Finally use forbidden-coordinate exclusion. Since the excluded coordinates are not rows of the carrier and are not exported by the public route, the Real-facing consumer cannot recover a quotient stream, host equality, selected limit, countable-choice row, ambient completeness theorem, or alternate completion channel from the ledger. □

Theorem 902.23 (Cauchy witness ledger downstream unblock package)**.** *Every downstream L10 consumer of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet that reads Real-completion data factors first through the finite ledger rows*

$$Q, B, S, K, H, C, P, N.$$

The consumer may read the Real-completion surface only after the diagonal-budget row Q, observation-budget row B, seal-synchronizer row S, completion-seal classifier row K, componentwise transport row H, route-replay row C, package-provenance row P, and local NameCert row N have been exposed on the displayed BEDC route.

Proof. Begin with Definition 902.5. It places the analytic read through $Q \longmapsto B \longmapsto S \longmapsto K$ before any completion-facing row can be consumed.

Next use Definition 902.13 and Definition 902.14. The first identifies the shared diagonal and observation source, and the second keeps the synchronizer and classifier attached to that same source.

Now apply Definition 902.17 and Definition 902.19. Replay supplies the row C for the same route, while public export carries exactly the finite surface with H, C, P, N to the downstream consumer.

Finally, Definition 902.18 removes every external completion coordinate. Thus the downstream L10 read is unblocked only by the displayed ledger packet, not by a hidden analytic principle. □

Theorem 902.24 (Cauchy witness ledger window seal consumer triad)**.** *In every accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet, the diagonal-budget row Q, observation-budget row B, and seal-synchronizer row S form the consumer triad that binds the* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *surfaces before the completion-seal classifier row K is readable. No downstream consumer may detach one of these four surfaces from the same $Q \longmapsto B \longmapsto S$ route.*

Proof. Read the budget order from Definition 902.5. The rows Q, B, and S occur before K, so the classifier cannot supply the first completion-facing surface.

Use Definition 902.13. It binds the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surfaces seen by B to the same source already fixed by Q.

Apply Definition 902.14. The synchronizer row S carries that same source into the classifier row K, which gives the three consumer rows their shared seal-facing boundary.

Finally combine Definition 902.17, Definition 902.19, and Definition 902.18. Replay and export preserve the triad for downstream use, and forbidden-coordinate exclusion rules out any detached stream, rational, dyadic, or Real surface. □

Theorem 902.25 (Cauchy witness ledger completion classifier readback)**.** *For every accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet, the completion-seal classifier row K is readable exactly through the displayed route*

$$Q \longmapsto B \longmapsto S \longmapsto K.$$

It is never readable through quotient streams, selected limits, countable choice, ambient completeness, or any Real-completion channel outside the finite ledger surface with H, C, P, N.

Proof. Start with Definition 902.5. It displays the only analytic path to K as $Q \longmapsto B \longmapsto S \longmapsto K$.

Next use Definition 902.13 and Definition 902.14. They keep the classifier attached to the same diagonal-budget, observation-budget, and seal-synchronizer source.

Apply Definition 902.17 and Definition 902.19. These theorems make the readback public only as the replayed finite route with the structural rows H, C, P, N.

Finally apply Definition 902.18. Since the forbidden coordinates are absent from the carrier and from the exported surface, K has no readback through quotient streams, selected limits, countable choice, ambient completeness, or an alternate completion channel. □

Theorem 902.26 (Cauchy witness ledger root downstream totality)**.** *Every downstream* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *ledger must expose exactly the rows*

$$Q, B, S, K, H, C, P, N.$$

The rows Q, B, S, and K are respectively the $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$, *and* $\mathsf{RealCompletionSealClassifierUp}$ *rows, while H, C, P, N are the componentwise transport, route replay, package-provenance, and local NameCert rows. No downstream consumer obtains a second Real-completion route or a row outside this finite ledger surface.*

Proof. First project the accepted carrier. By Definition 902.10, the only public rows are Q, B, S, K, H, C, P, N, with Q, B, S, and K naming the four displayed Real-completion route components.

Next apply Definition 902.20. It covers every accepted ledger route by the same eight rows, so any downstream read is already inside the finite carrier inventory.

Finally use Definition 902.22. A $\mathsf{Real}^{\uparrow}$-facing or completion-facing consumer receives no quotient stream, host equality, selected limit, countable-choice row, ambient completeness theorem, or alternate completion route. Thus the downstream surface is exactly the displayed ledger. □

Theorem 902.27 (Cauchy witness ledger root completion package)**.** *The diagonal-observation route, synchronizer-classifier lock, route replay exactness, and public export form one root handoff package for every L10* $\mathsf{Real}^{\uparrow}$ *completion consumer of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *ledger. The package exports the route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

with H, C, P, N, and it exports no quotient stream equality, host real equality, selected external limit, countable-choice row, or ambient completeness theorem.

Proof. Start with Definition 902.13. It places the observation row B after the diagonal-budget row Q over the same finite stream, regular-rational, dyadic, and Real-seal surface.

Next apply Definition 902.14. The synchronizer row S must consume the same $Q \longmapsto B$ source before the classifier row K becomes public.

Then use Definition 902.17. The displayed replay row C reaches $Q \longmapsto B \longmapsto S \longmapsto K$ before any $\mathsf{Real}^{\uparrow}$-facing read is admitted.

Finally apply Definition 902.19. The public surface exports exactly the analytic route with H, C, P, N and none of the external Real-completion coordinates. These four facts are the root handoff package available to the L10 consumer. □

Theorem 902.28 (Cauchy witness ledger root seal readback)**.** *Any completion-seal readback through an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *ledger reaches the classifier row K only after the displayed route*

$$Q \longmapsto B \longmapsto S$$

has been consumed. The readback cannot bypass the $\mathsf{RealCompletionSealClassifierUp}$ *row and cannot recover the seal from quotient stream equality, host real equality, selected external limits, countable choice, or ambient completeness.*

Proof. Begin with Definition 902.5. It orders the analytic route as $Q \longmapsto B \longmapsto S \longmapsto K$, so the completion-seal classifier is never the first row read.

Use Definition 902.14. The synchronizer-classifier lock keeps K attached to the same diagonal-budget and observation-budget source consumed by S.

Finally combine Definition 902.18 with Definition 902.22. The forbidden coordinates are absent from the ledger, and a Real-facing consumer receives no alternate completion channel. Therefore every seal readback reaches K only through the displayed finite route. □

Theorem 902.29 (Cauchy witness ledger StreamName window source lock)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every accepted* $\mathsf{StreamName}^{\uparrow}$ *window read used by L is sourced by the diagonal-budget row Q and the observation-budget row B, then transported through H, C, P, N. No hidden stream coordinate, hidden tail oracle, quotient stream, selected limit, countable-choice row, or ambient completeness theorem can supply a second window source for the ledger.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier streamname window source lock`

Proof. Start from the carrier definition Definition 902.1. It lists exactly the rows Q, B, S, K, H, C, P, N and gives no coordinate for a hidden stream or tail oracle.

The diagonal-observation route Definition 902.13 fixes B as the observation-budget read of the same finite stream surface exposed by Q. The synchronizer-classifier lock Definition 902.14 then keeps S and K attached to that same $Q \longmapsto B$ source.

Route coverage Definition 902.20 confines every ledger read to Q, B, S, K, H, C, P, N, and the budget-seal lock Definition 902.21 prevents the seal side from being read before the displayed budget rows have been consumed.

Finally, Definition 902.22 excludes the completion-facing escape coordinates. Hence every accepted $\mathsf{StreamName}^{\uparrow}$ window read in the ledger is sourced by Q and B through the displayed structural rows. □

Theorem 902.30 (Cauchy witness ledger RegSeqRat readback totality)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every* $\mathsf{RegSeqRat}^{\uparrow}$ *readback consumed by B, S, or K is supplied by the finite* $\mathsf{DyadicRatCore}^{\uparrow}$ *and* $\mathsf{StreamName}^{\uparrow}$ *route already displayed by Q and B, and then replayed through H, C, P, N. The ledger admits no detached rational readback, hidden dyadic completion, tail oracle, quotient stream, or ambient Real completeness coordinate.*

Proof. By Definition 902.1, the accepted packet has only the rows Q, B, S, K, H, C, P, N. Thus a rational readback consumed by B, S, or K must be read through one of the displayed ledger coordinates.

Use Definition 902.13 to identify the $\mathsf{RegSeqRat}^{\uparrow}$ readback surface with the finite $\mathsf{DyadicRatCore}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ data exposed by the diagonal and observation budgets. Then Definition 902.14 transports that readback through the synchronizer and classifier rows without adding a new rational source.

The route-coverage theorem Definition 902.20 and the budget-seal lock Definition 902.21 make the displayed route total for the ledger reads. The nonescape theorem Definition 902.22 removes the remaining Real-completion escape coordinates, so the readback is exactly the finite route already shown by Q and B. □

Theorem 902.31 (Cauchy witness ledger Real seal refusal boundary)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Any* $\mathsf{Real}^{\uparrow}$ *completion request outside the route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

lands in the forbidden-coordinate refusal boundary. Such a request exports no quotient stream, host equality, selected limit, countable-choice coordinate, ambient completeness theorem, hidden tail oracle, or alternate Real seal.

Proof. The carrier definition Definition 902.1 exposes only Q, B, S, K, H, C, P, N. A request outside $Q \longmapsto B \longmapsto S \longmapsto K$ therefore has no carrier row on which to land except the refusal boundary for forbidden coordinates.

The diagonal-observation route Definition 902.13 supplies the first budget handoff, and Definition 902.14 supplies the seal-facing continuation through S and K. Route coverage Definition 902.20 states that every accepted route is exhausted by those displayed rows.

The budget-seal lock Definition 902.21 prevents a direct Real seal read outside the budget route. Finally, Definition 902.22 rules out quotient streams, host equality, selected limits, countable choice, ambient completeness, hidden tails, and alternate Real seals. Hence every off-route completion request is refused at the forbidden-coordinate boundary. □

Theorem 902.32 (Cauchy witness ledger Real seal consumer totality)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every* $\mathsf{Real}^{\uparrow}$ *completion-facing consumer of L either factors through the displayed route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

with its transport, replay, provenance, and local-name rows H, C, P, N, or lands in the forbidden-coordinate refusal boundary of Definition 902.31. Thus the ledger has no completion-facing consumer outside the displayed diagonal-budget, observation-budget, seal-synchronizer, and completion-seal route.

Proof. Project the accepted packet through Definition 902.1. Its only completion-facing rows are Q, B, S, K together with the structural rows H, C, P, N, so a consumer must first read one of those displayed coordinates.

Route coverage Definition 902.20 makes that displayed route total for accepted ledger reads. The budget-seal lock Definition 902.21 then forces a seal-facing read to pass through the budget side before reaching S and K.

It remains to classify off-route requests. Apply Definition 902.22 and then the refusal boundary Definition 902.31. Every remaining completion demand is refused as a forbidden coordinate rather than exported as an alternate $\mathsf{Real}^{\uparrow}$ completion route. □

Falsifiable prediction: If a CauchyWitnessLedgerUp packet is accepted, every RealUp completion-facing read factors through the displayed diagonal-budget, observation-budget, seal-synchronizer, and completion-seal rows; a counterexample is any admitted read bypassing one row.

Independence witness: Nearest siblings: cauchydiagonalbudget, realobservationbudget, cauchysealbudgetsynchronizer, realcompletionsealclassifier. None is bijective to CauchyWitnessLedgerUp because each sibling lacks at least one of the four ledger coordinates and the combined packet has a NameCert obligation requiring simultaneous factorization through all four.

Theorem 902.33 (Cauchy witness ledger source sibling readback)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every completion-facing read of L exposes the four sibling source rows in the order*

$$\mathsf{CauchyDiagonalBudget}^{\uparrow} \longmapsto \mathsf{RealObservationBudget}^{\uparrow} \longmapsto \mathsf{CauchySealBudgetSynchronizer}^{\uparrow} \longmapsto \mathsf{RealCompletionSealC}$$

before any completion-seal classifier consumer reads K.

The consumer receives the displayed source rows, the componentwise transport row H, route replay C, package provenance P, and the local naming row N. It receives no quotient stream, host real equality, selected external limit, countable-choice row, or ambient completeness theorem.

Proof. Project the carrier of Definition 902.1. Its completion-facing source rows are exactly Q, B, S, K, with H, C, P, N carrying transport, replay, provenance, and local naming for those rows.

The budget factorization and source coherence are the displayed route constraints. The diagonal-observation route of Definition 902.13 first reads the $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ row Q and the $\mathsf{RealObservationBudget}^{\uparrow}$ row B. The synchronizer-classifier lock of Definition 902.14 then carries the read through S before the classifier row K is consumed.

Classifier consumer non-escape and forbidden-coordinate exclusion close the boundary. Apply Definition 902.22 and Definition 902.31. Any request for a quotient stream, host equality, selected limit, countable-choice row, or ambient completeness theorem has no carrier coordinate and is refused outside the source-sibling route. □

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier source sibling readback`

Theorem 902.34 (Cauchy witness ledger Real-and-Completion sibling route)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every Real-and-Completion consumer route that reads L and reaches the completion-seal classifier must pass through the finite-window surface of chapter 126, the regular readback of chapter 301, the dyadic ledger of chapter 291, the seal boundary of chapter 38, and the public route of chapter 386. The route exports no quotient stream, host equality, selected limit, hidden tail oracle, or ambient completeness coordinate.*

Proof. Project the carrier of Definition 902.1. The accepted packet supplies exactly the rows Q, B, S, K, H, C, P, N; thus any route to the completion-seal classifier must be read through the displayed diagonal-budget, observation-budget, synchronizer, classifier, transport, replay, provenance, and naming rows.

First use Definition 902.33. It orders the local route through $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$, and $\mathsf{RealCompletionSealClassifierUp}$ before the classifier row K is consumed.

Next attach the CauchyLimitSeal root L10 sibling route Definition 386.176 and its non-escape boundary Definition 386.179. Those results force the completion-facing seal route through the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ sibling surface before any public limit-facing read is admitted.

Combining the two routes places the witness ledger inside the same Real-and-Completion dependency lattice as the seal route. The structural rows H, C, P, N only transport, replay, package, and name that finite path; they add no quotient stream, host equality, selected limit, hidden tail oracle, or ambient completeness coordinate. □

Theorem 902.35 (Cauchy witness ledger Real seal cover consumer lock)**.** *Every* $\mathsf{Real}^{\uparrow}$ *completion-facing consumer that reads a* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet over a finite cover must pass through the displayed diagonal-budget row Q, observation-budget row B, seal synchronizer row S, completion-seal classifier row K, and the support rows H, C, P, N. Cover and tail refinements are delegated to the* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *handoff surface together with* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$*; the ledger exports no quotient stream, host equality, selected external limit, countable-choice row, ambient completeness principle, or second seal coordinate.*

Proof. Begin with budget factorization and the Real completion handoff. By Definition 902.5 and Definition 902.9, any completion-facing read reaches K only through the ordered route $Q \longmapsto B \longmapsto S \longmapsto K$ with support from H, C, P, N.

Use route determinacy and ledger exhaustion next. Definition 902.11 fixes the completion route once the displayed rows agree, and Definition 902.12 leaves no public coordinate outside Q, B, S, K, H, C, P, N.

For finite-cover and tail refinements, cite the L10 consumer route through Definition 902.64 and Definition 902.67. These results delegate the consumer-side refinement to the $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ handoff route.

Finally apply the tail-fusion surface of chapter 658. The $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ route supplies the finite cofinal tail consumer without adding quotient streams, host equality, selected external limits, countable choice, ambient completeness, or a second seal coordinate to the witness ledger. □

Theorem 902.36 (Cauchy witness ledger budget Real route totality)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every budget read,* $\mathsf{StreamName}^{\uparrow}$ *window read,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and* $\mathsf{Real}^{\uparrow}$ *completion-facing read of L routes through the finite rows Q, B, S, K, H, C, P, N. The route is the displayed diagonal-budget, observation-budget, synchronizer, and completion-seal path, with no completion choice, quotient representative, host limit, detached rational readback, or second stream source.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier budget real route totality`

Proof. Apply Definition 902.5. It orders the budget-facing route through $Q \longmapsto B \longmapsto S \longmapsto K$, while the carrier and NameCert rows supply only H, C, P, N as structural coordinates.

Use Definition 902.29, Definition 902.30, and Definition 902.31. These rows identify the StreamName source, the RegSeqRat readback, and the off-route Real refusal boundary with the same finite ledger. Hence every admitted read is exhausted by Q, B, S, K, H, C, P, N. □

Theorem 902.37 (Cauchy witness ledger StreamName RegSeq factorization)**.** *For an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet $L = (Q, B, S, K, H, C, P, N)$, the* $\mathsf{StreamName}^{\uparrow}$ *window source and every* $\mathsf{RegSeqRat}^{\uparrow}$ *readback factor through the same $Q \longmapsto B$ budget source before S or K is public. Componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}$ *row preserve this source without adding a tail oracle, detached dyadic completion, or host Real limit.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier streamname regseq factorization`

Proof. Read Definition 902.29. The stream window is fixed by the diagonal-budget and observation-budget rows, then transported through H, C, P, N.

Now apply Definition 902.30. The regular-rational readback is supplied by the same finite $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ route already displayed by Q and B. The synchronizer-classifier lock keeps S and K attached to that source, so no independent rational or Real-completion coordinate is introduced. □

Theorem 902.38 (Cauchy witness ledger Real completion nonescape)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be accepted. Any* $\mathsf{Real}^{\uparrow}$ *completion read admitted by L reaches the classifier row K only through the finite route $Q \longmapsto B \longmapsto S \longmapsto K$ and the structural rows H, C, P, N. Reads outside that route fall under the Real seal refusal boundary and export no selected limit, quotient stream, host equality, countable-choice row, ambient completeness theorem, hidden tail oracle, or alternate seal.*

Proof. Start with Definition 902.9 and Definition 902.28. They place every completion-facing read behind the diagonal budget, observation budget, synchronizer, and completion-seal classifier.

Finally use Definition 902.31. A request outside the displayed route has no carrier coordinate in BHist, no accepted hsame or Cont replay, and no Pkg or NameCert witness. Thus the read remains finite and cannot escape to an external completion principle. □

Theorem 902.39 (Cauchy witness ledger root budget row totality)**.** *Every accepted root read of $L = (Q, B, S, K, H, C, P, N)$ exposes the diagonal-budget row Q and the observation-budget row B before any completion-seal classifier read is public.*

Proof. Use Definition 902.1, Definition 902.5, and Definition 902.6. The carrier has Q and B as displayed analytic rows, the budget factorization orders them before S and K, and readback totality gives no root read outside Q, B, S, K, H, C, P, N. □

Theorem 902.40 (Cauchy witness ledger root seal route totality)**.** *Every root seal read of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet passes through the finite route $Q \longmapsto B \longmapsto S \longmapsto K$.*

Proof. Apply Definition 902.28 and Definition 902.14. The first theorem places seal readback behind the displayed route, and the second keeps K attached to the same $Q \longmapsto B \longmapsto S$ source. □

Theorem 902.41 (Cauchy witness ledger root NameCert threshold)**.** *The root rows Q, B, S, K together with H, C, P, N form the* $\mathsf{NameCert}_{\mathsf{CauchyWitnessLedger}^{\uparrow}}$ *threshold surface for the witness ledger.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root namecert threshold`

Proof. Read Definition 902.2, Definition 902.5, and Definition 902.14. These statements supply the displayed obligation rows, order the budget route, and bind the synchronizer-classifier threshold without adding any row outside Q, B, S, K, H, C, P, N. □

Theorem 902.42 (Cauchy witness ledger formal target surface)**.** *For an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet $L = (Q, B, S, K, H, C, P, N)$, the encoded target* `BEDC.Derived.CauchyWitnessLedgerUp.taste_gate` *is the formal target surface for the finite route Q, B, S, K, H, C, P, N. Any future scaffold checking of that target must preserve the diagonal-budget row, observation-budget row, synchronizer row, completion-seal classifier row, componentwise transport rows, displayed replay rows, provenance row, and local* NameCert *row.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier formal target surface`

Proof. The root budget threshold is Definition 902.39. It forces the diagonal-budget row Q and observation-budget row B to be public before the completion-seal classifier is read.

The root seal threshold is Definition 902.40. It confines the seal route to $Q \longmapsto B \longmapsto S \longmapsto K$.

The local naming threshold is Definition 902.41. Together with Definition 902.38, it keeps completion-facing reads inside the same finite route and excludes selected limits, quotient streams, host equality, countable choice, ambient completeness, hidden tails, and alternate seals. Thus the named Lean target is exactly the finite formal surface whose later checking must preserve those rows. □

Theorem 902.43 (Cauchy witness ledger four-face Real completion lock)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Its formal target surface factors through exactly the four Phase Real and Completion faces* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *together with only the support rows* BHist, hsame, Cont, Pkg, *and* NameCert. *Thus every roadmap-exit*

consumer of the ledger reads the same four-face route and no route adds quotient streams, selected limits, host sequence equality, ambient Real completeness, metric-completeness data, countable choice, or standard bridge rows.

Proof. Begin with Definition 902.42. It identifies the accepted formal surface with the finite route Q, B, S, K, H, C, P, N, so a consumer can expose only the budget, window, readback, Real-seal classifier, and structural rows already carried by L.

Next apply Definition 126.500 and Definition 126.502. These force the Real-completion exit route through the four displayed faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, and exhaust every consumer read at that boundary.

Finally use Definition 126.498. It attaches the Cauchy witness ledger to that same four-object exit packet through BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows. Since neither the ledger surface nor the exit packet carries quotient streams, selected limits, host sequence equality, ambient Real completeness, metric-completeness data, countable choice, or standard bridge rows, no second completion-facing route remains. □

Theorem 902.44 (Cauchy witness ledger budget-selector four-face exhaustion)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted $\mathsf{CauchyWitnessLedger}^{\uparrow}$ packet, and let $F = (B_0, S_0, W, D, R, E, H_0, C_0, P_0, N_0)$ be an accepted $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ packet whose selected finite windows W are the same $\mathsf{StreamName}^{\uparrow}$ window face consumed by L. Then every Phase Real and Completion consumer of L factors through the selector route of F and the same terminal four-face packet*

$$\mathsf{FiniteObservationBudgetSelector}^{\uparrow}, \quad \mathsf{StreamName}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}$$

together with only the support rows BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$.

Thus passing through the observation-budget selector preserves the terminal route already locked by L: the consumer receives the selected window face, the dyadic ledger face, the regular-rational readback face, and the Real seal face, but no quotient stream, selected limit, host sequence equality, ambient Real completeness, metric-completeness datum, countable-choice row, or standard bridge row.

Proof. Begin with Definition 902.43. It places every roadmap-exit consumer of L on the four Phase Real and Completion faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, with only the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support.

Move to the selector packet. By Definition 782.7, the accepted packet F determines one finite route from its budget row through the selected schedule, window family, dyadic ledger, regular readback, and seal. By Definition 782.9, every dyadic observation exported by D is already read from the selected finite windows W.

Use the shared-window hypothesis to identify W with the $\mathsf{StreamName}^{\uparrow}$ window face consumed by L. The selector therefore supplies exactly the same window and dyadic-ledger coordinates that the ledger route exposes before the $\mathsf{RegSeqRat}^{\uparrow}$ readback and $\mathsf{Real}^{\uparrow}$ seal are public.

Finally apply Definition 126.449. Once the shared window, dyadic ledger, readback, seal, and displayed support rows agree, the Phase Real and Completion consumer has no second terminal route. Since neither the selector route nor the ledger route carries quotient streams, selected limits, host sequence equality, ambient Real completeness, metric-completeness data, countable choice, or standard bridge rows, passing through $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ preserves the same terminal four-face packet. □

Theorem 902.45 (Cauchy witness ledger open-phase budget route handoff)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted $\mathsf{CauchyWitnessLedger}^{\uparrow}$ packet. Suppose its displayed rows include the budget selector*

route, the completion-seal route, the $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *factorization, and the* $\mathsf{Real}^{\uparrow}$ *completion nonescape boundary. Then* L *determines one Real-and-completion handoff surface through* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *supported only by the finite rows* BHist, hsame, Cont, Pkg, *and* NameCert.

Every open-phase consumer reading the packet therefore receives the same dyadic budget, named stream window, regular-rational readback, and Real seal coordinates. No off-packet completion coordinate, quotient stream, selected limit, host sequence equality, ambient Real completeness theorem, metric-completeness datum, countable-choice row, or standard bridge row is exported by the handoff.

Proof. Start with Definition 902.36 and Definition 902.40. These rows place the budget reads and the completion-seal reads on the finite route $Q \longmapsto B \longmapsto S \longmapsto K$, with H, C, P, N as the only structural support.

Next use Definition 902.37 and Definition 902.38. The named stream source and the regular-rational readback both factor through the same budget source, while every completion-facing read remains inside the displayed Real seal boundary.

Apply Definition 902.43 and Definition 902.44. They identify the terminal consumer surface with the four open Phase Real and Completion faces $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, even when the observation-budget selector mediates the selected windows.

Thus a downstream consumer can only replay the finite BHist, hsame, Cont, Pkg, and NameCert route already carried by L. Since each cited row is exhausted by that route, no coordinate remains from which an external completion object or second Real handoff could be read. □

Theorem 902.46 (Cauchy witness ledger selector-seal terminality)**.** *Let* $L = (Q, B, S, K, H, C, P, N)$ *be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Let* $T = (B_0, W, R, L_0, E, H_0, C_0, P_0, N_0)$ *be an accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet whose selected window row* W, $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R, *and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* L_0 *agree with the ledger route exposed by* L *through the observation-budget selector.*

Then every Phase Real and Completion consumer of L *factors through the unique terminal route*

$$\mathsf{CauchyWitnessLedger}^{\uparrow} \longmapsto \mathsf{FiniteObservationBudgetSelector}^{\uparrow} \longmapsto \mathsf{RealCompletionSelectorSeal}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto$$

with only the support rows BHist, hsame, Cont, Pkg, *and* NameCert. *No quotient stream, selected limit, host equality, ambient completeness, countable-choice row, second completion route, or standard bridge row remains after this factorization.*

Proof. Start with Definition 902.45. It places every open-phase consumer of L on the finite Real-and-completion handoff surface through the displayed budget, named stream window, regular-rational readback, and Real seal rows, with only BHist, hsame, Cont, Pkg, and NameCert support.

Next apply Definition 902.44. The observation-budget selector transports the same selected window and readback information without adding quotient streams, selected limits, host sequence equality, ambient Real completeness, metric-completeness data, countable choice, or standard bridge rows.

Use the agreement hypotheses for T. The selected window W, readback row R, and limit row L_0 are the same rows already consumed by the ledger route, so the selector-seal packet is attached to the handoff rather than forming a second completion source.

Finally use Definition 1081.3 and Definition 1081.4. Determinacy gives a single finite selector-seal route, and non-escape exhausts every completion consumer at $B_0, W, R, L_0, E, H_0, C_0, P_0, N_0$.

Hence the only remaining route is the displayed terminal chain from $\mathsf{CauchyWitnessLedger}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$ through the selector and seal packets. □

Theorem 902.47 (Cauchy witness ledger selector agreement terminal collapse)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Let $F = (B_0, S_0, W, D, R_F, E_F, H_F, C_F, P_F, N_F)$ be an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *packet, and let $T = (B_1, W_1, R_T, L_1, E_T, H_T, C_T, P_T, N_T)$ be an accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet. Suppose the three packets agree on the selected window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row, and the* $\mathsf{Real}^{\uparrow}$ *seal row exposed by the ledger route.*

Then every $\mathsf{RealAlgOrder}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, *or* $\mathsf{S}^{1\uparrow}$ *consumer of the Real-and-completion surface factors through the single terminal chain*

$$\mathsf{CauchyWitnessLedger}^{\uparrow} \longmapsto \mathsf{FiniteObservationBudgetSelector}^{\uparrow} \longmapsto \mathsf{RealCompletionSelectorSeal}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto$$

The consumer receives only the displayed selected-window route, regular-rational readback, limit-seal row, Real seal row, and the support rows BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$. *It cannot introduce quotient streams, selected limits, host equality, ambient completeness, countable choice, a second completion route, or any separate RealAlgOrder, MetricSpace, or* $\mathsf{S}^{1\uparrow}$ *completion source.*

Proof. First attach the ledger to the selector-seal route. By Definition 902.46, the accepted ledger packet and selector-seal packet already force every Phase Real and Completion consumer through the displayed route from $\mathsf{CauchyWitnessLedger}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$.

Next identify the four open faces. Apply Definition 126.449 to the agreed selected window, dyadic observation window, regular readback, and Real seal rows, and then apply Definition 38.728. These rows are consumed as one terminal four-face packet rather than as independent completion coordinates.

Now read the downstream positive-boundary consumers. The RealAlgOrder, MetricSpace, and $\mathsf{S}^{1\uparrow}$ consumer theorems use the same positive Real boundary: they read the Real row after the StreamName, RegSeqRat, CauchyLimitSeal, and Real seal faces have already been fixed. Since the hypotheses identify those faces across L, F, and T, no consumer in this family has another source from which a completion route could be read.

Finally use nonescape for the selector-seal and ledger routes. The selector-seal packet exports no quotient stream, selected limit, host equality, ambient completeness, countable choice, or second completion route, and the ledger route exports no off-packet Real completion data. Thus the only available route for the three consumer families is the displayed terminal chain. □

Corollary 902.48 (Cauchy witness ledger budget Real route strict local obstruction)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Any displayed failure, refusal, separation, or countermodel row attached to the budget Real route of L is a strict local obstruction: it blocks only the proposed converse read, detached reuse, or off-route completion request that tries to bypass*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

and the structural rows H, C, P, N. Every consumer-facing use that remains admitted factors through the diagonal-budget row, observation-budget row, synchronizer row, completion-seal classifier row, componentwise transport row, displayed replay row, provenance row, and local $\mathsf{NameCert}$ *row. A request using any unlisted coordinate is refused at the Real seal boundary and exports no selected limit, quotient stream, host equality, countable-choice row, ambient completeness theorem, hidden tail oracle, alternate seal, or external validation witness.*

Consequently the obstruction cannot be reinterpreted as a global impossibility theorem for $\mathsf{Real}^{\uparrow}$ *completion-facing reads, as a host theorem about Real completeness, or as hidden validation by an external completion principle. It is only the local refusal of the named converse or reuse route outside the displayed ledger packet.*

Proof. Start with Definition 902.36. It says that every budget read, $\mathsf{StreamName}^{\uparrow}$ window read, $\mathsf{RegSeqRat}^{\uparrow}$ readback, and $\mathsf{Real}^{\uparrow}$ completion-facing read admitted by L routes through exactly the finite rows Q, B, S, K, H, C, P, N. The same statement names the diagonal-budget, observation-budget, synchronizer, and completion-seal path as the whole admitted route and excludes completion choice, quotient representatives, host limits, detached rational readbacks, and second stream sources from that path.

Now apply Definition 902.38. A completion read reaches K only through $Q \longmapsto B \longmapsto S \longmapsto K$ together with H, C, P, N. If a displayed failure, refusal, separation, or countermodel row is triggered, it is triggered by a request outside that finite route; the nonescape theorem sends such a request to the Real seal refusal boundary and gives it no selected limit, quotient stream, host equality, countable-choice row, ambient completeness theorem, hidden tail oracle, or alternate seal.

Thus the consumer-facing alternatives split sharply. An admitted consumer factors through the displayed ledger rows by totality. A non-admitted consumer is rejected as an unlisted coordinate by nonescape. The refusal branch therefore has no carrier coordinate from which to state a global impossibility result, no host Real object from which to derive an ambient theorem, and no exported external witness from which hidden validation could be read. The only blocked object is the named converse or reuse request that attempted to leave the finite ledger route. □

Theorem 902.49 (Cauchy witness ledger root source lock)**.** *Let* $L = (Q, B, S, K, H, C, P, N)$ *be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. The diagonal-budget row* Q*, observation-budget row* B*, synchronizer row* S*, and completion-seal classifier row* K *use one shared finite* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *source surface. Thus the public root read of* L *cannot attach* K *to a stream, rational, dyadic, or Real source separate from the source already read by* Q*,* B*, and* S*.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root source lock`

Proof. Begin with Definition 902.1. The accepted packet exposes only Q, B, S, K, H, C, P, N, so every source visible at the root must be read through one of those rows.

Apply Definition 902.5 and Definition 902.13. The budget factorization orders the analytic route as $Q \longmapsto B \longmapsto S \longmapsto K$, and the diagonal-observation route identifies the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surface seen by B with the one already fixed by Q.

Finally use Definition 902.14. The synchronizer carries the same $Q \longmapsto B$ source into K, so the classifier has no separate source row from which an alternate completion-facing read could be exposed. □

Theorem 902.50 (Cauchy witness ledger root source-window route lock)**.** *Every accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *completion-facing root read uses one shared finite* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *source-window route through*

$$Q \longmapsto B \longmapsto S \longmapsto K.$$

The read cannot attach a second stream window, rational readback, dyadic tolerance, real seal, hidden tail, quotient stream, host real equality, or ambient completeness row to the displayed carrier rows Q, B, S, K, H, C, P, N*.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root source window route lock`

Proof. First apply the root source lock of Definition 902.49. It identifies the stream, regular-rational, dyadic, and real source surface of the completion-seal classifier with the source surface already read by Q, B, S.

Next use Definition 902.29. The stream window visible to a completion consumer is the window supplied by the same finite budget route, so the consumer cannot attach a separate window source before reading K.

Apply the refusal boundary of Definition 902.52. Any proposed rational readback, dyadic tolerance, real seal, hidden tail, quotient stream, host real equality, or ambient completeness coordinate outside the route $Q \longmapsto B \longmapsto S \longmapsto K$ is refused at the root boundary.

Finally, Definition 902.55 says every downstream completion-facing consumer factors through the displayed ledger rows. The common source-window route is therefore the whole consumer-facing route, not one branch among several. □

Theorem 902.51 (Cauchy witness ledger root budget coherence)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ and $L' = (Q', B', S', K', H', C', P', N')$ be accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packets. If the two public reads agree on Q, B, S, H, C, P, N, then they determine the same public completion-seal classifier read K. In particular, no accepted root read can split the classifier from the displayed budget route $Q \longmapsto B \longmapsto S \longmapsto K$.*

Proof. Start with Definition 902.11. Agreement on the displayed route and structural rows fixes the completion-facing route, so the public read has no second branch on which K could vary.

Use Definition 902.7. The rows Q, B, and S share one finite $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ source before K is exposed.

Now apply Definition 902.25. The classifier readback is exactly the displayed route through $Q \longmapsto B \longmapsto S \longmapsto K$ together with H, C, P, N. Since those route and structural rows already agree, the public classifier read agrees as well. □

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root budget coherence`

Theorem 902.52 (Cauchy witness ledger root budget refusal boundary)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Any attempted public root read that gives the completion-seal classifier K a stream,* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *tail, limit, or seal source not already exposed through*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

is routed to the displayed refusal boundary. Such a read cannot export a quotient stream, host $\mathsf{Real}^{\uparrow}$ *equality, selected external limit, countable-choice row, hidden tail, alternate seal, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root budget refusal boundary`

Proof. Read the accepted carrier through Definition 902.1. Its public root surface is exactly Q, B, S, K, H, C, P, N, and the completion-facing rows are displayed through the finite route $Q \longmapsto B \longmapsto S \longmapsto K$.

Apply Definition 902.49. The stream, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ sources visible to K are the same sources already read by Q, B, and S, so a proposed second source for the classifier is not a carrier row.

Next apply Definition 902.51. Once Q, B, S, H, C, P, N are fixed, the public classifier read K is determined by the displayed budget route, so a different tail, limit, or seal source cannot produce a second accepted classifier read.

Finally use Definition 902.55. Downstream completion consumers have no escape coordinate outside the displayed ledger, and the requested quotient stream, host $\mathsf{Real}^{\uparrow}$ equality, selected external limit, countable-choice row, hidden tail, alternate seal, or ambient completeness coordinate is therefore refused rather than exported. □

Theorem 902.53 (Cauchy witness ledger root budget classifier dichotomy)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every public completion-seal classifier read of L is exactly one of the following:*

1. *it follows the displayed route*
$$Q \longmapsto B \longmapsto S \longmapsto K$$
over the shared $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *source surface exposed by the root ledger;*

2. *it is routed to the refusal boundary and therefore exports no quotient stream, host* $\mathsf{Real}^{\uparrow}$ *equality, selected external limit, countable-choice row, hidden tail, alternate seal, or ambient completeness coordinate.*

Proof. First fix the source surface. By Definition 902.49, the rows Q, B, S, K read one shared $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ source, so an accepted classifier read cannot begin from a second stream, rational, dyadic, or Real source.

Next bind the accepted branch. Definition 902.51 says that once the displayed budget route and structural rows are fixed, the completion-seal classifier read is determined by $Q \longmapsto B \longmapsto S \longmapsto K$. This gives the first side of the dichotomy.

It remains to account for every read not carried by that route. Definition 902.52 sends any classifier read with a detached source, tail, limit, or seal coordinate to the refusal boundary.

Finally apply Definition 902.55. Downstream $\mathsf{Real}^{\uparrow}$-completion consumers have no coordinate outside the displayed ledger, so a classifier read is either the accepted route above or a refused request, with no third exported surface. □

Theorem 902.54 (Cauchy witness ledger root diagnostic refusal dichotomy)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every root diagnostic read or completion-facing consumer read of L is exactly one of the following:*

1. *it follows the displayed route*
$$Q \longmapsto B \longmapsto S \longmapsto K$$
over the shared $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *faces exposed by the ledger;*

2. *it is refused at the displayed root boundary and exports no quotient stream, selected limit, host equality, countable-choice row, ambient completeness coordinate, hidden tail, alternate seal, or standard bridge row.*

Proof. First fix the source boundary. The root source lock of Definition 902.49 and the source-window route lock of Definition 902.50 place every accepted root read on the same $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ source route through $Q \longmapsto B \longmapsto S \longmapsto K$.

Next classify diagnostic reads. Apply Definition 902.53; the classifier side has only the accepted displayed route or the refusal branch.

Finally attach the consumer boundary. The refusal boundary of Definition 902.52 blocks the excluded quotient, limit, host-equality, countable-choice, ambient-completeness, tail, seal, and bridge rows, while Definition 902.55 says completion-facing consumers have no coordinate outside the displayed ledger. Thus the root diagnostic surface has no third export case. □

Theorem 902.55 (Cauchy witness ledger root consumer exhaustion)**.** *Every downstream* $\mathsf{Real}^{\uparrow}$*-completion consumer of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet* $L = (Q, B, S, K, H, C, P, N)$ *factors through*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

and the structural rows H, C, P, N*. Such a consumer has no quotient stream, host real equality, selected external limit, countable-choice row, hidden tail, alternate seal, or ambient completeness coordinate outside the displayed ledger.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root consumer exhaustion`

Proof. First apply Definition 902.12 and Definition 902.38. Ledger exhaustion confines every public read to Q, B, S, K, H, C, P, N, and Real-completion nonescape places every admitted completion read on the route $Q \longmapsto B \longmapsto S \longmapsto K$.

Next use Definition 902.29 and Definition 902.30. The StreamName window source and RegSeqRat readback are both supplied by the same finite budget source, so a downstream consumer cannot detach a stream window, rational readback, dyadic tolerance row, or hidden tail from the ledger.

Finally apply Definition 902.31. Any request outside the displayed route lands at the refusal boundary rather than at a quotient stream, host Real equality, selected external limit, countable-choice row, alternate seal, or ambient completeness coordinate. □

Corollary 902.56 (Cauchy witness ledger root source-lock strict obstruction)**.** *Let* $L = (Q, B, S, K, H, C, P, N)$ *be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. The refusal boundary of Definition 902.52, read under the source lock of Definition 902.49, is a strict local obstruction: it blocks exactly an attempted completion-seal classifier read that detaches* K *from the displayed route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

or that tries to reuse the classifier through an unlisted quotient stream, host $\mathsf{Real}^{\uparrow}$ *equality, selected external limit, countable-choice row, hidden tail, alternate seal, or ambient completeness coordinate. It does not assert a global failure of Cauchy completion, does not supply a host theorem, and does not validate any hidden external completion route.*

Proof. The root source lock fixes the source side first. By Definition 902.49, the stream, regular-rational, dyadic, and Real source surface visible to K is the same finite source already read by Q, B, and S. Hence a request that reaches K by a separate stream, rational, dyadic, or Real source is not a second accepted root read of L; it is precisely a detached classifier-source request.

Now apply the refusal boundary of Definition 902.52. That theorem lists the refused coordinates: quotient stream, host $\mathsf{Real}^{\uparrow}$ equality, selected external limit, countable-choice row, hidden tail, alternate seal, and ambient completeness coordinate, together with any tail, limit, or seal source not exposed through $Q \longmapsto B \longmapsto S \longmapsto K$. These are the only coordinates named by the displayed obstruction, so the obstruction is confined to the named converse or reuse route for the root classifier.

Finally use the consumer exhaustion statement of Definition 902.55. Every downstream completion-facing consumer factors through the displayed ledger rows and has no coordinate outside Q, B, S, K, H, C, P, N.

Therefore the refusal cannot be reinterpreted as a statement about all Cauchy completions, as a theorem of an ambient host theory, or as evidence for a hidden validation route. It only rejects off-route uses of the local source-locked witness ledger. □

Theorem 902.57 (Cauchy witness ledger root diagnostic budget totality)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every root diagnostic read of L consumes the diagonal-budget row Q, observation-budget row B, seal-synchronizer row S, completion-seal classifier row K, componentwise transport row H, displayed continuation row C, provenance row P, and local NameCert row N. No such root read can bypass the diagonal budget, observation budget, synchronizer, or completion-seal classifier.*

Proof. Begin with Definition 902.1. The carrier exposes only Q, B, S, K, H, C, P, N, so any root diagnostic read must land on the displayed ledger rows.

Apply Definition 902.2. The local NameCert surface requires carrier admission, budget exposure, synchronizer exposure, classifier exposure, transport, replay, provenance, and local naming for the same finite packet.

Now use Definition 902.5. It orders the analytic budget route through Q, then B, then S, then K. Since the root diagnostic read is a read of the accepted packet, it cannot omit any one of those budget rows while still preserving the displayed NameCert surface. □

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root diagnostic budget totality`

Theorem 902.58 (Cauchy witness ledger root seal classifier lock)**.** *For an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet $L = (Q, B, S, K, H, C, P, N)$, the completion-seal classifier row K is exposed only after the route*

$$Q \longmapsto B \longmapsto S$$

has been displayed. A consumer cannot read K as a detached classifier row before the diagonal-budget row, observation-budget row, and seal-synchronizer row have been consumed.

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root seal classifier lock`

Proof. First read the carrier in Definition 902.1. The row K is one coordinate of the same finite packet as Q, B, S, H, C, P, N, not a separate classifier object.

Apply Definition 902.2 to bind K to the local certificate for the packet. The certificate exposes K together with the displayed budget and synchronizer rows.

Finally use Definition 902.5. The factorization places the classifier after $Q \longmapsto B \longmapsto S$, so a detached read of K would skip part of the certified route and would not be a root read of the accepted packet. □

Theorem 902.59 (Cauchy witness ledger root budget classifier determinacy)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ and $L' = (Q', B', S', K', H', C', P', N')$ be accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packets. Suppose their public root reads agree on the displayed budget route*

$$Q \longmapsto B \longmapsto S$$

and on the structural rows H, C, P, N. Then the completion-seal classifier read is determined on that public route: K and K' name the same route-bound classifier read. In particular, no second completion-seal classifier for the same public root route can be attached to a different stream source, $\mathsf{RegSeqRat}$ *source,* $\mathsf{DyadicRatCore}$ *source,* $\mathsf{Real}^{\uparrow}$ *source, tail source, limit source, or seal source.*

Proof. Use Definition 902.57 for both packets. Every public root diagnostic read exposes exactly the diagonal-budget row, observation-budget row, seal-synchronizer row, completion-seal classifier row, componentwise transport row, displayed continuation row, provenance row, and local NameCert row.

The assumed agreement on $Q \longmapsto B \longmapsto S$ and on H, C, P, N therefore identifies the public route on which the classifier row is read. Apply Definition 902.58: K is available only after that displayed route and cannot be read as a detached classifier before the budget and synchronizer rows have been consumed.

It remains to exclude an off-route classifier with a different completion source. Apply Definition 902.60 and Definition 902.61. Since the root packet has no quotient stream equality, host real equality, selected external limit, countable-choice row, ambient completeness coordinate, or detached classifier, every terminal completion-facing read is exhausted by the same finite ledger surface. Thus any classifier attached to the agreed public route is the route-bound classifier read already named by K and K'. □

Theorem 902.60 (Cauchy witness ledger root forbidden coordinate exclusion packet)**.** *The root packet of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *carrier* $L = (Q, B, S, K, H, C, P, N)$ *contains no quotient stream equality, host real equality, selected external limit, countable-choice row, or ambient completeness coordinate. All root completion-facing reads are confined to the displayed budget route, structural rows, provenance row, and local NameCert row.*

Proof. Start from Definition 902.1. Its root coordinates are exactly Q, B, S, K, H, C, P, N, and none of these is a quotient stream equality, host real equality, selected external limit, countable-choice row, or ambient completeness coordinate.

Use Definition 902.5 to locate every completion-facing read on the budget route through Q, B, S, K. The structural rows H, C, P, N preserve and name that route rather than adding a separate completion source.

Finish with Definition 902.18. That theorem rules out the forbidden coordinates for the ledger surface, and the present root packet exposes no additional row on which such a coordinate could be introduced. □

Theorem 902.61 (Cauchy witness ledger root terminal route exhaustion)**.** *Every terminal root diagnostic or completion-facing read of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet* $L = (Q, B, S, K, H, C, P, N)$ *is exhausted by the displayed route* Q, B, S, K, H, C, P, N*. The classifier row* K *is available only after the route*

$$Q \longmapsto B \longmapsto S$$

has been displayed, and the structural rows H, C, P, N *transport, replay, package, and name that same route.*

No terminal read exports quotient stream equality, host real equality, a selected external limit, a countable-choice row, an ambient completeness coordinate, or a detached classifier.

Proof. Apply Definition 902.57. It places every root diagnostic read on the packet rows Q, B, S, K, H, C, P, N, with the budget and synchronizer rows present before the terminal read can complete.

Next use Definition 902.58. The classifier K is not a detached object: it is read only after $Q \longmapsto B \longmapsto S$ and remains tied to the same local packet.

Finally apply Definition 902.60. Since quotient stream equality, host real equality, selected external limits, countable choice, ambient completeness, and detached classifiers are not root coordinates, the terminal route is exactly the displayed finite ledger surface. □

Theorem 902.62 (Cauchy witness ledger root diagnostic budget transport)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ and $L' = (Q', B', S', K', H', C', P', N')$ be accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packets. Suppose the displayed budget route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

is transported componentwise through the displayed H, H' rows and through the displayed continuation rows C, C', with the history comparison governed by the stated hsame rows and the continuation comparison governed by the stated Cont *rows. Then root diagnostic reads and completion-facing terminal reads are stable along that transport: the transported route reads the same root budget, synchronizer, route-bound classifier, structural transport, continuation, provenance, and local NameCert rows.*

Moreover, this transport does not introduce quotient stream equality, host real equality, a selected external limit, a countable-choice row, an ambient completeness coordinate, or a detached classifier.

Proof. First apply Definition 902.57 to both accepted packets. The only rows visible to a root diagnostic read are the finite packet rows Q, B, S, K, H, C, P, N and $Q', B', S', K', H', C', P', N'$.

Use Definition 902.58 to read the order of the route. The classifier rows K and K' are available only after their displayed routes through $Q \longmapsto B \longmapsto S$ and $Q' \longmapsto B' \longmapsto S'$, so componentwise transport cannot detach the classifier from the budget and synchronizer rows.

Now apply Definition 902.59. Since the transport is through the displayed H, H' and C, C' rows, with the comparison confined to the stated *hsame* and Cont rows, the classifier read on the transported public route is the route-bound read already named by K and K'.

It remains to identify the terminal surface. Apply Definition 902.60 and Definition 902.61. The terminal completion-facing read is exhausted by the same finite ledger surface, and none of the forbidden coordinates can be supplied by transport through H, H' or C, C'. □

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root diagnostic budget transport`

Corollary 902.63 (Cauchy witness ledger root diagnostic budget use determinacy)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet, and let t be an accepted consumer-facing root diagnostic budget use of L. Once the displayed rows Q, B, S, H, C, P, N are fixed, the use t has only one accepted landing: it factors through the finite route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

with route replay supplied by C, componentwise transport supplied by H, provenance supplied by P, and local naming supplied by N. Hence any other accepted consumer presentation over the same fixed rows chooses the same route-bound completion-seal classifier K, the same replay normal form through C, and the same exactness/readback decision named by the chapter. No alternate hidden coordinate, detached tail, selected external limit, duplicate classifier source, quotient stream equality, host real equality, countable-choice row, or ambient completeness coordinate can be used to produce a second accepted diagnostic budget use.

Proof. Apply Definition 902.57 to the accepted use t. Every root diagnostic read of L consumes exactly the diagonal-budget row Q, observation-budget row B, seal-synchronizer row S, completion-seal classifier row K, componentwise transport row H, displayed continuation row C, provenance row P, and local NameCert row N. In particular, after Q, B, S, H, C, P, N are fixed, the only remaining classifier-facing row visible to t is the route-bound row K.

Now compare t with any second accepted consumer presentation over the same fixed local rows. The hypotheses give agreement on the displayed budget route

$$Q \longmapsto B \longmapsto S$$

and on the structural rows H, C, P, N. By Definition 902.59, the completion-seal classifier read is determined on that public route: the second presentation cannot attach a different stream source, $\mathsf{RegSeqRat}$ source, $\mathsf{DyadicRatCore}$ source, $\mathsf{Real}^{\uparrow}$ source, tail source, limit source, or seal source to the same diagnostic budget use.

The replay and exactness components are also fixed. By Definition 902.17, the displayed Cont row C replays the route through $Q \longmapsto B \longmapsto S \longmapsto K$ before any $\mathsf{Real}^{\uparrow}$-facing read is admitted. By Definition 902.25, the classifier readback for K is public exactly through that displayed route with H, C, P, N. Thus an accepted presentation over the fixed rows has the same replay normal form and the same exactness/readback decision.

Finally use Definition 902.61 together with Definition 902.60. The terminal diagnostic surface is exhausted by the displayed finite ledger rows, and the forbidden external coordinates are not root coordinates. Therefore no hidden coordinate or duplicate classifier source remains from which a second accepted use of t could be produced. □

Theorem 902.64 (Cauchy witness ledger completion consumer factorization)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every completion-facing consumer of L factors through the displayed sibling route*

$$\mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}$$

and through the internal ledger route

$$Q \longmapsto B \longmapsto S \longmapsto K.$$

The structural rows H, C, P, N preserve the same two routes as componentwise transport, displayed continuation, package provenance, and local naming data; no consumer reaches a completion-facing read through a detached dyadic core, a second stream name, an unregistered regular rational readback, or an external Real completion selector.

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier completion consumer factorization`

Proof. Start with Definition 902.37. It places the $\mathsf{StreamName}^{\uparrow}$ window source and $\mathsf{RegSeqRat}^{\uparrow}$ readback on the same $Q \longmapsto B$ budget source, with $\mathsf{DyadicRatCore}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ already named in the shared source surface.

Next apply Definition 902.38. Completion-facing reads reach K only through $Q \longmapsto B \longmapsto S \longmapsto K$ and the structural rows H, C, P, N.

Finally use Definition 902.18. Since the carrier has no detached dyadic, stream, regular-rational, or external Real-completion coordinate, the sibling route and the internal ledger route are the only public factorization surfaces available to completion consumers. □

Theorem 902.65 (Cauchy witness ledger regular Real dependency scope)**.** *The exact BEDC dependency scope of the* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *regular-Real route is*

BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyDiagonalBudget}^{\uparrow}$,

Within this scope, $L = (Q, B, S, K, H, C, P, N)$ exports only the finite budget, stream-name, regular-rational, Real-seal, synchronizer, classifier, transport, continuation, provenance, and naming rows. It excludes host equality, quotient streams, selected limits, countable choice, and ambient completeness.

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier regular real dependency scope`

Proof. Project the carrier in Definition 902.1. Its analytic rows name the four packet dependencies $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$, and $\mathsf{RealCompletionSealClassifier}$ while its structural rows name BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$.

Use Definition 902.7 and Definition 902.37. These identify the regular-Real source surface as the shared $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ route read through Q and B before S and K are exposed.

Apply Definition 902.18. The excluded objects have no carrier coordinate, no transport row, no continuation replay, no provenance row, and no local NameCert entry, so they are outside the exact dependency scope. □

Theorem 902.66 (Cauchy witness ledger root-unblock obligation package)**.** *For downstream root consumers, the* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *obligation package is the union of the local* $\mathsf{NameCert}_{\mathsf{CauchyWitnessLedger}^{\uparrow}}$ *obligations of Definition 902.2, the completion-consumer factorization of Definition 902.64, and the regular-Real dependency scope of Definition 902.65. Thus any root consumer may rely on exactly the displayed rows Q, B, S, K, H, C, P, N, the sibling route* $\mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}$*, and the named BEDC kernel rows* $\mathsf{BHist}, \mathsf{hsame}, \mathsf{Cont}, \mathsf{Pkg}, \mathsf{NameCert}$*; it may not import a host equality, quotient-stream, selected-limit, choice, or ambient-completeness witness.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerUp StdBridge`
↪ variant `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root namecert threshold`

Proof. First read the local certificate surface from Definition 902.2. It admits exactly Q, B, S, K, H, C, P, N as the public ledger rows.

Next apply Definition 902.64. This supplies the downstream completion-facing route through both the sibling chain and the internal ledger chain.

Finally combine that route with Definition 902.65. The dependency theorem names every allowed BEDC object and excludes the off-scope completion principles, so the resulting package is precisely the root-unblock surface available to downstream consumers. □

Theorem 902.67 (Cauchy witness ledger terminal L10 pullback)**.** *For any downstream root consumer of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet $L = (Q, B, S, K, H, C, P, N)$, the terminal L10 surface is the single finite pullback*

$$\mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}$$

together with the internal ledger route

$$Q \longmapsto B \longmapsto S \longmapsto K.$$

Every read of the root surface factors through these two displayed chains and the structural rows H, C, P, N; no consumer receives a second stream-name branch, an alternate regular-rational readback, or a detached Real completion endpoint.

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root streamname pullback`

Proof. Begin with Definition 902.64. It already places every completion-facing consumer on the sibling chain from $\mathsf{DyadicRatCore}^{\uparrow}$ through $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$, and on the internal ledger route $Q \longmapsto B \longmapsto S \longmapsto K$.

Use Definition 902.65. This identifies the exact BEDC dependency scope of the regular-Real route and keeps the dyadic core, stream name, regular rational readback, and Real endpoint attached to the same finite carrier surface.

Finally apply Definition 902.66. The root package admits only the displayed ledger rows and the named sibling route, so the two chains form the terminal L10 pullback available to root consumers. □

Theorem 902.68 (Cauchy witness ledger root completion nonescape)**.** *The terminal pullback of Definition 902.67 exports no quotient stream, selected limit, host equality, choice row, ambient completeness principle, metric-completion datum, or standard bridge row. Its public data are exactly the finite sibling route* $\mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}$*, the ledger route* $Q \longmapsto B \longmapsto S \longmapsto K$*, and the structural rows* H, C, P, N*.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier root real completion nonescape`

Proof. Read the allowed data from Definition 902.67. It exposes only the sibling chain, the internal ledger chain, and the structural rows.

The regular-Real dependency scope of Definition 902.65 excludes host equality, quotient streams, selected limits, countable choice, and ambient completeness from the dependency surface.

The root-unblock obligation package of Definition 902.66 supplies the same exclusion to downstream root consumers. Since no metric-completion datum or standard bridge row is one of Q, B, S, K, H, C, P, N or one of the four sibling objects, neither is exported by the terminal pullback. □

Theorem 902.69 (Cauchy witness ledger root seal-selector exhaustion)**.** *Every root seal-selector read of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet factors through the two displayed routes*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

and

$$\mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}.$$

The read may use the structural rows H, C, P, N*, but it has no separate selector row, no hidden tail selector, no detached* $\mathsf{Real}^{\uparrow}$ *endpoint, and no off-route completion coordinate.*

Proof. Start with the root pullback of Definition 902.67. It fixes the sibling route through $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ together with the internal ledger route $Q \longmapsto B \longmapsto S \longmapsto K$.

Apply root completion nonescape from Definition 902.68. A selector-facing read cannot leave those displayed rows to obtain a quotient stream, selected limit, host equality, choice row, ambient completeness principle, metric-completion datum, or standard bridge row.

Finally use the root budget refusal boundary of Definition 902.52. Any requested seal selector not carried by the displayed routes lands at the refusal boundary, so the two chains exhaust every admitted root seal-selector read. □

Theorem 902.70 (Cauchy witness ledger completion observer refusal factorization)**.** *Let* $L = (Q, B, S, K, H, C, P, N)$ *be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every observer-filter or selector-seal consumer of* L *either reads the displayed ledger route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

together with the sibling route $\mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}$*, or lands in the refusal boundary for off-route completion requests. No third observer channel is exported.*

Proof. First read the admitted route from Definition 902.69. It gives the only seal-selector path available to a root consumer.

Next apply terminal observer exactness, Definition 902.73. The observer side is forced onto the same four terminal faces and the same structural support rows, so an observer-filter consumer has no independent completion face to inspect.

For requests outside those rows, use Definition 902.52. The refusal boundary receives the off-route quotient, selected-limit, host-equality, countable-choice, ambient-completeness, hidden-tail, alternate-seal, and bridge-shaped requests. Thus observer-filter and selector-seal consumers factor through the displayed route or through refusal, with no third case. □

Theorem 902.71 (Cauchy witness ledger terminal four-face refusal exactness)**.** *Once the* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *faces of an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet are fixed, the terminal consumer surface contains exactly those faces, the ledger route* $Q \longmapsto B \longmapsto S \longmapsto K$*, and the structural rows* H, C, P, N*. No quotient stream, selected limit, host equality, countable-choice row, ambient completeness principle, metric-completion datum, or standard bridge row remains.*

Proof. Begin with terminal selector-observer uniqueness, Definition 902.76. Agreement on the four terminal faces and the support rows identifies the ledger route, observer-filter route, and selector-seal route as the same finite selector-observer route.

Use terminal observer exactness, Definition 902.73, to remove residual observer data. The observer can read only the fixed four faces and the displayed support rows.

Finally combine root completion nonescape and completion observer refusal factorization, Definition 902.68 and Definition 902.70. Off-route completion requests are refused, while admitted requests use the displayed routes. Hence none of the quotient, limit, host-equality, choice, ambient-completeness, metric-completion, or bridge rows remains at the terminal surface. □

Corollary 902.72 (Cauchy witness ledger completion consumer strict local obstruction)**.** *Let* $L = (Q, B, S, K, H, C, P, N)$ *be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Any displayed failure, refusal, separation, or countermodel row attached to the completion-consumer surface of* L *is a strict local obstruction. It blocks only a proposed converse read, detached reuse, second stream-name route, unregistered regular-rational readback, external* $\mathsf{Real}^{\uparrow}$ *completion selector, or bridge-shaped completion request that tries to bypass the displayed sibling route*

$$\mathsf{DyadicRatCore}^{\uparrow} \longmapsto \mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}$$

and the internal ledger route

$$Q \longmapsto B \longmapsto S \longmapsto K.$$

Every admitted completion-facing consumer still factors through those two routes together with the structural rows H, C, P, N*. A request using an unlisted coordinate cannot be reinterpreted as a*

global impossibility theorem for $\mathsf{Real}^{\uparrow}$ *completion, as a host theorem about Real completeness, or as hidden validation by an external completion principle.*

Proof. Begin with Definition 902.64. It states that every completion-facing consumer of L factors through the sibling route from $\mathsf{DyadicRatCore}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$ and through the internal route $Q \longmapsto B \longmapsto S \longmapsto K$. The same theorem also fixes the role of H, C, P, N: they preserve those routes as componentwise transport, displayed continuation, package provenance, and local naming data, and they do not create a detached dyadic core, a second stream name, an unregistered regular-rational readback, or an external Real completion selector.

Now apply Definition 902.68. The terminal pullback exports no quotient stream, selected limit, host equality, choice row, ambient completeness principle, metric-completion datum, or standard bridge row. Its public data are exactly the four-object sibling route, the ledger route $Q \longmapsto B \longmapsto S \longmapsto K$, and the structural rows H, C, P, N.

These two statements leave only two consumer-facing cases. In the admitted case, the consumer factors through the displayed routes and the structural rows by completion-consumer factorization. In the refused case, the attempted coordinate is one of the unlisted completion, quotient, host, choice, bridge, or detached readback coordinates excluded by root completion nonescape. Such a coordinate has no exported carrier row, no structural replay through H, C, P, N, and no terminal pullback datum from which a host theorem or hidden external validation route could be read. Hence the displayed obstruction is strict and local: it rejects only the named converse or reuse attempt outside the ledger packet, while leaving the admitted completion-consumer factorization intact. □

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyWitnessLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{CauchyWitnessLedger}^{\uparrow}$ packet is generated from a Cauchy diagonal budget, Real observation budget, Cauchy seal-budget synchronizer, Real completion-seal classifier, componentwise transports, displayed routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CauchyWitnessLedger}^{\uparrow}}$, maturePackageClosed)

902.1 Cauchy witness ledger terminal observer exactness

Theorem 902.73 (Cauchy witness ledger terminal observer exactness)**.** *Let* $L = (Q, B, S, K, H, C, P, N)$ *be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Any observer that reads the same* $\mathsf{StreamName}^{\uparrow}$

window face, $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger face,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback face,* $\mathsf{Real}^{\uparrow}$ *seal face, and displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows determines the same terminal Real-completion observer surface.*

Consequently, the observer has no residual quotient stream, selected limit, host sequence equality, ambient Real completeness, metric-completeness datum, countable-choice row, second completion route, or standard bridge row to read after the four faces and support rows have been fixed.

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier terminal observer exactness`

Proof. Begin with Definition 902.46. It places every Phase Real and Completion consumer of L on the selector-seal route ending at $\mathsf{Real}^{\uparrow}$, with only the displayed BHist, hsame, Cont, Pkg, and NameCert rows as support.

Next use Definition 902.45 and Definition 902.44. The handoff supplies the shared dyadic budget, named stream window, regular-rational readback, and Real seal coordinates, while the selector exhaustion shows that an observation-budget mediator exports the same four terminal faces and no off-route completion coordinate.

Finally apply Definition 126.449. Once two observers agree on the $\mathsf{StreamName}^{\uparrow}$ window face, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger face, $\mathsf{RegSeqRat}^{\uparrow}$ readback face, $\mathsf{Real}^{\uparrow}$ seal face, and the displayed support rows, the open Phase Real and Completion surface is terminal. The exclusions in the cited Cauchy ledger route and StreamName terminality theorem leave no quotient stream, selected limit, host sequence equality, ambient Real completeness, metric-completeness datum, countable-choice row, second completion route, or standard bridge row outside that surface. □

Theorem 902.74 (Cauchy witness ledger observer-filter budget-selector lock)**.** *Let* $L = (Q, B, S, K, H, C, P, N)$ *be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet, and let* $G = (F, I, S_{\mathrm{obs}}, O, B_{\mathrm{obs}}, W, D, R, E, H_{\mathrm{obs}}, C_{\mathrm{obs}}, P_{\mathrm{obs}}, N_{\mathrm{obs}})$ *be an accepted* $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet. Suppose the selected* $\mathsf{StreamName}^{\uparrow}$ *window family* W *of* G *agrees with the terminal* $\mathsf{StreamName}^{\uparrow}$ *window face of* L*, together with the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows. Then every Real-completion observer whose finite observations are selected by* G *factors through the single route*

$$\mathsf{ObserverHistoryIdentity}^{\uparrow} \to \mathsf{ObserverFilter}^{\uparrow} \to \mathsf{ObserverFilterBudgetSelector}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to$$

The omitted rows of G *and every off-route completion datum remain outside this factorization.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier observer filter budget selector lock`

Proof. Begin with Definition 902.73. The agreement hypothesis identifies the terminal Cauchy ledger window face with the selected $\mathsf{StreamName}^{\uparrow}$ window family exported by G, and it fixes the same support rows for the dyadic ledger, regular-rational readback, and Real seal.

Next apply Definition 1042.3. It forces every finite observation consumed by G through the observer-history identity row, the observer filter, the selected row, the finite budget selector, and then the $\mathsf{StreamName}^{\uparrow}$ window family before any dyadic, regular-rational, or Real-completion row is exposed.

The NameCert surface of Definition 1042.2 supplies the boundary check for the omitted ledger. Its coordinates place omitted rows only in the boundary and support rows, while W, D, R, E are the sole observation and completion coordinates available on the selected route.

Coordinate exhaustion now gives the claimed lock. Since the Cauchy terminal observer has no residual quotient stream, host real equality, selected limit, countable-choice row, ambient completeness, second completion route, metric-completion datum, or standard bridge row to read,

and since the observer-filter budget selector has no coordinate that can turn an omitted row into W, D, R, or E, every Real-completion observer selected by G factors through the displayed route and nowhere else. □

Theorem 902.75 (Cauchy witness ledger observer-filter omitted-row boundary)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet, and let*

$$G = (F, I, S_{\text{obs}}, O, B_{\text{obs}}, W, D, R, E, H_{\text{obs}}, C_{\text{obs}}, P_{\text{obs}}, N_{\text{obs}})$$

be an accepted $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet. Suppose G selects the same* $\mathsf{StreamName}^{\uparrow}$ *window family,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and* $\mathsf{Real}^{\uparrow}$ *seal row as the terminal Cauchy ledger route of L, with the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows identified. Then every Real-and-Completion observer factors through the selected route*

$$\mathsf{ObserverHistoryIdentity}^{\uparrow} \to \mathsf{ObserverFilter}^{\uparrow} \to \mathsf{ObserverFilterBudgetSelector}^{\uparrow} \to \mathsf{StreamName}^{\uparrow} \to \mathsf{DyadicRatCore}^{\uparrow} \to$$

and the omitted ledger O of G remains boundary-only data. No omitted row can be repacked as a $\mathsf{StreamName}^{\uparrow}$ *window, dyadic ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal, quotient stream, selected limit, host equality, choice row, ambient completeness principle, or second completion route.*

Proof. First use terminal observer exactness, Definition 902.73. The shared terminal faces force every Real-and-Completion observer of L onto the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surface, with no residual quotient stream, selected limit, host equality, choice row, ambient completeness principle, metric-completion datum, or second completion route.

Next apply the observer-filter budget-selector lock, Definition 902.74. The agreement with G places the same observer on the route through $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{ObserverFilter}^{\uparrow}$, $\mathsf{ObserverFilterBudgetSelector}$ and then the selected W, D, R, E coordinates.

Finally invoke omitted-row exclusion for the observer-filter budget selector, Definition 1042.4. It keeps O outside the selected StreamName window, dyadic ledger, regular-rational readback, and Real seal coordinates. Combining this boundary exclusion with the terminal Cauchy exhaustion leaves no carrier position where an omitted row could be repacked as any of the off-route completion objects listed in the statement. □

Theorem 902.76 (Cauchy witness ledger terminal selector-observer uniqueness)**.** *Let $L_{\text{cw}} = (Q, B_{\text{cw}}, S, K, H_{\text{cw}}, C_{\text{cw}}, P_{\text{cw}}, N_{\text{cw}})$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet, let*

$$G = (F, I, S_{\text{obs}}, O, B_{\text{obs}}, W, D, R_{\text{obs}}, E_{\text{obs}}, H_{\text{obs}}, C_{\text{obs}}, P_{\text{obs}}, N_{\text{obs}})$$

be an accepted $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet, and let*

$$T = (B, W, R, L, E, H, C, P, N)$$

be an accepted $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet. Suppose these three packets agree on the selected* $\mathsf{StreamName}^{\uparrow}$ *window family, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger face, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback face, the* $\mathsf{Real}^{\uparrow}$ *seal face, and the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows. Then every terminal Real-completion observer selected through the ledger route of L_{cw} and every terminal Real-completion observer selected through the observer-filter route of G is the same finite selector-observer route through T.*

The route has no quotient stream coordinate, selected limit object, host equality row, ambient completeness principle, metric-completeness datum, countable-choice row, second completion route, or standard bridge row.

Proof. First apply Definition 902.73. The shared $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces identify every terminal observer read from L_{cw} with the displayed Cauchy witness ledger surface and its support rows.

Next apply Definition 902.74. The observer-filter packet G sends every selected finite observation through the observer-history identity, observer filter, budget selector, selected stream window, dyadic ledger face, regular-rational readback, and Real seal. Thus the observer-filter route reaches the same four terminal faces fixed by the ledger route.

Now use Definition 1081.3. Since the accepted selector-seal packet T displays the same selector budget, selected window, readback row, limit-seal handoff, Real endpoint, and structural rows, any completion consumer exposed by either upstream route determines the same finite Real and Completion handoff route.

Finally apply Definition 1081.4. Non-escape removes the remaining possible bypasses: quotient streams, selected or detached limits, host equality, ambient completeness, metric-completeness data, countable choice, second completion routes, and standard bridge rows are not carrier coordinates of the shared packet.

Coordinate exhaustion over the shared finite faces therefore leaves only one selector-observer route. It is simultaneously the terminal observer route read from L_{cw}, the selected observer-filter route read from G, and the selector-seal route read from T. □

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier terminal selector observer uniqueness`

Theorem 902.77 (Cauchy witness ledger terminal selector-observer support exhaustion)**.** *Let* $L_{\mathrm{cw}} = (Q, B_{\mathrm{cw}}, S, K, H_{\mathrm{cw}}, C_{\mathrm{cw}}, P_{\mathrm{cw}}, N_{\mathrm{cw}})$ *be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet, let*

$$G = (F, I, S_{\mathrm{obs}}, O, B_{\mathrm{obs}}, W, D, R_{\mathrm{obs}}, E_{\mathrm{obs}}, H_{\mathrm{obs}}, C_{\mathrm{obs}}, P_{\mathrm{obs}}, N_{\mathrm{obs}})$$

be an accepted $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet, and let*

$$T = (B, W, R, L, E, H, C, P, N)$$

be an accepted $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet. Suppose these three packets agree on the selected* $\mathsf{StreamName}^{\uparrow}$ *window family, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger face, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback face, the* $\mathsf{Real}^{\uparrow}$ *seal face, and the displayed* BHist, hsame, Cont, Pkg, *and* NameCert *support rows. Then every terminal selector-observer read exposed by these packets is exhausted by exactly those four shared faces and the displayed support rows.*

No quotient stream, selected limit, host equality, ambient completeness principle, metric-completeness datum, countable-choice row, second completion route, standard bridge row, or extra support row remains after the shared $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *inventory is fixed.*

Proof. Apply Definition 902.73. It reduces every terminal observer read from the accepted Cauchy witness ledger packet to the four displayed terminal faces together with the BHist, hsame, Cont, Pkg, and NameCert rows.

Next apply Definition 902.74. The observer-filter budget selector cannot expose an omitted observation row as a completion coordinate; every selected finite observation must pass through the shared stream window, dyadic ledger, regular-rational readback, and Real seal.

Then use Definition 902.76. The ledger route, observer-filter route, and selector-seal route determine the same finite selector-observer route, so their support inventories cannot split into competing terminal reads.

Finally apply Definition 1081.4. Non-escape removes the possible residual rows named in the statement from the accepted selector-seal carrier. The only remaining readable surface is therefore the shared $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ faces with the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support rows. □

Corollary 902.78 (Cauchy witness ledger terminal observer exactness determinacy)**.** *Let* $L_{\mathrm{cw}} = (Q, B_{\mathrm{cw}}, S, K, H_{\mathrm{cw}}, C_{\mathrm{cw}}, P_{\mathrm{cw}}, N_{\mathrm{cw}})$ *be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet, let*

$$G = (F, I, S_{\mathrm{obs}}, O, B_{\mathrm{obs}}, W, D, R_{\mathrm{obs}}, E_{\mathrm{obs}}, H_{\mathrm{obs}}, C_{\mathrm{obs}}, P_{\mathrm{obs}}, N_{\mathrm{obs}})$$

be an accepted $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet, and let*

$$T = (B, W, R, L, E, H, C, P, N)$$

be an accepted $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet. Suppose the three packets agree on the selected* $\mathsf{StreamName}^{\uparrow}$ *window family, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger face, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback face, the* $\mathsf{Real}^{\uparrow}$ *seal face, and the displayed* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *support rows. Then any accepted consumer-facing use of the terminal observer exactness surface has a determined finite read: it must choose the route, normal form, and exactness decision read from the single chain*

$$\mathsf{CauchyWitnessLedger}^{\uparrow} \to \mathsf{ObserverHistoryIdentity}^{\uparrow} \to \mathsf{ObserverFilter}^{\uparrow} \to \mathsf{ObserverFilterBudgetSelector}^{\uparrow} \to \mathsf{RealCompl}$$

No accepted use can choose an alternate hidden coordinate, omitted-row classifier, duplicate classifier source, quotient stream, selected limit, host equality row, ambient completeness principle, metric-completeness datum, countable-choice row, second completion route, or standard bridge row after those local rows have been fixed.

Proof. Apply Definition 902.73. The shared $\mathsf{StreamName}^{\uparrow}$ window face, $\mathsf{DyadicRatCore}^{\uparrow}$ ledger face, $\mathsf{RegSeqRat}^{\uparrow}$ readback face, $\mathsf{Real}^{\uparrow}$ seal face, and displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows determine one terminal Real-completion observer surface for the accepted Cauchy witness ledger packet. Thus an accepted consumer-facing use of terminal observer exactness has no remaining Real-completion coordinate outside that surface from which to read a different exactness decision.

Now apply Definition 902.76. The ledger route, the observer-filter route, and the selector-seal route determine the same finite selector-observer route through T. In particular, the observer-filter part of the read passes through $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{ObserverFilter}^{\uparrow}$, $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$, the selected $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger face, the $\mathsf{RegSeqRat}^{\uparrow}$ readback face, and the $\mathsf{Real}^{\uparrow}$ seal face; the selector-seal part reads the same selector budget, selected window, readback row, seal handoff, Real endpoint, and structural rows.

The two cited results exhaust both possible sources of variation. Exactness fixes the terminal observer surface once the four faces and support rows are fixed, while uniqueness, with the componentwise transport reference Definition 902.16, identifies every selected terminal observer with the same finite route through the displayed packets. Hence the consumer cannot replace the route by an omitted-row classifier, a second NameCert source, or any of the excluded completion coordinates named in the statement. The route, its normal form as a finite read, and the exactness decision exposed to the consumer are therefore determined by the displayed local rows alone. □

902.2 Cauchy witness ledger classifier route coverage

Theorem 902.79 (Cauchy witness ledger classifier route coverage)**.** *Let $L = (Q, B, S, K, H, C, P, N)$ be an accepted* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *packet. Every public consumer of the completion-seal classifier row K factors through the displayed Real-facing route*

$$Q \longmapsto B \longmapsto S \longmapsto K$$

together with the structural rows H, C, P, N. In particular, no classifier consumer can replace that route by quotient stream equality, host $\mathsf{Real}^{\uparrow}$ *equality, selected external limits, countable choice, ambient completeness, hidden tails, or an alternate* $\mathsf{Real}^{\uparrow}$ *seal.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessLedgerUp.CauchyWitnessLedgerCarrier classifier route coverage`

Proof. Project the accepted packet by Definition 902.1. Its public coordinates are exactly the diagonal budget Q, observation budget B, synchronizer S, completion-seal classifier K, and structural rows H, C, P, N.

Apply Definition 902.2 and Definition 902.5. The NameCert surface certifies the displayed rows, while the budget factorization orders the Real-facing route as $Q \longmapsto B \longmapsto S \longmapsto K$ before any classifier read is available to a public consumer.

Next use Definition 902.7 and Definition 902.14. The source coherence identifies the finite stream, dyadic, regular-rational, and Real faces consumed by Q and B; the synchronizer-classifier lock carries that same source through S into K without adding a second classifier route.

It remains to connect this finite route to the Real-facing seal. Apply Definition 902.11 and Definition 902.9. Once the route and structural rows are fixed, the completion-seal classifier read is determined, and every $\mathsf{Real}^{\uparrow}$-facing handoff reaches K only through the displayed budget, observation, and synchronizer rows.

Finally apply Definition 902.18. The excluded objects have no carrier coordinate, no NameCert entry, and no structural row in H, C, P, N. A public consumer of K therefore cannot replace the displayed route by quotient stream equality, host $\mathsf{Real}^{\uparrow}$ equality, selected external limits, countable choice, ambient completeness, hidden tails, or an alternate $\mathsf{Real}^{\uparrow}$ seal. □

The $\mathsf{CauchyWitnessLedger}^{\uparrow}$ row is the witness-ledger surface recovered by chapter 1117 and consumed by chapter 1110 inside the Real-completion route. In that lattice position the ledger remains the finite BHist, hsame, Cont, Pkg, and NameCert surface over the displayed budget, observation, synchronizer, and classifier rows; it supplies no quotient stream equality, choice principle, or ambient completeness theorem.

Chapter 903

A Concrete Naming Certificate for $\mathsf{ObservationBudgetLimiter}^{\uparrow}$

The $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ packet realizes the finite request-cap side of the Real and Completion route of chapter 9238. It sits between the observation-budget service of chapter 611 and the seal-facing routes of chapter 126, chapter 301, chapter 291, and chapter 38. The packet is a concrete gate: it records which finite request rows may be served before any $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, or $\mathsf{Real}^{\uparrow}$ seal read is consumed.

Falsifiable prediction: Deleting the budget-cap row permits a RealUp seal consumer to bypass the finite request bound, while deleting the window or dyadic rows breaks StreamName and RegSeqRat readback.

Independence witness: Nearest siblings: realobservationbudget, cauchysealbudgetsynchronizer, realcompletionsealclassifier, streamname, and regseqrat; none is bijective because this carrier has a separate budget-cap gate between request and seal rows.

Definition 903.1 (Observation-budget limiter carrier)**.** *An* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (E, B, K, W, D, R, S, H, C, P, N)$$

with the following displayed rows:

1. *E is the incoming finite precision or observation request;*
2. *B is the accepted* $\mathsf{RealObservationBudget}^{\uparrow}$ *service row covering the request;*
3. *K is the budget-cap row that bounds how many request windows may be served before the seal is read;*
4. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *window ledger admitted under the cap;*
5. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger read through those windows;*
6. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row assembled from W and D;*
7. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after the capped request, window, dyadic, and regular readback rows have been consumed;*
8. *H stores componentwise* hsame *transports for $E, B, K, W, D, R, S, C, P, N$;*

9. *C stores the displayed* Cont *routes from the request to the budget row, from the budget-cap row to the window ledger, from the window and dyadic ledgers to the regular readback, and from the readback to the seal;*
10. *P records* Pkg *provenance over* $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}$ *row.*

The carrier exports a finite budget gate for Real and Completion consumers. It exports no unbounded observation schedule, quotient stream, selected limit, host real equality, trichotomy row, independent real carrier, or ambient completeness principle.

Lean4 ✓ `BEDC.Derived.ObservationBudgetLimiterUp.ObservationBudgetLimiterTasteGate single carrier alignment`

Theorem 903.2 (Observation-budget limiter NameCert obligations)**.** *For the carrier of Definition 903.1, the local* $\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}$ *surface consists of six finite obligations:*

1. *carrier admission for the displayed packet $L = (E, B, K, W, D, R, S, H, C, P, N)$;*
2. *budget-cap admission, requiring K to be read after the request row E and budget row B and before any window row W is served;*
3. *finite-window coverage, requiring every served window to be one of the* $\mathsf{StreamName}^{\uparrow}$ *rows admitted by W under K;*
4. *dyadic and regular readback, requiring each* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation in D and the resulting* $\mathsf{RegSeqRat}^{\uparrow}$ *row R to be read through the same capped window route;*
5. *seal handoff, requiring the* $\mathsf{Real}^{\uparrow}$ *seal row S to be consumed only after E, B, K, W, D, R have been displayed;*
6. *non-escape, excluding unbounded schedules, quotient streams, selected limits, host real equality, trichotomy, independent real carriers, and ambient completeness.*

Proof. Carrier admission is projection from Definition 903.1. The request, observation budget, cap, window, dyadic, regular readback, seal, transport, route, provenance, and local name are all explicit coordinates.

Budget-cap admission reads K between B and W. Thus the finite request is served by the displayed budget row before any window ledger is exposed, and the cap row fixes which subsequent windows are available.

Finite-window coverage, dyadic readback, and regular readback are then read along the displayed route $K \to W \to D \to R$. Componentwise transports in H preserve the same rows, and the continuation rows in C replay them without adding another observation source.

Finally the seal handoff reads S only after R. Since the carrier contains no row for an unbounded schedule, quotient stream, selected limit, host real equality, trichotomy, independent real carrier, or ambient completeness principle, the non-escape obligation is exactly the visible finite inventory. □

Theorem 903.3 (Observation-budget limiter cap admission)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P, N)$ be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *carrier. Every admitted read of the finite window row W, dyadic ledger row D, regular readback row R, or real seal row S first reads the incoming request row E, then the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row B, and then the budget-cap row K. The cap admission row is therefore a carrier projection certified by the local* $\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}$ *obligations, not a numerical side condition external to the packet.*

Lean4 ✓ `BEDC.Derived.ObservationBudgetLimiterUp.ObservationBudgetLimiterCarrier cap admission`

Proof. Project the accepted carrier L and apply Definition 903.2. Carrier admission exposes the rows $E, B, K, W, D, R, S, H, C, P, N$, while budget-cap admission places K after E and B and before any served window row.

The finite-window, dyadic readback, regular readback, and seal handoff obligations all depend on that displayed cap row. Hence any consumer attempting to read W, D, R, or S without first reading K has no carrier coordinate and no NameCert clause from which such a route can be certified.

The non-escape clause excludes replacing this route by an unbounded schedule, quotient stream, selected limit, host equality, trichotomy row, independent real carrier, or ambient completeness witness. Thus cap admission is exactly the visible carrier order E, B, K before the downstream surface. □

Theorem 903.4 (Observation-budget limiter seal ordering)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P, N)$ be an accepted* ObservationBudgetLimiter$^{\uparrow}$ *carrier. A seal-facing* Real$^{\uparrow}$ *consumer reaches S only through the ordered finite route*

$$E \to B \to K \to W \to D \to R \to S.$$

The displayed hsame*,* Cont*,* Pkg*, and* NameCert *rows certify this order and certify no route that reads S before the budget cap, window ledger, dyadic ledger, and regular readback have been displayed.*

Proof. Use Definition 903.2. The seal handoff obligation permits the Real$^{\uparrow}$ seal row only after the request, observation-budget, cap, window, dyadic, and regular readback rows are visible.

The continuation rows in C display the same ordered route, and the componentwise transports in H preserve the chosen rows rather than adding a second seal route. The provenance row P and local naming row N authenticate this finite route as the packet's seal-facing surface.

Finally apply the non-escape obligation. Since L contains no independent real carrier, selected limit, host equality, quotient stream, trichotomy row, or completeness witness, there is no carrier projection from which an out-of-order seal read can be formed. □

Lean4 ✓ `BEDC.Derived.ObservationBudgetLimiterUp.ObservationBudgetLimiter seal ordering`

Theorem 903.5 (Observation-budget limiter capped-window transport)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P, N)$ and $L' = (E', B', K', W', D', R', S', H', C', P', N')$ be accepted* ObservationBudgetLimiter$^{\uparrow}$ *carriers whose request, budget, cap, window, dyadic, regular, and seal rows are related by the displayed componentwise* hsame *rows. If both packets read downstream consumers through the budget row and cap row before the window, dyadic, regular, and seal rows, then the transported consumer route remains inside the capped finite surface*

$$E, B, K, W, D, R, S, H, C, P, N.$$

It cannot escape to an uncapped window schedule, quotient stream, selected limit, external equality, independent real carrier, or ambient completeness witness.

Proof. Begin with carrier projection for L and L'. The local obligations read E through B, then K, before any of W, D, R, S becomes available.

Use the componentwise hsame rows to transport each displayed coordinate to the matching coordinate of L'. The continuation rows replay the capped route through $K' \to W' \to D' \to$

$R' \to S'$, so transport preserves the finite window service rather than introducing a new consumer source.

The non-escape obligation applies on both carriers. Because neither packet contains an uncapped schedule, quotient stream, selected limit, external equality, independent real carrier, or completeness row, the transported route remains exactly a capped-window transport of the displayed carrier surface. □

Theorem 903.6 (Observation-budget limiter budget monotonicity)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P, N)$ and $L' = (E', B', K', W', D', R', S', H', C', P', N')$ be accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *carriers. If the request and budget rows agree componentwise and the budget-cap row K' admits every window admitted by K, then every seal-facing read admitted by L is also admitted by L' through the transported rows W', D', R', S' and the displayed* hsame*,* Cont*,* Pkg*, and* NameCert *evidence.*

Proof. Start with the carrier rows of L. A seal-facing read must pass through E, B, K, W, D, R, S in that order by Definition 903.2.

Use the componentwise agreement of the request and budget rows to transport the entry route from E, B to E', B'. The cap hypothesis then sends each K-admitted window to a K'-admitted window, so the same finite window service is available in W'.

Read the dyadic and regular rows through the transported windows. The rows D', R' are the matching dyadic and $\mathsf{RegSeqRat}^{\uparrow}$ readback rows under the larger cap, and the route to S' is displayed by C' with provenance P', N'. Thus widening the cap preserves every previously admitted seal read and does not add any excluded analytic object. □

Theorem 903.7 (Observation-budget limiter window non-escape)**.** *Every* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer served by an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *carrier factors through the finite rows*

$$E, B, K, W, D, R, S, H, C, P, N.$$

In particular, no consumer may reach the regular readback row R or the real seal row S without first displaying the budget-cap row K, the finite window row W, and the dyadic observation row D.

Proof. Project the accepted carrier and apply Definition 903.2. The obligations order the request, budget, cap, window, dyadic, regular, and seal rows before any consumer-facing read is available.

For a $\mathsf{StreamName}^{\uparrow}$ consumer, the route stops at the capped window ledger W. For a $\mathsf{RegSeqRat}^{\uparrow}$ consumer, the route continues through D to R. For a $\mathsf{Real}^{\uparrow}$ consumer, the route continues through the same readback to S.

The displayed transport, continuation, provenance, and naming rows authenticate these routes and no others. Therefore any route that bypasses K, W, or D has no carrier coordinate from which to read R or S. □

Theorem 903.8 (Observation-budget limiter vision handoff)**.** *The Real and Completion route of chapter 9238 may consume an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet as the finite gate between observation-budget availability and seal consumption. The handoff first reads the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row, then the budget cap, then the* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observations,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and finally the* $\mathsf{Real}^{\uparrow}$ *seal. The resulting route is compatible with chapter 886 and chapter 900 as a capped observation service, not as a completeness principle.*

Proof. Begin with the observation-budget row B and the cap row K. These rows turn the availability of an observation service into a finite request gate before any stream or seal consumer is reached.

Next compose the capped window route with the dyadic and regular readback rows. The route W, D, R is the same finite surface used by StreamName, DyadicRatCore, and RegSeqRat consumers, so it gives the Real and Completion side a displayed readback rather than an implicit analytic primitive.

Finally read the seal row S through the same packet. The synchronizer and completion-seal classifier chapters may consume this packet as a capped observation service before they read their seal-facing rows. Since the carrier contains no completeness, quotient, selected-limit, host-equality, trichotomy, or independent-real coordinate, the handoff is a finite gate and not an analytic closure theorem. □

Theorem 903.9 (Observation-budget limiter cap totality)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P, N)$ be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *carrier. Every accepted packet reads the finite request row E and the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row B before the budget-cap row K. No consumer route to the* $\mathsf{StreamName}^{\uparrow}$ *window row W, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger D, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R, or the* $\mathsf{Real}^{\uparrow}$ *seal row S is available without first displaying K with the same* hsame*,* Cont*,* Pkg*, and* NameCert *provenance.*

Proof. Apply Definition 903.2 to the displayed packet L. The budget-cap admission obligation places K after E and B and before any served window row.

Apply Definition 903.7. It identifies K as part of every route that reaches W, D, R, S, so a consumer missing the cap row has no carrier coordinate from which to read any downstream seal-facing row.

The monotonicity theorem Definition 903.6 shows that enlarging the cap changes only which K-admitted windows may be transported; it does not remove the requirement that the route pass through a displayed cap. Hence cap totality is a structural obligation of the carrier rather than a numerical side condition. □

Theorem 903.10 (Observation-budget limiter window readback exactness)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P,$ be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *carrier. Each served* $\mathsf{StreamName}^{\uparrow}$ *window in W, each* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row in D, and each* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row in R shares the same capped route*

$$K \to W \to D \to R.$$

The displayed hsame *and* Cont *rows in H and C preserve that route, and the* Pkg *and* NameCert *rows P, N certify no second uncapped readback route.*

Proof. Use the dyadic and regular readback obligation from Definition 903.2. It requires the dyadic ledger D and the regular readback R to be read through the same capped window route that admits W.

The route itself is the finite chain $K \to W \to D \to R$. Componentwise hsame transports in H preserve the chosen cap, window, dyadic, and regular rows, while the displayed Cont rows in C replay the same chain for consumers.

Apply Definition 903.7 to exclude any read of R that bypasses K, W, D. Apply Definition 903.6 only as a transport principle: a larger accepted cap may carry the same readback through transported rows, but the readback remains tied to one capped route. □

Lean4 ✓ `BEDC.Derived.ObservationBudgetLimiterUp.ObservationBudgetLimiter window readback exactness`

Theorem 903.11 (Observation-budget limiter Real seal cap boundary)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P, N)$ be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *carrier. Every* $\mathsf{Real}^{\uparrow}$ *seal row S exported by L is reached only after the sequence*

$$E \to B \to K \to W \to D \to R \to S.$$

The boundary displayed to a seal consumer consists exactly of the componentwise hsame *rows in H, the* Cont *rows in C, the* Pkg *provenance P, and the local* $\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}$ *row N over that sequence.*

Proof. Apply the seal handoff obligation of Definition 903.2. It permits the $\mathsf{Real}^{\uparrow}$ seal row S only after the request, observation-budget, cap, window, dyadic, and regular readback rows have all been displayed.

Apply Definition 903.9 for the entry side of the boundary and Definition 903.10 for the middle readback. Together they make the seal route pass through E, B, K, W, D, R before S.

Finally apply Definition 903.8. The Real and Completion consumer may use this packet only as a capped observation service. The visible boundary is therefore the same H, C, P, N provenance carried by L, with no completeness, quotient, selected-limit, host-equality, trichotomy, or independent-real coordinate added at the seal. □

Theorem 903.12 (Observation-budget limiter finite service triad)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P, N)$ be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. The finite service surface exposed by L consists exactly of the request row E, the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row B, the cap row K, the* $\mathsf{StreamName}^{\uparrow}$ *window ledger W, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger D, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R, the* $\mathsf{Real}^{\uparrow}$ *seal row S, the componentwise transports H, the displayed routes C, the package provenance P, and the local* $\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}$ *row N. A downstream Real or Completion consumer may cite this surface as the limiter triad*

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N),$$

and receives no additional unbounded schedule, quotient stream, host real equality, selected limit, trichotomy row, independent real carrier, or ambient completeness row.

Proof. Project the accepted carrier through Definition 903.1 and apply Definition 903.2. These rows expose the request, budget, cap, window, dyadic, readback, seal, transport, route, provenance, and naming coordinates as the whole carrier surface.

For the entry part, use Definition 903.3 and Definition 903.9. They force every served window, readback, or seal read to pass through E, B, K before any downstream row is available.

For the middle part, use Definition 903.5, Definition 903.6, and Definition 903.7. These theorems keep the window and dyadic service inside the displayed W, D, R rows under the same cap.

For the exit part, apply Definition 903.10 and Definition 903.11. The seal row is therefore read only after the exact capped source-window-readback chain, with H, C, P, N recording the visible transport, route, package, and local certificate data. □

Theorem 903.13 (Observation-budget limiter source-window-readback lock)**.** *Let $L = (E, B, K, W, D, R, S, H, C,$ be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. Every downstream read of the capped service factors through the same source-window-readback rows*

$$E \to B \to K \to W \to D \to R.$$

In particular, no downstream read may replace W, D, R by host real equality, a hidden selector, an uncapped schedule, or a second readback route outside the displayed hsame, Cont, Pkg, *and* NameCert *rows of L.*

Proof. Begin with Definition 903.3. It places the source request and observation-budget rows before the cap row, and it makes the cap a coordinate of the accepted packet rather than an external numerical side condition.

Next apply Definition 903.5. Transport may move the displayed rows componentwise, but it does not create a new observation source or an uncapped service. The monotonicity theorem Definition 903.6 has the same shape: it can widen an accepted cap while preserving the same displayed route discipline.

Finally use Definition 903.7 and Definition 903.10. They identify $K \to W \to D \to R$ as the only regular readback route in the packet. Hence a host equality, hidden selector, uncapped schedule, or second readback has no carrier row and no local NameCert clause from which a downstream read can be certified. □

Theorem 903.14 (Observation-budget limiter downstream seal eligibility)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P,$ be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. A* $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{UniformLimit}^{\uparrow}$, *or Real-route consumer is eligible to consume the limiter only after it has read the finite service triad of Definition 903.12. Thus every eligible seal consumer has already displayed the request-budget-cap entry, the source-window-readback middle, and the* $\mathsf{Real}^{\uparrow}$ *seal boundary with the same H, C, P, N provenance.*

Proof. First read the limiter as a finite service packet by Definition 903.12. This exposes the three parts of the surface without adding a completion theorem, quotient stream, selected limit, host equality, or independent real carrier.

Next apply Definition 903.13. Any downstream consumer of the capped service must use the same E, B, K, W, D, R chain, so the consumer cannot replace the middle route by a hidden selector or host real equality.

Finally apply Definition 903.4 and Definition 903.11. They place the $\mathsf{Real}^{\uparrow}$ seal row after the capped readback and identify H, C, P, N as the seal-facing boundary. A $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{UniformLimit}^{\uparrow}$, or Real-route consumer therefore becomes eligible only after the displayed finite service triad has been read. □

Theorem 903.15 (Observation-budget limiter kernel scope)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P, N)$ be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. Every accepted limiter read is scoped by the displayed* BHist *carrier rows E, B, K, W, D, R, S, the componentwise* hsame *row H, the continuation-route row C, the package provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}$ *row N. No accepted read of the limiter may cite a kernel object outside those rows before it reaches a downstream seal consumer.*

Lean4 ✓ `BEDC.Derived.ObservationBudgetLimiterUp.ObservationBudgetLimiter kernel scope fields`

Proof. Project the carrier through Definition 903.1. The only carrier coordinates are $E, B, K, W, D, R, S, H, C, P, N$ with H storing the componentwise hsame transports and C storing the displayed Cont routes.

Apply Definition 903.2. Its cap, window, dyadic, regular, seal, and non-escape clauses read those coordinates as the local NameCert surface.

Finally use Definition 903.14. A downstream seal consumer becomes eligible only after the same finite service triad has been read, so the kernel scope is exactly the displayed BHist, hsame, Cont, Pkg, and NameCert surface. □

Theorem 903.16 (Observation-budget limiter TasteGate carrier alignment)**.** *The paper carrier fields of* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *are exactly the fields that a Lean* `ChapterTasteGate` *and* `BHistCarrier` *instance for this chapter must expose: the request row E, observation-budget row B,*

cap row K, window row W, dyadic row D, regular readback row R, seal row S, transport row H, continuation row C, package row P, and local name row N. The alignment asks for no extra Real carrier, quotient stream, selected limit, host equality, trichotomy row, or ambient completeness field.

Proof. Read the field list from Definition 903.1. The chapter's carrier is a finite BHist packet with precisely the eleven displayed coordinates.

Use Definition 903.15 to identify the same coordinates as the whole accepted-read scope. A Lean carrier instance for this paper site therefore has to expose those rows and their rowwise transport, route, provenance, and name data.

The exclusion part follows from Definition 903.12 and Definition 903.25. Both theorems deny extra analytic fields, so the TasteGate-facing carrier aligns with the paper carrier rather than with a stronger completion object. □

Theorem 903.17 (Observation-budget limiter seal field boundary)**.** *For every accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet $L = (E, B, K, W, D, R, S, H, C, P, N)$, the seal field S is reachable only through the displayed sequence $E, B, K, W, D, R, S, H, C, P, N$. The packet exports no independent Real carrier, no hidden completeness row, and no seal-facing field outside the request, budget, cap, window, dyadic, regular, transport, continuation, package, and local naming surface.*

Proof. Apply Definition 903.4. It places the seal row after the finite route $E \to B \to K \to W \to D \to R \to S$.

Apply Definition 903.11. The rows H, C, P, N are the only seal-facing provenance boundary attached to that route.

Finally use Definition 903.15. Since every accepted limiter read remains inside the displayed kernel rows, there is no independent Real carrier or completeness coordinate from which another seal field could be exported. □

Theorem 903.18 (Observation-budget limiter primitive scope)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P, N)$ be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. Every cap, window, dyadic observation,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal, transport, continuation, package, and* $\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}$ *obligation of L factors only through the displayed* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows. No obligation of the packet factors through a quotient stream, host real equality, selected limit, trichotomy row, independent real carrier, or ambient completeness principle.*

Proof. Project the accepted carrier through Definition 903.1. The coordinates of L are exactly the request, observation-budget, cap, window, dyadic, regular readback, seal, transport, continuation, package, and local naming rows listed there.

Apply Definition 903.2. Its obligations read those coordinates as carrier admission, cap admission, finite-window service, dyadic and regular readback, seal handoff, and non-escape clauses, all inside the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ surface.

Use Definition 903.12 and Definition 903.13 to identify the only downstream route as the finite triad

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N).$$

The non-escape clauses in those results exclude quotient streams, host real equality, selected limits, trichotomy, independent real carriers, and ambient completeness, so every listed obligation remains in the primitive scope. □

Theorem 903.19 (Observation-budget limiter scoped route factorization)**.** *Let* $L = (E, B, K, W, D, R, S, H, C, P, N$ *be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. Every* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{UniformLimit}^{\uparrow}$, $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$, *or* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *consumer of* L *factors through the same scoped primitive route*

$$E \to B \to K \to W \to D \to R \to S,$$

with H, C, P, N *as the only transport, continuation, provenance, and* $\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}$ *boundary. In particular, the consumer may read the limiter only as a finite BEDC primitive service and not through a quotient stream, host real equality, selected limit, trichotomy row, independent real carrier, or ambient completeness principle.*

Proof. Project the accepted packet through Definition 903.1. The carrier supplies exactly the rows $E, B, K, W, D, R, S, H, C, P, N$. Apply Definition 903.2 to read the same coordinates as the local $\mathsf{NameCert}$ obligations for carrier admission, cap admission, finite-window service, dyadic and regular readback, seal handoff, and non-escape.

The ordered primitive route is forced by the cap and readback clauses. Use Definition 903.3 to place K after the source request and observation-budget rows. Then use Definition 903.13 and Definition 903.10 to make $W \to D \to R$ the only regular readback route downstream from that cap.

For downstream consumers, apply Definition 903.14. It makes each $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{UniformLimit}^{\uparrow}$, and Real-route consumer read the finite service triad before a seal-facing row is available. Use Definition 903.22 for $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ consumers and Definition 903.23 for $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ consumers; both results factor their reads through the same limiter triad.

Finally combine Definition 903.18 with Definition 903.25. The primitive-scope theorem confines every obligation to the displayed BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows, while the service-triad coverage theorem says the listed consumers receive no second source, hidden selector, quotient stream, host real equality, selected limit, trichotomy row, independent real carrier, or ambient completeness. Thus every listed consumer factors through $E \to B \to K \to W \to D \to R \to S$ with H, C, P, N as the only boundary rows. □

Theorem 903.20 (Observation-budget limiter TasteGate boundary)**.** *The falsifiable prediction, independence witness, carrier rows, cap-admission theorem, seal-ordering theorem, capped-window transport theorem, and primitive-scope theorem of this chapter present the exact finite carrier boundary that a later Lean* `Nontrivial` *plus* `FieldFaithful` *TasteGate instance for* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *must compile. The boundary is the finite limiter packet surface and not an ambient Real completeness, quotient, selected-limit, host-equality, trichotomy, or independent-carrier assertion.*

Proof. The prediction and independence witness at the start of the chapter isolate the falsifiable role of the budget-cap gate: deleting it changes the Real and Completion service, and no listed sibling is bijective with the carrier.

The carrier boundary is then fixed by Definition 903.1. Apply Definition 903.3, Definition 903.4, and Definition 903.5 to make the accepted packet usable only through its finite cap, ordered seal route, and transported capped window.

Finally apply Definition 903.18. It states that every obligation used by the packet remains inside the displayed BEDC rows. Therefore the later TasteGate instance has a precise finite boundary to compile and receives no analytic completion principle from this paper theorem. □

Theorem 903.21 (Observation-budget limiter obligation closure package)**.** *For an accepted* ObservationBudgetLimi *packet* $L = (E, B, K, W, D, R, S, H, C, P, N)$*, the NameCert obligations, cap admission, seal ordering, capped-window transport, budget monotonicity, window non-escape, vision handoff, finite service triad, source-window-readback lock, downstream seal eligibility, primitive scope, and TasteGate boundary jointly form the paper obligation package for the finite limiter packet.*

Proof. Start with Definition 903.2. It supplies the local carrier, cap, window, readback, seal, and non-escape clauses that every later route must project from.

Use Definition 903.3, Definition 903.4, and Definition 903.5 for the main route obligations. These place K before W, D, R, S, order the seal after readback, and keep transported consumers inside the same capped service.

Use Definition 903.6, Definition 903.7, and Definition 903.8 for stability and downstream handoff. They preserve the displayed rows under cap enlargement, exclude escape from the finite source window, and hand the service to Real and Completion consumers as a capped observation service.

Finally use Definition 903.12, Definition 903.13, Definition 903.14, Definition 903.18, and Definition 903.20. These identify the exported triad, lock source-window-readback use, require seal consumers to read the triad first, keep the whole packet in primitive scope, and specify the finite TasteGate-facing boundary. Their composition is exactly the obligation package stated in the theorem. □

Theorem 903.22 (Observation-budget limiter selector compatibility)**.** *Let* $L = (E, B, K, W, D, R, S, H, C, P, N)$ *be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. Any* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *consumer may read the limiter only through the request-budget-cap service triad*

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N).$$

In particular, selector-facing use of the cap row K *does not expose a hidden selector, an uncapped observation schedule, a quotient stream, selected host limit, host real equality, or ambient completeness.*

Proof. Start with Definition 903.12. It identifies the whole exported surface of the limiter as the request-budget-cap entry, the source-window-readback middle, and the seal boundary with H, C, P, N.

Apply Definition 903.13. A selector-facing consumer cannot replace E, B, K, W, D, R by a hidden selector or second readback route, because the capped service has no such carrier row.

Finally use Definition 903.14. Any downstream consumer that continues toward a seal must already have displayed the same finite service triad, so selector compatibility is a projection of the limiter surface rather than a separate observation primitive. □

Theorem 903.23 (Observation-budget limiter Cauchy tail-budget factorization)**.** *Let* $L = (E, B, K, W, D, R, S, H,$ *be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. Any* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *consumer that uses* L *as its* O *row must first factor that row through the same limiter triad*

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N)$$

before it serves tail windows, dyadic observations, regular readback, and seal rows. Thus the tail-budget route inherits the limiter's displayed H, C, P, N *provenance and no uncapped observation source.*

Proof. Apply Definition 903.12 to expose the service consumed as O. The limiter row contributes exactly $E, B, K, W, D, R, S, H, C, P, N$ and no external cap primitive.

Use Definition 903.13 for the window and readback portion. It forces any downstream use of the capped service to pass through $E \to B \to K \to W \to D \to R$ before a seal-facing row is available.

Then apply Definition 903.4 and Definition 903.14. They make any tail-budget seal consumer eligible only after the same triad has been read, so a $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ packet can consume O only as this finite limiter service. □

Theorem 903.24 (Observation-budget limiter tail-budget shared cap)**.** *Let $L = (E, B, K, W, D, R, S, H, C, P, N)$ be an accepted $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ packet. If an accepted $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ packet consumes L as its observation-budget row O, then its tail threshold, finite windows, dyadic observations, regular readback, and seal route all inherit the same displayed cap row K. No uncapped observation source and no second budget gate are available to that tail-budget consumer.*

Proof. Start with Definition 903.23. It forces the consumed O row to factor through the limiter triad

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N).$$

Apply Definition 903.9 to the entry side of that triad. The cap row K is the displayed budget gate for every served observation, so the tail threshold, windows, dyadic observations, regular readback, and seal route cannot select an uncapped source.

Finally use the $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ observation gate of Definition 906.3. That gate reads O as the observation-budget surface for the tail packet, so the factorized limiter row supplies the same K to all downstream tail-budget fields and leaves no second budget gate to project. □

Theorem 903.25 (Observation-budget limiter service triad coverage)**.** *Every listed $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{UniformLimit}^{\uparrow}$, and Real-route consumer of an accepted $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ packet receives exactly the visible service triad*

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N),$$

including the same transport, continuation, package, and local naming rows H, C, P, N. No such consumer receives an unbounded schedule, hidden selector, quotient stream, selected host limit, host real equality, independent real carrier, or ambient completeness row.

Proof. First apply Definition 903.14. It states that $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{UniformLimit}^{\uparrow}$, and Real-route consumers become eligible only after the finite service triad has been read.

Next apply Definition 903.4. The seal row is reached only through $E \to B \to K \to W \to D \to R \to S$, so the visible triad covers the full entry, readback, and seal-facing route.

Finally use Definition 903.12 and Definition 903.13. These identify H, C, P, N as the displayed provenance for that route and exclude any second source, hidden selector, host equality, quotient, selected limit, independent real carrier, or completeness witness. □

Theorem 903.26 (Observation-budget limiter public seal interface)**.** *Every public consumer of an accepted $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ packet reads the capped finite window, budget cap, selector compatibility, Cauchy tail-budget factorization, and Real-seal boundary only through the displayed carrier rows*

$$E, B, K, W, D, R, S, H, C, P, N$$

and their Cont, Pkg, *and local* $\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}$ *provenance. No public consumer receives an unbounded observation schedule, hidden selector, quotient stream, selected limit, host real equality, independent real carrier, or ambient completeness row from the packet.*

Proof. Begin with the public service triad of Definition 903.25. It identifies the consumer-visible surface as

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N).$$

Apply Definition 903.22. Selector-facing consumers must read the capped service through $E, B, K, W, D, R, S, H, C, P, N$, so selector compatibility is a carrier projection rather than a hidden selector row.

Next apply Definition 903.23 and Definition 903.24. A $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ consumer inherits the same cap row K and the same provenance rows when it consumes the limiter as its observation-budget field.

Finally use Definition 903.11 and Definition 903.19. The Real-seal endpoint is reached only through the displayed route, and the route exports no unbounded schedule, hidden selector, quotient stream, selected limit, host equality, independent carrier, or ambient completeness principle. □

Theorem 903.27 (Observation-budget limiter cap intersection)**.** *Let* $L = (E, B, K, W, D, R, S, H, C, P, N)$ *be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. Suppose two accepted limiter packets share the transported request row* E*, observation-budget row* B*, and budget-cap row* K *with* L*. Then every shared* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer factors through the intersection of the displayed cap routes*

$$E \to B \to K \to W \to D \to R \to S$$

and cannot project an observation read outside the common K, H, C, P, N *provenance.*

Proof. Begin with Definition 903.9. Once the transported request and observation-budget rows agree, the shared cap row K is the only displayed gate from which served observations can enter the window, dyadic ledger, regular readback, and Real-seal rows.

Next apply Definition 903.13. It locks the source, finite window, dyadic observation, and regular readback rows along the same route, so a shared consumer cannot leave the common cap route after the K projection.

Finally use Definition 903.25. The public consumer surface is exactly the triad

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N),$$

hence the shared $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ consumers factor through the intersection of the two displayed cap routes rather than through an external observation source. □

Theorem 903.28 (Observation-budget limiter selector tail-budget compatibility)**.** *Let* $L = (E, B, K, W, D, R, S, H$ *be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. Any accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *consumer and any accepted* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *consumer that read the same limiter row* L *must read the same finite service triad*

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N).$$

In particular, the selector side and the tail-budget side use the same request, cap, window, dyadic ledger, regular readback, seal, transport, continuation, package, and local naming data.

Proof. First apply Definition 903.22. A selector-facing consumer reads the capped service through the displayed rows $E, B, K, W, D, R, S, H, C, P, N$ and does not receive a hidden selector row from the limiter.

Next apply Definition 903.23. A $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ consumer that uses L as its observation-budget row factors through the same displayed request, cap, window, dyadic ledger, regular readback, seal, and provenance rows.

Finally combine Definition 903.24 with Definition 903.27. The selector and tail-budget reads have the same accepted limiter row, so both accesses intersect at K and then continue through the common W, D, R, S, H, C, P, N service surface. □

Theorem 903.29 (Observation-budget limiter Real-route budget exhaustion)**.** *Every Real-route,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{UniformLimit}^{\uparrow}$*,* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$*, or* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *consumer of an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet exhausts its limiter access through the displayed finite triad*

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N).$$

The packet supplies no unbounded observation schedule, quotient stream, selected limit, host equality, trichotomy, independent $\mathsf{Real}^{\uparrow}$ *carrier, or completeness row to any of those consumers.*

Proof. Project the accepted carrier as $L = (E, B, K, W, D, R, S, H, C, P, N)$. For public Real-route, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{UniformLimit}^{\uparrow}$ consumers, apply Definition 903.26; it exposes only the displayed finite service route and excludes the listed escape surfaces.

For selector and tail-budget consumers, use Definition 903.28. Both consumers read the same triad from L, and Definition 903.27 pins their shared readback to the common cap route through K.

Finally close with Definition 903.18 and Definition 903.25. The primitive scope contains only the finite request, cap, window, dyadic ledger, regular readback, seal, transport, continuation, package, and local naming rows, so every listed consumer exhausts its access inside that finite surface. □

Theorem 903.30 (Observation-budget limiter budget readback saturation)**.** *Let* $L = (E, B, K, W, D, R, S, H, C, P$ *be an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet. Every served* $\mathsf{StreamName}^{\uparrow}$ *window in* W*, every* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger read in* D*, every* $\mathsf{RegSeqRat}^{\uparrow}$ *readback in* R*, and every* $\mathsf{Real}^{\uparrow}$ *seal read in* S *consumes the same displayed budget-cap row* K *along the route*

$$E \to B \to K \to W \to D \to R \to S.$$

No such read can be split across two budget services, and no downstream consumer can replace K *by an uncapped observation source outside the displayed* H, C, P, N *provenance.*

Proof. First apply Definition 903.9. It places the cap row K after the request and observation-budget rows E, B, and before any served window, dyadic ledger, regular readback, or seal row can be read.

Next use Definition 903.10. The middle route $K \to W \to D \to R$ is exact for the served windows, dyadic observations, and regular readback rows, so the readback part cannot change to a second cap service.

Finally compose Definition 903.24 with Definition 903.26. Tail-budget consumers and public seal consumers both read the limiter through the same displayed carrier rows and provenance fields, hence the downstream readback saturates one cap row K rather than two independent budget gates. □

Theorem 903.31 (Observation-budget limiter Real and Completion consumer boundary)**.** *Every Real or Completion consumer of an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet may use the limiter only as the finite route*

$$E \to B \to K \to W \to D \to R \to S$$

with the displayed H, C, P, N *provenance. The packet supplies a capped observation service for downstream Real and Completion chapters, not Real completeness, host real equality, quotient streams, selected limits, trichotomy, or an independent real carrier.*

Proof. Start with Definition 903.19. It factors every public route through the ordered primitive spine from E to S and keeps H, C, P, N as the visible transport, continuation, package, and local naming rows.

Then apply Definition 903.25. Real-route consumers and listed seal consumers receive the same service triad

$$(E, B, K) \quad (W, D, R) \quad (S, H, C, P, N).$$

Finally use Definition 903.26. The public interface already excludes completeness, host equality, quotient streams, selected limits, trichotomy, and independent real carriers, so Real and Completion consumers can cite the limiter only as the displayed finite service route. □

Theorem 903.32 (Observation-budget limiter tail-service downstream readback)**.** *Any* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer that reads an accepted* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *packet inherits the same budget-readback route through* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*:*

$$K \to W \to D \to R \to S.$$

The inherited route carries the same E, B, H, C, P, N *boundary data and does not expose a second observation budget, host equality, quotient stream, selected limit, or ambient completeness row.*

Proof. First apply Definition 903.23. A $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ consumer that uses the limiter as its observation row must factor that row through the same finite limiter triad before it serves windows, dyadic observations, regular readback, or seal rows.

Next use Definition 903.24. The tail threshold, finite windows, dyadic observations, regular readback, and seal route inherit one displayed cap row K, so the tail-service readback cannot draw from a second observation budget.

Finally apply Definition 903.14. A $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer is eligible only after the finite service triad has been read, so the downstream seal read continues through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ with the same E, B, H, C, P, N boundary. □

The follow-up Lean TasteGate for this chapter must provide `Nontrivial ObservationBudgetLimiterUp` and `FieldFaithful ObservationBudgetLimiterUp` instances for the same carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}$**.**

Constructive story: An $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ packet is generated from a finite request row, observation-budget row, budget-cap row, finite StreamName window ledger, DyadicRatCore observation ledger, RegSeqRat readback row, RealUp seal row, componentwise transports, displayed routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObservationBudgetLimiter}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 903.1, Definition 903.2, Definition 903.3, Definition 903.4, Definition 903.5, Definition 903.6, Definition 903.7, Definition 903.8, Definition 903.18, Definition 903.19, Definition 903.21, Definition 903.22, Definition 903.23, Definition 903.24, Definition 903.25, Definition 903.26, Definition 903.27, Definition 903.28, Definition 903.29, Definition 903.30, Definition 903.31, and Definition 903.32 bind finite request caps, NameCert rows, selector compatibility, Cauchy tail-budget factorization, tail-budget shared-cap routing, cap intersection, Real-route budget exhaustion, service-triad coverage, the mature public-consumer seal surface, downstream Real and Completion readback,

the paper bridge surface, and the primitive route $E \to B \to K \to W \to D \to R \to S$ before StreamName, RegSeqRat, DyadicRatCore, and RealUp seal reads.

Formal verification: FormalStatus(NameCert$_{\text{ObservationBudgetLimiter}\uparrow}$, axiomClean)

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, Real completeness, quotient streams, host real equality, selected limits, trichotomy, independent real carriers, or ambient completeness.

Upgrade path: The theory axis is complete for the displayed finite-service and Real-seal cap boundary; Lean-side bridge checking remains a formal-axis task.

Chapter 904

A Concrete Naming Certificate for MetaCICAuditMatrix$^{\uparrow}$

The MetaCICAuditMatrix$^{\uparrow}$ packet realizes the matrix and critical-path reading of chapter 9385 as a finite NameCert surface. It sits beside the normalization frontier of chapter 892, the subject-reduction discharge ledger of chapter 720, the closed-normal consistency packet of chapter 739, and the audit-map dependency weave of chapter 839. Those siblings expose frontier rows, discharge rows, closed-normal endpoint rows, and cross-map routing rows; the present packet records the status matrix that keeps positive rows, non-claim rows, blocked edges, synthesis consumers, and non-escape ledgers inspectable in one carrier.

Definition 904.1 (MetaCIC audit matrix carrier)**.** *A* MetaCICAuditMatrix$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (A, N, B, S, E, H, C, P, L)$$

with the following displayed rows:

1. *A is the available-row matrix, recording closed-normal consistency, candidate-mediated normalization, local decidable checking, closed substitution, and conditional confluence as positive audit rows;*
2. *N is the non-claim row matrix, recording full closed consistency, arbitrary closed Church–Rosser, candidate-free normalization, unrestricted beta-conversion decidability, and host substitution semantics as non-exported endpoints;*
3. *B is the blocked-edge matrix, with the subject-reduction lift as the critical edge from arbitrary closed proof terms to the closed-normal consistency branch;*
4. *S is the synthesis-consumer row, naming the consumers that may read the matrix before using closed-normal packets, discharge ledgers, or audit-map dependency routes;*
5. *E is the non-escape ledger, recording that every consumer route must preserve A, N, B, S as displayed rows;*
6. *H records componentwise* hsame *transports for A, N, B, S, E and the structural rows;*
7. *C records the displayed* Cont *routes by which a consumer reads available rows, non-claim rows, blocked edges, synthesis consumers, and non-escape ledgers in matrix order;*
8. *P is the* Pkg *provenance over chapter 9385, chapter 892, chapter 720, chapter 739, and chapter 839;*

9. L is the local $\mathsf{NameCert}_{\mathsf{MetaCICAuditMatrix}^{\uparrow}}$ *row.*
The carrier has no coordinate for removing the blocked subject-reduction edge, no hidden full-consistency theorem, no host reduction semantics, and no quotient equality of MetaCIC terms.

Lean4 ✓ `BEDC.Derived.MetaCICAuditMatrixUp.MetaCICAuditMatrixTasteGate single carrier alignment`

Theorem 904.2 (MetaCIC audit matrix NameCert obligations)**.** *For the carrier of Definition 904.1, the local* $\mathsf{NameCert}_{\mathsf{MetaCICAuditMatrix}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$M = (A, N, B, S, E, H, C, P, L),$$

available-row exposure, non-claim row exposure, blocked-edge exposure, synthesis-consumer exposure, non-escape ledger exposure, componentwise hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and the local naming row.*

Lean4 ✓ `BEDC.Derived.MetaCICAuditMatrixUp.MetaCICAuditMatrixUp obligation surface`

Proof. Carrier admission is projection from Definition 904.1. The rows $A, N, B, S, E, H, C, P, L$ are the complete finite packet.

The positive matrix entries are read from A and routed through the sibling frontier and closed-normal packets named in P. The non-claim entries are read from N, so the unavailable endpoints remain explicit rows rather than omitted side conditions.

The critical edge is read from B, while the consumers are read from S. The non-escape row E then records that those consumers receive the displayed matrix and not an erased endpoint.

Finally H, C, P, L supply transport, route replay, provenance, and local naming for the same rows. Since no additional coordinate exists, the NameCert obligations are exhausted by the displayed packet. □

Theorem 904.3 (MetaCIC audit matrix critical-path route)**.** *Every accepted* $\mathsf{MetaCICAuditMatrix}^{\uparrow}$ *carrier routes closed MetaCIC consistency consumers through the matrix order*

$$A \longrightarrow B \longrightarrow S \longrightarrow E.$$

The available rows A may feed the closed-normal consistency packet and audit-map dependency weave, but any consumer seeking full closed consistency must first read the blocked subject-reduction edge B and the synthesis-consumer row S.

Lean4 ✓ `BEDC.Derived.MetaCICAuditMatrixUp.MetaCICAuditMatrixCarrier critical path route`

Proof. Project the accepted carrier and read the continuation row C. Its displayed route reads the available matrix rows before the blocked-edge and consumer rows.

Use the provenance row P to identify the sibling surfaces. The closed-normal consistency packet supplies the positive endpoint, the subject-reduction discharge ledger supplies the required preservation slots, and the audit-map dependency weave supplies the cross-map consumer route.

The route cannot bypass B. The blocked-edge matrix is a coordinate of the same packet as A, S, E, so a full-consistency consumer has to expose it before any synthesis handoff can be read. □

Theorem 904.4 (MetaCIC audit matrix non-escape)**.** *Every consumer-facing route out of an accepted* $\mathsf{MetaCICAuditMatrix}^{\uparrow}$ *carrier factors through*

$$A, N, B, S, E, H, C, P, L.$$

If the subject-reduction blocked edge B is removed from the packet, the non-escape ledger E no longer has a row through which to refuse the full closed-consistency read. Such a packet therefore fails the non-escape theorem for $\mathsf{MetaCICAuditMatrix}^{\uparrow}$.

Proof. Start with the carrier inventory. The available rows, non-claim rows, blocked edge, synthesis consumers, and non-escape ledger are all named coordinates of one finite packet.

The continuation and provenance rows C and P can only replay and package those displayed coordinates. They do not create a second route to full closed consistency, host substitution semantics, or quotient equality of MetaCIC terms.

Now remove B from the packet. The row E is defined as the ledger that preserves A, N, B, S under consumer reads, so without the blocked-edge coordinate it cannot certify refusal of the full closed-consistency route. Hence any accepted packet missing B is outside the stated non-escape boundary. □

Theorem 904.5 (MetaCIC audit matrix obligation surface)**.** *Every accepted* $\mathsf{MetaCICAuditMatrix}^{\uparrow}$ *carrier exposes the matrix obligations of the rows*

$$A, N, B, S, E, H, C, P, L.$$

The available row A, non-claim row N, blocked-edge row B, synthesis-consumer row S, and non-escape ledger E are all inspectable before structural transport, route replay, package provenance, and local naming are read. No consumer may erase one of these rows and still claim to read the same audit matrix.

Proof. Project the carrier of Definition 904.1. The rows A, N, B, S, E are the displayed audit rows, while H, C, P, L are the structural rows that transport, replay, source, and name the same packet.

Use the NameCert obligations of Definition 904.2. They already require carrier admission, available-row exposure, non-claim exposure, blocked-edge exposure, synthesis-consumer exposure, and non-escape ledger exposure.

Finally apply the non-escape theorem. Since every consumer route factors through the whole row sequence, deleting any of A, N, B, S, E changes the carrier surface rather than producing another read of $\mathsf{MetaCICAuditMatrix}^{\uparrow}$. □

Theorem 904.6 (MetaCIC audit matrix scope route)**.** *Every consumer of the* $\mathsf{MetaCICAuditMatrix}^{\uparrow}$ *matrix routes through the normalization frontier, subject-reduction discharge ledger, closed-normal consistency packet, and audit-map dependency weave named by the provenance row P. The route exposes what the matrix makes available and what it refuses; it does not supply full closed consistency, arbitrary closed Church–Rosser, candidate-free normalization, unrestricted beta-conversion decidability, host substitution semantics, or quotient equality.*

Proof. Start with the critical-path route of Definition 904.3. It sends closed MetaCIC consistency consumers from available rows to blocked edges, synthesis consumers, and the non-escape ledger.

Read the sibling anchors from P. The normalization frontier supplies the available normalization-facing rows, the subject-reduction discharge ledger names the blocked preservation edge, the closed-normal consistency packet supplies the positive endpoint, and the audit-map dependency weave records the cross-map consumer route.

The non-claim row N remains visible along this route. Therefore each unavailable endpoint is refused as a matrix row rather than silently imported from a sibling chapter or a host MetaCIC semantics. □

Theorem 904.7 (MetaCIC audit matrix closure ledger)**.** *The blocked-edge ledger of an accepted* $\mathsf{MetaCICAuditMatrix}^{\uparrow}$ *packet remains visible under every closure-facing read. In particular, the subject-reduction blocked edge* B *is carried together with* A, N, S, E, H, C, P, L *whenever a consumer reads available rows, synthesis consumers, closed-normal packets, discharge ledgers, or audit-map dependency routes from the matrix.*

Proof. Use the obligation surface theorem. It makes the blocked-edge row B one of the displayed obligations of the carrier, not an external annotation.

Apply the scope route theorem. Any closure-facing consumer reaches sibling data through the provenance and continuation rows while preserving the visible matrix order through available rows, non-claims, blocked edges, synthesis consumers, and non-escape ledgers.

Finally invoke non-escape. If B is removed, the ledger E can no longer refuse the full closed-consistency read. Hence closure-facing reads keep the blocked-edge ledger visible as part of the finite packet. □

Theorem 904.8 (MetaCIC audit matrix obligation closure package)**.** *For the carrier of Definition 904.1, the same finite* $\mathsf{MetaCICAuditMatrix}^{\uparrow}$ *packet closes the obligation surface consisting of carrier admission, matrix-row exactness, critical-path routing, blocked-edge preservation, non-escape, and TasteGate field faithfulness. Concretely, any accepted packet*

$$M = (A, N, B, S, E, H, C, P, L)$$

that satisfies the local $\mathsf{NameCert}_{\mathsf{MetaCICAuditMatrix}^{\uparrow}}$ *row exposes exactly the available-row matrix* A*, non-claim matrix* N*, blocked-edge matrix* B*, synthesis-consumer row* S*, non-escape ledger* E*, transport rows* H*, route rows* C*, provenance row* P*, and naming row* L *before a consumer may read the MetaCIC audit surface. No route through this package erases* B*, bypasses* E*, replaces* P *by host MetaCIC semantics, or reads TasteGate field faithfulness from a different carrier.*

Proof. Carrier admission is the carrier statement of Definition 904.1, and the local naming obligations are the obligations listed in Definition 904.2. These give the rows $A, N, B, S, E, H, C, P, L$ as one finite packet.

Matrix-row exactness and critical-path routing are supplied by Definition 904.5 and Definition 904.3. The surface theorem fixes which rows are visible, while the route theorem fixes the order in which closed MetaCIC consistency consumers must read available rows, blocked edges, synthesis consumers, and the non-escape ledger.

Blocked-edge preservation follows from Definition 904.7. Non-escape follows from Definition 904.4, and the consumer scope is the scope route of Definition 904.6. These three results keep B and E inside every closure-facing read.

Finally, the TasteGate field-faithfulness clause is read as a requirement on the same displayed packet, not on a sibling or host carrier. Since the package uses the carrier, route, non-escape, obligation surface, scope route, and closure ledger for the same M, the obligation closure surface is bound to one finite audit matrix. □

Falsifiable prediction: Any accepted $\mathsf{MetaCICAuditMatrix}^{\uparrow}$ packet with the subject-reduction blocked edge removed fails Definition 904.4.

Independence witness: metacicnormalizationfrontier, subjectreductiondischargeledger, closednormalconsistencypacket, auditmapdependencyweave: none carries all four available-row, non-claim-row, blocked-edge, and synthesis-consumer matrices as one NameCert packet.

The Lean follow-up target is `lean4/BEDC/Derived/MetaCICAuditMatrixUp/TasteGate.lean`, with explicit `Nontrivial MetaCICAuditMatrixUp` and `FieldFaithful MetaCICAuditMatrixUp` instances.

Theorem 904.9 (MetaCIC audit matrix scoped status)**.** *Every scoped read of an accepted* $\mathsf{MetaCICAuditMatrix}^{\uparrow}$ *packet factors through the available-row matrix A, non-claim matrix N, blocked-edge matrix B, synthesis-consumer row S, non-escape ledger E, normalization frontier, subject-reduction discharge ledger, closed-normal consistency packet, and audit-map dependency weave before any closed-consistency consumer reads the matrix. The read therefore preserves the finite dependency order*

$$A, N, B, S, E, H, C, P, L$$

and cannot erase the subject-reduction blocked edge, replace P by host MetaCIC semantics, or treat a non-claim row as a closed-consistency theorem.

Proof. Start with the critical-path route of Definition 904.3. It places closed MetaCIC consistency consumers after the available-row matrix, the blocked-edge matrix, the synthesis-consumer row, and the non-escape ledger.

Use the obligation surface and scope route of Definition 904.5 and Definition 904.6. These results expose the same rows $A, N, B, S, E, H, C, P, L$ and force the provenance row through the normalization frontier, subject-reduction discharge ledger, closed-normal consistency packet, and audit-map dependency weave.

Finally apply the closure ledger and non-escape theorems. The ledger keeps B visible in every closure-facing read, while non-escape refuses any route that deletes the blocked edge before reading closed-consistency consumers. Thus the accepted packet supplies scoped status exactly through the displayed MetaCIC audit matrix route. □

Closure status for $\mathsf{NameCert}_{\mathsf{MetaCICAuditMatrix}^{\uparrow}}$**.**

Constructive story: A $\mathsf{MetaCICAuditMatrix}^{\uparrow}$ packet is generated from available audit rows, non-claim rows, blocked-edge rows, synthesis-consumer rows, a non-escape ledger, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{MetaCICAuditMatrix}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 904.1, Definition 904.2, Definition 904.3, Definition 904.4, Definition 904.5, Definition 904.6, Definition 904.7, Definition 904.8, and Definition 904.9 bind the finite MetaCIC audit matrix packet, its carrier and NameCert obligations, critical-path route, non-escape boundary, scope route, blocked-edge ledger, obligation-closure package, and scoped consumer status.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{MetaCICAuditMatrix}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.MetaCICAuditMatrixUp.MetaCICAuditMatrixTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close subject reduction, full closed consistency, arbitrary closed Church–Rosser, candidate-free normalization, unrestricted beta-conversion decidability, host substitution semantics, public closure, or bridge checking.

Upgrade path: Public closure requires an export theorem showing that the scoped MetaCIC audit matrix route is the public read surface for closed-consistency consumers.

Chapter 905

A Concrete Naming Certificate for $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$

The $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ packet realizes the diagonal witness route of chapter 9238 as one finite grid. It joins the witness ledger of chapter 902, the completion-seal classifier of chapter 900, the selector-budget surface of chapter 678, and the tail-witness envelope of chapter 898. The grid is a NameCert surface for the displayed selector, ledger, seal, and tail rows; it is not a quotient stream, host real equality, selected external limit, countable-choice row, or ambient completeness theorem.

Definition 905.1 (Real Cauchy witness grid carrier)**.** *A* $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (B, L, K, T, S, R, E, H, C, P, N)$$

with the following displayed rows:

1. *B is the* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *row exposing the finite selector modulus and selected observation window for the diagonal request;*
2. *L is the* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *row recording the diagonal budget, observation budget, seal synchronizer, and completion-seal classifier route;*
3. *K is the* $\mathsf{RealCompletionSealClassifierUp}$ *row reached by the completion-facing seal read;*
4. *T is the* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *row storing the selected StreamName window, finite-window endpoint ledger, tail comparison, tail-agreement seal, and RealUp readback;*
5. *S records the* $\mathsf{StreamName}^{\uparrow}$ *finite windows shared by the selector and tail rows;*
6. *R records the* $\mathsf{RegSeqRat}^{\uparrow}$ *witness rows assembled from the selected windows;*
7. *E records the* $\mathsf{Real}^{\uparrow}$ *seal and readback rows exported after the ledger and classifier rows are displayed;*
8. *H records componentwise* hsame *transports for $B, L, K, T, S, R, E, C, P, N$;*
9. *C records displayed* Cont *routes from the selector budget to the witness ledger, completion-seal classifier, tail-witness envelope, StreamName rows, RegSeqRat rows, RealUp seal rows, provenance, and local naming row;*
10. *P records* Pkg *provenance over* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$, $\mathsf{CauchyWitnessLedger}^{\uparrow}$, $\mathsf{RealCompletionSealClassifi}$ $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{RealCauchyWitnessGrid}^{\uparrow}}$ *row.*
The carrier contains no coordinate for quotient stream equality, host real equality, selected external limits, countable choice, hidden selector enlargement, or ambient Real completeness.

Theorem 905.2 (Real Cauchy witness grid NameCert obligations)**.** *For the carrier of Definition 905.1, the local* $\mathsf{NameCert}_{\mathsf{RealCauchyWitnessGrid}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$G = (B, L, K, T, S, R, E, H, C, P, N),$$

selector-budget exposure through B, witness-ledger exposure through L, completion-seal classifier exposure through K, tail-witness exposure through T, shared StreamName window exposure through S, RegSeqRat witness exposure through R, RealUp seal exposure through E, componentwise hsame *transport through H, displayed* Cont *route replay through C,* Pkg *provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.RealCauchyWitnessGridUp.RealCauchyWitnessGridUp obligation surface`

Proof. Carrier admission is projection from the displayed tuple. The rows $B, L, K, T, S, R, E, H, C, P, N$ are all public coordinates of the grid.

The analytic rows are read in order. The selector-budget row B supplies the finite modulus and window request; the witness-ledger row L stores the diagonal budget, observation budget, synchronizer, and classifier route; the classifier row K reads the completion-seal boundary; and the tail-witness row T stores the selected tail envelope.

The shared rows S, R, E expose the StreamName, RegSeqRat, and RealUp handoff data consumed by those four packets. The structural rows H, C, P, N transport, replay, authenticate, and name the same grid. Since the carrier has no forbidden analytic coordinate, these rows exhaust the NameCert surface. □

Theorem 905.3 (Real Cauchy witness grid selector exactness)**.** *Every selector read admitted by an accepted* $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ *carrier factors through the displayed finite route*

$$B \longmapsto (S, R) \longmapsto (L, T)$$

before the completion-seal classifier K or RealUp seal row E can be consumed. Thus the selected modulus and window are the only selector source for both the ledger side and the tail-witness side of the grid.

Proof. Project the accepted carrier to $G = (B, L, K, T, S, R, E, H, C, P, N)$. The only selector-budget coordinate is B, and the only shared observation and regular-witness coordinates are S and R.

Apply the NameCert obligation surface. It exposes selector-budget data through B, shared StreamName data through S, and RegSeqRat witness data through R before either the ledger row L or tail-witness row T is consumed.

The route rows in C replay exactly this order, while H preserves the same coordinates under componentwise transport. No second selector or hidden window coordinate remains in the carrier, so the selector route is exact. □

Theorem 905.4 (Real Cauchy witness grid Real handoff)**.** *Every Real-completion consumer of an accepted* $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ *carrier reaches* $\mathsf{Real}^{\uparrow}$ *only through the finite route*

$$B, S, R, L, T, K, E, H, C, P, N.$$

In particular, the consumer first reads the selector-budget row, the shared StreamName and RegSeqRat rows, the ledger and tail-witness rows, and the completion-seal classifier before receiving the RealUp seal or readback row.

Proof. Start with selector exactness. By Definition 905.3, the selected window and RegSeqRat witness are fixed by B, S, R before the ledger row L or tail-witness row T can be used.

Read the sibling packets. The witness ledger of chapter 902 supplies the diagonal budget and synchronizer route, while the tail-witness envelope of chapter 898 supplies the finite tail readback route.

The completion-seal classifier of chapter 900 is then reached through K, and the RealUp seal or readback row is E. The structural rows H, C, P, N preserve and name this route, so no Real-completion consumer receives a different handoff. □

Theorem 905.5 (Real Cauchy witness grid non-escape)**.** *An accepted* $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ *carrier exports only the displayed rows* $B, L, K, T, S, R, E, H, C, P, N$*. It exports no quotient stream equality, host real equality, selected external limit, countable-choice row, hidden selector enlargement, unlisted tail witness, or ambient Real completeness theorem. Lean-facing work for this packet must provide* $\mathsf{Nontrivial\ RealCauchyWitnessGrid}^{\uparrow}$ *with an explicit witness pair and* $\mathsf{FieldFaithful\ RealCauchyWitnessGri}$ *by constructor-field injection.*

Proof. Project the carrier and apply the NameCert obligation theorem. Every exported row is one of the selector-budget, witness-ledger, completion-seal classifier, tail-witness, StreamName, RegSeqRat, RealUp, transport, route, provenance, and local naming rows.

The selector-exactness theorem prevents replacement of B, S, R by another selector source. The Real handoff theorem prevents replacement of L, T, K, E by a host limit or a detached RealUp output.

The excluded objects have no coordinate in the tuple. Therefore no accepted consumer can recover them from the grid, and the Lean-facing nontriviality and field-faithfulness tasks must be witnessed over the displayed fields. □

Theorem 905.6 (Real Cauchy witness grid ledger-tail pullback)**.** *Let*

$$G = (B, L, K, T, S, R, E, H, C, P, N)$$

be an accepted $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ *carrier. The* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *row* L *and the* $\mathsf{CauchyTailWitnessEnvelop}$ *row* T *read the same selector-budget row* B*, the same* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows* S*, and the same* $\mathsf{RegSeqRat}^{\uparrow}$ *witness rows* R*. Thus no accepted grid can assign one selector route to the ledger side and a different selector route to the tail side.*

Proof. Project the accepted grid to the displayed carrier tuple. The only selector-budget coordinate is B, the only StreamName-window coordinate is S, and the only RegSeqRat witness coordinate is R.

Apply selector exactness from Definition 905.3. It fixes the route $B \longmapsto (S, R) \longmapsto (L, T)$ before either L or T is consumed.

The route row C and transport row H replay those same coordinates into the sibling packets. Since the carrier contains no second selector, hidden window, or unlisted RegSeqRat witness, the ledger and tail rows pull back to the same B, S, R selector surface. □

Theorem 905.7 (Real Cauchy witness grid completion-seal selector lock)**.** *Let*

$$G = (B, L, K, T, S, R, E, H, C, P, N)$$

be an accepted $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ *carrier. The completion-seal classifier row* K *is reachable only after the shared selector-ledger-tail route*

$$B \longmapsto (S, R) \longmapsto (L, T)$$

has been read and authenticated by the displayed hsame*,* Cont*,* Pkg*, and* NameCert *rows* H, C, P, N*. In particular,* K *cannot be reached from a detached completion seal, host real equality, selected external limit, countable-choice row, or ambient completeness principle.*

Proof. Start with the ledger-tail pullback of Definition 905.6. It says that L and T already share the selector-budget, StreamName, and RegSeqRat rows B, S, R.

Use the Real handoff theorem, Definition 905.4. A Real-completion consumer reads the selector, shared rows, ledger, and tail-witness rows before the completion-seal classifier row K and RealUp row E are available.

Finally apply non-escape from Definition 905.5. The forbidden bypasses have no coordinate in G, and the structural rows H, C, P, N can authenticate only the displayed route. Hence the completion-seal classifier is locked behind the shared selector-ledger-tail route. □

Theorem 905.8 (Real Cauchy witness grid obligation closure)**.** *The accepted* $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ *packet closes its local obligation surface over* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$*,* $\mathsf{CauchyWitnessLedger}^{\uparrow}$*,* RealCompletionSealClassifierUp*,* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. Carrier admission, selector exactness, Real handoff, non-escape, ledger-tail pullback, and completion-seal selector locking are all witnessed by the same finite grid*

$$G = (B, L, K, T, S, R, E, H, C, P, N).$$

Proof. Carrier admission and the local NameCert surface are supplied by Definition 905.1 and Definition 905.2. They expose the displayed selector, ledger, classifier, tail, StreamName, RegSeqRat, RealUp, transport, route, provenance, and naming rows.

Selector exactness is supplied by Definition 905.3, and the Real handoff is supplied by Definition 905.4. These two clauses bind the selector-budget and Real-facing reads to the same finite route.

Non-escape is supplied by Definition 905.5. The ledger-tail pullback of Definition 905.6 and the completion-seal selector lock of Definition 905.7 add the two obligation-level locks needed by downstream Real-completion witness packets.

All six clauses use the same rows $B, L, K, T, S, R, E, H, C, P, N$. Therefore the chapter's obligation surface is finite and local to the named BEDC packets, with no quotient stream, host real equality, selected external limit, countable choice, hidden selector enlargement, or ambient completeness theorem. □

Theorem 905.9 (Real Cauchy witness grid standard bridge)**.** *Every standard-facing read of an accepted* $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ *carrier factors through the displayed selector, ledger, completion-seal classifier, tail,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, transport, route, provenance, and* NameCert *rows*

$$G = (B, L, K, T, S, R, E, H, C, P, N).$$

The bridge exposes only that finite witness grid. It exports no quotient stream, selected external limit, countable choice, host real equality, ambient completeness row, hidden selector enlargement, or off-grid Real-completion witness.

Proof. Project the accepted carrier to $G = (B, L, K, T, S, R, E, H, C, P, N)$. The NameCert obligation theorem exposes exactly the selector, ledger, classifier, tail, StreamName, RegSeqRat, RealUp, transport, route, provenance, and naming coordinates.

Apply selector exactness and Real handoff. The selector exactness theorem fixes the route from B through S, R to L, T, while the Real handoff theorem places K, E, H, C, P, N on the same public-facing path before any Real-completion consumer receives a read.

Next use the ledger-tail pullback and completion-seal selector lock. They force the ledger row and tail row to share the same selector surface and keep the completion-seal classifier behind the authenticated selector-ledger-tail route.

Finally apply non-escape and obligation closure. The non-escape theorem removes quotient streams, selected external limits, countable choice, host real equality, hidden selector enlargements, off-grid Real witnesses, and ambient completeness rows from the export surface. The obligation-closure theorem repacks the remaining rows as the finite public grid, so every standard-facing read factors through the displayed carrier. □

Falsifiable prediction: If the witness grid is atomic, then every Real-completion diagonal consumer factors through the displayed selector-budget and completion-seal grid before reaching RealUp; a consumer bypassing both sibling ledgers refutes the chapter.

Independence witness: Nearest siblings: cauchywitnessledger, realcompletionsealclassifier, regularcauchyselectorbudget, cauchytailwitnessenvelope. The grid is not bijective to any one sibling because it simultaneously stores selector rows, ledger rows, seal-classifier rows, and tail-witness rows, while each sibling omits at least one of those obligation rows.

Closure status for $\mathsf{NameCert}_{\mathsf{RealCauchyWitnessGrid}^{\uparrow}}$.

Constructive story: A $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ packet is generated from a selector budget, witness ledger, completion-seal classifier, tail-witness envelope, shared StreamName rows, RegSeqRat witness rows, RealUp seal rows, componentwise transports, displayed routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RealCauchyWitnessGrid}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 905.1, Definition 905.2, Definition 905.3, Definition 905.4, Definition 905.5, Definition 905.6, Definition 905.7, Definition 905.8, and Definition 905.9 bind the finite diagonal witness grid for the public Real-completion consumer route and the mature standard-facing read through the displayed selector, non-escape surface, obligation closure, ledger, classifier, tail, StreamName, RegSeqRat, RealUp, transport, route, provenance, and naming rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RealCauchyWitnessGrid}^{\uparrow}}$, axiomClean)

Lean4 ✓ `BEDC.Derived.RealCauchyWitnessGridUp.taste gate`

Lean target: `BEDC.Derived.RealCauchyWitnessGridUp.RealCauchyWitnessGridTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close Real completeness, quotient streams, host real equality, selected external limits, countable choice, ambient completeness, Lean verification, or bridge checking.

Upgrade path: The paper closure axis is complete for this finite witness grid; Lean bridge checking remains an independent formal-axis obligation.

Chapter 906

A Concrete Naming Certificate for $\mathsf{RegularCauchyTailBudget}^{\uparrow}$

The $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ packet realizes the finite observation-service side of the Real and Completion route of chapter 9238. It binds a regular Cauchy tail threshold to the finite budget gate of chapter 903, the witness envelope of chapter 898, and the seal synchronizer of chapter 886 before a $\mathsf{Real}^{\uparrow}$ completion-facing consumer reads the tail route. The packet supplies a finite tail-threshold, observation-budget, window-service, dyadic-readback, $\mathsf{RegSeqRat}^{\uparrow}$ handoff, and $\mathsf{Real}^{\uparrow}$ seal surface; it does not assert Real completeness.

Falsifiable prediction: Removing the tail-budget row permits a $\mathsf{Real}^{\uparrow}$ seal consumer to read a regular Cauchy tail without a displayed finite observation service; removing the observation-budget row breaks the $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$ handoff.

Independence witness: Nearest siblings: regular-cauchy-tail-fiber, cauchy-tail-witness-envelope, observationbudgetlimiter, cauchy-seal-budget-synchronizer, and real-completion-seal-classifier. None is bijective to $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ because the tail-fiber packet compares two source tails without a service cap, the witness envelope stores selector and agreement rows without the shared budget threshold, the limiter stores capped observations without a regular Cauchy tail row, the synchronizer stores seal-budget compatibility without the RegSeqRat readback service, and the completion-seal classifier stores equivalence of seal reads rather than the finite tail-service row itself.

Definition 906.1 (Regular Cauchy tail-budget carrier)**.** *A* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (R, T, O, W, D, Q, S, H, C, P, N)$$

with the following displayed rows:

1. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *source row whose regular Cauchy tail is being served;*
2. *T is the shared tail-threshold row naming the first accepted tail index for the service request;*
3. *O is the* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *row that bounds the finite observation service available after T is displayed;*
4. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *window-service ledger admitted by O for the tail threshold;*
5. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger read through the windows in W;*

6. *Q is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row assembled from the displayed tail threshold, finite windows, and dyadic observations;*
7. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after R, T, O, W, D, Q have been consumed;*
8. *H records the componentwise* hsame *rows for the source, threshold, budget limiter, windows, dyadic ledger, readback, seal, replay, provenance, and local naming fields;*
9. *C records the displayed* Cont *routes from the regular source to the tail threshold, from the threshold to the observation budget, from the budget to window service, from window service to dyadic observation, from dyadic observation to regular readback, and from readback to the seal;*
10. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTailBudget}^{\uparrow}}$ *row.*

The carrier accepts only packets whose regular Cauchy tail threshold is served by a displayed finite observation budget before any $\mathsf{Real}^{\uparrow}$ *seal row is read.*

Lean4 ✓ `BEDC.Derived.RegularCauchyTailBudgetUp.taste gate`

Theorem 906.2 (Regular Cauchy tail-budget NameCert obligations)**.** *For the carrier of Definition 906.1, the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTailBudget}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$B = (R, T, O, W, D, Q, S, H, C, P, N),$$

tail-threshold exposure through T, observation-budget exposure through O, finite window service through W, dyadic observation through D, regular readback through Q, seal handoff through S, componentwise hsame *transport through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Proof. Project the carrier. The rows $R, T, O, W, D, Q, S, H, C, P, N$ are the only fields of the accepted packet.

Read the analytic service rows in order. The regular source R supplies the tail to be served, T fixes the shared tail threshold, and O supplies the finite observation-budget gate before any window is exposed.

The window, dyadic, and readback rows then form the service body. The rows W, D, Q display exactly how the finite observations are read back into a $\mathsf{RegSeqRat}^{\uparrow}$ row before S is available.

Finally H, C, P, N transport, replay, package, and name the same route. No additional row can export quotient streams, host real equality, selected limits, countable choice, or ambient completeness. □

Theorem 906.3 (Regular Cauchy tail-budget observation gate)**.** *Every accepted* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *consumer read of a* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet factors through the finite observation route*

$$R \longmapsto T \longmapsto O \longmapsto W \longmapsto D \longmapsto Q \longmapsto S.$$

In particular, the regular Cauchy tail may not be read as a $\mathsf{Real}^{\uparrow}$ *seal unless the tail threshold and the observation-budget limiter have both been displayed.*

Proof. Start with a source-facing read. The only regular source row is R, and the only tail threshold attached to that source is T.

Use the budget gate next. The observation service is controlled by O, so a consumer cannot reach the finite window row W before the limiter row has been displayed.

Read W, D, Q through the displayed routes in C. These rows provide the finite window service, dyadic observation ledger, and regular readback handoff. The seal row S is reached only after this route has been replayed.

The structural rows H, C, P, N authenticate that same route and do not create an alternate observation channel. Thus every consumer read factors through the displayed finite observation gate. □

Theorem 906.4 (Regular Cauchy tail-budget seal non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet receives only the displayed surface*

$$R, T, O, W, D, Q, S, H, C, P, N.$$

It receives no quotient stream, no host real equality, no selected host limit, no countable-choice selector, and no ambient completeness theorem. The seal row is a finite handoff from a budgeted regular Cauchy tail service, not a proof that all Cauchy names converge.

Proof. Inspect the carrier coordinates. The only seal-facing row is S, and it is positioned after R, T, O, W, D, Q in the displayed service route.

Apply the observation-gate theorem. Any $\mathsf{Real}^{\uparrow}$ consumer must first pass through the shared tail threshold, observation-budget limiter, finite windows, dyadic observations, and regular readback.

The excluded analytic objects have no coordinate in the packet. Since the route contains only finite carrier rows, componentwise transports, displayed continuations, package provenance, and a local naming row, the seal cannot export quotient equality, a selected limit, countable choice, or ambient completeness. □

Theorem 906.5 (Regular Cauchy tail-budget obligation package)**.** *An accepted* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet assembles the finite tail-service obligation package*

$$R, T, O, W, D, Q, S, H, C, P, N.$$

The package consists of carrier admission for the regular source row R, tail-threshold exposure T, observation-budget exposure O, finite $\mathsf{StreamName}^{\uparrow}$ *window service W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation D,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback Q,* $\mathsf{Real}^{\uparrow}$ *seal handoff S, componentwise* hsame *rows H, displayed* Cont *routes C,* Pkg *provenance P, and local* $\mathsf{NameCert}_{\mathsf{RegularCauchyTailBudget}^{\uparrow}}$ *rows N. It does not include quotient streams, host real equality, selected-limit existence, countable choice, or ambient completeness.*

Proof. Start with Definition 906.1. The accepted carrier exposes exactly the rows $R, T, O, W, D, Q, S, H, C, P, N$, so every obligation in the package must be read from those coordinates.

Apply Definition 906.2. This supplies carrier admission, the local naming row, the componentwise transport rows, the displayed continuation routes, and the package provenance for the same finite carrier.

Now use Definition 906.3. It orders the tail threshold, observation budget, window service, dyadic observation, and regular readback rows as one finite service route before any seal-facing consumer can read S.

Finally apply Definition 906.4. Since the seal is only a handoff from the displayed route and the excluded analytic objects have no carrier coordinate, the package closes over the finite tail-service rows and exports no quotient stream, host real equality, selected limit, countable-choice selector, or ambient completeness theorem. □

Theorem 906.6 (Regular Cauchy tail-budget window-budget compatibility)**.** *Let*

$$B = (R, T, O, W, D, Q, S, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet. Every served* $\mathsf{StreamName}^{\uparrow}$ *window row in* W *and every* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row in* D *is admitted through the same* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *row* O *and the same tail-threshold row* T*. Thus the finite window service and the dyadic observation ledger share the single budgeted route*

$$R \longmapsto T \longmapsto O \longmapsto W \longmapsto D.$$

Proof. Project the accepted carrier. The only rows available for tail threshold, observation budget, window service, and dyadic observation are T, O, W, D.

Apply Definition 906.3. It places every $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{DyadicRatCore}^{\uparrow}$ consumer read after R, T, O and before the readback and seal rows.

Apply Definition 906.4 to exclude a second observation channel. Since no quotient stream, selected host limit, host real equality, countable-choice selector, or ambient completeness row exists in the packet, the served windows and dyadic observations can only be read through the displayed T, O budget route. □

Theorem 906.7 (Regular Cauchy tail-budget readback factorization)**.** *Let*

$$B = (R, T, O, W, D, Q, S, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet. The* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q *factors through the finite chain*

$$R \longmapsto T \longmapsto O \longmapsto W \longmapsto D \longmapsto Q,$$

with H *transporting the component rows,* C *displaying the continuation routes,* P *recording package provenance, and* N *certifying the local name for that same chain.*

Proof. Begin with Definition 906.2. It identifies Q as the regular readback row assembled from the displayed tail threshold, finite windows, and dyadic observations.

Use Definition 906.6 for the middle service. The rows W and D have already passed through the same T, O budget route before Q can be read.

Finally read the structural rows. The transports in H, the continuations in C, the provenance row P, and the local name N authenticate the same R, T, O, W, D, Q factorization and provide no separate readback service. □

Theorem 906.8 (Regular Cauchy tail-budget downstream lattice)**.** *Let*

$$B = (R, T, O, W, D, Q, S, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet. Any downstream* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, or* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *consumer of* B *must share the single route*

$$R \longmapsto T \longmapsto O \longmapsto W \longmapsto D \longmapsto Q \longmapsto S,$$

with componentwise hsame *transport through H and* Cont *replay through C preserving the same tail-threshold row T and observation-budget row O for the window, dyadic, readback, and seal surfaces.*

Proof. Begin with the observation gate. It places every $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ read after the source row R, tail threshold T, and observation budget O, and before the seal row S can be consumed.

Use window-budget compatibility for the middle of the route. The finite windows in W and dyadic observations in D are admitted through the same threshold and budget rows, so a downstream consumer cannot choose a second budget service for those observations.

Apply readback factorization. The $\mathsf{RegSeqRat}^{\uparrow}$ row Q is assembled from the displayed R, T, O, W, D chain and is authenticated by the same H, C, P, N structural rows.

Finally apply seal non-escape. Since the seal row S is only a finite handoff after the displayed readback and no carrier coordinate stores quotient streams, selected host limits, host real equality, countable choice, or ambient completeness, the $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{RealDiagonalCompletion}^{\uparrow}$ consumers share the same budget lattice. □

Theorem 906.9 (Regular Cauchy tail-budget tail-threshold service exactness)**.** *Let*

$$B = (R, T, O, W, D, Q, S, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet. Every served tail read of R is exposed only through the route*

$$R \longmapsto T \longmapsto O \longmapsto W \longmapsto D \longmapsto Q \longmapsto S.$$

In particular, neither the finite window row W nor the seal row S can be read before the tail-threshold row T has been displayed.

Proof. Project the carrier of Definition 906.1. The only source row is R, the only tail-threshold row attached to that source is T, and the service rows following it are O, W, D, Q, S.

Apply Definition 906.3. It forces each served $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ read to pass through the displayed route from R to S.

Use Definition 906.6 for the middle service rows. The window and dyadic ledgers are admitted only after the same threshold and budget rows have been read.

Finally apply Definition 906.7 and Definition 906.4. The readback row factors through T, O, W, D, and the seal row consumes that displayed readback rather than opening an earlier window or seal-facing route. □

Theorem 906.10 (Regular Cauchy tail-budget observation-budget gate totality)**.** *Let*

$$B = (R, T, O, W, D, Q, S, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet. Every consumer route landing in* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *passes through the same* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *row O. Thus all window service, dyadic observation, regular readback, and seal handoff rows share the single budget gate*

$$R \longmapsto T \longmapsto O.$$

Proof. Start from the carrier definition. The packet has one displayed observation-budget limiter row, namely O, and the continuation record C routes the tail threshold to that row before any service body is available.

Apply Definition 906.3. It covers the four consumer surfaces named in the statement and places each of them after R, T, O in the finite route.

Use Definition 906.6. It identifies O as the shared gate for W and D, so the downstream readback row Q cannot obtain its displayed observations from a second budget row.

Now apply Definition 906.7 and Definition 906.4. The readback and seal rows consume the same budgeted service route, and no quotient stream, selected host limit, host real equality, countable-choice selector, or ambient completeness row supplies an alternate consumer route. □

Theorem 906.11 (Regular Cauchy tail-budget RegSeqRat readback seal handoff)**.** *Let*

$$B = (R, T, O, W, D, Q, S, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet. The row Q is the unique* $\mathsf{RegSeqRat}^{\uparrow}$ *readback surface for the displayed window row W and dyadic ledger row D. The seal row S may consume only this displayed readback surface together with the structural rows H, C, P, N.*

Proof. Inspect Definition 906.1. The packet contains one regular source row R and one regular readback row Q, while W and D are the only window-service and dyadic-observation rows feeding that readback.

Apply Definition 906.6. It places both W and D under the same T, O service route before any readback can be formed.

Apply Definition 906.7. The row Q is exactly the displayed factor through R, T, O, W, D, with H, C, P, N authenticating the same chain.

Finally use Definition 906.4. Since S is only a finite seal handoff after the displayed readback and no other analytic row is present, a seal-facing consumer can read S only through Q and the accompanying structural rows. □

Theorem 906.12 (Regular Cauchy tail-budget completion boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet may read the seal row S only as the finite budgeted readback boundary*

$$R \longmapsto T \longmapsto O \longmapsto W \longmapsto D \longmapsto Q \longmapsto S,$$

together with the displayed H, C, P, N rows. The consumer receives no quotient stream, no selected host limit, no countable-choice selector, no host real equality, and no ambient completeness principle.

Proof. Apply Definition 906.7. It makes the readback row Q a finite factor through the source, tail threshold, budget limiter, windows, and dyadic ledger.

Then apply Definition 906.4. The seal row is available only after that readback route has been consumed, and the excluded analytic objects have no carrier coordinate.

The displayed rows H, C, P, N record transport, continuation, provenance, and naming for the same boundary. Hence a completion-facing consumer can consume S as this finite budgeted handoff and not as a Real-completeness theorem. □

Theorem 906.13 (Regular Cauchy tail-budget obligation-closure package)**.** *For an accepted* RegularCauchyTailBud *packet*

$$B = (R, T, O, W, D, Q, S, H, C, P, N),$$

the carrier of Definition 906.1, the local $\mathsf{NameCert}_{\mathsf{RegularCauchyTailBudget}^{\uparrow}}$ *obligations of Definition 906.2, the observation gate of Definition 906.3, the seal non-escape boundary of Definition 906.4, the*

window-budget compatibility of Definition 906.6, the readback factorization of Definition 906.7, the tail-threshold service exactness of Definition 906.9, the observation-budget gate totality of Definition 906.10, the $\mathsf{RegSeqRat}^{\uparrow}$ *readback seal handoff of Definition 906.11, and the completion boundary of Definition 906.12 form the paper-side obligation package over the displayed fields* $R, T, O, W, D, Q, S, H, C, P, N$.

The package is fieldwise: the regular source, tail threshold, observation budget, windows, dyadic observations, readback, seal, transports, continuation routes, provenance, and local name remain separate coordinates throughout every Real-facing and Completion-facing read.

Proof. Project the carrier of Definition 906.1. The eleven rows $R, T, O, W, D, Q, S, H, C, P, N$ are the complete coordinate list available to any local certificate or downstream consumer.

Apply Definition 906.2 for the local certificate surface, then apply Definition 906.3 and Definition 906.4 for the first route boundary. These theorems identify the same fields without adding quotient streams, host real equality, selected limits, choice, or ambient completeness.

Next use Definition 906.6, Definition 906.7, Definition 906.9, and Definition 906.10. They account for the finite service route from the regular source through the threshold, budget, windows, dyadic ledger, and readback.

Finally apply Definition 906.11 and Definition 906.12. The seal and completion-facing boundary consume the same displayed readback route, so the obligation package closes over exactly the listed carrier fields. □

Theorem 906.14 (Regular Cauchy tail-budget field-faithful boundary)**.** *Any later* FieldFaithful RegularCauchyTailB *instance for the carrier of Definition 906.1 must preserve the eleven displayed fields* $R, T, O, W, D, Q, S, H, C, P, N$ *separately. In particular, the tail threshold* T*, observation budget* O*, finite windows* W*, dyadic observations* D*, regular readback* Q*, and seal* S *cannot be collapsed into a single parameter echo, nor may the transport, continuation, provenance, or local naming rows replace one another.*

Thus a faithful instance must expose constructor-field injection for the regular source, tail threshold, observation budget, finite windows, dyadic observations, regular readback, seal, transport, continuation, package, and local naming fields as separate facts.

Proof. Read the constructor shape in Definition 906.1. Each coordinate is named by its own row and has its own role in the displayed finite route.

Use the route theorems to separate the service fields. The observation gate, window-budget compatibility, readback factorization, tail-threshold service exactness, observation-budget gate totality, and readback seal handoff assign different positions to T, O, W, D, Q, S in the route

$$R \longmapsto T \longmapsto O \longmapsto W \longmapsto D \longmapsto Q \longmapsto S.$$

Use the non-escape and completion-boundary theorems to separate the structural fields. The rows H, C, P, N authenticate transport, route replay, provenance, and local naming for the same packet; none of them supplies a replacement tail threshold, observation budget, window ledger, dyadic ledger, readback row, or seal.

Therefore any field-faithful certificate for this carrier must project and preserve the eleven rows one by one. A single echo parameter cannot witness the stated finite observation-service boundary. □

Theorem 906.15 (Regular Cauchy tail-budget threshold totality)**.** *For an accepted* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet*

$$B = (R, T, O, W, D, Q, S, H, C, P, N),$$

the finite tail threshold T is the unique entry row through which any $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *consumer may reach the served tail. The consumer may read W, D, Q, S only after the displayed route*

$$R \longmapsto T \longmapsto O \longmapsto W \longmapsto D \longmapsto Q \longmapsto S$$

has exposed the same threshold, observation-budget limiter, and local $\mathsf{NameCert}_{\mathsf{RegularCauchyTailBudget}^{\uparrow}}$ *provenance.*

Proof. Project the carrier of Definition 906.1. The row T is the only threshold coordinate attached to the regular source row R.

Apply Definition 906.9. It binds every served tail request to the displayed threshold before any window, dyadic observation, readback, or seal row is available.

Then apply Definition 906.10. The observation-budget row O is read after T, so the finite service route cannot bypass the threshold by selecting W, D, Q, or S directly.

Finally use Definition 906.7. The $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows all factor through the same $R, T, O, W, D, Q, S, H, C, P, N$ surface, leaving no second tail-threshold entry row. □

Theorem 906.16 (Regular Cauchy tail-budget selector handoff)**.** *Every selector-facing handoff from an accepted* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet to* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *consumers factors through the displayed rows T, O, W, D, Q before the seal row S is exposed. The handoff is therefore a finite tail-selector service over the carrier of Definition 906.1, not a countable-choice selector, quotient stream, selected host limit, or ambient completion theorem.*

Proof. Start with Definition 906.6. It binds the finite windows W to the threshold T and observation-budget row O.

Use Definition 906.9 to make the selector-facing tail request pass through the same threshold. The selector receives a displayed finite service row rather than an unbounded family of choices.

Next apply Definition 906.7 and Definition 906.11. These theorems route W through D and Q before S becomes available to a Real-facing consumer.

The non-escape clause is supplied by Definition 906.4. Since the carrier has no countable-choice selector, quotient stream, selected host limit, or ambient completion coordinate, the handoff remains finite and fieldwise. □

Theorem 906.17 (Regular Cauchy tail-budget Real-seal consumer scope)**.** *Any* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet reads the Real-seal row S only as the endpoint of the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *service route*

$$R, T, O, W, D, Q, S, H, C, P, N.$$

The consumer receives no host real equality, quotient stream, selected limit, countable-choice selector, trichotomy row, or ambient Real completeness principle beyond the finite carrier surface.

Proof. Project the carrier of Definition 906.1. The seal coordinate S is displayed only after the source, threshold, observation budget, finite windows, dyadic observations, and regular readback rows.

Apply Definition 906.11. It identifies the Real-facing seal handoff as a consumer of the regular readback row Q, not as an independent Real carrier.

Next use Definition 906.12. It confines completion-facing reads to the same $R, T, O, W, D, Q, S, H, C, P, N$ packet and keeps the seal boundary separate from Real completeness.

Finally apply Definition 906.13. The carrier rows, NameCert obligations, readback factorization, threshold service, observation-budget gate, handoff, and completion boundary compose as one fieldwise package, so the Real-seal consumer cannot extract host equality, quotient streams, selected limits, choice, trichotomy, or ambient completeness. □

Theorem 906.18 (Regular Cauchy tail-budget promoted obligation closure)**.** *The carrier admission of Definition 906.1, the local naming obligations of Definition 906.2, the tail-threshold service of Definition 906.9, the observation-budget gate of Definition 906.10, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback of Definition 906.7, and the Real seal route of Definition 906.11 form one obligation-closure package over the displayed rows* $R, T, O, W, D, Q, S, H, C, P, N$*.*

Proof. Project the carrier of Definition 906.1. The rows $R, T, O, W, D, Q, S, H, C, P, N$ are the only fields available to the local naming surface.

Apply Definition 906.2 for carrier admission and local certificate exposure. Then use Definition 906.9 and Definition 906.10 to route every served tail request through the shared threshold and observation budget.

Finally use Definition 906.7 and Definition 906.11. The readback row and the seal row consume the same finite budgeted service, so the listed components close as one obligation package. □

Theorem 906.19 (Regular Cauchy tail-budget window readback totality)**.** *Every finite budget request admitted by a* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet has a displayed window and readback route through the packet's budget and dyadic rows. Concretely, a request reaches* Q *only along*

$$R \longmapsto T \longmapsto O \longmapsto W \longmapsto D \longmapsto Q,$$

with S, H, C, P, N *recording the seal-facing endpoint, transports, routes, provenance, and local naming row.*

Proof. Start from the threshold service. By Definition 906.9, a served request first reads the displayed tail threshold T attached to the regular source row R.

Next apply Definition 906.10. The observation budget O admits the request before any window or dyadic row can be consumed.

Use Definition 906.6 and Definition 906.7. These bind the finite windows W and dyadic observations D to the readback row Q, giving the displayed route for every finite budget request. □

Theorem 906.20 (Regular Cauchy tail-budget Real seal non-escape package)**.** *The* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{RealDiagonalCompletion}^{\uparrow}$ *consumers of an accepted* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *packet obtain only the finite seal route through* $R, T, O, W, D, Q, S, H, C, P, N$*. They obtain no quotient stream, countable-choice selector, selected host limit, host real equality, trichotomy row, or ambient completeness oracle.*

Proof. Use Definition 906.17. It makes the Real-facing consumer read S only after the source, threshold, observation budget, finite windows, dyadic observations, and regular readback rows.

Apply Definition 906.12. Completion-facing consumers receive the same finite route, not a separate completeness coordinate.

Finally use Definition 906.4. The excluded analytic objects have no coordinate in the carrier, so the Real seal package cannot export a quotient stream, choice principle, selected limit, host equality, trichotomy, or ambient oracle. □

Theorem 906.21 (Regular Cauchy tail-budget obligation-rank surface)**.** *For* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$*, the rows for carrier admission, tail-threshold exposure, observation-budget gating, finite window service, dyadic observation,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal handoff,* hsame *transport,* Cont *replay,* Pkg *provenance, local* NameCert*,* Nontrivial *witnessing, and* FieldFaithful *row faithfulness are the complete obligation-rank surface of the finite packet*

$$R, T, O, W, D, Q, S, H, C, P, N.$$

No additional analytic row, hidden limit selector, host equality row, quotient stream row, or ambient completeness oracle is part of the obligation rank.

Proof. Project the carrier in Definition 906.1. It exposes exactly the source, threshold, observation budget, finite windows, dyadic observations, regular readback, seal, transport, continuation, provenance, and local naming rows.

Apply the NameCert obligations of Definition 906.2 and the promoted package of Definition 906.18. These bind carrier admission, local naming, transport, continuation replay, package provenance, threshold service, observation gating, and the nontrivial and field-faithful witness rows to the same displayed packet.

Use Definition 906.19 to force every finite budget read through T, O, W, D, Q. Then apply Definition 906.20 for the Real seal endpoint S and its non-escape boundary.

The listed rows therefore exhaust the obligation-rank surface. Anything outside them has no carrier coordinate and cannot be supplied by the local $\mathsf{NameCert}_{\mathsf{RegularCauchyTailBudget}^{\uparrow}}$ route. □

The Lean TasteGate.lean contract for this chapter requires `Nontrivial RegularCauchyTailBudgetUp` and `FieldFaithful RegularCauchyTailBudgetUp` instances whose witnesses include an explicit `witness_pair` and constructor-field injection proofs for the regular source, tail threshold, observation budget, finite windows, dyadic observations, regular readback, seal, transport, continuation, package, and local naming fields.

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyTailBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ packet is generated from a $\mathsf{RegSeqRat}^{\uparrow}$ source row, shared tail-threshold row, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ row, finite $\mathsf{StreamName}^{\uparrow}$ window-service ledger, $\mathsf{DyadicRatCore}^{\uparrow}$ observation ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback row, $\mathsf{Real}^{\uparrow}$ seal row, componentwise transports, displayed routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyTailBudget}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 906.1, Definition 906.2, Definition 906.18, Definition 906.19, Definition 906.20, and Definition 906.21 specify the finite regular Cauchy tail-budget packet whose displayed obligation-rank, budget-window readback, and Real-seal non-escape rows form the public export surface, with the checked TasteGate instance `BEDC.Derived.RegularCauchyTailBudget`

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyTailBudget}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.RegularCauchyTailBudgetUp.RegularCauchyTailBudgetTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Real completeness, quotient equality of streams, host real equality, selected-limit existence, countable choice, or bridge checking for $\mathsf{RegularCauchyTailBudget}^{\uparrow}$.

Upgrade path: Mature paper closure is recorded here; machine bridge checking remains a separate verification-axis obligation for the finite tail-budget public route.

Chapter 907

A Concrete Naming Certificate for $\mathsf{PiApplicationAdequacyRoute}^{\uparrow}$

The $\mathsf{PiApplicationAdequacyRoute}^{\uparrow}$ packet realizes the application-facing route in chapter 9383 as finite NameCert data. It refines the candidate-mediated surface of chapter 758 by separating Pi-candidate function evidence, domain-candidate argument evidence, and application-candidate handoff before a closed typed application may be read through chapter 562. The acceptance-facing replay is audited beside chapter 547, so the route is a packet over displayed rows rather than an unconditional normalization theorem.

Definition 907.1 (Pi application adequacy route carrier)**.** *A* $\mathsf{PiApplicationAdequacyRoute}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (F, A, P, D, K, S, C, N, R, H, Q)$$

with the following displayed rows:

1. *F is the Pi-candidate function evidence row, naming the function candidate and the Pi-head evidence consumed by the application route;*
2. *A is the domain-candidate argument evidence row, naming the argument, its domain candidate, and the candidate read used by the Pi body;*
3. *P is the application candidate row, recording the handoff from the Pi-head evidence and domain-candidate argument evidence to the candidate assigned to the application;*
4. *D is the closed typed application row, keeping the function, argument, application term, and typing ledger in one displayed packet;*
5. *K is the step-strong-normalization row read from the candidate evidence already displayed in F, A, P, D;*
6. *S is the no-infinite-reduction row projected from K and not from an external evaluator;*
7. *C is the displayed* Cont *route from the Pi candidate and domain candidate rows through the application candidate row to the closed typed application row;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{PiApplicationAdequacyRoute}^{\uparrow}}$ *row;*
9. *R records* Pkg *provenance over chapter 9383, chapter 758, chapter 562, chapter 547,* BHist*,* hsame*,* Cont*, and* $\mathsf{NameCert}$ *rows;*

10. *H stores componentwise* hsame *transports for the Pi-head evidence, argument evidence, application candidate, typed application, step-SN, and no-infinite-reduction rows;*
11. *Q is the query boundary that records which application-normalization question is answered by this finite route and refuses any stronger global-normalization query.*

The carrier has no coordinate for evidence-free strong normalization, unrestricted application adequacy, quotient equality over reduction traces, a host evaluator, a selected normalization strategy, or ambient consistency.

Lean4 (definition) `BEDC.Derived.PiApplicationAdequacyRouteUp.PiApplicationAdequacyRouteUp`
Lean4 ✓ `BEDC.Derived.PiApplicationAdequacyRouteUp.PiApplicationAdequacyRouteTasteGate single carrier alignment`

Theorem 907.2 (Pi application adequacy route NameCert obligations)**.** *Every accepted* PiApplicationAdequacyRou *packet binds exactly the obligation surface displayed in Definition 907.1: Pi-candidate function evidence through F, domain-candidate argument evidence through A, application candidate handoff through P, closed typed application through D, step strong normalization through K, no-infinite-reduction projection through S, displayed route through C, local naming through N, provenance through R, transport through H, and query boundary through Q.*

Proof. Project the carrier $Z = (F, A, P, D, K, S, C, N, R, H, Q)$. The positive application route begins with the Pi-candidate function row and the domain-candidate argument row, so a consumer cannot read the application candidate before both F and A have been exposed.

The handoff row P then supplies the application candidate used by the closed typed application row D. The strong-normalization and no-infinite-reduction rows K, S are downstream from that candidate-mediated handoff, not independent termination assertions.

The support rows preserve the same finite surface. The route row C, local NameCert row N, provenance row R, componentwise transport row H, and query boundary Q name and restrict only the displayed coordinates, so the listed rows exhaust the local NameCert obligations. □

Theorem 907.3 (Pi application adequacy route nonescape)**.** *Every closed application strong-normalization read exported by an accepted* PiApplicationAdequacyRoute$^{\uparrow}$ *packet factors through the displayed rows*

$$F, A, P, D, K, S, C, N, R, H, Q.$$

The read may be consumed by the candidate-mediated route of chapter 758 and by the endpoint discipline of chapter 562, with acceptance replay bounded by chapter 547. It cannot be reread as evidence-free global strong normalization, unconditional application adequacy, quotient equality over reductions, host evaluation, or ambient consistency.

Proof. Start from a closed application strong-normalization read. The only step-SN coordinate is K, and its route passes through F, A, P, D before the no-infinite-reduction projection S can be consumed.

Use the continuation row C and componentwise transport row H to replay the same candidate-mediated path under accepted packet agreement. Provenance R and the local NameCert row N then present that route to the sibling candidate-evidence, typed-normal-form, and kernel-acceptance audit surfaces.

Finally inspect the query boundary Q and the absence of excluded coordinates. Since the packet stores no host evaluator, quotient trace equality, global-normalization row, unrestricted adequacy row, or ambient consistency row, no consumer can escape the displayed application route. □

Falsifiable prediction: If the route is atomic, a consumer cannot derive closed application strong normalization from componentwise function and argument SN without the Pi-candidate and domain-candidate rows.

Independence witness: metacicnormalizationaudit, candidateevidencesnroute, typedreductionnormalform, subjectreduction, kernelacceptanceauditwitness: PiApplicationAdequacyRouteUp is not bijective to these because it carries both Pi-head evidence and application-candidate handoff rows, while each sibling lacks at least one of those route coordinates.

The Lean-side `TasteGate.lean` obligation surface for $\mathsf{PiApplicationAdequacyRoute}^{\uparrow}$ consists of `Nontrivial PiApplicationAdequacyRouteUp` and `FieldFaithful PiApplicationAdequacyRouteUp`, with explicit witness-pair and field projection proofs over the displayed carrier rows.

Closure status for $\mathsf{NameCert}_{\mathsf{PiApplicationAdequacyRoute}^{\uparrow}}$.

Constructive story: A $\mathsf{PiApplicationAdequacyRoute}^{\uparrow}$ packet is generated from Pi-candidate function evidence, domain-candidate argument evidence, application-candidate handoff rows, closed typed application rows, step-SN rows, no-infinite-reduction rows, displayed continuations, local naming, provenance, componentwise transport, and a query boundary.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{PiApplicationAdequacyRoute}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 907.1, Definition 907.2, and Definition 907.3 bind the finite candidate-mediated application adequacy route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{PiApplicationAdequacyRoute}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close evidence-free global strong normalization, unconditional application adequacy, quotient equality over reduction traces, host evaluation, ambient consistency, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, application-candidate handoff exactness, no-infinite projection exactness, query-boundary refusal, provenance, and local NameCert rows.

Chapter 908

A Concrete Naming Certificate for $\mathsf{ObservationScheduleEnvelope}^{\uparrow}$

The $\mathsf{ObservationScheduleEnvelope}^{\uparrow}$ packet realizes the Type IV finite-record schedule socket of section 9394.5 as a finite envelope over accepted schedule rows. It consumes the prefix and request-window discipline of chapter 539, the finite naming surface of chapter 126, and the Real-facing budget route of chapter 611. The envelope gives downstream Real and Completion consumers one packet that displays the schedule source, request window, refusal boundary, transport, route, provenance, and local name without reading observed prefixes as completed streams.

Falsifiable prediction: Any RealUp-facing schedule read from an accepted envelope factors through the displayed request-window and StreamName source rows; a read without those rows refutes the envelope.

Independence witness: Nearest siblings: countableobservationschedule, streamname, realobservationbudget, finiteobservationbudgetselector, and observationbudgetlimiter. None is bijective to $\mathsf{ObservationScheduleEnvelope}^{\uparrow}$ because the envelope has a joint refusal row and a consumer-handoff row tying the schedule source to the Real-facing window; no sibling alone carries both rows in one local NameCert packet.

Definition 908.1 (Observation schedule envelope carrier)**.** *An* $\mathsf{ObservationScheduleEnvelope}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (Q, S, W, R, J, H, C, P, N)$$

with the following displayed rows:

1. *Q is the accepted* $\mathsf{CountableObservationSchedule}^{\uparrow}$ *source packet supplying observed prefixes and finite request windows;*
2. *S is the finite* $\mathsf{StreamName}^{\uparrow}$ *source row through which the schedule is addressed;*
3. *W is the Real-facing request-window row read by budget and completion consumers;*
4. *R is the joint refusal row blocking completed streams, future-law claims, hidden persistence, and unbounded observation schedules;*
5. *J is the consumer-handoff row tying the schedule source Q, StreamName row S, and Real-facing window W into one envelope;*
6. *H records componentwise* hsame *transports for Q, S, W, R, J, C, P, N;*

7. *C records the displayed* Cont *routes that expose schedule prefixes, StreamName source names, Real-facing windows, refusal data, and the handoff row;*
8. *P records* Pkg *provenance over* $\mathsf{CountableObservationSchedule}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ObservationScheduleEnvelope}^{\uparrow}}$ *row.*

The carrier is exactly this finite envelope. It exports no completed countable stream, no unobserved future row, no hidden causal-continuity principle, no quotient schedule equality, no selected Real value, and no ambient completion theorem.

Lean4 ✓ `BEDC.Derived.ObservationScheduleEnvelopeUp.ObservationScheduleEnvelopeTasteGate single carrier alignment`

Theorem 908.2 (Observation schedule envelope NameCert obligations)**.** *For the carrier of Definition 908.1, the local* $\mathsf{NameCert}_{\mathsf{ObservationScheduleEnvelope}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$E = (Q, S, W, R, J, H, C, P, N),$$

schedule-source exposure, StreamName source accountability, Real-facing request-window exposure, joint refusal, consumer handoff, componentwise hsame *stability, displayed* Cont *replay,* Pkg *provenance, and non-escape for completed streams, future observations, hidden persistence laws, quotient schedule equality, selected Real values, and ambient completion.*

Proof. Carrier admission is projection from Definition 908.1. The rows $Q, S, W, R, J, H, C, P, N$ are all displayed coordinates of one finite BHist packet.

Schedule-source exposure reads Q through chapter 539. StreamName accountability reads S through chapter 126, while the Real-facing window W is the only route by which a budget consumer may ask for schedule data.

The refusal and handoff rows then bind the envelope. The refusal row R blocks completed streams and future-law data, and the handoff row J forces the consumer to carry Q, S, W together before the route is authenticated by H, C, P, N. □

Lean4 ✓ `BEDC.Derived.ObservationScheduleEnvelopeUp.TasteGate.ObservationScheduleEnvelopeNameCert obligations`

Theorem 908.3 (Observation schedule envelope window transport)**.** *For an accepted* ObservationScheduleEnvelope *carrier $E = (Q, S, W, R, J, H, C, P, N)$, any displayed transport of the Real-facing request window preserves the same source schedule row Q, StreamName source row S, joint refusal row R, and consumer-handoff row J. Transport may replay the window through H and C, but it may not enlarge W, replace S by an unlisted source, or turn the observed prefix carried by Q into a completed stream.*

Lean4 ✓ `BEDC.Derived.ObservationScheduleEnvelopeUp.ObservationScheduleEnvelope window transport`

Proof. Project the carrier and read the componentwise transport row H. The row records transport for the schedule source, StreamName source, Real-facing window, refusal row, handoff row, route row, provenance row, and local name.

Replay the consumer route through C. A transported Real-facing read still reaches W only together with Q, S, R, J, so the same finite source and refusal boundary remain visible.

Apply non-escape from Definition 908.2. Since the envelope has no coordinate for window enlargement, an unlisted source, or a completed stream, transport cannot create any of those rows. □

Theorem 908.4 (Observation schedule envelope StreamName handoff)**.** *Every* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$, *or* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *consumer of an accepted* $\mathsf{ObservationScheduleEnvelope}^{\uparrow}$ *packet reads the schedule through the same StreamName source row* S *and the same Real-facing window row* W*. The consumer receives the handoff row* J *with the schedule source* Q*, refusal row* R*, componentwise transport* H*, displayed routes* C*, provenance* P*, and local name* N*; it receives no independent schedule carrier and no completed stream.*

Proof. Begin with the sibling surfaces. The schedule row Q supplies finite prefixes and request windows, while the StreamName chapter supplies the named source row S through which the schedule is addressed.

For a Real-facing consumer, route the same source through W and J. The handoff row ties Q, S, W before budget selectors or limiters can read the schedule, so the consumer sees one envelope rather than separate replacement rows.

The refusal row and non-escape clause exclude the missing objects. A consumer can inspect the displayed envelope, but it cannot obtain an independent carrier, a completed stream, a future observation law, or ambient completion from the handoff. □

Theorem 908.5 (Observation schedule envelope non-escape)**.** *Every consumer of an accepted* $\mathsf{ObservationScheduleEnvelope}^{\uparrow}$ *packet factors through the finite rows*

$$Q, S, W, R, J, H, C, P, N.$$

No consumer may replace those rows by a completed countable stream, an unobserved future row, a hidden causal-continuity principle, quotient schedule equality, selected Real data, an independent observation-budget carrier, or an ambient completion theorem.

Proof. Read the carrier inventory in Definition 908.1. It lists exactly the schedule source, StreamName source, Real-facing request window, refusal row, handoff row, transports, routes, provenance, and local naming row.

Use the NameCert obligation surface to authenticate the inventory. Each consumer-facing read must pass through the displayed rows and then through H, C, P, N.

The excluded objects have no coordinate in the packet. Therefore a route that asks for a completed stream, a future observation, hidden persistence, quotient equality, selected Real data, an independent budget carrier, or ambient completion exits the accepted envelope. □

The Lean TasteGate surface for this chapter carries `Nontrivial ObservationScheduleEnvelopeUp` and `FieldFaithful ObservationScheduleEnvelopeUp` instances for the same finite envelope carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{ObservationScheduleEnvelope}^{\uparrow}}$.

Constructive story: An $\mathsf{ObservationScheduleEnvelope}^{\uparrow}$ packet is generated from finite BHist rows for request windows, observation schedule, envelope boundary, budget rows, route rows, transports, provenance, and local naming. The envelope admits only displayed finite observation routes: Cont carries each request through schedule and budget rows before any downstream read can inspect a selected window. Componentwise hsame preserves the schedule, envelope, budget, and route inventory, while Pkg records the observation, StreamName, budget, Real, and completion-adjacent dependencies. The packet names a finite observation envelope and refuses completed streams or hidden persistence.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObservationScheduleEnvelope}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the observation-schedule envelope carrier, route obligations, excluded-object boundary, and finite envelope surface for $\mathsf{ObservationScheduleEnvelope}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObservationScheduleEnvelope}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim completed streams, future observations, hidden persistence, quotient equality, selected Real data, independent budget carriers, or ambient completion.

Upgrade path: Obligation closure requires Lean encodings of the envelope carrier, schedule route, budget boundary, field-faithful surface, and non-escape theorem.

Chapter 909

A Concrete Naming Certificate for $\mathsf{RegularCauchyDiagonalMeet}^{\uparrow}$

The $\mathsf{RegularCauchyDiagonalMeet}^{\uparrow}$ interface packages the finite shared-threshold diagonal route used by the Real-completeness vision of chapter 9238. It consumes the tail-meet surface of chapter 560, the shared-modulus surface of chapter 462, the witness envelope of chapter 898, and the diagonal window coverage row used by the completion route. The packet records the diagonal threshold comparison as data, not as a host-selected limit, quotient stream, or ambient completeness theorem.

Definition 909.1 (RegularCauchyDiagonalMeet carrier)**.** *A* $\mathsf{RegularCauchyDiagonalMeet}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (T, M, E, W, Q, H, C, P, N)$$

with the following displayed coordinates:

1. *T is the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *row that exposes the paired regular-Cauchy tails through one tail threshold;*
2. *M is the* $\mathsf{CauchyModulusMeet}^{\uparrow}$ *row that supplies the shared bound consumed by the tail route;*
3. *E is the* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *row that stores the selected window, finite-window envelope, tail comparison, tail-agreement seal, and RealUp readback;*
4. *W is the* $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$ *row that records the diagonal window coverage available to the Real-completion route;*
5. *Q is the shared diagonal threshold comparison row, read only after T, M, E, W have been displayed;*
6. *H stores componentwise* hsame *transports for the tail-meet row, modulus-meet row, witness envelope, diagonal coverage row, comparison row, provenance, and local name;*
7. *C stores the displayed* Cont *routes for reading the shared modulus, applying it to the tail meet, passing through the witness envelope, checking diagonal coverage, and exposing the comparison row;*
8. *P is the* Pkg *provenance over* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{CauchyModulusMeet}^{\uparrow}$, $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$, $\mathsf{RealDiagonalWindowCoverage}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyDiagonalMeet}^{\uparrow}}$ *row.*

The classifier compares accepted packets only through these displayed rows, their transports, their continuation routes, package provenance, and local naming provenance.

Lean4 (definition) `BEDC.Derived.RegularCauchyDiagonalMeetUp.RegularCauchyDiagonalMeetUp`

Theorem 909.2 (RegularCauchyDiagonalMeet NameCert obligations)**.** *For the carrier of Definition 909.1, the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyDiagonalMeet}^{\uparrow}}$ *surface consists exactly of carrier admission for* $D = (T, M, E, W, Q, H, C, P, N)$*, tail-meet admission through* T*, shared-modulus admission through* M*, witness-envelope admission through* E*, diagonal-window coverage through* W*, shared-threshold comparison through* Q*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.RegularCauchyDiagonalMeetUp.RegularCauchyDiagonalMeetNameCertObligations`

Proof. Project the displayed carrier. Its rows name the tail meet, shared modulus, witness envelope, diagonal coverage, shared comparison, transport, route, package, and local certificate.

Read the analytic rows in the order required by the Real-completeness diagonal route. The shared modulus row M supplies the bound consumed by T, the envelope row E records the finite witness route, and the coverage row W makes the diagonal window visible before Q is exposed.

The remaining rows are structural. The transports in H, routes in C, provenance row P, and local name N replay and identify the same finite packet, so the local NameCert surface has no coordinate for quotient streams, host real equality, selected limits, or ambient completeness. □

Theorem 909.3 (RegularCauchyDiagonalMeet shared-threshold factorization)**.** *Every Real-completion consumer of an accepted* $\mathsf{RegularCauchyDiagonalMeet}^{\uparrow}$ *carrier reads the diagonal threshold comparison through the finite route*

$$M \longmapsto T \longmapsto E \longmapsto W \longmapsto Q.$$

The route uses the shared-bound packet of chapter 462, the shared-tail packet of chapter 560, the witness envelope of chapter 898, and the diagonal-window coverage row described by chapter 9238.

Lean4 ✓ `BEDC.Derived.RegularCauchyDiagonalMeetUp.RegularCauchyDiagonalMeetSharedThresholdFactorization`

Proof. Start with a Real-completion read of the comparison row. The carrier has exactly one comparison coordinate Q, and the continuation route to it passes through the rows M, T, E, W.

The shared-bound route is first read through M and then consumed by T. This is the finite meet route: the source moduli and tail windows are synchronized before any diagonal comparison is available.

Next the witness route is exposed through E, and the diagonal window coverage is exposed through W. Only after these rows have been displayed can Q be consumed. Thus every comparison read factors through the stated finite route, with H, C, P, N carrying transport, replay, provenance, and naming. □

Theorem 909.4 (RegularCauchyDiagonalMeet transport induction)**.** *Let an accepted* $\mathsf{RegularCauchyDiagonalMeet}^{\uparrow}$ *carrier display the rows* M, T, E, W, Q *and the componentwise transport row* H *of Definition 909.1. If the shared modulus, tail meet, witness envelope, diagonal coverage, and comparison rows are transported componentwise along* H*, then every consumer route to the comparison row still factors through*

$$M \longmapsto T \longmapsto E \longmapsto W \longmapsto Q.$$

The transported packet therefore preserves the displayed diagonal route without identifying quotient streams, selecting limits, or asserting host RealUp equality.

Lean4 ✓ `BEDC.Derived.RegularCauchyDiagonalMeetUp.RegularCauchyDiagonalMeetTransportInduction`

Proof. Induct over the finite continuation route displayed in the carrier. The base read is the shared modulus row M; transporting it by the corresponding component of H keeps the same shared-bound coordinate and supplies the first node of the route.

For the tail-meet, witness-envelope, and diagonal-coverage steps, use the next component of H together with the carrier rows T, E, W. Each step replaces only the visible row by an hsame-transported row while preserving the continuation order recorded by C.

At the final comparison step, apply the shared-threshold factorization theorem above. Since every transported read has already replayed M, T, E, W, the transported comparison row Q is still reached through the same displayed route. No step introduces a quotient stream equality, selected limit, or host equality coordinate, because those objects are absent from the carrier. □

Theorem 909.5 (RegularCauchyDiagonalMeet non-escape)**.** *An accepted* RegularCauchyDiagonalMeet$^{\uparrow}$ *carrier exports only the finite rows $T, M, E, W, Q, H, C, P, N$ of Definition 909.1. It exports no quotient stream equality, host real equality, selected limit, countable-choice diagonal selector, analytic completeness theorem, or ambient RealUp completion principle.*

Lean4 ✓ `BEDC.Derived.RegularCauchyDiagonalMeetUp.RegularCauchyDiagonalMeetNonescape`

Proof. Inspect the carrier. The only mathematical rows are the tail meet, modulus meet, witness envelope, diagonal coverage row, and shared comparison row.

Apply the local NameCert obligations. They force every accepted read to remain inside the displayed carrier, and the shared-threshold factorization theorem forces comparison-facing reads through M, T, E, W, Q.

The excluded objects would require carrier coordinates or continuation routes not present in D. Since the packet contains only finite BEDC rows and their structural provenance, no downstream consumer can recover quotient streams, host equality, selected limits, choice selectors, analytic completeness, or an ambient completion principle from it. □

Theorem 909.6 (RegularCauchyDiagonalMeet obligation closure)**.** *The carrier of Definition 909.1, the NameCert obligations of Definition 909.2, the shared-threshold factorization of Definition 909.3, the transport induction of Definition 909.4, the non-escape theorem of Definition 909.5, and the ChapterTasteGate single-carrier rows for field faithfulness and nontriviality exhaust the paper-side obligation surface for the diagonal meet route.*

Lean4 ✓ `BEDC.Derived.RegularCauchyDiagonalMeetUp.RegularCauchyDiagonalMeetObligationClosure`

Proof. Project an accepted carrier

$$D = (T, M, E, W, Q, H, C, P, N).$$

The carrier definition displays exactly the tail-meet, shared-modulus, witness-envelope, diagonal-window, comparison, transport, continuation, provenance, and local naming rows available to a consumer.

The NameCert obligations force every accepted read through those rows. The shared-threshold factorization orders the comparison route as M, T, E, W, Q, while the transport induction preserves the same route under componentwise hsame. The TasteGate rows read the same displayed carrier as field-faithful and nontrivial, so they add no hidden classifier or second carrier.

Finally apply non-escape. Quotient stream equality, host Real equality, selected limits, countable-choice diagonal selectors, analytic completeness, and ambient RealUp completion have no coordinate in D. Therefore no further obligation remains inside the displayed diagonal meet packet. □

Theorem 909.7 (RegularCauchyDiagonalMeet scoped consumer boundary)**.** *Every completion-facing consumer of an accepted* RegularCauchyDiagonalMeet$^{\uparrow}$ *carrier* $D = (T, M, E, W, Q, H, C, P, N)$ *reads the exact route*

$$M \longmapsto T \longmapsto E \longmapsto W \longmapsto Q.$$

The scope of this boundary is limited to RegularCauchyTailMeet$^{\uparrow}$, CauchyModulusMeet$^{\uparrow}$, CauchyTailWitnessEnvelope$^{\uparrow}$ RealDiagonalWindowCoverage$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert. *It refuses quotient streams, selected limits, countable-choice diagonal selectors, analytic completeness, and ambient* Real$^{\uparrow}$ *completion.*

Lean4 ✓ `BEDC.Derived.RegularCauchyDiagonalMeetUp.RegularCauchyDiagonalMeetScopedConsumerBoundary`

Proof. Use the shared-threshold factorization theorem to force every comparison read through M, T, E, W, Q. The transport induction theorem keeps that same route stable under the componentwise hsame rows in H.

The non-escape theorem rules out quotient streams, selected limits, countable-choice diagonal selectors, analytic completeness, and ambient completion rows. The obligation-closure theorem then identifies the remaining consumer surface with the displayed carrier, its replay, provenance, and local naming rows.

Thus the boundary is exactly the listed finite route over RegularCauchyTailMeet$^{\uparrow}$, CauchyModulusMeet$^{\uparrow}$, CauchyTailWitnessEnvelope$^{\uparrow}$, RealDiagonalWindowCoverage$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert. □

The public diagonal-meet export is the scoped consumer route of Definition 909.7 together with the checked ChapterTasteGate carrier surface.

Lean4 ✓ `BEDC.Derived.RegularCauchyDiagonalMeetUp.taste gate`

Closure status for NameCert$_{\text{RegularCauchyDiagonalMeet}^{\uparrow}}$**.**

Constructive story: A RegularCauchyDiagonalMeet$^{\uparrow}$ packet is generated from finite BHist rows for a regular-Cauchy tail meet, shared modulus meet, witness envelope, diagonal-window coverage, shared-threshold comparison, transports, continuations, provenance, and local naming. The Real-completion-facing comparison is routed by Cont through the shared modulus, tail meet, witness envelope, and diagonal coverage rows before Q is exposed. Componentwise hsame preserves the same tail, modulus, envelope, coverage, and comparison rows, while Pkg records the tail-meet, modulus-meet, witness-envelope, diagonal-window, and Real dependencies. The packet is a finite diagonal meet, not completion.

Theory closure: TheoryGate(NameCert$_{\text{RegularCauchyDiagonalMeet}^{\uparrow}}$, publicClosed)

Scope closed: This chapter binds the regular Cauchy diagonal-meet carrier, NameCert obligations, obligation closure, non-escape theorem, and scoped consumer boundary over RegularCauchyTailMeet$^{\uparrow}$, CauchyModulusMeet$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus(NameCert$_{\text{RegularCauchyDiagonalMeet}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim quotient stream equality, host real equality, selected limits, countable-choice diagonal selectors, analytic completeness, or ambient RealUp completion.

Upgrade path: The next paper-axis target is a bridge route beyond the public diagonal-meet export, still without adding RealUp completeness, quotient streams, selected limits, or choice selectors.

Chapter 910

A Concrete Naming Certificate for $\mathsf{SubstitutionGeneratorAudit}^{\uparrow}$

The $\mathsf{SubstitutionGeneratorAudit}^{\uparrow}$ packet realizes the generator-closure route isolated by the MetaCIC substitution audit map of chapter 9380. It sits beside the substitution audit map of chapter 779 and the substitution audit window route of chapter 824: those chapters expose the closed substitution rows and their windowed handoff route, while this packet records the generator replay surface that keeps closed shift, closed substitution, closed composition, and subject-reduction boundary reads inside a finite NameCert carrier.

Definition 910.1 (Substitution generator-audit carrier)**.** *A* $\mathsf{SubstitutionGeneratorAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (T, C, R, S, K, W, H, Q, P, N)$$

with the following displayed rows:

1. *T is the MetaCIC* Term *row whose substitution generators are audited;*
2. *C is the* ClosedAt *boundary row attached to T;*
3. *R is the closed shift row, recording the admitted* shift *generator route under C;*
4. *S is the closed substitution row, recording the admitted* substitute *generator route under C;*
5. *K is the closed-composition row for the available closed substitution compositions;*
6. *W is the generator-route replay and obstruction ledger row, recording the finite order in which R, S, K and the subject-reduction handoff boundary may be inspected;*
7. *H records componentwise* hsame *transports for term, boundary, generator, composition, replay, provenance, route, and naming rows;*
8. *Q records the displayed* Cont *routes by which consumers replay the generator audit without leaving the packet;*
9. *P is the* Pkg *provenance over chapter 9380, chapter 779, chapter 824,* BHist, hsame, Cont, Pkg, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{SubstitutionGeneratorAudit}^{\uparrow}}$ *row.*

The classifier accepts exactly packets whose rows display the closed boundary, closed shift, closed substitution, closed composition, generator-route replay, transport, continuation, provenance, and

local naming data above. It exports no unrestricted substitution calculus, no beta-substitution preservation theorem, no closed subject-reduction theorem, no quotient equality, and no host semantic equality coordinate.

Theorem 910.2 (Substitution generator-audit NameCert obligations)**.** *For the carrier of Definition 910.1, the local* $\mathsf{NameCert}_{\mathsf{SubstitutionGeneratorAudit}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$G = (T, C, R, S, K, W, H, Q, P, N),$$

with the following finite obligations:

1. *carrier admission for* $G = (T, C, R, S, K, W, H, Q, P, N)$*;*
2. *closed-boundary exposure through* T, C*;*
3. *closed shift exposure through* R*;*
4. *closed substitution exposure through* S*;*
5. *closed-composition exposure through* K*;*
6. *generator-route replay and obstruction-ledger exposure through* W*;*
7. *componentwise transport through* H*;*
8. *displayed continuation through* Q*;*
9. *package provenance through* P*;*
10. *local naming through* N*.*

Proof. Carrier admission is projection from Definition 910.1. The rows $T, C, R, S, K, W, H, Q, P, N$ are the complete finite packet.

Read T, C first. They expose the MetaCIC term and the closed boundary at which the generator actions are admitted, matching the closed slice recorded in chapter 9380.

Read R, S, K, W next. The shift, substitution, and composition rows record the checked closed generator fragments, while W fixes the replay route and obstruction ledger through which a consumer may inspect them before any subject-reduction handoff boundary is named.

Finally inspect H, Q, P, N. These rows transport, replay, package, and name the same finite packet. Since no additional coordinate is present, the listed obligations exhaust the local NameCert surface. □

Theorem 910.3 (Substitution generator-audit route lock)**.** *For every accepted* $\mathsf{SubstitutionGeneratorAudit}^{\uparrow}$ *packet*

$$G = (T, C, R, S, K, W, H, Q, P, N),$$

any consumer route that reaches the subject-reduction handoff boundary first passes through the closed boundary C*, the closed shift row* R*, the closed substitution row* S*, the closed-composition row* K*, and the generator-route replay row* W*. The route may export those finite syntax-side audit rows, but it cannot export unrestricted substitution, beta-substitution preservation, dependent typing preservation, closed subject reduction, quotient equality, or host semantic equality.*

Lean4 ✓ `BEDC.Derived.SubstitutionGeneratorAuditUp.SubstitutionGeneratorAudit route lock rows`

Proof. Project the accepted carrier. The only generator rows are R, S, K, and the only replay row that orders them for downstream use is W.

Use Definition 910.2. It forces any accepted read to expose T, C before the movement rows and to pass through W before the administrative rows H, Q, P, N can replay the packet.

The sibling route of chapter 824 records the same closed-window handoff discipline, while chapter 779 records the wider audit map. The present carrier keeps the generator replay as a finite packet between those two surfaces.

The excluded endpoints have no row in G. Therefore a route that claims unrestricted substitution, beta preservation, dependent typing preservation, closed subject reduction, quotient equality, or host semantic equality leaves the accepted generator-audit carrier. □

Theorem 910.4 (Substitution generator-audit TasteGate obligation)**.** *The* `\origin{ai}` *chapter for* $\mathsf{SubstitutionGeneratorAudit}^{\uparrow}$ *is admissible to the TasteGate route only when the Lean follow-up for namespace* BEDC.Derived.SubstitutionGeneratorAuditUp *supplies both a* Nontrivial $\mathsf{SubstitutionGeneratorAudit}^{\uparrow}$ *instance and a* FieldFaithful $\mathsf{SubstitutionGeneratorAudit}^{\uparrow}$ *instance for the same finite carrier*

$$G = (T, C, R, S, K, W, H, Q, P, N).$$

Those instances must preserve the displayed closed-boundary, generator, replay, transport, continuation, provenance, and local naming rows, and they may not replace the obstruction ledger by a hidden subject-reduction theorem.

Lean4 ✓ `BEDC.Derived.SubstitutionGeneratorAuditUp.SubstitutionGeneratorAuditTasteGate single carrier alignment`

Proof. Start from the carrier and NameCert obligations. They identify exactly which fields are available to a TasteGate consumer: the closed boundary, closed generator rows, replay row, transports, continuations, provenance, and local name.

Nontriviality requires a genuine accepted witness for this carrier rather than an empty one-row shell. Field faithfulness requires each displayed coordinate to be recoverable from the carrier projections used by the TasteGate route.

The route lock supplies the obstruction side. Since subject reduction and unrestricted substitution are not fields of G, a TasteGate witness that obtains them without the generator-closure row and obstruction ledger would not be faithful to this carrier. □

Falsifiable prediction: A SubstitutionGeneratorAuditUp packet admits no subject-reduction handoff unless the generator-closure row and obstruction ledger are both present.

Independence witness: substitutionauditmap, closedsubstitutionboundary, closedsubstitutionseal, substitutionauditwindowroute, subjectreductiondischarge: the generator-audit carrier is not equivalent to any sibling because it carries a dedicated generator-route replay row W tying closed shift, closed substitution, closed composition, and handoff refusal into one finite packet.

Closure status for $\mathsf{NameCert}_{\mathsf{SubstitutionGeneratorAudit}^{\uparrow}}$.

Constructive story: A $\mathsf{SubstitutionGeneratorAudit}^{\uparrow}$ packet is generated from a MetaCIC term row, a ClosedAt boundary, closed shift and substitution rows, closed-composition rows, a generator-route replay row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SubstitutionGeneratorAudit}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 910.1, Definition 910.2, Definition 910.3, and Definition 910.4 bind the finite generator-audit packet, its replay lock, and its TasteGate instance obligations.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SubstitutionGeneratorAudit}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Not claimed: This chapter does not close unrestricted substitution, beta-substitution preservation, dependent typing preservation, closed subject reduction, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, generator-route replay, obstruction-ledger non-escape, and TasteGate nontriviality and field faithfulness for the same finite packet.

Chapter 911

A Concrete Naming Certificate for $\mathsf{MinkowskiRateGeometry}^{\uparrow}$

The $\mathsf{MinkowskiRateGeometry}^{\uparrow}$ interface realizes the Lorentz-geometry step of the Inter-Hist Locality chain of chapter 9419. It consumes the finite multi-history configuration surface of chapter 474, the causal witness rows of chapter 478, the maximum-rate boundary of chapter 594, and the observer-symmetric frame-rate packet of chapter 617. Its new content is a symmetric distance-shape ledger: the packet records which rate-induced comparisons may be read as a Minkowski-like boundary, while still exporting no metric tensor, global frame, synchronized clock, host real-valued coordinate, or ambient Lorentz manifold.

Definition 911.1 (Minkowski rate geometry carrier)**.** *A* $\mathsf{MinkowskiRateGeometry}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (G, X, R, L, D, H, C, P, N)$$

with the following displayed rows:

1. *G is an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *row displaying the finite observer-history configuration and its no-global-sync boundary;*
2. *X is the finite family of* $\mathsf{CrossHistCausal}^{\uparrow}$ *rows over selected pairs of histories in G;*
3. *R is an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *row whose unary bound is read over G and the causal family X;*
4. *L is an accepted* $\mathsf{LorentzFrameRate}^{\uparrow}$ *row tying the same G, X, R surface to an observer-symmetric frame-rate ledger;*
5. *D is the symmetric distance-shape ledger, recording the rate-induced light-boundary comparisons licensed by L and requiring the same row after swapping the two displayed observer histories;*
6. *H records componentwise* hsame *transport for G, X, R, L, D, the continuation routes, provenance, and local naming row;*
7. *C records visible* Cont *routes by which a consumer reads G, then X, then R, then L, then D, and transports the packet through H into the local certificate;*
8. *P is the* Pkg *provenance over* $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, $\mathsf{LorentzFrameRate}^{\uparrow}$, *the distance-shape ledger,* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{MinkowskiRateGeometry}^{\uparrow}}$ *row.*

The carrier exports only this finite ledger surface. The word "geometry" names the symmetric boundary shape induced by the maximum-rate invariant, not an imported continuum, coordinate chart, or metric tensor.

Theorem 911.2 (Minkowski rate geometry NameCert obligations)**.** *For the carrier of Definition 911.1, the local* $\mathsf{NameCert}_{\mathsf{MinkowskiRateGeometry}^{\uparrow}}$ *surface consists exactly of six finite obligations:*

1. *carrier admission for the displayed packet* $M = (G, X, R, L, D, H, C, P, N)$*;*
2. *upstream exactness, requiring* G*,* X*,* R*, and* L *to be the displayed multi-Hist, causal, maximum-rate, and Lorentz-frame-rate rows read in that order;*
3. *distance-shape exactness, requiring every entry of* D *to be induced by the observer-symmetric maximum-rate row of* L*;*
4. *observer symmetry, requiring the* D *row to be stable under swapping the two displayed observer histories and transporting the swap through* H*;*
5. *route stability, requiring all reads of* D *to pass through the visible* Cont *routes in* C *and the provenance row* P*;*
6. *non-escape, excluding global frames, synchronized clocks, metric tensors, host real-valued coordinates, ambient Lorentz manifolds, and distance rows not generated by* $G, X, R, L, D, H, C, P, N$*.*

Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 911.1. The packet displays the configuration, causal family, maximum-rate row, frame-rate row, distance-shape ledger, transport rows, continuation routes, provenance, and local name before any consumer reads the certificate.

Upstream exactness reads the rows in dependency order. The maximum-rate row R is tied to G and X, and the Lorentz-frame-rate row L is tied to the same G, X, R surface.

Distance-shape exactness then reads D only after L. Thus the boundary shape is a rate-induced ledger row, not an independent metric object.

Observer symmetry and route stability are the componentwise H and C clauses. They move the displayed rows together and keep every read inside the same finite packet.

The non-escape clause is the carrier inventory. Since no excluded structure is a coordinate of M, no local naming projection can export one. □

Theorem 911.3 (Minkowski rate geometry symmetry)**.** *Let*

$$M = (G, X, R, L, D, H, C, P, N)$$

be an accepted $\mathsf{MinkowskiRateGeometry}^{\uparrow}$ *carrier. Every distance-shape comparison in* D *is observer-symmetric: swapping the two displayed observer histories in a listed pair and transporting the packet through* H *returns the same distance-shape row in* D *along the visible routes in* C*.*

Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometrySymmetry`

Proof. Read the distance-shape ledger D through the route required by Definition 911.1. Each row of D is attached to the observer-symmetric frame-rate packet L.

The frame-rate row inherits its maximum-rate row from the same G and X surface, so swapping the displayed observers does not select a different rate source. It only reorders the same selected pair inside the finite configuration.

Finally transport through H and replay the routes in C. The comparison returns to the same distance-shape ledger row, because D records symmetric shape data and has no coordinate for a privileged observer slot. □

Theorem 911.4 (Minkowski rate geometry non-escape)**.** *The public boundary of an accepted* $\mathsf{MinkowskiRateGeometry}^{\uparrow}$ *packet exports no global frame, synchronized clock, metric tensor, host real-valued coordinate system, ambient Lorentz manifold, or distance comparison detached from the maximum-rate invariant. A consumer can read a Minkowski-like boundary only through the finite route*

$$G, X, R, L, D, H, C, P, N.$$

Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryNonescape`

Proof. Project the accepted carrier. Its coordinates are exactly the upstream configuration, causal, maximum-rate, and Lorentz-frame-rate rows, the distance-shape ledger, transport rows, continuation routes, provenance, and local name.

The NameCert obligations require every distance-shape row to be induced by L, and L is itself tied to the displayed maximum-rate row R over G and X. Hence no detached distance comparison is available.

The symmetry theorem keeps the boundary observer-symmetric under componentwise transport. It does not add a metric tensor, coordinate chart, or global frame.

Therefore the public packet is a finite rate-to-geometry boundary. Any richer geometric structure would require a coordinate absent from $G, X, R, L, D, H, C, P, N$. □

Theorem 911.5 (Minkowski rate geometry TasteGate obligation)**.** *The later Lean* `TasteGate.lean` *development for* $\mathsf{MinkowskiRateGeometry}^{\uparrow}$ *must include explicit* $\mathsf{Nontrivial\ MinkowskiRateGeometry}^{\uparrow}$ *and* $\mathsf{FieldFaithful\ MinkowskiRateGeometry}^{\uparrow}$ *instances. These instances must preserve the multi-Hist row, causal family, maximum-rate row, Lorentz-frame-rate row, symmetric distance-shape ledger,* hsame *transport,* Cont *routes, package provenance, and local naming row.*

Proof. The carrier is not determined by any single upstream row. It adds D, the symmetric distance-shape ledger, after the observer-symmetric maximum-rate surface has already been exposed by L.

Nontriviality rules out collapsing the packet to a bare maximum-rate row or a bare Lorentz-frame-rate row. Field faithfulness records preservation of every coordinate $G, X, R, L, D, H, C, P, N$, so a downstream TasteGate consumer can distinguish the rate-induced geometry boundary from each sibling surface it consumes. □

Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryTasteGate single carrier alignment`

Theorem 911.6 (Minkowski rate geometry carrier envelope)**.** *Every accepted* $\mathsf{MinkowskiRateGeometry}^{\uparrow}$ *packet is exhausted by the displayed carrier coordinates*

$$G, X, R, L, D, H, C, P, N.$$

The NameCert obligations of Definition 911.2, the symmetry theorem Definition 911.3, the non-escape theorem Definition 911.4, and the TasteGate marker `BEDC.Derived.MinkowskiRateGeometryUp.Minkowsk` *leave no additional geometry coordinate outside the finite carrier envelope.*

Proof. Project the carrier of Definition 911.1. Its coordinates are exactly the multi-Hist configuration G, causal family X, maximum-rate row R, Lorentz-frame-rate row L, symmetric distance-shape ledger D, transport row H, continuation row C, provenance row P, and local name N.

Apply the NameCert obligations and non-escape theorem. They require every consumer read to expose the same displayed rows and exclude global frames, synchronized clocks, metric tensors, host real-valued coordinates, ambient Lorentz manifolds, and detached distance comparisons.

Finally use the symmetry theorem and the TasteGate marker. Symmetry keeps the distance-shape ledger inside the same observer-swapping route, while field faithfulness records every coordinate of the single carrier, so no hidden geometry field remains beyond $G, X, R, L, D, H, C, P, N$. □

Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryCarrier envelope`

Theorem 911.7 (Minkowski rate geometry classifier stability)**.** *Let two accepted* $\mathsf{MinkowskiRateGeometry}^{\uparrow}$ *packets be related by the componentwise* hsame *transport row displayed in their carriers. Then the classifier preserves the symmetric distance-shape row only through the route*

$$G, X, R, L, D, H, C, P, N.$$

In particular, classifier stability may use the NameCert obligations, observer symmetry, non-escape, and the TasteGate marker, but it may not compare packets through an external metric tensor, ambient Lorentz manifold, global frame, synchronized clock, or host real-valued coordinate.

Proof. Read the componentwise transport row H from the carrier. It transports the upstream configuration, causal family, maximum-rate row, Lorentz-frame-rate row, distance-shape ledger, continuation routes, provenance, and local name together.

Apply Definition 911.3. The transported comparison remains the same symmetric distance-shape row because swapping observers is handled inside D and replayed through C.

Apply Definition 911.4 and the TasteGate marker. Non-escape forbids external comparison coordinates, and field faithfulness keeps the classifier aligned with the displayed single-carrier route. □

Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryCarrier classifier stability`

Theorem 911.8 (Minkowski rate geometry ledger exactness)**.** *For every accepted* $\mathsf{MinkowskiRateGeometry}^{\uparrow}$ *packet, the distance-shape ledger D is induced by the displayed* $\mathsf{MaxCausalRate}^{\uparrow}$ *row R and* $\mathsf{LorentzFrameRate}^{\uparrow}$ *row L through the NameCert route*

$$G, X, R, L, D, H, C, P, N.$$

The ledger cannot export a metric tensor, coordinate chart, global frame, synchronized clock, host real-valued coordinate, or ambient Lorentz manifold. Its exact public content is the symmetric rate-induced boundary named by the carrier, the NameCert obligations, the symmetry and non-escape theorems, and the TasteGate marker.

Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryCarrier ledger exactness`

Proof. Project the rows R, L, D from the accepted carrier. The maximum-rate row R is read over the same G, X surface, and the Lorentz-frame-rate row L ties that maximum-rate surface to the observer-symmetric frame-rate ledger.

The NameCert obligations require every entry of D to be induced by L rather than supplied as an independent metric object. The symmetry theorem keeps this induced ledger invariant under the displayed observer swap.

Use non-escape and the TasteGate marker to close the ledger boundary. Since the carrier is field-faithful for $G, X, R, L, D, H, C, P, N$ and contains no metric-tensor or manifold coordinate, the public ledger is exactly the finite rate-induced distance-shape row. □

Theorem 911.9 (Minkowski rate geometry scope binding)**.** *The finite rate-to-geometry packet is scoped only over* MultiHistConfig$^{\uparrow}$, CrossHistCausal$^{\uparrow}$, MaxCausalRate$^{\uparrow}$, LorentzFrameRate$^{\uparrow}$, BHist, hsame, Cont, Pkg, NameCert, *and the displayed TasteGate marker*

`BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryTasteGate_single_carrier_alignment`.

Within that scope, promotion reads only the finite carrier $G, X, R, L, D, H, C, P, N$ and never a metric tensor, coordinate chart, synchronized clock, global frame, host real-valued speed, curved spacetime, or ambient Lorentz manifold.

Proof. Start with the carrier of Definition 911.1. Its public rows are the multi-Hist configuration G, cross-Hist causal family X, maximum-rate row R, Lorentz-frame-rate row L, distance-shape ledger D, transport H, continuation C, provenance P, and local name N.

Apply the NameCert obligations of Definition 911.2. They force upstream exactness through MultiHistConfig$^{\uparrow}$, CrossHistCausal$^{\uparrow}$, MaxCausalRate$^{\uparrow}$, and LorentzFrameRate$^{\uparrow}$ before any distance-shape row is visible.

Use non-escape and ledger exactness from Definition 911.4 and Definition 911.8. These theorems keep every geometry read inside the rate-induced ledger and rule out external metric, coordinate, clock, frame, speed, spacetime, and manifold coordinates.

Finally read the TasteGate marker

```
BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryTasteGate_single_carrier_alignment.
```

It aligns field faithfulness with the same single carrier; it does not enlarge the scope. Therefore promotion is bound exactly to the listed finite packet and its displayed kernel rows. □

Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryScopeBinding`

Theorem 911.10 (Minkowski rate geometry public certificate)**.** *The public certificate exported by* MinkowskiRateGeometry$^{\uparrow}$ *is exactly the finite route*

$$G, X, R, L, D, H, C, P, N.$$

It consumes the displayed MultiHistConfig$^{\uparrow}$, CrossHistCausal$^{\uparrow}$, MaxCausalRate$^{\uparrow}$, *and* LorentzFrameRate$^{\uparrow}$ *rows, then exposes only the rate-induced distance-shape ledger, componentwise transport, continuation route, provenance, and local name. It refuses metric tensors, host real coordinates, synchronized clocks, global frames, and ambient Lorentz manifolds as public certificate fields.*

Proof. Start with the carrier envelope of Definition 911.1 and Definition 911.6. These identify the complete public inventory as $G, X, R, L, D, H, C, P, N$.

Apply the NameCert obligations, observer symmetry, non-escape, ledger exactness, and scope binding from Definition 911.2, Definition 911.3, Definition 911.4, Definition 911.8, and Definition 911.9. They force every distance-shape read to pass through the upstream multi-Hist, causal, maximum-rate, and Lorentz-frame-rate rows before it reaches D.

Finally use the TasteGate marker

```
BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryTasteGate_single_carrier_alignment.
```

It records field faithfulness for the single carrier and does not admit any extra coordinate. Hence the certificate is public exactly at the listed finite route and refuses continuum Lorentz data outside that route. □

Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryPublicCertificate`

Theorem 911.11 (Minkowski rate geometry public export)**.** *Any downstream consumer may cite the finite route*

$$G, X, R, L, D, H, C, P, N$$

as the public $\mathsf{MinkowskiRateGeometry}^{\uparrow}$ *certificate. The export is exactly the rate-induced distance-shape ledger carried by the accepted packet, and it still refuses metric tensors, coordinate charts, synchronized clocks, global frames, host real speeds, curved spacetime, and ambient Lorentz manifolds.*

Proof. Start with the carrier envelope and NameCert obligations of Definition 911.6 and Definition 911.2. They make $G, X, R, L, D, H, C, P, N$ the complete public inventory and require every distance-shape read to pass through the displayed upstream rows.

Use ledger exactness, non-escape, and scope binding from Definition 911.8, Definition 911.4, and Definition 911.9. These keep the geometry surface inside the finite rate-induced ledger and exclude every external tensor, chart, clock, frame, host-speed, spacetime, or manifold coordinate.

Finally apply the public certificate theorem, Definition 911.10. It identifies the cited route as the public certificate itself, so the export is precisely the finite rate-induced distance-shape ledger and nothing outside that ledger. □

Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometry public export route`
Lean4 ✓ `BEDC.Derived.MinkowskiRateGeometryUp.MinkowskiRateGeometryPublicExport`

Falsifiable prediction: Deleting the observer-symmetry row permits two observers over the same MaxCausalRateUp packet to read incompatible geometry rows, while deleting the MaxCausalRateUp row leaves no rate-induced distance boundary.

Independence witness: Nearest siblings: multihistconfig, crosshistcausal, maxcausalrate, lorentzframerate, and observerlocalitytransport; no bijection exists because this carrier adds a symmetric distance-shape ledger that each sibling explicitly lacks or refuses.

Closure status for $\mathsf{NameCert}_{\mathsf{MinkowskiRateGeometry}^{\uparrow}}$**.**

Constructive story: A $\mathsf{MinkowskiRateGeometry}^{\uparrow}$ packet is generated from a multi-Hist configuration, finite cross-Hist causal rows, a maximum-rate row, an observer-symmetric Lorentz-frame-rate row, a symmetric distance-shape ledger, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{MinkowskiRateGeometry}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 911.1, Definition 911.2, Definition 911.3, Definition 911.4, Definition 911.5, Definition 911.6, Definition 911.7, Definition 911.8, and Definition 911.9 specify the finite rate-to-geometry packet, its NameCert obligations, observer-symmetry boundary, non-escape surface, TasteGate instance surface, carrier envelope, classifier stability, ledger exactness, and finite scope binding.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{MinkowskiRateGeometry}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Not claimed: This chapter does not close a metric tensor, coordinate chart, synchronized clock, global frame, ambient Lorentz manifold, host real-valued speed, curved spacetime, Lean verification, or bridge checking for $\mathsf{MinkowskiRateGeometry}^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, upstream exactness, distance-shape exactness, observer symmetry, route stability, non-escape, and TasteGate nontriviality with field faithfulness.

Chapter 912

A Concrete Naming Certificate for $\mathsf{AuthoredRecordBoundary}^{\uparrow}$

The $\mathsf{AuthoredRecordBoundary}^{\uparrow}$ surface makes the inscription-event vision of chapter 9397 into a finite authored-record carrier. It sits after the observer-history identity row of chapter 477, the finite prefix scheduling row of chapter 539, and the stream naming row of chapter 126. Those siblings supply the public history, schedule, and finite name rows; this chapter records the boundary at which a mismatch notice is accepted as an authored route and then exported as a public record.

Definition 912.1 (Authored-record boundary carrier)**.** *An* $\mathsf{AuthoredRecordBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (O, S, M, R, W, F, T, Q, V, H, C, P, N)$$

with the following displayed rows:

1. *O is the observer-history row consumed from* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$*;*
2. *S is the countable finite-prefix schedule row consumed from* $\mathsf{CountableObservationSchedule}^{\uparrow}$*;*
3. *M is the mismatch-notice row that identifies the finite gap between the prior record surface and the proposed authored record;*
4. *R is the accepted-route row that binds the mismatch notice to a reusable public record route;*
5. *W is the written public-record row;*
6. *F is the refusal row excluding bypass reads that skip M or R;*
7. *T is the transport row for moving O, S, M, R, W, F componentwise through displayed* hsame *comparisons;*
8. *Q is the route-replay row of displayed* Cont *steps from prior record, through mismatch notice and accepted route, to public record;*
9. *V is the provenance row naming the source vision, observer-history, schedule, stream-name, closed-observation-system, and inscription-acceptance-budget dependencies;*
10. *H records the local handoff to* $\mathsf{ClosedObservationSystem}^{\uparrow}$ *and* $\mathsf{InscriptionAcceptanceBudget}^{\uparrow}$ *consumers;*
11. *C records the public consumer routes for authored-record reads;*

12. *P is the* Pkg *provenance over* BHist, hsame, Cont, ObserverHistoryIdentity$^{\uparrow}$, CountableObservationSchedule$^{\uparrow}$, StreamName$^{\uparrow}$, ClosedObservationSystem$^{\uparrow}$, InscriptionAcceptanceBudget$^{\uparrow}$, *and* NameCert *rows;*
13. *N is the local* $\mathsf{NameCert}_{\mathsf{AuthoredRecordBoundary}^{\uparrow}}$ *row.*

The classifier for accepted carriers compares only the displayed prior-record, mismatch-notice, accepted-route, public-record, refusal, transport, route, provenance, handoff, consumer, package, and local naming rows. It has no coordinate for private intention, raw byte authorship, host psychological identity, hidden checker state, or a record route that bypasses M or R.

Theorem 912.2 (Authored-record boundary NameCert obligations)**.** *For the carrier of Definition 912.1, the local* $\mathsf{NameCert}_{\mathsf{AuthoredRecordBoundary}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier exposure: every accepted packet exposes exactly $A = (O, S, M, R, W, F, T, Q, V, H, C, P, N)$;*
2. *mismatch accountability: the public record row W is admitted only after the mismatch-notice row M is displayed against the prior observer-history and schedule rows O, S;*
3. *accepted-route accountability: every authored-record read passes through the accepted-route row R and the route-replay row Q;*
4. *refusal stability: the refusal row F is transported by T and remains visible to every consumer route in C;*
5. *provenance exactness: observer-history, finite schedule, stream-name, closed-observation-system, inscription-acceptance-budget, package, and local naming dependencies are exhausted by V, H, P, N.*

Lean4 ✓ `BEDC.Derived.AuthoredRecordBoundaryUp.AuthoredRecordBoundaryTasteGate single carrier alignment`

Proof. Carrier exposure is projection from Definition 912.1. The displayed tuple lists the prior record rows, mismatch notice, accepted route, public record, refusal, transport, route replay, provenance, handoff, consumer, package, and local naming rows.

Mismatch accountability reads M beside O and S. Since W is not a standalone row but the public record reached after the mismatch and route rows are displayed, an authored-record read cannot begin at the written record alone.

Accepted-route accountability reads R and Q. The route row names the accepted articulation, and the continuation row replays the finite path from prior record through mismatch notice to the public record.

Refusal stability is the role of F and T. The refusal row records that bypassing M or R is outside the carrier, and transport moves that refusal together with the other displayed rows.

Finally, provenance exactness is obtained by inspecting V, H, P, N. These rows name the observer-history, schedule, stream-name, closed-observation-system, inscription-acceptance-budget, package, and local certificate surfaces consumed by the boundary, with no extra source coordinate. □

Theorem 912.3 (Authored-record boundary non-escape)**.** *Every public read of an accepted* AuthoredRecordBounda *carrier factors through the finite rows*

$$O, S, M, R, W, F, T, Q, V, H, C, P, N.$$

A read that bypasses the mismatch-notice row M, bypasses the accepted-route row R, imports private intention, treats raw byte equality as authorship, or replaces the displayed provenance rows by a hidden host process has left the accepted carrier.

Proof. Project the accepted carrier. Its public-record coordinate is W, but its admission route is the displayed chain through O, S, M, R, Q with refusal, transport, provenance, and consumer rows F, T, V, H, C, P, N.

Apply Definition 912.2. The mismatch-accountability and accepted-route clauses force every authored-record read through M and R, while the refusal-stability clause records the boundary for bypass attempts.

No coordinate of the packet stores private intention, byte-level authorship, hidden checker state, or a host process trace. Therefore every public read is exhausted by the displayed rows listed above. □

Theorem 912.4 (Authored-record boundary vision handoff)**.** *The authored-record boundary realizes the inscription-event reading of chapter 9397 as a finite NameCert packet: prior record rows are supplied by* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *and* $\mathsf{CountableObservationSchedule}^{\uparrow}$*, finite naming is supplied by* $\mathsf{StreamName}^{\uparrow}$*, the closed observation side is bounded by* $\mathsf{ClosedObservationSystem}^{\uparrow}$*, the accepted-route budget is bounded by* $\mathsf{InscriptionAcceptanceBudget}^{\uparrow}$*, and the public authored record is exported only through* $M, R, W, F, T, Q, V, H, C, P, N$*.*

Proof. Start with the source vision. Its inscription event requires a prior-record surface, a mismatch or gap notice, an accepted route, and a public named record. These are exactly the O, S, M, R, W coordinates of Definition 912.1.

The sibling dependencies supply the finite inputs. Observer-history identity gives the public history row, countable observation schedules give finite prefix windows, StreamName gives the nameable stream surface, closed observation systems bound the prior-record side, and inscription-acceptance budgets bound the accepted route and downstream consumer side.

The non-escape theorem Definition 912.3 then supplies the handoff boundary. A public authored-record consumer receives only the displayed mismatch, accepted-route, record, refusal, transport, route, provenance, package, and local naming rows. □

Falsifiable prediction: A public authored-record read that bypasses the mismatch-notice row or accepted-route row refutes the carrier.

Independence witness: observerhistoryidentity, countableobservationschedule, streamname, closedobservationsystem, inscriptionacceptancebudget: $\mathsf{AuthoredRecordBoundary}^{\uparrow}$ is not bijective to any listed sibling because it carries the paired mismatch-notice and accepted-route rows together with public-record refusal and authored-record provenance; each sibling lacks at least one of those boundary rows.

The follow-up Lean TasteGate must provide $\mathsf{Nontrivial\ AuthoredRecordBoundary}^{\uparrow}$ and $\mathsf{FieldFaithful\ AuthoredRecor}$ instances before the carrier can be promoted beyond the paper-side obligation surface. The expected Lean target is BEDC.Derived.AuthoredRecordBoundaryUp.AuthoredRecordBoundaryTasteGate_single_carrier_

Closure status for $\mathsf{NameCert}_{\mathsf{AuthoredRecordBoundary}^{\uparrow}}$.

Constructive story: An $\mathsf{AuthoredRecordBoundary}^{\uparrow}$ packet is generated from prior observer-history and schedule rows, mismatch notice, accepted route, public record, refusal, componentwise transport, route replay, provenance, handoff, public consumer, package, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AuthoredRecordBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 912.1, Definition 912.2, Definition 912.3, and Definition 912.4 bind the finite authored-record boundary over observer-history, schedule, stream-name, closed-observation-system, and inscription-acceptance-budget rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{AuthoredRecordBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, private intention, raw byte authorship, hidden checker state, or authored-record reads that bypass the mismatch-notice and accepted-route rows.

Upgrade path: Obligation closure requires a checked TasteGate carrier together with Nontrivial and FieldFaithful instances for AuthoredRecordBoundary$^{\uparrow}$.

Chapter 913

A Concrete Naming Certificate for $\mathsf{BudgetedRealSealRoute}^{\uparrow}$

The $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ packet realizes the Real-completion budget route as one finite NameCert surface. It consumes the budget selector of chapter 782, the shared threshold row of chapter 560, the entrance budget of chapter 611, the sealed limit route of chapter 386, and the Real readback surface of chapter 38. Its observation rows remain tied to the finite stream, regular-rational, and dyadic sources of chapter 126, chapter 301, and chapter 291.

Definition 913.1 (Budgeted real seal route carrier)**.** *A* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (S, T, O, L, R, H, C, P, N)$$

with the following displayed rows:

1. *S is the* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *row selecting the finite observation budget used by the route;*
2. *T is the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold row that must be displayed before the completion route may expose a seal;*
3. *O is the* $\mathsf{RealObservationBudget}^{\uparrow}$ *entrance row tying the selected budget to the Real-facing observation surface;*
4. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route row that carries the sealed Cauchy-limit handoff;*
5. *R is the* $\mathsf{Real}^{\uparrow}$ *seal and readback row exposed only after S, T, O, L have been displayed;*
6. *H records componentwise* hsame *transports for the selector, threshold, entrance, limit-seal, Real readback, route, provenance, and local name rows;*
7. *C records the displayed* Cont *replay by which consumers read the selector, threshold, observation-budget entrance, limit seal, Real readback, provenance, and local name rows;*
8. *P is the* Pkg *provenance over* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$, $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}$ $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{BudgetedRealSealRoute}^{\uparrow}}$ *row.*

The classifier compares accepted packets only through $S, T, O, L, R, H, C, P, N$. It has no coordinate for quotient streams, host real equality, countable choice, an external limit selector, or an ambient completeness theorem.

Lean4 (definition) `BEDC.Derived.BudgetedRealSealRouteUp.BudgetedRealSealRouteUp`

Theorem 913.2 (Budgeted real seal route NameCert obligations)**.** *For the carrier of Definition 913.1, the local* $\mathsf{NameCert}_{\mathsf{BudgetedRealSealRoute}^{\uparrow}}$ *surface consists exactly of carrier admission for* $B = (S, T, O, L, R, H, C, P, N)$*, budget selector admission through* S*, TailMeet threshold admission through* T*, observation-budget entrance through* O*, CauchyLimitSeal route handoff through* L*, Real seal and readback exactness through* R*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.BudgetedRealSealRouteUp.BudgetedRealSealRouteCarrier namecert obligations`

Proof. Project the displayed packet $B = (S, T, O, L, R, H, C, P, N)$. Each obligation names one carrier coordinate or one structural route attached to that coordinate.

The budget route starts with S, enters the Real-facing observation surface through O, and then requires the threshold row T before the limit seal L can hand a read to R. Thus the Real seal read is tied to the same finite selector, threshold, observation-budget, and limit-seal rows.

The structural rows H, C, P, N transport, replay, identify, and name the same finite packet. Since the carrier contains no external completion coordinate, these rows exhaust the local NameCert surface. □

Theorem 913.3 (Budgeted real seal route selector admission)**.** *Every accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *packet must first expose the finite observation-budget selector row* S*. The rows* O*,* L*, and* R *are readable only as downstream route coordinates after* S *has been admitted through the selector surface of chapter 782.*

Proof. Project the carrier of Definition 913.1. Its packet is displayed as $B = (S, T, O, L, R, H, C, P, N)$, with S named as the $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ row selecting the finite observation budget used by the route.

Apply the NameCert obligation theorem. The same local surface lists budget selector admission through S before observation-budget entrance through O, CauchyLimitSeal handoff through L, and Real seal readback through R.

The sibling selector chapter supplies the admission surface for S. Since the carrier has no alternate selector coordinate, any accepted packet that reads O, L, or R must have passed through that displayed S row. □

Theorem 913.4 (Budgeted real seal route TailMeet threshold handoff)**.** *In every accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *packet, the TailMeet threshold row* T *sits between selector admission and the CauchyLimitSeal handoff. Thus a seal-facing read can reach* L *only through the route segment* $S \to T \to O \to L$*, with* T *supplied by the shared-threshold surface of chapter 560 and* L *consumed by the CauchyLimitSeal route of chapter 386.*

Proof. Read the displayed packet in Definition 913.1. The selector row S fixes the finite observation budget, while T is the regular Cauchy tail threshold that must be displayed before the completion route may expose a seal.

Use the aggregate obligation theorem to align these carrier rows with the local NameCert surface. It records selector admission through S, threshold admission through T, observation-budget entrance through O, and CauchyLimitSeal route handoff through L as obligations of the same packet.

The TailMeet sibling supplies the shared threshold interpretation of T, and the CauchyLimitSeal sibling supplies the handoff interpretation of L. Because no coordinate bypasses T, every seal-facing read from the accepted packet passes through the stated route segment. □

Theorem 913.5 (Budgeted real seal route Real-seal readback exactness)**.** *For every accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *packet, the Real seal row R is available only through the displayed route $S \to T \to O \to L \to R$ together with the structural rows H, C, P, N. No accepted packet exposes a quotient stream, host real equality, selected limit, countable-choice selector, or ambient completeness row as part of the readback.*

Proof. Project the carrier. The only Real-facing coordinate is R, and the carrier definition places it after the selector row S, threshold row T, observation-budget entrance row O, and CauchyLimitSeal route row L.

Apply the local NameCert obligation theorem. It identifies Real seal and readback exactness through R as one obligation of the same finite packet, while H, C, P, N supply transport, replay, provenance, and local naming for that displayed route.

Finally use the non-escape boundary of Definition 913.6. The objects excluded in the statement require coordinates absent from $B = (S, T, O, L, R, H, C, P, N)$, so the Real readback has exactly the displayed route and no hidden completion-facing row. □

Theorem 913.6 (Budgeted real seal route non-escape)**.** *Every accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *packet exports only the displayed rows*

$$S, T, O, L, R, H, C, P, N.$$

In particular, no accepted packet may expose the $\mathsf{Real}^{\uparrow}$ *seal row R without the TailMeet threshold row T, and no consumer may recover a quotient stream, host equality of real names, countable-choice selector, external limit, or ambient Real-completion principle from the packet.*

Proof. Inspect the carrier. The only Real-facing coordinate is R, and it is reached through the route rows S, T, O, L together with the structural rows H, C, P, N.

Apply the NameCert obligation theorem. It requires threshold admission through T and limit-seal handoff through L before Real readback exactness through R is available.

The excluded objects would require coordinates not present in the carrier. Because every export must factor through the displayed rows, the packet has no route to quotient streams, host equality, choice selectors, external limits, or an ambient completeness theorem. □

Theorem 913.7 (Budgeted real seal route TasteGate obligation)**.** *The Lean follow-up for* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *must provide* $\mathsf{Nontrivial\ BudgetedRealSealRoute}^{\uparrow}$ *and* $\mathsf{FieldFaithful\ BudgetedRealSealRoute}^{\uparrow}$ *in* `TasteGate.lean`*. These instances must preserve the selector row S, threshold row T, observation-budget row O, CauchyLimitSeal route row L, Real seal row R, transport row H, replay row C, provenance row P, and local naming row N.*

Proof. Use Definition 913.1 to read the nine displayed rows. A nontrivial gate witness must distinguish a packet by at least one of those finite coordinates rather than by an ambient real-completion object.

Field faithfulness is the same row preservation requirement. The gate-facing instance may transport and replay rows through H and C, but it cannot identify two packets after dropping S, T, O, L, R, P, or N.

Thus the TasteGate work is tied to the finite route packet itself, with no hidden completion principle or host equality field. □

Lean4 ✓ `BEDC.Derived.BudgetedRealSealRouteUp.BudgetedRealSealRouteTasteGate single carrier alignment`

Theorem 913.8 (Budgeted real seal route obligation closure)**.** *For the carrier of Definition 913.1, the obligation surface is complete at the displayed route packet*

$$B = (S, T, O, L, R, H, C, P, N).$$

It consists exactly of carrier admission, selector admission through S, TailMeet threshold admission through T, $\mathsf{RealObservationBudget}^{\uparrow}$ *entrance through O,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff through L,* $\mathsf{Real}^{\uparrow}$ *seal readback through R, componentwise* hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through P, and the local* $\mathsf{NameCert}_{\mathsf{BudgetedRealSealRoute}^{\uparrow}}$ *row N.*

Proof. Start from the NameCert obligation list in Definition 913.2. It projects precisely the carrier row, selector row, threshold row, observation-budget entrance, CauchyLimitSeal handoff, Real readback, transport row, continuation row, provenance row, and local naming row.

Use the selector admission, TailMeet handoff, and Real-seal readback theorems to read the dynamic route. Theorems 913.3, 913.4, and 913.5 force every accepted read through S, T, O, L, R in that order.

Finally apply non-escape, Definition 913.6. Since no hidden completion, quotient stream, host equality, selected limit, or choice coordinate is present, the listed rows exhaust the obligation surface. □

Theorem 913.9 (Budgeted real seal route ledger scope)**.** *Every obligation of an accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *packet is grounded in* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, *and the sibling chapter rows for* $\mathsf{FiniteObservationBudgetS}$ $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *No obligation is grounded in quotient streams, host equality of real names, countable choice, selected host limits, or an ambient completeness theorem.*

Proof. Read the provenance coordinate P in Definition 913.1. It lists the kernel support rows and the sibling concrete-instance sources consumed by the budgeted Real-seal route.

The obligation closure theorem identifies the complete local surface. Each listed route obligation is therefore one of the carrier rows S, T, O, L, R or one of the structural rows H, C, P, N, and those structural rows are exactly hsame, Cont, Pkg, and $\mathsf{NameCert}$ support over the same BHist packet.

The excluded sources are absent from both the carrier and the provenance list. By Definition 913.6, an accepted consumer cannot add them as ledger grounds after the packet has been admitted. □

Theorem 913.10 (Budgeted real seal route source exactness)**.** *For every accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *packet, the displayed source route*

$$S \longmapsto T \longmapsto O \longmapsto L \longmapsto R$$

is exact: selector admission, TailMeet threshold admission, RealObservationBudget entrance, CauchyLimitSeal handoff, and Real readback occur in that order and through those rows only. The structural rows H, C, P, N transport, replay, package, and name the route without adding another source.

Proof. First apply selector admission, Definition 913.3. The route must begin at the finite observation-budget selector row S.

Next apply the TailMeet threshold handoff, Definition 913.4. It places T between selector admission and the CauchyLimitSeal handoff and binds O as the RealObservationBudget entrance row.

Then apply Real-seal readback exactness, Definition 913.5. It identifies R as readable only after the displayed S, T, O, L route and confines H, C, P, N to transport, replay, provenance, and local naming. □

Theorem 913.11 (Budgeted real seal route public export)**.** *For every accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *packet*

$$B = (S, T, O, L, R, H, C, P, N),$$

the rows $S, T, O, L, R, H, C, P, N$ *export the public* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *interface consumed by finite Real-completion readers. The exported interface is exactly the selector row, TailMeet threshold, observation-budget entrance, CauchyLimitSeal handoff, Real seal readback, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{BudgetedRealSealRoute}^{\uparrow}}$ *row.*

Proof. Start with obligation closure, Definition 913.8. It identifies the complete displayed packet surface and leaves no row outside $S, T, O, L, R, H, C, P, N$.

Apply ledger scope, Definition 913.9. The public reader may use the same BHist, hsame, Cont, Pkg, and NameCert grounds already listed by the packet, but it does not receive an additional ground.

Finally apply source exactness, Definition 913.10. The readable Real route is $S \longmapsto T \longmapsto O \longmapsto L \longmapsto R$, and the remaining rows transport, replay, package, and name that route. This is exactly the public finite Real-completion interface. □

Theorem 913.12 (Budgeted real seal route public consumer exactness)**.** *Any public finite Real-completion consumer of an accepted* $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ *packet factors through the exported route* $S, T, O, L, R, H, C, P, N$*. No such consumer factors through a quotient stream, host real equality, countable choice, selected limit, ambient completeness theorem, or bridge row.*

Proof. Use the public export theorem to fix the consumer surface. Its rows are the only exported coordinates of the accepted packet, so a public consumer must read through $S, T, O, L, R, H, C, P, N$.

The source-exactness theorem then pins down the order of the Real route: selector admission, TailMeet threshold admission, RealObservationBudget entrance, CauchyLimitSeal handoff, and Real readback. The structural rows H, C, P, N carry transport, replay, provenance, and naming for that route.

The ledger-scope theorem excludes every proposed bypass. Quotient streams, host real equality, countable choice, selected limits, ambient completeness, and bridge rows are absent from the carrier and from the ledger grounds, so they cannot be routes for a public consumer of the displayed packet. □

Falsifiable prediction: If the displayed TailMeet threshold row T is absent, no accepted $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ packet can expose the $\mathsf{Real}^{\uparrow}$ seal row R.

Independence witness: finiteobservationbudgetselector, regularcauchytailmeet, real-observation-budget, cauchylimitseal, real: $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ combines a selector row, a TailMeet threshold, a Real observation-budget entrance, a CauchyLimitSeal handoff, and a Real seal/readback row; none of the named siblings is bijective to this combined route packet because each omits at least one required route coordinate.

Closure status for $\mathsf{NameCert}_{\mathsf{BudgetedRealSealRoute}^{\uparrow}}$**.**

Constructive story: A $\mathsf{BudgetedRealSealRoute}^{\uparrow}$ packet is generated from a finite observation-budget selector, a TailMeet threshold row, a Real observation-budget entrance, a CauchyLimitSeal route, a Real seal and readback row, componentwise transports, displayed replay routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{BudgetedRealSealRoute}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 913.1, Definition 913.2, Definition 913.8, Definition 913.9, Definition 913.10, Definition 913.11, Definition 913.12, Definition 913.6, and Definition 913.7 bind the selector row, TailMeet threshold, observation budget, CauchyLimitSeal handoff, Real readback row, hsame, Cont, Pkg, and local NameCert rows as one public finite Real-completion budget route.

Formal verification: FormalStatus(NameCert$_{\mathsf{BudgetedRealSealRoute}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.BudgetedRealSealRouteUp.BudgetedRealSealRouteTasteGate\_single\_carrier\_alignment`

Bridge status: none

Not claimed: This chapter does not close quotient streams, host real equality, countable choice, external limit selection, ambient Real completeness, or bridge checking for BudgetedRealSealRoute$^{\uparrow}$.

Upgrade path: No paper-side closure upgrade remains for the displayed selector, TailMeet threshold, observation budget, CauchyLimitSeal handoff, Real readback, hsame, Cont, Pkg, and NameCert route.

Chapter 914

A Concrete Naming Certificate for $\mathsf{CompactNetModulusSelector}^{\uparrow}$

The $\mathsf{CompactNetModulusSelector}^{\uparrow}$ interface is the concrete finite selector behind the compact-uniform-continuity construction of chapter 9237. It consumes the compact finite-net rows of chapter 60, the pointwise-modulus rows of chapter 59, the metric-distance rows of chapter 57, the positive rational order rows of chapter 37, and the finite lower-bound fold surface of chapter 619. Its output is the single finite packet a uniform-modulus consumer reads when a tolerance history is converted into a precision history by a compact net.

The selected precision row is assembled from sibling concrete packets: the finite cover and budget surface of chapter 648, the fold output of chapter 619, and the downstream precision packet read by chapter 369. The selector therefore records a horizontal dependency route from compact cover data through a finite lower-bound fold to the uniform-modulus consumer boundary.

Definition 914.1 (Compact net modulus selector carrier)**.** *A* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$$

with the following visible rows:

1. *X is the displayed compact metric source row, including the located finite-net coverage data for the requested tolerance history;*
2. *Y is the displayed target metric row whose distance comparisons are consumed after the pointwise-modulus reads;*
3. *E is the positive* $\mathsf{Rat}^{\uparrow}$ *tolerance history requested by the uniform-modulus consumer;*
4. *$\mathcal{P}$ is the nonempty finite* $\mathsf{ProbeBundle}$ *spine of compact-net centers;*
5. *C records bundled center histories and half-radius coverage rows for the source metric;*
6. *R records the positive* $\mathsf{Rat}^{\uparrow}$ *subordinate radius rows attached to the bundled centers;*
7. *M records the* $\mathsf{CFun}^{\uparrow}$ *pointwise-modulus rows at the centers of $\mathcal{P}$ for the tolerance history E;*
8. *F is the accepted* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *lower-bound row over $\mathcal{P}$ and R;*
9. *D is the selected positive precision history exported by the fold row F;*
10. *H records componentwise* hsame *transport for the metric, compact-net, tolerance, radius, pointwise-modulus, fold, precision, route, provenance, and naming rows;*

11. *Q records the displayed* Cont *routes through which compact, continuous, metric, rational, fold, and uniform-modulus consumers read the packet;*
12. *P is the* Pkg *provenance over* $\mathsf{Compact}^{\uparrow}$, $\mathsf{CFun}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{FiniteNetMinimumFold}^{\uparrow}$, ProbeBundle, BHist, hsame, Cont, *and local naming rows;*
13. *N is the local* $\mathsf{NameCert}_{\mathsf{CompactNetModulusSelector}^{\uparrow}}$ *row.*

The carrier exports only the compact-net input, pointwise-modulus radii, selected lower-bound fold row, tolerance-to-precision handoff, transport rows, continuation routes, package provenance, and local naming row. It has no coordinate for open-cover compactness, a host minimum, a choice-selected center, a quotient of point histories, or an external modulus function.

Theorem 914.2 (Compact net modulus selector NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CompactNetModulusSelector}}$ *surface consists exactly of five finite obligations:*

1. *carrier admission for the packet of Definition 914.1;*
2. *compact-net exactness, requiring $X, \mathcal{P}, C, R$ to display the located finite ε-net rows read from the compact source certificate;*
3. *pointwise-modulus exactness, requiring every row of M to be attached to a bundled center and to the displayed tolerance history E;*
4. *lower-bound fold exactness, requiring F to be the* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *row over the same $\mathcal{P}$ and R and requiring D to be its exported positive lower-bound history;*
5. *non-escape, requiring every consumer read of D to pass through $X, Y, E, \mathcal{P}, C, R, M, F, H, Q, P, N$ and forbidding open-cover compactness, host minima, choice-selected centers, quotient point equality, and external modulus functions.*

Proof. Carrier admission is projection from Definition 914.1. The packet displays the source and target metric rows, tolerance history, finite probe spine, compact coverage rows, subordinate radius rows, pointwise-modulus rows, fold row, selected precision, transports, routes, provenance, and local name.

Compact-net exactness reads the finite coverage surface from $X, \mathcal{P}, C, R$. The center and radius rows are not reconstructed by the selector; they are the displayed input rows supplied by the compact naming certificate.

Pointwise-modulus exactness then reads M only at bundled centers. Each local row is tied to the same tolerance history E and to the source and target metric rows already displayed in the carrier.

Lower-bound fold exactness reads F over the same probe spine and radius ledger. The selected precision D is accepted only as the positive lower-bound output of that finite fold.

The non-escape obligation is the carrier inventory together with the displayed routes. Since no excluded object is a coordinate of S, no local naming projection or continuation route can export one. □

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorNameCertObligations`

Theorem 914.3 (Compact net modulus selector fold soundness)**.** *Let*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$$

be an accepted $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier. If a source-distance read is certified below the selected precision history D, then the compact-continuous handoff for tolerance E factors through*

one bundled center of $\mathcal{P}$, the corresponding pointwise-modulus row in M, and the same lower-bound fold certificate F.

The handoff uses the selected row only as a finite $\mathsf{Rat}^{\uparrow}$ *lower bound below every displayed subordinate radius row in R.*

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorCarrier fold soundness`

Proof. Begin with the compact-net coordinate. The accepted carrier exposes $\mathcal{P}$ as a nonempty finite probe spine and C as the coverage row assigning each source-point history to a bundled center with a displayed half-radius comparison.

Read the selected precision through F. By the lower-bound fold exactness obligation, D is below every radius ledger in R through the $\mathsf{Rat}^{\uparrow}$ classifier and the stored transport rows in H.

Use the metric rows of X to route a source-distance read below D through the bundled center supplied by C. The comparison $D \leq R_p$ keeps the second point inside the local ball named by the same probe.

Finally apply the corresponding pointwise-modulus row of M and the target metric row Y. The output distance estimate is therefore read from $X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$, not from an external modulus selector. □

Theorem 914.4 (Compact net modulus selector non-escape)**.** *Every consumer read of an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet factors through the displayed compact-net input, pointwise-modulus radii, selected lower-bound fold row, transport rows, continuation routes, provenance, and local naming row of Definition 914.1. The packet exports no open-cover compactness principle, no host minimum over rationals, no choice-selected center, no quotient point equality, no sequential compactness argument, and no external modulus function.*

Proof. Project the accepted carrier. Its coordinates are exactly $X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$.

The NameCert obligations force compact reads through $X, \mathcal{P}, C, R$, pointwise-modulus reads through M, and selected-precision reads through F, D. The transport and continuation rows H, Q replay those same routes componentwise.

No coordinate remains from which a consumer could read open-cover compactness, host minima, choice-selected centers, quotient point equality, sequential compactness, or an external modulus function. Thus every public read stays within the finite selector packet. □

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorCarrier nonescape`

Theorem 914.5 (Compact net modulus selector independence boundary)**.** *The* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier is not bijective, as a NameCert obligation surface, to any one of its compact, continuous, metric, rational, finite-net-minimum-fold, or uniform-modulus siblings. It is the joint packet that stores the compact-net input, pointwise-modulus radii, selected lower-bound fold row, and tolerance-only handoff together.*

Proof. The compact sibling supplies finite-net coverage but has no pointwise-modulus row, no selected lower-bound fold output, and no target-metric handoff.

The continuous sibling supplies pointwise-modulus rows but has no compact probe spine and no finite lower-bound fold over a bundled radius ledger.

The metric and rational siblings supply distance and order readbacks only. They do not carry the compact coverage row, the bundled center ledger, or the tolerance-to-precision handoff.

The finite-net-minimum-fold sibling supplies the lower-bound fold but not the compact coverage input, pointwise-modulus rows, or target-metric consumer route. The uniform-modulus sibling

reads the resulting precision packet, while this selector records the compact-net and pointwise-modulus source rows that justify that precision. Hence no bijection preserves the listed NameCert obligations. □

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorCarrier independence boundary`

Theorem 914.6 (Compact net modulus selector TasteGate obligation)**.** *The later Lean TasteGate file for namespace* BEDC.Derived.CompactNetModulusSelectorUp *must provide* Nontrivial CompactNetModulusSelecto *and* FieldFaithful CompactNetModulusSelector$^{\uparrow}$ *instances for the same finite carrier. These instances must preserve the compact-net input, pointwise-modulus radius rows, selected lower-bound fold row, tolerance-to-precision handoff,* hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row.*

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorTasteGate single carrier alignment`

Proof. Nontriviality is witnessed by the dependency mix of the carrier. Removing the compact-net rows leaves no bundled source for the fold; removing the pointwise-modulus rows leaves no local continuity handoff; removing the fold row leaves no selected tolerance-only precision.

Field faithfulness records that these rows are preserved as one packet. A TasteGate consumer must therefore distinguish CompactNetModulusSelector$^{\uparrow}$ from its compact, continuous, metric, rational, finite-fold, and uniform-modulus siblings by the full coordinate surface $X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$. □

Theorem 914.7 (Compact net modulus selector root obligation triad)**.** *Every accepted* CompactNetModulusSelecto *packet exposes exactly the compact finite-net row $X, \mathcal{P}, C$, the pointwise-modulus radius rows R, M, the lower-bound fold row F, the selected precision D, and the structural rows H, Q, P, N of Definition 914.1. The root obligation surface is therefore the triad consisting of finite-net input, pointwise-radius input, and metric-selector output. It exports no open-cover compactness, host minimum, quotient point equality, choice-selected center, or external modulus function.*

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorRootObligationTriad`

Proof. Read the carrier definition. The finite-net part is visible in $X, \mathcal{P}, C$, the radius and pointwise-modulus part is visible in R, M, and the selected metric precision is visible through F, D.

Use Definition 914.2. Its compact-net exactness, pointwise-modulus exactness, lower-bound fold exactness, and non-escape clauses bind those rows to the same local naming surface.

The fold, non-escape, and TasteGate rows then exhaust the public consumer route. By Definition 914.3, Definition 914.4, and Definition 914.6, the output precision is read as one finite packet and not as any excluded compactness, minimum, quotient, center-selection, or external-modulus object. □

Theorem 914.8 (Compact net modulus selector pointwise radius route)**.** *For an accepted* CompactNetModulusSelec *carrier $S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$, each center radius is read through the* CFun$^{\uparrow}$ *pointwise-modulus row M, the positive* Rat$^{\uparrow}$ *radius row R, and the* Met$^{\uparrow}$ *source and target rows X, Y before the finite lower-bound fold row F can select the precision history D. No center radius is consumed as a free scalar, a host metric fact, or a hidden modulus choice.*

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorCarrier pointwise radius route`

Proof. Begin with the displayed center ledger. The probe spine $\mathcal{P}$ and coverage row C identify the bundled centers, while the radius row R records positive rational histories attached to those centers.

Next read the pointwise route. The row M supplies the $\mathsf{CFun}^{\uparrow}$ pointwise-modulus data at the bundled centers, and the rows X, Y supply the source and target $\mathsf{Met}^{\uparrow}$ distance reads through the continuation routes in Q.

Only after those rows are visible does the fold row F select D. The NameCert obligations and fold soundness force F to fold over the same $\mathcal{P}$ and R, so the selected precision cannot be read before the pointwise-radius and metric boundaries are in place. □

Theorem 914.9 (Compact net modulus selector metric consumer boundary)**.** *Downstream compact-uniform-continuity consumers of an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier receive a finite metric selector packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$$

and nothing outside that packet. The delivered boundary consists of compact finite-net input, pointwise-modulus radius rows, the finite lower-bound fold, selected precision, transport rows, continuation routes, provenance, and the local NameCert *row; it does not deliver open-cover compactness, a host minimum, quotient point equality, a choice-selected center, or an external modulus function.*

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorCarrier metric consumer boundary`

Proof. Project the consumer-facing packet from Definition 914.1. Its metric content is displayed by X, Y, R, D together with the finite center and fold rows $\mathcal{P}, C, M, F$.

Apply the NameCert and non-escape theorems. They require every consumer read to pass through the listed carrier rows, transports, routes, provenance, and local name.

The sibling inputs cited in the chapter introduction supply the compact, continuous, metric, rational, and fold readings, but this selector exports only their assembled finite packet. Thus the compact-uniform-continuity consumer receives a selector boundary rather than an open-cover compactness principle, host minimum, quotient equality, selected center, or external modulus. □

Theorem 914.10 (Compact net modulus selector consumer factorization)**.** *Every downstream* $\mathsf{UniformModulus}^{\uparrow}$ *consumer of an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$$

factors through compact finite-net input $X, \mathcal{P}, C$, pointwise continuous radius rows R, M, metric rows X, Y, the positive rational tolerance row E, finite lower-bound fold F, selected precision D, and structural rows H, Q, P, N. No such consumer may replace this route by open-cover compactness, a host minimum, quotient point equality, a choice-selected center, sequential compactness, or an external modulus function.

Proof. Begin with the local NameCert obligations. They attach the accepted selector to the displayed compact, continuous, metric, rational, fold, selected-precision, transport, route, provenance, and naming rows of S.

Use fold soundness and the pointwise radius route. The fold row F reads the finite probe spine and radius ledger, while each radius row reaches D only through the pointwise continuous row M, metric rows X, Y, and positive rational tolerance row E.

Now apply the metric consumer boundary. A downstream $\mathsf{UniformModulus}^{\uparrow}$ consumer receives the assembled selector packet, not a detached compactness theorem or detached modulus function.

Finally invoke non-escape. Since the carrier has no row for open-cover compactness, host minima, quotient point equality, choice-selected centers, sequential compactness, or external modulus functions, every consumer factors through the displayed rows $X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$. □

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorCarrier consumer factorization`

Theorem 914.11 (Compact net modulus selector request obligation surface)**.** *For an accepted carrier*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

the request obligation surface distinguishes precision requests by visible tolerance and finite-net rows. If two requests have tolerance rows E_0 and E_1 or finite-net rows $(\mathcal{P}_0, C_0, R_0)$ and $(\mathcal{P}_1, C_1, R_1)$ that are not identified by the displayed hsame *rows H, then their selected precision histories must be read as distinct request packets through Q, P, N. This obligation is part of the TasteGate surface of Definition 914.6.*

Proof. Project the carrier. The tolerance row E, finite probe spine $\mathcal{P}$, coverage row C, subordinate radius row R, selected precision row D, transports H, routes Q, provenance P, and local name N are visible coordinates of S.

Use the NameCert obligations and fold soundness. They require selected precision to be read through the same tolerance, compact-net, pointwise-modulus, and fold rows that produced it.

Apply the TasteGate obligation surface. Because TasteGate preservation must keep the displayed carrier rows, a change in visible tolerance or finite-net data that is not transported by H cannot be collapsed into the same request packet by Q, P, N. □

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorRequestObligationSurface`

Theorem 914.12 (Compact net modulus selector TasteGate nontriviality boundary)**.** *The TasteGate obligation for* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *is nontrivial on the displayed carrier $S = (X, Y, E, \mathcal{P}, C, R, M, F, I$ At least the request with tolerance row E_0 and finite-net row $(\mathcal{P}_0, C_0, R_0)$ and the request with tolerance row E_1 or finite-net row $(\mathcal{P}_1, C_1, R_1)$ must remain distinguishable whenever their visible rows are not connected by the displayed* hsame *transport H.*

Thus the carrier cannot be replaced by a one-element surface while preserving the compact-net input, pointwise-modulus rows, lower-bound fold row, selected precision history, Cont *routes,* Pkg *provenance, and local* NameCert *row named in Definition 914.6.*

Proof. Start from the request obligation surface. It ties a selected precision history to the tolerance row and finite-net rows that generated the request.

If two requests differ in visible tolerance or finite-net data and H does not identify those rows, the local classifier has no displayed transport that can merge them. The routes Q and provenance row P must therefore preserve the difference when the local name N exports the packet.

The TasteGate obligation requires preservation of the full coordinate surface. A one-element carrier would erase the displayed distinction between the two request packets, so it cannot satisfy the nontriviality boundary for this NameCert surface. □

Theorem 914.13 (Compact net modulus selector field-faithful row)**.** *Any consumer preserving all displayed rows of an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$$

preserves the exported precision history D together with its compact-net, pointwise-modulus, lower-bound fold, transport, route, provenance, and naming evidence. This field-faithful row is the paper-side obligation that allows future Lean instances for $\mathsf{Nontrivial\ CompactNetModulusSelector}^{\uparrow}$ *and* $\mathsf{FieldFaithful\ CompactNetModulusSelector}^{\uparrow}$ *to use the displayed request packets rather than a one-element carrier.*

Proof. Read D through the carrier and the fold soundness theorem. The selected precision is not a free output; it is the lower-bound fold result tied to $E, \mathcal{P}, C, R, M, F$.

Use non-escape and the TasteGate obligation. Every public consumer of the selected precision must preserve the transport rows H, continuation routes Q, package provenance P, and local name N along with the compact, continuous, metric, rational, and fold inputs.

Therefore a row-preserving consumer preserves the exported precision history as a field of the same packet. This is exactly the field-faithful surface needed for later Lean instances, without collapsing the NameCert carrier to one element. □

Theorem 914.14 (Compact net modulus selector source coverage)**.** *Let*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$$

be an accepted $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier. Every accepted selector packet reads the compact cover rows, finite-net fold row, continuous pointwise-modulus rows, source and target metric distance rows, positive* $\mathsf{Rat}^{\uparrow}$ *precision row, and* $\mathsf{UniformModulus}^{\uparrow}$ *output handoff through the displayed carrier coordinates of Definition 914.1. No source row is supplied by an ambient compactness principle, host minimum, quotient point equality, choice-selected center, or external modulus function.*

Proof. Start with the carrier inventory of Definition 914.1. The compact source is visible in $X, \mathcal{P}, C, R$, the continuous pointwise rows are visible in M, the metric rows are visible in X, Y, and the positive precision row is visible in D.

Apply Definition 914.3 and Definition 914.8. The fold reads only the displayed probe spine and radius ledger, while each center radius reaches the selected precision only through the pointwise-modulus and metric rows already stored in S.

Finally use Definition 914.9 and Definition 914.13. A downstream $\mathsf{UniformModulus}^{\uparrow}$ consumer receives the same field-preserving selector packet, so every public source read remains inside the listed carrier coordinates. □

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorSourceCoverage`

Theorem 914.15 (Compact net modulus selector center ledger exposure)**.** *Let*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$$

be an accepted $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier. Every accepted selector packet exposes the finite probe spine $\mathcal{P}$, center coverage row C, subordinate radius row R, and pointwise-modulus row M before the selected precision row D can be read. Thus the precision handoff is never read from a hidden center selector, a quotient point equality, an ambient compactness principle, or an external modulus function.*

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorCenterLedgerExposure`

Proof. Project S through Definition 914.1. The finite probe spine, center coverage row, subordinate radius row, and pointwise-modulus row are displayed coordinates of the same accepted packet as the selected precision row.

Apply Definition 914.2. Its compact-net exactness and pointwise-modulus exactness rows force C, R, M to be public before a consumer can reach the lower-bound fold or the selected precision.

Finally use Definition 914.8. Each center radius reaches the precision threshold only through the displayed pointwise-modulus and metric rows, so no hidden center choice, quotient equality, ambient compactness principle, or external modulus function can supply D. □

Theorem 914.16 (Compact net modulus selector fold radius exhaustion)**.** *For an accepted carrier*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

the fold row F consumes exactly the displayed finite probe spine $\mathcal{P}$ and subordinate radius ledger R before it exports the selected precision row D. The fold cannot read a host minimum, a choice-selected center, quotient point equality, or an external modulus as a second source for the selected radius budget.

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorCarrier fold radius exhaustion`

Proof. Start with Definition 914.3. It identifies the lower-bound fold as a read over the displayed probe spine and radius ledger.

Use Definition 914.21. The selected precision is exact only as the fold output over $\mathcal{P}$ and R, so a second host minimum or external rational infimum has no carrier coordinate.

Apply non-escape and field faithfulness, Definition 914.4 and Definition 914.13. Public consumers preserve the displayed fold route and cannot replace it by choice-selected center data, quotient point equality, or an external modulus. □

Theorem 914.17 (Compact net modulus selector UniformModulus handoff)**.** *Any downstream* $\mathsf{UniformModulus}^{\uparrow}$ *read of the selected precision row D from an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet passes through the already exposed compact row $X, \mathcal{P}, C, R$, continuous pointwise row M, metric rows X, Y, rational tolerance row E, fold row F, transport row H, continuation row Q, provenance row P, and local* NameCert *row N. The handoff therefore consumes the selector obligation surface rather than a parameter-only modulus promise.*

Proof. Begin with source coverage, Definition 914.14. It places every public source read for the uniform-modulus output inside the displayed selector coordinates.

Next use the metric consumer boundary, Definition 914.9. A metric-facing consumer must keep the compact, continuous, rational, and fold inputs attached to the selected threshold rather than reading the threshold as a detached number.

Finally apply the request obligation surface and public handoff rows, Definition 914.6 and Definition 914.22. They carry the same transport, continuation, provenance, and local naming rows into $\mathsf{UniformModulus}^{\uparrow}$, so the downstream read of D is exactly the exposed selector route. □

Theorem 914.18 (Compact net modulus selector metric threshold stability)**.** *For accepted* CompactNetModulusSel *carriers*

$$S_0 = (X_0, Y_0, E_0, \mathcal{P}_0, C_0, R_0, M_0, F_0, D_0, H_0, Q_0, P_0, N_0)$$

and

$$S_1 = (X_1, Y_1, E_1, \mathcal{P}_1, C_1, R_1, M_1, F_1, D_1, H_1, Q_1, P_1, N_1),$$

componentwise hsame *transport along the displayed carrier rows and replay through the displayed* Cont *routes preserves the chosen precision threshold. Thus any metric consumer that reads D_0 below the pointwise-radius fold route of S_0 reads the transported threshold D_1 through the corresponding fold, radius, pointwise-modulus, metric, provenance, and naming rows of S_1.*

Proof. Project both packets with Definition 914.1. The transport rows H_0, H_1 name the componentwise hsame identifications for compact-net data, tolerance histories, radius ledgers, pointwise-modulus rows, folds, selected precision histories, routes, provenance, and local names.

Use Definition 914.8 to identify the threshold route before the fold is read. The selected precision is available only after the corresponding radius and pointwise-modulus rows have been transported through the displayed metric rows.

Apply Definition 914.3. Since the fold row is over the transported probe spine and radius ledger, the selected threshold is preserved as the same finite lower-bound read rather than as a host minimum.

The consumer-facing statement follows from Definition 914.9 and Definition 914.13. Field-preserving consumers must keep the selected precision together with its compact, continuous, metric, rational, fold, route, provenance, and naming evidence. □

Theorem 914.19 (Compact net modulus selector ledger route exactness)**.** *Every public read of an accepted* CompactNetModulusSelector$^{\uparrow}$ *selector packet factors through the finite ledger rows*

$$X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$$

named by Definition 914.1. In particular, compact-cover reads, pointwise-modulus reads, metric-threshold reads, rational-precision reads, finite-fold reads, and UniformModulus$^{\uparrow}$ *handoff reads use the same displayed ledger route, with no host minimum and no ambient compactness principle.*

Proof. First read the ledger from Definition 914.1. The listed coordinates are the only rows exported by the selector packet.

Next apply Definition 914.3 and Definition 914.8. They force the selected precision to pass through the displayed compact-net, radius, pointwise-modulus, metric, and fold rows before any consumer can use it.

Finally apply Definition 914.9 and Definition 914.13. Public consumers preserve exactly the carrier fields they receive, so the route cannot be replaced by a host minimum, ambient compactness principle, quotient equality, selected-center choice, or external modulus. □

Theorem 914.20 (Compact net modulus selector compact-cover consumer lock)**.** *Let*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$$

be an accepted CompactNetModulusSelector$^{\uparrow}$ *carrier. Every compact-cover consumer of S reads the source metric row X, finite probe spine $\mathcal{P}$, coverage ledger C, and subordinate radius row R before it can read the pointwise-modulus row M, the fold row F, or the selected precision row D. The consumer imports no open-cover compactness principle and no choice-selected center.*

Proof. Project the carrier of Definition 914.1. The compact-cover portion is displayed by $X, \mathcal{P}, C, R$, while M, F, D are later rows in the same finite selector packet.

Use the NameCert obligations and fold soundness. Compact-net exactness binds cover reads to $X, \mathcal{P}, C, R$, and lower-bound fold exactness can only use the already displayed probe spine and radius ledger.

Finally apply non-escape and the TasteGate obligation row. Since neither open-cover compactness nor a choice-selected center is a carrier coordinate, no compact-cover consumer can import either object before the selector reaches M, F, D. □

Theorem 914.21 (Compact net modulus selector finite-fold budget exactness)**.** *For an accepted carrier*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

the selected precision history D is exact only as the $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *output F over the displayed probe spine $\mathcal{P}$ and radius ledger R. No host minimum, external rational infimum, hidden compactness choice, or quotient of center histories can serve as a second budget source for D.*

Proof. Read D through the carrier. The only row that exports a selected lower-bound history is F, and F is named as the fold over $\mathcal{P}$ and R.

Apply the NameCert lower-bound fold obligation together with Definition 914.3. These rows force the budget comparison to remain inside the displayed finite probe spine and radius ledger.

Use non-escape and TasteGate preservation to exclude alternate sources. A host minimum, external infimum, hidden center choice, or quotient center history is not preserved as a field of S, so it cannot be the exactness witness for D. □

Theorem 914.22 (Compact net modulus selector uniform-modulus public handoff)**.** *Every* $\mathsf{UniformModulus}^{\uparrow}$ *consumer downstream of an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet receives exactly the assembled finite packet*

$$X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N.$$

It receives the tolerance row, compact finite-net rows, pointwise-modulus rows, selected fold budget, transports, continuation routes, provenance, and local naming row, and it receives no open-cover compactness, host minimum, choice-selected center, quotient point equality, or external modulus function.

Proof. Start with the carrier and the NameCert obligations. They expose $X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$ as the full selector packet and bind cover, pointwise, fold, and route reads to those rows.

Use fold soundness to identify D as the precision handed to the uniform-modulus consumer. The selected precision is produced over the displayed probe spine and radius ledger, not by an external selector.

Finally apply non-escape and the TasteGate obligation row. Every downstream public handoff preserves the same finite fields, so excluded compactness, minimum, choice, quotient, and external-modulus objects are not delivered to $\mathsf{UniformModulus}^{\uparrow}$. □

Theorem 914.23 (Compact net modulus selector carrier admission scope)**.** *For an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

carrier admission exposes the compact source metric row X, target metric row Y, tolerance row E, finite probe bundle $\mathcal{P}$, coverage ledger C, subordinate radius row R, pointwise-modulus row M, lower-bound fold row F, selected precision row D, transport rows H, continuation routes Q, provenance P, and local naming row N as one finite surface. A consumer entering $\mathsf{UniformModulus}^{\uparrow}$

through this carrier must keep all public reads on those rows and cannot replace them by open-cover compactness, a host minimum, a choice-selected center, quotient point equality, or an external modulus function.

Proof. Project the carrier through Definition 914.2. Carrier admission and the local NameCert clauses expose exactly the displayed tuple S and bind the compact-net, pointwise-modulus, lower-bound, transport, route, provenance, and naming rows to the same packet.

Use Definition 914.12. The finite probe surface is admitted only as the displayed bundle with its local rows, so the carrier cannot be read as a hidden open-cover compactness principle or as a selected-center choice.

Finally apply Definition 914.13 and Definition 914.22. Field faithfulness preserves the tuple coordinates, and the public handoff delivers the same finite selector surface to $\mathsf{UniformModulus}^{\uparrow}$. □

Theorem 914.24 (Compact net modulus selector lower-bound route totality)**.** *For an accepted carrier*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

every public read of the selected precision row D is total only through the finite lower-bound fold row F over $\mathcal{P}$ and R, followed by the route rows H, Q, P, N that deliver the selector into $\mathsf{UniformModulus}^{\uparrow}$*. No consumer may read D as a host infimum, host minimum, ambient compactness witness, quotient of centers, or external modulus.*

Proof. Begin with Definition 914.21. It identifies D as the exact output of the displayed lower-bound fold F over the finite probe spine and subordinate radius ledger.

Apply Definition 914.2. The lower-bound clause is part of the same carrier admission surface, so the route from F to D must keep $X, Y, E, \mathcal{P}, C, R, M, H, Q, P, N$ attached.

The public handoff of Definition 914.22, together with the TasteGate boundary and field-faithful row of Definition 914.12 and Definition 914.13, then sends precisely that finite lower-bound route to $\mathsf{UniformModulus}^{\uparrow}$ and excludes every host or quotient substitute for D. □

Theorem 914.25 (Compact net modulus selector obligation envelope)**.** *The obligation envelope of an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$$

is the finite carrier-admission row, the TasteGate nontriviality surface for $\mathcal{P}$, the field-faithful row, the lower-bound fold route F, the selected precision row D, and the public consumer route into $\mathsf{UniformModulus}^{\uparrow}$*. This envelope is exactly the surface available to downstream consumers, and it contains no open-cover compactness, sequential compactness, host minimum, choice-selected center, quotient point equality, or external modulus function.*

Proof. First read the NameCert obligations through Definition 914.2. They collect carrier admission, compact-net exactness, pointwise-modulus exactness, lower-bound fold exactness, transport stability, and non-escape into one local packet.

Next use Definition 914.21. This pins the selected precision row D to the finite fold row F over $\mathcal{P}$ and R rather than to any ambient minimum principle.

Finally combine Definition 914.22, Definition 914.12, and Definition 914.13. The handoff exports the same tuple to $\mathsf{UniformModulus}^{\uparrow}$, TasteGate keeps the probe surface finite and nontrivial, and field faithfulness prevents a consumer from replacing the displayed rows by hidden compactness, choice, quotient, or external-modulus data. □

Theorem 914.26 (Compact net modulus selector route primitive scope)**.** *Every accepted* CompactNetModulusSelec *packet binds the* $\mathsf{Compact}^{\uparrow}$ *finite-net rows,* $\mathsf{CFun}^{\uparrow}$ *pointwise-modulus rows,* $\mathsf{Met}^{\uparrow}$ *distance rows,* $\mathsf{Rat}^{\uparrow}$ *positive precision rows,* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *lower-bound rows,* ProbeBundle *rows,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *as its complete primitive scope. The selector supplies no open-cover compactness, sequential compactness, host minima, choice-selected centers, quotient point equality, or external modulus functions.*

Proof. First project the carrier and NameCert obligations, Definition 914.1 and Definition 914.2. They display exactly the compact-net, metric, positive rational, probe, pointwise-modulus, lower-bound fold, transport, continuation, provenance, and local naming rows.

Next use the pointwise-radius route and finite-fold budget exactness, Definition 914.8 and Definition 914.21. These routes force every radius and selected precision read through $X, Y, E, \mathcal{P}, C, R, M, F, D$ before a public handoff can occur.

Finally apply the uniform-modulus public handoff and obligation envelope, Definition 914.22 and Definition 914.25. The downstream consumer receives the same finite selector packet, so any open-cover, sequential compactness, host-minimum, choice, quotient, or external-modulus object would require a primitive coordinate absent from the accepted carrier. □

Theorem 914.27 (Compact net modulus selector request route determinacy)**.** *For an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

the visible tolerance row E and finite-net rows $X, \mathcal{P}, C, R$ determine the request packet read by the selector. A public request consumer may continue through M, F, D, H, Q, P, N, but it cannot replace the request by open-cover compactness, selected centers, host metric data, quotient point equality, or an external modulus function.

Proof. Begin with the request obligation surface, Definition 914.11. It binds the tolerance, finite-net, metric, and pointwise-radius rows to the same selector request before the selected precision can be read.

Next apply Definition 914.2. The carrier admission and local naming clauses keep E and $X, \mathcal{P}, C, R$ inside one accepted packet with the pointwise-modulus and fold rows.

Finally use Definition 914.13 and Definition 914.22. Field faithfulness preserves the displayed rows, and the handoff sends exactly that request packet to $\mathsf{UniformModulus}^{\uparrow}$ without adding host compactness, selected centers, quotient equality, or an external modulus. □

Theorem 914.28 (Compact net modulus selector fold consumer exhaustion)**.** *Every public read of the selected precision row D is exhausted by the finite fold row F over the same* ProbeBundle $\mathcal{P}$ *and radius ledger R. The read retains the compact, continuous, metric, rational, transport, route, provenance, and local naming rows of S, and it exports no host minimum, selected-center choice, quotient point equality, or open-cover compactness witness.*

Proof. Start from Definition 914.21. It identifies D as the output of the displayed fold F over $\mathcal{P}$ and R, not as a host minimum or external rational infimum.

Use Definition 914.3 together with Definition 914.8. The fold reads only the bundled probes and subordinate radii supplied by the same metric and pointwise-modulus rows.

Apply Definition 914.2 and Definition 914.13. These keep the fold, selected precision, transports, routes, provenance, and local naming rows attached to the carrier, so no unlisted center, quotient equality, or host minimum can supply D. □

Theorem 914.29 (Compact net modulus selector uniform request factorization)**.** *Every* $\mathsf{UniformModulus}^{\uparrow}$ *consumer of an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet factors through the compact, continuous, metric,* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows displayed by Definition 914.26. The factorization exports the selected request and precision boundary only through those rows.*

Proof. First combine Definition 914.27 with Definition 914.28. The request is fixed by the tolerance and finite-net rows, and the selected precision is fixed by the finite fold over the same probe bundle and radius ledger.

Next apply Definition 914.2. The carrier, compact-net, pointwise-modulus, lower-bound, transport, route, provenance, and local naming clauses keep these request rows in one finite packet.

Finally use Definition 914.22 and Definition 914.26. They pass the same packet to $\mathsf{UniformModulus}^{\uparrow}$ and identify all public primitive rows, so no open-cover compactness, host metric primitive, selected center, quotient point equality, or external modulus remains available. □

Theorem 914.30 (Compact net modulus selector selected precision exactness)**.** *For an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *carrier*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

a downstream $\mathsf{UniformModulus}^{\uparrow}$ *consumer reads the selected precision row* D *if and only if the same visible tolerance row* E*, finite probe spine* $\mathcal{P}$*, coverage row* C*, subordinate radius rows* R*, pointwise-modulus rows* M*, fold row* F*, transports* H*, routes* Q*, provenance* P*, and local* $\mathsf{NameCert}$ *row* N *are displayed. The read is therefore completely determined by those visible rows and exports no open-cover compactness, host minimum, quotient point equality, choice-selected center, or external modulus function.*

Proof. For necessity, start with Definition 914.29. Any downstream $\mathsf{UniformModulus}^{\uparrow}$ consumer must factor through the displayed selector route before it can read D.

Apply Definition 914.2. The carrier, compact-net, pointwise-modulus, lower-bound fold, transport, route, provenance, and local naming clauses keep $E, \mathcal{P}, C, R, M, F, H, Q, P, N$ attached to the same accepted packet.

For sufficiency, use Definition 914.3. Once the finite probe spine, radius ledger, pointwise-modulus rows, and fold row are displayed inside the same packet, D is the selected finite lower-bound read rather than a host minimum.

Finally apply Definition 914.19 and Definition 914.29. The ledger route and uniform request factorization carry exactly that visible packet to the downstream consumer, so open-cover compactness, host minima, quotient point equality, choice-selected centers, and external modulus functions have no coordinate from which to determine D. □

Theorem 914.31 (CompactNetModulusSelector finite-net budget route)**.** *For an accepted* $\mathsf{CompactNetModulusSel}$ *packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

every modulus read factors through the $\mathsf{Compact}^{\uparrow}$ *finite-net rows* $X, \mathcal{P}, C, R$*, the* $\mathsf{Met}^{\uparrow}$ *distance rows* X, Y*, the* $\mathsf{Rat}^{\uparrow}$ *tolerance row* E*, and the* $\mathsf{UniformModulus}^{\uparrow}$ *request rows before exposing the selected net budget* D*. The route exports no open-cover compactness, choice-selected point, host real metric, quotient center equality, or external modulus function.*

Proof. Project the carrier through Definition 914.23. It exposes the compact finite-net rows, metric rows, rational tolerance, pointwise-modulus row, lower-bound fold, selected precision, transport, route, provenance, and local naming rows as one finite surface.

Use the pointwise-radius and lower-bound routes, Definition 914.8 and Definition 914.24. They force the selected budget to pass through the displayed finite probe spine, subordinate radii, and lower-bound fold before D is readable.

Apply the uniform-modulus public handoff and route primitive scope, Definition 914.22 and Definition 914.26. These rows deliver the same finite selector packet into $\mathsf{UniformModulus}^{\uparrow}$ and exclude open-cover compactness, host metric supply, selected centers, quotient point equality, and external modulus functions. □

Theorem 914.32 (CompactNetModulusSelector primitive-scope closure)**.** *For every accepted* CompactNetModulus *packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

the public selector route is scoped exactly by the $\mathsf{Compact}^{\uparrow}$, $\mathsf{CFun}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{FiniteNetMinimumFold}^{\uparrow}$, ProbeBundle, BHist, hsame, Cont, Pkg, *and* NameCert *rows displayed in Definition 914.1. Every* $\mathsf{UniformModulus}^{\uparrow}$ *read of D factors through those rows, and the exported surface contains no open-cover compactness, sequential compactness, host minimum, selected center, quotient point equality, or external modulus function.*

Proof. Project the accepted packet through Definition 914.1. This reads $X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$ as the whole finite selector carrier and leaves no additional compactness or modulus coordinate.

Apply Definition 914.26. It identifies the primitive public route as the displayed compact, continuous, metric, rational, finite-fold, probe-bundle, history, transport, continuation, provenance, and local naming rows.

Use Definition 914.31 to bind the selected budget D to the compact finite-net rows, pointwise-radius route, and finite lower-bound fold before any uniform-modulus consumer can read it.

Finally combine Definition 914.22 with Definition 914.25. The downstream $\mathsf{UniformModulus}^{\uparrow}$ handoff therefore sees only the finite selector route and not open-cover compactness, sequential compactness, a host minimum, a selected center, quotient point equality, or an external modulus function. □

Theorem 914.33 (CompactNetModulusSelector center-radius monotonicity)**.** *For every accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

the selected precision row D stays below every displayed center radius in the finite radius ledger R as read through the finite fold row F. The comparison is a finite selector comparison inside the same packet and not an open-cover compactness argument, host minimum, quotient point equality, choice-selected center, or external modulus computation.

Proof. Start with fold soundness and lower-bound route totality, Definition 914.3 and Definition 914.24. They identify D as the lower-bound fold output read from the same nonempty probe spine and displayed radius ledger.

Next apply finite-fold budget exactness, Definition 914.21. The comparison of D with each displayed center radius is made through F over $\mathcal{P}$ and R, so no ambient minimum or quotient equality can supply a different bound.

Finally use primitive-scope closure from Definition 914.32. The public selector route contains only $X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$, which keeps the center-radius monotonicity inside the finite packet. □

Theorem 914.34 (CompactNetModulusSelector fold-output positive)**.** *For every accepted* CompactNetModulusSel *packet $S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$, the fold output D remains a positive* $\mathsf{Rat}^{\uparrow}$ *precision history. Its positivity is read through the same nonempty finite probe spine $\mathcal{P}$ and radius ledger R that feed the fold row F, and not through a host minimum, open-cover compactness principle, selected center, quotient point equality, or external modulus.*

Proof. Begin with the accepted carrier and fold soundness, Definition 914.1 and Definition 914.3. The carrier stores a positive tolerance history and positive subordinate radius rows, while fold soundness reads the output through the displayed finite fold.

Use lower-bound route totality and finite-fold budget exactness, Definition 914.24 and Definition 914.21. These results keep D on the same nonempty probe spine and radius ledger, so the fold output is a $\mathsf{Rat}^{\uparrow}$ precision history rather than a host-selected real number.

Finally apply center-radius monotonicity from Definition 914.33. Since D is read below the displayed positive radii through F, positivity remains part of the finite selector packet and cannot be replaced by an external compactness or modulus object. □

Theorem 914.35 (CompactNetModulusSelector uniform-consumer precision lock)**.** *Every downstream compact-uniform-continuity consumer of an accepted* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet receives only the finite selector route*

$$X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N.$$

The consumer cannot replace the selected precision row by open-cover compactness, a host minimum, quotient point equality, a choice-selected center, or an external modulus function.

Proof. Start with the uniform-modulus public handoff, Definition 914.22. It sends the downstream $\mathsf{UniformModulus}^{\uparrow}$ consumer the same finite selector packet rather than an ambient compactness or modulus object.

Next combine finite-net budget routing with fold-output positivity, Definition 914.31 and Definition 914.34. The selected precision row is a positive $\mathsf{Rat}^{\uparrow}$ fold output tied to $X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$.

Finally apply primitive-scope closure from Definition 914.32. The primitive route exposes no open-cover compactness, host minimum, quotient point equality, selected-center oracle, or external modulus coordinate, so the uniform consumer is locked to the displayed precision row D. □

Definition 914.36 (Compact net modulus selector root readiness)**.** *The root-readiness packet for* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *is the finite tuple*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$$

read with the following public roles:

1. *$X, \mathcal{P}, C$ are the compact-net source rows from* $\mathsf{Compact}^{\uparrow}$*, including the finite center spine and its coverage rows;*
2. *R, M are the subordinate positive* $\mathsf{Rat}^{\uparrow}$ *radius rows and the* $\mathsf{CFun}^{\uparrow}$ *pointwise-modulus rows attached to the same centers and tolerance row E;*
3. *F, D are the* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$ *fold output and the selected positive precision row exported from that fold;*

4. *H, Q are the displayed* hsame *transport rows and* Cont *consumer routes through the metric, compact, continuous, rational, fold, and uniform-modulus interfaces;*

5. *P, N are the package provenance and the local* $\mathsf{NameCert}_{\mathsf{CompactNetModulusSelector}^{\uparrow}}$ *row.*

Root readiness means that these rows are sufficient for downstream uniform-modulus consumers to read the selector as a finite compact-net handoff: compact coverage is exposed through $X, \mathcal{P}, C$, pointwise-radius control through R, M, finite lower-bound selection through F, D, and all public transport through H, Q, P, N.

Theorem 914.37 (Compact net modulus selector finite-net exposure)**.** *For every accepted root-ready* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

each selected precision row exposes a nonempty finite ProbeBundle *spine $\mathcal{P}$, the compact coverage rows C over the source row X, and the subordinate positive* $\mathsf{Rat}^{\uparrow}$ *radius rows R used by the finite fold. The exposure is public only through the compact-net source rows, the pointwise-modulus rows M, and the selected fold rows F, D of Definition 914.36.*

Proof. Read the root-ready tuple through Definition 914.1 and Definition 914.36. The compact part of the packet is exactly $X, \mathcal{P}, C, R$, with $\mathcal{P}$ named as the nonempty finite probe spine and C naming the coverage rows over the source metric.

Use Definition 914.2. Its compact-net exactness clause keeps $X, \mathcal{P}, C, R$ attached to the local NameCert row, while its pointwise-modulus clause ties each row of M to the same centers and tolerance history E.

Finally apply Definition 914.3. The selected precision row D is read through the finite fold F over the same probe spine and radius ledger, so the downstream consumer sees finite compact-net exposure rather than an ambient compactness principle. □

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorFiniteNetExposure`

Theorem 914.38 (Compact net modulus selector totally bounded handoff)**.** *Every downstream* $\mathsf{TotallyBounded}^{\uparrow}$ *or* $\mathsf{UniformModulus}^{\uparrow}$ *consumer of a root-ready* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet receives the compact finite-net rows only through the displayed fold row F and selected precision row D. The handoff preserves the source rows $X, \mathcal{P}, C$, the subordinate radius rows R, the pointwise-modulus rows M, and the routes H, Q, P, N, but it does not supply any separate compactness witness or external modulus function.*

Proof. Start with the root obligation triad, Definition 914.7. It identifies the public surface as finite-net input, pointwise-radius input, and metric-selector output on the same carrier.

Next use Definition 914.31 and Definition 914.32. These theorems route every modulus read through the compact, continuous, metric, rational, finite-fold, transport, continuation, provenance, and local naming rows displayed by the selector.

The sibling chapters supply the source interfaces: chapter 60 supplies compact finite-net rows, chapter 59 supplies pointwise-modulus rows, chapter 57 supplies metric reads, chapter 37 supplies positive rational order rows, chapter 619 supplies the finite fold, and chapter 369 reads the selected precision boundary. The selector hands them forward only as F, D together with the displayed route rows. □

Theorem 914.39 (Compact net modulus selector consumer non-escape)**.** *No downstream consumer of a root-ready* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet can read open-cover compactness, a host minimum, a choice-selected center, quotient point equality, sequential compactness, or an external modulus function. Every consumer read factors through*

$$X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$$

as displayed in Definition 914.36.

Proof. Project the packet through Definition 914.36. Its public coordinates are the compact-net rows, pointwise-radius rows, finite fold, selected precision, transport rows, continuation routes, provenance, and local name.

Apply Definition 914.4 and Definition 914.9. They already forbid consumer reads outside the displayed selector packet and identify the delivered boundary as a finite metric selector packet.

Finally use Definition 914.30 and Definition 914.32. The selected precision is determined by the visible finite-net, radius, pointwise-modulus, fold, transport, route, provenance, and naming rows, leaving no coordinate for open-cover compactness, host minima, choice-selected centers, quotient point equality, sequential compactness, or external modulus functions. □

Theorem 914.40 (Compact net modulus selector cover-radius synchronization)**.** *For every accepted root-ready* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

the compact cover rows C and the positive $\mathsf{Rat}^{\uparrow}$ *radius rows R are synchronized over the same finite probe spine $\mathcal{P}$. A cover read through C cannot be consumed without the corresponding positive radius ledger R, and a radius read through R cannot be consumed without the compact-net cover rows C over the source metric row X.*

Proof. Project S through Definition 914.36. The displayed carrier stores $X, \mathcal{P}, C, R$ as the compact finite-net input and makes R the subordinate positive-radius ledger attached to that same probe spine.

Use Definition 914.37. It exposes the compact coverage rows and the positive radius rows together, with no separate coordinate for a detached cover row or a detached radius row.

Finally apply Definition 914.39. Since every downstream read factors through the displayed tuple, a consumer cannot separate C from R while remaining inside the accepted selector surface. □

Theorem 914.41 (Compact net modulus selector fold-output positivity)**.** *For every accepted root-ready* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

the fold output row D is a positive precision row only through the positive $\mathsf{Rat}^{\uparrow}$ *radius ledger R, the pointwise-modulus rows M, and the finite lower-bound fold row F. No consumer may treat D as a host minimum, a nonpositive bound, or a choice-selected external modulus value.*

Proof. Read D through Definition 914.3. The finite fold row F computes the selected lower-bound precision from the positive radius and pointwise-modulus rows already present in the carrier.

Use Definition 914.30. It fixes the precision row by the visible compact-net, radius, pointwise-modulus, fold, transport, route, provenance, and naming rows, so positivity is inherited from the $\mathsf{Rat}^{\uparrow}$ radius ledger and the admitted fold route.

Definition 914.39 excludes host minima, choice-selected centers, quotient point equality, and external modulus functions. Thus the only public interpretation of D is the positive fold output carried by R, M, F inside the displayed packet. □

Theorem 914.42 (Compact net modulus selector request-to-precision factorization)**.** *Every tolerance request E accepted by a root-ready* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet factors to the selected precision row D through*

$$X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N.$$

The handoff first reads compact coverage through $X, \mathcal{P}, C$, then positive subordinate radii through R, then pointwise-modulus rows through M, then the finite fold output through F, D, and finally the transport, route, provenance, and local certificate rows H, Q, P, N.

Proof. Begin with Definition 914.36. The tolerance row E is displayed with the source and target metric rows, the compact finite-net input, the pointwise-modulus rows, and the selected fold output.

Apply Definition 914.40. It forces every compact cover read to carry the matching positive radius ledger, so the request cannot bypass $X, \mathcal{P}, C, R$.

Next apply Definition 914.41. The fold output D is admitted only through R, M, F, and therefore the tolerance request reaches a precision row only through the finite selector fold.

Finally use Definition 914.39. The displayed transport, route, provenance, and local naming rows H, Q, P, N are the only remaining public coordinates, so the request-to-precision handoff factors through exactly the root-ready carrier. □

Theorem 914.43 (Compact net modulus selector fold-consumer coherence)**.** *Every fold consumer of a root-ready* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet that preserves the selected precision row D also preserves the same* ProbeBundle *spine $\mathcal{P}$ and positive radius ledger R. Consequently the fold handoff cannot be reinterpreted as a host minimum, quotient center equality, or external modulus function.*

Proof. Project the consumer read through Definition 914.1. The only fold data in the carrier are the finite fold row F, the selected precision row D, the bundled centers $\mathcal{P}$, and the radius ledger R.

Now use Definition 914.36 and Definition 914.37. They identify D as the fold-selected precision attached to the same finite probe spine and subordinate positive radius rows.

Apply Definition 914.38. Any consumer preserving D along the finite fold route receives the compact finite-net rows through F, D and therefore keeps $\mathcal{P}$ and R in the same public ledger.

Definition 914.39 excludes every alternate read of a host minimum, quotient center equality, and external modulus function. The preserved selected precision is therefore coherent only with the original probe bundle and radius ledger. □

Theorem 914.44 (Compact net modulus selector root-budget admission)**.** *For every accepted root-ready* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

the selector budget D is admitted for downstream use only with the displayed finite probe spine $\mathcal{P}$, compact coverage row C, positive radius rows R, pointwise-modulus rows M, finite fold row F, selected precision row D, transport rows H, route rows Q, provenance row P, and local NameCert *row N. Thus the budget is a finite root-ready handoff and not a parameter-only compactness promise.*

Lean4 ✓ `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorRootBudgetAdmission`

Proof. Read the packet through Definition 914.1 and Definition 914.36. These two displays enumerate exactly the root rows $X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$ and assign the budget role to the selected precision row D.

Apply Definition 914.37. It binds D to the nonempty finite probe spine, compact coverage rows, subordinate positive radius ledger, pointwise-modulus rows, and selected fold output.

Use Definition 914.38 to pass the same rows to the downstream compact-net and uniform-modulus consumers. The handoff keeps the finite fold and selected precision visible together with the transport, route, provenance, and local naming rows.

Finally invoke Definition 914.39. Since no consumer can leave the displayed packet, a budget read without any one of the root rows is not an admitted selector read. □

Theorem 914.45 (Compact net modulus selector uniform-modulus entry exhaustion)**.** *Every* $\mathsf{UniformModulus}^{\uparrow}$ *entry through a root-ready* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet exhausts the visible route through* $\mathsf{Compact}^{\uparrow}$*,* $\mathsf{CFun}^{\uparrow}$*,* $\mathsf{Met}^{\uparrow}$*,* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{FiniteNetMinimumFold}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. No additional entry point supplies compactness, continuity, metric control, rational positivity, finite selection, history transport, package provenance, or local naming data.*

Proof. Begin with Definition 914.1. It lists the compact source rows, continuous pointwise-modulus rows, metric rows, rational tolerance and radius rows, finite fold data, history transport, continuation route, package provenance, and local name certificate.

Definition 914.36 turns that carrier list into the root-ready packet. The displayed roles specify how $X, \mathcal{P}, C, R, M, F, D, H, Q, P, N$ become the finite selector handoff.

Use Definition 914.37 and Definition 914.38. Together they force the selected precision read through the compact finite-net spine, pointwise-modulus rows, positive rational ledger, finite fold, and route rows before it reaches $\mathsf{UniformModulus}^{\uparrow}$.

Finally apply Definition 914.39. Since every downstream read factors through the root-ready tuple, the visible route is exhausted and no separate entry point can supply the omitted compactness, continuity, metric, rational, fold, history, transport, provenance, or naming data. □

Theorem 914.46 (Compact net modulus selector downstream coverage)**.** *For every accepted root-ready* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet*

$$S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N),$$

every accepted local consumer of the selected budget D is exhausted by the finite alternatives already displayed in the selector file: the compact coverage rows $X, \mathcal{P}, C$, the positive radius ledger R, the pointwise-modulus rows M, the finite fold and selected precision rows F, D, and the transport, route, provenance, and local naming rows H, Q, P, N. Any requested alternative that asks for open-cover compactness, sequential compactness, a host minimum, a choice-selected center, quotient point equality, a detached compactness witness, or an external modulus function is not an accepted local consumer of the $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *packet.*

Proof. Start with the root budget admission of Definition 914.44. It admits the selected budget D for downstream use only together with the displayed finite probe spine $\mathcal{P}$, compact coverage row C, positive radius rows R, pointwise-modulus rows M, finite fold row F, selected precision row D, transport rows H, route rows Q, provenance row P, and local $\mathsf{NameCert}$ row N. Thus an accepted consumer cannot read D as a parameter-only modulus promise.

Next use Definition 914.45. A $\mathsf{UniformModulus}^{\uparrow}$ entry through the same root-ready packet exhausts the visible route through $\mathsf{Compact}^{\uparrow}$, $\mathsf{CFun}^{\uparrow}$, $\mathsf{Met}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{FiniteNetMinimumFold}^{\uparrow}$, BHist,

hsame, Cont, Pkg, and NameCert. These are precisely the typed interfaces carried by the displayed rows of S: compact coverage by $X, \mathcal{P}, C$, rational radius and tolerance control by E, R, D, pointwise continuity by M, finite selection by F, and structural delivery by H, Q, P, N.

Combine the two readings. The admission theorem fixes which root rows may accompany the budget, while the exhaustion theorem fixes which downstream entry points can consume those rows. Therefore every accepted local consumer is already one of the enumerated coverage, ledger, fold, route, provenance, or naming reads in the selected file.

Finally apply the exclusion clauses in both the root admission and entry exhaustion statements. Since no coordinate of S supplies open-cover compactness, sequential compactness, host minima, choice-selected centers, quotient point equality, detached compactness witnesses, or external modulus functions, any request for one of those alternatives fails to remain inside the accepted CompactNetModulusSelector$^{\uparrow}$ packet. □

Theorem 914.47 (Compact net modulus selector public modulus handoff)**.** *Every public* UniformModulus$^{\uparrow}$ *read from an accepted* CompactNetModulusSelector$^{\uparrow}$ *packet factors through the finite selector rows*

$$X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N$$

of Definition 914.1. The public handoff exposes the compact metric source through CompactMetric$^{\uparrow}$ *and* Met$^{\uparrow}$ *rows, the selected precision through* UniformModulus$^{\uparrow}$ *and* FiniteNetMinimumFold$^{\uparrow}$ *rows, the dyadic and regular request boundary through* DyadicRatCore$^{\uparrow}$*,* StreamName$^{\uparrow}$*, and* RegSeqRat$^{\uparrow}$ *rows, and the structural boundary through* hsame*,* Cont*,* Pkg*, and* NameCert *rows. It is grounded at the TasteGate surface of Definition 914.6 and exports no open-cover compactness, host minimum, selected center, quotient point equality, sequential compactness, or external modulus function.*

Proof. Project the accepted selector carrier. The rows $X, Y, E, \mathcal{P}, C, R, M, F, D$ are the only compact-net, metric, tolerance, pointwise-modulus, fold, and selected-precision data available to a public consumer.

Apply Definition 914.10. It forces every downstream UniformModulus$^{\uparrow}$ read through the compact finite-net input, pointwise continuous radius rows, metric rows, rational tolerance row, lower-bound fold, selected precision, and structural rows of the same packet.

Apply Definition 914.42 and Definition 914.43. These results bind the tolerance request to the finite probe spine, positive radius ledger, pointwise-modulus rows, fold output, and selected precision before any public modulus read is exported.

The TasteGate alignment cited in the statement preserves the same single carrier as a field-faithful public packet. Since no excluded object appears among the carrier rows or the cited handoff theorems, the public surface is exactly the displayed selector-to-modulus route. □

Theorem 914.48 (Compact net modulus selector bridge envelope)**.** *The public compact-net selector handoff of Definition 914.47 is the paper-side bridge envelope from compact finite-net rows, pointwise-modulus rows, lower-bound fold rows, selected precision, and* UniformModulus$^{\uparrow}$ *consumer rows to the standard acceptance schema. For every accepted* CompactNetModulusSelector$^{\uparrow}$ *packet* $S = (X, Y, E, \mathcal{P}, C, R, M, F, D, H, Q, P, N)$*, the envelope reads the compact source rows* $X, \mathcal{P}, C, R$*, pointwise rows* M*, fold row* F*, selected precision* D*, and consumer rows* H, Q, P, N *in that order, and exports no open-cover compactness, host minimum, selected center outside* $\mathcal{P}$*, quotient point equality, sequential compactness, or external modulus function.*

Proof. Start from the accepted selector carrier and the public handoff theorem. The finite compact source is already displayed as $X, \mathcal{P}, C, R$, so the envelope begins with the compact finite-net rows rather than an open-cover compactness principle.

Next read the pointwise-modulus and fold rows. The rows M, F, D bind each pointwise radius ledger to the selected precision by the lower-bound fold, so the handoff cannot be reinterpreted as a host minimum or an external modulus.

Finally pass to the consumer rows H, Q, P, N. They provide componentwise transport, continuation replay, provenance, and local naming for the same packet, matching the acceptance schema's demand for a single visible source route.

The excluded rows are absent from the carrier and from the public handoff. Hence the displayed handoff is precisely the bridge envelope from the compact selector packet to the standard acceptance boundary. □

Falsifiable prediction: Removing the selected lower-bound row breaks the uniform-modulus handoff while leaving compact-net coverage and pointwise-modulus rows readable.

Independence witness: Compare compact, continuous, metric, finite-net-minimum-fold, and uniform-modulus siblings: none is bijective because this carrier alone stores the compact-net input, pointwise-modulus radii, selected lower-bound fold row, and tolerance-only handoff together.

Closure status for $\mathsf{NameCert}_{\mathsf{CompactNetModulusSelector}^{\uparrow}}$.

Constructive story: A $\mathsf{CompactNetModulusSelector}^{\uparrow}$ packet is generated from a compact metric finite-net row, a target metric row, a positive tolerance history, a nonempty ProbeBundle of centers, positive subordinate radius rows, pointwise-modulus rows at the bundled centers, a finite lower-bound fold, selected precision, displayed hsame and Cont routes, Pkg provenance, and a local NameCert row.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CompactNetModulusSelector}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.CompactNetModulusSelectorUp.CompactNetModulusSelectorTasteGate\_single\_carrier\_alignm`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close bridge checking, open-cover compactness, sequential compactness, a host minimum, a choice-selected center, quotient point equality, or an external modulus function for $\mathsf{CompactNetModulusSelector}^{\uparrow}$.

Upgrade path: Bridge checking remains the formal-axis task; the paper closure already binds the compact-net selector packet through the public handoff and bridge envelope.

Chapter 915

A Concrete Naming Certificate for $\mathsf{KernelInductiveAcceptance}^{\uparrow}$

The $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ packet realizes the inductive-declaration branch of chapter 9364 as finite NameCert data. It sits beside the accepted-declaration packet of chapter 549, the generic acceptance trace of chapter 557, the generator closure classifier of chapter 486, the type-classifier membership surface of chapter 476, and the subject-reduction boundary of chapter 483. Those siblings expose acceptance, trace, closure, membership, and preservation rows; this packet isolates the constructor-signature plus emitted-eliminator ledger required for accepted inductive declarations.

Definition 915.1 (KernelInductiveAcceptance carrier)**.** *A* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$I = (D, S, E, P, R, H, C, Q, N)$$

with the following displayed rows:

1. *D is the inductive declaration candidate row, including the carrier name, parameters, indices, universe data, and constructor-name inventory;*
2. *S is the constructor-signature ledger, recording the finite domain and target signature of every constructor accepted for D;*
3. *E is the emitted-eliminator ledger, recording the recursor, induction principle, and computation rows generated from the accepted signature;*
4. *P is the positivity-refusal row, recording that a candidate whose constructor signature violates the local positivity discipline is refused rather than entered into the environment;*
5. *R is the recursion-discipline row, recording that eliminator and recursor consumers may read only the emitted rows in E;*
6. *H records componentwise* hsame *transports for D, S, E, P, R, Q, N;*
7. *C records the displayed* Cont *routes from the declaration candidate to constructor signatures, from constructor signatures to emitted eliminators, from failed signatures to positivity refusal, and from emitted eliminators to downstream consumers;*
8. *Q is the* Pkg *provenance over chapter 9364, chapter 549, chapter 557, chapter 486, chapter 476, chapter 483,* BHist*,* hsame*,* Cont*, and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{KernelInductiveAcceptance}^{\uparrow}}$ *row.*

The carrier contains no theorem-proof row, no generic theorem trace, no generator-closure theorem, no type-membership theorem, and no subject-reduction target row beyond the emitted eliminator ledger displayed in E.

Lean4 (definition) `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp`

Theorem 915.2 (KernelInductiveAcceptance NameCert obligations)**.** *For the carrier of Definition 915.1, the local* $\mathsf{NameCert}_{\mathsf{KernelInductiveAcceptance}^{\uparrow}}$ *surface has five rows:*

1. *carrier admission for the finite packet $I = (D, S, E, P, R, H, C, Q, N)$;*
2. *constructor-signature exactness, requiring every accepted constructor read to be one of the displayed entries of S;*
3. *emitted-eliminator ledger exactness, requiring every recursor, induction-principle, and computation read to pass through E after S is visible;*
4. *positivity-refusal stability, requiring a failed positivity check to land in P rather than in an environment-entry row;*
5. *environment-entry non-escape, requiring downstream acceptance, trace, generator, type-classifier, and subject-reduction consumers to read only $D, S, E, P, R, H, C, Q, N$ and not a hidden kernel-correctness theorem.*

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp namecert obligations`

Proof. Carrier admission is projection from the displayed packet. The declaration candidate, constructor-signature ledger, emitted-eliminator ledger, positivity refusal, recursion discipline, transport, route, provenance, and local name are all coordinates of the same finite BHist object.

Constructor-signature exactness and emitted-eliminator exactness are the two accepted rows. The accepted constructor inventory is read from S, and each eliminator or recursor consumer must first expose S before reading the generated ledger E.

The refusal and environment clauses separate accepted and rejected packets. A failed positivity read lands in P and never reaches the environment-entry route, while an accepted read may enter the environment only through the displayed D, S, E, R, H, C, Q, N rows.

The sibling chapters then consume only the finite rows they name. KernelAcceptanceWitness and KernelAcceptanceTrace can read the environment entry, GeneratorClosure can read the accepted generator boundary, TypeClassifierMembership can read emitted type-classifier data, and SubjectReduction can read recursor-facing preservation boundaries; none of those reads adds an unrecorded proof of kernel correctness. □

Theorem 915.3 (KernelInductiveAcceptance nontrivial boundary)**.** *The* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *packet has a nontrivial boundary for TasteGate: an accepted packet displays at least one accepted environment-entry route through D, S, E, R, H, C, Q, N, while a candidate whose constructor signature lacks the required positivity row lands in P and is not accepted. Phase C must realize this as a Nontrivial* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *instance in* $\mathsf{BEDC.Derived.KernelInductiveAcceptanceUp.TasteGate}$.

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceNontrivialBoundary`

Proof. Use the carrier to separate accepted and refused rows. Accepted packets expose constructor signatures and emitted eliminators through S and E, while refused packets expose the positivity boundary P.

The NameCert obligation surface makes the separation observable. Environment-entry non-escape permits an accepted route only after the displayed constructor-signature and eliminator ledgers are present, and positivity-refusal stability prevents a failed candidate from taking that route.

Thus the TasteGate boundary is not empty: it has an accepted side and a refused side, both represented by finite rows of the same carrier. □

Theorem 915.4 (KernelInductiveAcceptance field-faithful boundary)**.** *The* KernelInductiveAcceptance$^{\uparrow}$ *packet is field-faithful for TasteGate: any accepted read that preserves $D, S, E, P, R, H, C, Q, N$ componentwise preserves the inductive-declaration acceptance row, and any read that drops either the constructor-signature ledger S or the emitted-eliminator ledger E is not a faithful read of this carrier. Phase C must realize this as a FieldFaithful* KernelInductiveAcceptance$^{\uparrow}$ *instance in* BEDC.Derived.KernelInductiveAcceptanceUp.TasteGate*.*

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceFieldFaithfulBoundary`

Proof. Start with two accepted reads matched componentwise by the displayed hsame row. The declaration candidate, signature ledger, eliminator ledger, refusal boundary, recursion discipline, routes, provenance, and local name are therefore transported together.

Apply constructor-signature exactness and emitted-eliminator exactness from the NameCert surface. These two rows are the fields that distinguish inductive acceptance from a generic accepted declaration or trace.

If either row is absent, the carrier no longer exposes the paired signature-plus-eliminator surface. The read may belong to a sibling acceptance packet, but it is not faithful to KernelInductiveAcceptance$^{\uparrow}$. □

Theorem 915.5 (KernelInductiveAcceptance constructor ledger exhaustion)**.** *Every accepted constructor read of a* KernelInductiveAcceptance$^{\uparrow}$ *packet is exhausted by the displayed declaration row D, constructor-signature ledger S, componentwise* hsame *transports H, displayed* Cont *routes C, package provenance Q, and local* NameCert *row N. No accepted constructor consumer can read a constructor signature outside the finite ledger S.*

Proof. Use the carrier of Definition 915.1. The declaration candidate D, constructor-signature ledger S, transports H, routes C, provenance Q, and naming row N are displayed coordinates of the same finite BHist packet.

Apply the constructor-signature exactness clause of Definition 915.2. It requires every accepted constructor read to be one of the displayed entries of S, with its declaration source and route recorded by the surrounding rows.

The TasteGate commitments are preserved because the read is still through the paired inductive-declaration surface. A consumer that drops S or replaces it by a hidden theorem-proof row leaves the field-faithful boundary of Definition 915.4. □

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceConstructorLedgerExhaustion`

Theorem 915.6 (KernelInductiveAcceptance eliminator ledger exhaustion)**.** *Every recursor, induction-principle, or computation read of an accepted* KernelInductiveAcceptance$^{\uparrow}$ *packet factors through the constructor-signature ledger S before entering the emitted-eliminator ledger E. No eliminator consumer may read a hidden theorem-proof row or bypass S on the way to E.*

Proof. Use the carrier of Definition 915.1. The rows D, S, E, R, H, C, Q, N are displayed coordinates of the same finite BHist packet, so a recursor or induction-principle consumer has no carrier coordinate outside them.

Apply the constructor-signature exactness and emitted-eliminator exactness clauses of Definition 915.2. They force each accepted eliminator read to expose S before E.

Finally use the sibling anchors named in the chapter introduction. The accepted-declaration, trace, generator, type-classifier, and subject-reduction chapters consume the emitted route after E is visible, but none of them inserts an extra theorem-proof row between S and E. □

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp eliminator ledger exhaustion`

Theorem 915.7 (KernelInductiveAcceptance refusal nonescape)**.** *Every constructor-signature candidate for* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *that fails the local positivity row lands in the refusal row P and cannot be transported into the accepted environment-entry route D, S, E, R, H, C, Q, N. The failed candidate remains outside the accepted declaration, trace, generator, type-classifier, and subject-reduction consumer paths.*

Proof. Begin with the carrier row P of Definition 915.1. It is the displayed place for failed positivity candidates, distinct from the accepted constructor-signature ledger S and emitted-eliminator ledger E.

Apply the positivity-refusal stability clause of Definition 915.2. A failed signature is routed to P rather than to the accepted environment-entry path.

The nontrivial boundary of Definition 915.3 separates the accepted and refused sides of the TasteGate surface. Thus the failed candidate cannot be read by the accepted-declaration, trace, generator, type-classifier, or subject-reduction consumers as an entered inductive declaration. □

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp refusal nonescape`

Theorem 915.8 (KernelInductiveAcceptance obligation closure package)**.** *The carrier of Definition 915.1, NameCert obligations of Definition 915.2, TasteGate nontrivial boundary of Definition 915.3, field-faithful boundary of Definition 915.4, constructor-ledger exhaustion of Definition 915.5, eliminator-ledger exhaustion of Definition 915.6, and positivity-refusal nonescape of Definition 915.7 assemble the full paper-side obligation surface for* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$*. The assembled package exports no theorem-proof row, generic theorem trace, generator-closure theorem, type-membership theorem, subject-reduction target, or hidden kernel-correctness theorem.*

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceObligationClosurePackage`

Proof. Project the carrier tuple $I = (D, S, E, P, R, H, C, Q, N)$. These coordinates display the declaration candidate, constructor-signature ledger, emitted-eliminator ledger, positivity refusal, recursion discipline, transport, continuation, provenance, and local naming rows.

Apply Definition 915.2. Its five rows give carrier admission, constructor-signature exactness, emitted-eliminator exactness, positivity-refusal stability, and environment-entry non-escape for the same finite packet.

Use Definition 915.3 and Definition 915.4. They enforce the AI TasteGate discipline by keeping the accepted and refused sides distinct and by making faithful reads preserve the paired constructor-signature plus emitted-eliminator fields.

The accepted read surface is exhausted by Definition 915.5 and Definition 915.6. Constructor consumers return to S, and recursor, induction-principle, and computation consumers pass through S before E.

Finally apply Definition 915.7. Failed positivity routes stay in P, so the package cannot leak into accepted declaration, trace, generator, type-classifier, or subject-reduction consumers through a hidden kernel-correctness theorem. □

Theorem 915.9 (KernelInductiveAcceptance accepted declaration route)**.** *Every accepted-declaration consumer of a* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *packet must pass through the displayed rows* D, S, E, R, H, C, Q, N *of the carrier. The consumer may read the declaration candidate, constructor-signature ledger, emitted-eliminator ledger, recursion discipline, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows, but it receives no hidden theorem-proof row and no accepted-declaration certificate outside those displayed rows.*

Proof. Project the carrier of Definition 915.1. Its accepted side is the finite route D, S, E, R, H, C, Q, N, with the refused positivity candidates separated into P.

Apply the NameCert obligations of Definition 915.2. Carrier admission, constructor-signature exactness, emitted-eliminator exactness, and environment-entry non-escape force an accepted-declaration read to expose D, then S, then E, with R, H, C, Q, N carrying the route structure.

The field-faithful boundary of Definition 915.4 prevents a consumer from dropping the signature or eliminator ledgers. The obligation package of Definition 915.8, together with the existing TasteGate anchor recorded by this chapter, keeps the AI TasteGate read anchored in the displayed carrier rather than in a hidden theorem-proof row. □

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp accepted declaration route`

Theorem 915.10 (KernelInductiveAcceptance generator closure route)**.** *Every generator-closure consumer of a* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *packet may read the constructor-signature ledger* S *and emitted-eliminator ledger* E *only through the displayed route rows* D, S, E, R, H, C, Q, N *and the local* $\mathsf{NameCert}_{\mathsf{KernelInductiveAcceptance}^{\uparrow}}$ *row. It cannot replace those rows by a generator-closure theorem, a theorem-proof trace, or an off-carrier closure certificate.*

Proof. Begin with constructor-ledger and eliminator-ledger exhaustion, Definition 915.5 and Definition 915.6. They identify S and E as the only visible signature and generated-eliminator ledgers available to downstream generator consumers.

Use the NameCert surface to attach those ledgers to D, R, H, C, Q, N. The displayed Cont row records the route from declaration candidate to constructor signatures and from signatures to emitted eliminators, while Q and N supply provenance and local naming.

Finally apply the obligation closure package and the field-faithful boundary. A generator-closure consumer preserving the TasteGate surface must preserve the paired S, E fields, so it cannot substitute a hidden theorem-proof trace or an off-carrier closure theorem for the displayed route. □

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceGeneratorClosureRoute`

Theorem 915.11 (KernelInductiveAcceptance subject reduction route)**.** *Every subject-reduction consumer of a* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *packet receives emitted eliminator and computation rows only after the constructor signatures in* S *are visible. Failed positivity candidates remain in the refusal row* P*, and no subject-reduction consumer can transport such a candidate into the accepted route* D, S, E, R, H, C, Q, N*.*

Proof. Start with the emitted-eliminator exactness clause in Definition 915.2. It requires every recursor, induction-principle, and computation read to pass through E after the constructor-signature ledger S is visible.

Apply Definition 915.6. This pins the subject-reduction-facing rows to the displayed route D, S, E, R, H, C, Q, N and rules out a bypass from declaration candidate directly to computation rows.

It remains to separate failed positivity candidates. By Definition 915.7, such candidates land in P and remain outside accepted declaration, trace, generator, type-classifier, and subject-reduction paths. The obligation closure package and the existing TasteGate anchor recorded by this chapter therefore leave subject reduction with only the displayed accepted route and no hidden theorem-proof row. □

Theorem 915.12 (KernelInductiveAcceptance environment scope route)**.** *For the carrier $I = (D, S, E, P, R, H, C, Q, N)$ of Definition 915.1, every KernelAcceptanceWitness or KernelAcceptanceTrace consumer of an accepted inductive declaration reads the environment-entry and trace surface only through the displayed rows D, S, E, R, H, C, Q, N. The refusal row P remains visible as the rejected side, but it is not transported into the accepted environment route.*

Proof. Project the accepted declaration route of Definition 915.9. It identifies the environment-entry surface with the displayed declaration row, constructor-signature ledger, emitted-eliminator ledger, recursion row, componentwise transport, continuation route, provenance, and local naming rows.

Use constructor-ledger exhaustion and eliminator-ledger exhaustion to make the trace route determinate. KernelAcceptanceWitness and KernelAcceptanceTrace may name the accepted declaration and its trace, but their readback cannot skip S or E and cannot introduce a theorem-proof row outside the finite packet.

Finally apply refusal nonescape. Failed positivity candidates stay in P, so the trace and witness consumers see the refused side only as a boundary row and never as an accepted environment entry. □

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp environment scope route`

Theorem 915.13 (KernelInductiveAcceptance type-classifier scope route)**.** *Every TypeClassifierMembership consumer of a* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *packet is scoped by the displayed constructor-signature ledger S, emitted-eliminator ledger E, componentwise* hsame *row H, displayed* Cont *row C, package provenance Q, and local* NameCert *row N. It may classify emitted inductive data only through $D, S, E, P, R, H, C, Q, N$ and may not substitute a hidden type-membership theorem for those rows.*

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp typeclassifier scope route`

Proof. Begin with the NameCert obligations. Constructor-signature exactness and emitted-eliminator exactness force any classifier-facing read to expose S before it reads the generated rows in E.

Use the continuation route totality theorem to bind the classifier route to C. Since the route from signatures to emitted eliminators is already displayed, a TypeClassifierMembership consumer has no off-carrier route by which to classify an unrecorded eliminator or computation row.

Transport is controlled by the componentwise hsame scope. The row H preserves S, E, P, R, Q, N, so classifier transport preserves the same finite carrier rows rather than replacing them with a hidden membership theorem. □

Theorem 915.14 (KernelInductiveAcceptance subject-reduction scope lock)**.** *SubjectReduction consumers of a* KernelInductiveAcceptance$^{\uparrow}$ *packet are locked to the emitted-eliminator route D, S, E, R, H, C, Q, N. Once S and E are fixed, a subject-reduction read cannot import an external preservation theorem, cannot read a computation row outside E, and cannot turn a failed positivity candidate from P into an accepted preservation boundary.*

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp subject reduction scope lock`

Proof. Start with Definition 915.11. It already requires every preservation-facing consumer to receive emitted eliminator and computation rows only after the constructor signatures in S are visible.

Apply eliminator-ledger exhaustion and continuation route totality. Together they make E the only emitted-eliminator inventory and C the only route by which a subject-reduction consumer reaches it.

It remains to rule out refused candidates. Refusal nonescape keeps failed positivity rows in P, and classifier stability prevents componentwise transport from converting such a row into an accepted route. The subject-reduction consumer is therefore locked to the displayed accepted surface. □

Theorem 915.15 (KernelInductiveAcceptance scoped consumer package)**.** *The rows $D, S, E, P, R, H, C, Q, N$ form a scoped consumer package for KernelAcceptanceWitness, KernelAcceptanceTrace, GeneratorClosure, TypeClassifierMembership, and SubjectReduction. Each named sibling may consume only the carrier-local route assigned to it by the accepted-declaration route, generator-closure route, type-classifier scope route, subject-reduction scope lock, constructor-ledger exhaustion, eliminator-ledger exhaustion, refusal nonescape, continuation totality, and componentwise transport scope.*

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp scoped consumer package`

Proof. First assemble the accepted environment side. The environment scope route binds KernelAcceptanceWitness and KernelAcceptanceTrace to D, S, E, R, H, C, Q, N, while refusal nonescape leaves P as the separated rejected side.

Next assemble the generator and classifier sides. The generator-closure route consumes the paired S, E ledgers through the carrier, and the type-classifier scope route makes classifier membership read the same emitted rows through H, C, Q, N.

Finally assemble the preservation side. The subject-reduction scope lock, together with eliminator-ledger exhaustion and continuation route totality, keeps SubjectReduction on the emitted-eliminator route and blocks external preservation or theorem-proof rows.

These routes exhaust the sibling consumers named in the introduction. Since the carrier contains no theorem-proof row, generic theorem trace, generator theorem, type-membership theorem, subject-reduction theorem, or hidden kernel-correctness witness, the package is scoped precisely by $D, S, E, P, R, H, C, Q, N$. □

Theorem 915.16 (KernelInductiveAcceptance environment-entry determinacy)**.** *For the carrier $I = (D, S, E, P, R, H, C, Q, N)$ of Definition 915.1, every accepted environment-entry read is determined by the displayed route D, S, E, R, H, C, Q, N. If two accepted reads preserve the declaration candidate, constructor-signature ledger, emitted-eliminator ledger, recursion-discipline row, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *row, then*

they present the same environment-entry surface for KernelInductiveAcceptance$^{\uparrow}$. *The positivity-refusal row P remains outside the accepted entry surface.*

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp environment entry determinacy`

Proof. Project the NameCert obligation surface of Definition 915.2. Carrier admission, constructor-signature exactness, emitted-eliminator exactness, and environment-entry non-escape identify the accepted side as the displayed D, S, E, R, H, C, Q, N route.

Use constructor-ledger exhaustion and eliminator-ledger exhaustion, Definition 915.5 and Definition 915.6. These prevent a second constructor or emitted-eliminator source from distinguishing two accepted environment entries with the same displayed rows.

Finally apply the accepted declaration route theorem Definition 915.9. It gives downstream consumers no accepted-declaration certificate outside the displayed route, while refusal nonescape keeps P separate from the accepted entry. □

Theorem 915.17 (KernelInductiveAcceptance emitted-eliminator consumer coverage)**.** *Once the constructor signatures in S are visible, every recursor consumer, induction-principle consumer, and computation-row consumer of an accepted* KernelInductiveAcceptance$^{\uparrow}$ *packet is covered by the emitted-eliminator ledger E together with D, S, R, H, C, Q, N. No such consumer reads an eliminator outside E, a theorem-proof row, a generic trace theorem, or an off-carrier generator certificate.*

Proof. Begin with the emitted-eliminator exactness clause of Definition 915.2. It requires every recursor, induction-principle, and computation read to pass through E after the constructor-signature ledger S is visible.

Apply Definition 915.6. The consumer route has no carrier coordinate outside D, S, E, R, H, C, Q, N, and the ledger E is the only emitted-eliminator inventory available to the read.

Use the generator closure route and subject reduction route, Definition 915.10 and Definition 915.11. Generator and preservation consumers are downstream of the same emitted ledger, so their coverage is exhausted by E and the displayed route rows rather than by a hidden theorem or trace certificate. □

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp emitted eliminator consumer coverage`

Theorem 915.18 (KernelInductiveAcceptance positivity-refusal classifier stability)**.** *Every constructor-signature candidate that fails the local positivity classifier remains in the refusal row P under componentwise classifier transport. Such a candidate cannot be transported into the accepted route D, S, E, R, H, C, Q, N, cannot acquire an emitted eliminator in E, and cannot become a subject-reduction or generator-closure consumer row.*

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp positivity refusal classifier stability`

Proof. Start with the positivity-refusal stability clause of Definition 915.2. A failed positivity candidate is routed to P rather than to the accepted constructor-signature ledger S.

Apply the refusal nonescape theorem Definition 915.7. It separates P from accepted declaration, trace, generator, type-classifier, and subject-reduction paths, so classifier transport cannot turn a refused candidate into an accepted environment entry.

Finally combine the accepted declaration route, generator closure route, and subject reduction route. Theorems 915.9, 915.10, and 915.11 all consume only the displayed accepted route after S

and E are visible. Since a refused candidate remains in P, it cannot enter any of those consumer rows. □

Theorem 915.19 (KernelInductiveAcceptance continuation route totality)**.** *For the carrier $I = (D, S, E, P, R, H, C, Q, N)$ of Definition 915.1, every accepted declaration route, constructor-signature route, emitted-eliminator route, positivity-refusal route, generator-closure consumer route, and subject-reduction consumer route factors through the displayed* Cont *row C. No consumer of* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *may read a declaration, constructor, eliminator, refusal, generator boundary, or preservation boundary through a route outside C.*

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp cont route totality`

Proof. Project the carrier tuple. The row C is the displayed continuation coordinate, and Definition 915.1 assigns to it the declaration-to-signature, signature-to-eliminator, failed-signature-to-refusal, and emitted-eliminator-to-consumer routes.

Apply constructor-ledger exhaustion and eliminator-ledger exhaustion. These identify S and E as the only accepted constructor and eliminator ledgers, so accepted declaration, constructor, and eliminator consumers can enter only through the continuation coordinates already displayed in C.

For failed signatures, use positivity-refusal nonescape. The failed candidate lands in P, and the only recorded route from failed signature data to refusal data is the corresponding component of C.

For generator and subject-reduction consumers, use Definition 915.10 and Definition 915.11. Both consumers are downstream of the emitted-eliminator surface, so their carrier-local readback is exhausted by the same $D, S, E, P, R, H, C, Q, N$ packet and cannot introduce an off-carrier continuation. □

Theorem 915.20 (KernelInductiveAcceptance hsame transport scope)**.** *Componentwise* hsame *transport through the displayed row H preserves the constructor-signature ledger S, emitted-eliminator ledger E, positivity-refusal row P, recursion row R, package provenance Q, and local* NameCert *row N of a* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *carrier. The transport scope contains no theorem-proof row and no hidden kernel-correctness witness.*

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp hsame transport scope`

Proof. Start with the transport row H in Definition 915.1. Its scope is componentwise over the displayed rows D, S, E, P, R, Q, N, with C recording the routes that make those transported rows readable by consumers.

The constructor and eliminator ledgers are preserved by the field-faithful boundary and the two ledger-exhaustion theorems. A transport that drops S or E is not a faithful read of this carrier, and a transport that preserves them keeps each accepted constructor and emitted eliminator inside the finite displayed ledgers.

The refusal and recursion rows are preserved by the NameCert obligations. Positivity-refusal stability keeps failed signatures in P, and emitted-eliminator exactness makes recursor and induction-principle consumers pass through the displayed recursion row R rather than an unrecorded proof surface.

Finally, provenance and local naming are carrier coordinates. Transport through H therefore carries Q and N together with the ledgers and refusal row, leaving no place for an additional theorem-proof row or hidden kernel-correctness witness. □

Theorem 915.21 (KernelInductiveAcceptance sibling consumer scope)**.** *The sibling consumers named in the chapter introduction may consume a* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ *packet only through the displayed KernelAcceptanceWitness, KernelAcceptanceTrace, GeneratorClosure, TypeClassifierMembership, and SubjectReduction routes over* $D, S, E, P, R, H, C, Q, N$*. They may not read an accepted-declaration certificate, trace certificate, generator theorem, type-membership theorem, subject-reduction theorem, or theorem-proof row outside those displayed carrier rows.*

Proof. Use the introduction and the carrier definition to identify the sibling boundary. KernelAcceptanceWitness and KernelAcceptanceTrace read accepted declaration and trace data, GeneratorClosure reads the accepted generator boundary, TypeClassifierMembership reads emitted classifier data, and SubjectReduction reads preservation-facing eliminator data.

The accepted-declaration and generator consumers are already restricted by Definition 915.9 and Definition 915.10. Both pass through the finite carrier rows and receive no off-carrier certificate.

Subject-reduction consumers are restricted by Definition 915.11, while constructor, eliminator, refusal, continuation, and transport scope are restricted by Definition 915.5, Definition 915.6, Definition 915.7, Definition 915.19, and Definition 915.20.

Thus every named sibling read is a carrier-local readback over $D, S, E, P, R, H, C, Q, N$. The carrier lacks theorem-proof, generic trace theorem, generator theorem, type-membership theorem, and subject-reduction theorem rows, so no sibling can consume such a row from this packet. □

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceUp sibling consumer scope`

Theorem 915.22 (KernelInductiveAcceptance mature package)**.** *The carrier of Definition 915.1, the constructor-ledger exhaustion of Definition 915.5, the eliminator-ledger exhaustion of Definition 915.6, the refusal nonescape boundary of Definition 915.7, the nontrivial boundary of Definition 915.3, the field-faithful boundary of Definition 915.4, and the sibling consumer routes of Definition 915.21 form the mature paper package for* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$*. The package is mature exactly as a carrier-local inductive-acceptance readback: every accepted constructor, emitted eliminator, refused positivity candidate, TasteGate boundary, field-faithful read, and named sibling consumer remains inside* $D, S, E, P, R, H, C, Q, N$*.*

Proof. Start with the carrier and NameCert obligations. They display the declaration candidate, constructor-signature ledger, emitted-eliminator ledger, positivity-refusal row, recursion discipline, transport, replay, provenance, and local naming as one finite packet.

The constructor and eliminator ledgers are exhausted by their dedicated theorems. Thus accepted constructor reads return to S, and recursor, induction-principle, and computation reads pass through S before they reach E.

The refused side is separated by refusal nonescape, nontriviality, and field-faithfulness. A failed positivity candidate stays in P, an accepted read preserves the paired S, E surface, and a read that drops either ledger is outside this carrier.

Finally the sibling consumer scope theorem packages the downstream routes. KernelAcceptanceWitness, KernelAcceptanceTrace, GeneratorClosure, TypeClassifierMembership, and SubjectReduction consume only the displayed carrier rows, so the mature package exports no theorem-proof row, generic trace theorem, generator theorem, type-membership theorem, subject-reduction theorem, or hidden kernel-correctness witness. □

Falsifiable prediction: If the carrier is atomic, every accepted row exposes a constructor signature and emitted eliminator ledger; a packet lacking either row is rejected by the local classifier.

Independence witness: kernelacceptancewitness, kernelacceptancetrace, generatorclosure, typeclassifiermembership, subjectreduction: none is bijective because those siblings lack the paired constructor-signature plus emitted-eliminator ledger row, while this carrier lacks their theorem-proof, generic trace, generator-closure, or subject-reduction target rows.

Closure status for $\mathsf{NameCert}_{\mathsf{KernelInductiveAcceptance}^{\uparrow}}$.

Constructive story: A $\mathsf{KernelInductiveAcceptance}^{\uparrow}$ packet is generated from an inductive declaration candidate, constructor-signature ledger, emitted-eliminator ledger, positivity-refusal row, recursion-discipline row, componentwise hsame transport, displayed Cont routes, Pkg provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{KernelInductiveAcceptance}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 915.1, Definition 915.2, Definition 915.3, Definition 915.4, Definition 915.5, Definition 915.6, Definition 915.7, Definition 915.8, Definition 915.9, Definition 915.10, Definition 915.11, Definition 915.12, Definition 915.13, Definition 915.14, Definition 915.15, Definition 915.19, Definition 915.20, Definition 915.21, and Definition 915.22 bind the carrier, local NameCert obligation, TasteGate boundary, ledger exhaustion, refusal nonescape, accepted declaration route, generator route, subject-reduction route, environment scope, type-classifier scope, subject-reduction scope lock, scoped consumer package, displayed Cont row, componentwise hsame transport, sibling consumer scope, and mature package to one carrier-local readback surface.

Lean4 ✓ `BEDC.Derived.KernelInductiveAcceptanceUp.taste gate`

Lean target: `BEDC.Derived.KernelInductiveAcceptanceUp.KernelInductiveAcceptanceTasteGate\_single\_carrier\_alignm`

Bridge status: none

Origin: human

Not claimed: This chapter does not prove full kernel correctness, subject reduction, theorem-proof soundness, generic trace completeness, generic theorem proof rows, or any bridge theorem.

Upgrade path: Bridge closure requires a checked bridge for the same carrier-local readback package.

Chapter 916

A Concrete Naming Certificate for $\mathsf{ClosedNormalEndpointTransport}^{\uparrow}$

The $\mathsf{ClosedNormalEndpointTransport}^{\uparrow}$ packet realizes the typed normal endpoint boundary isolated by chapter 9376. It sits beside the endpoint ledger of chapter 837, the route certificate of chapter 858, and the subject-reduction route of chapter 787: those siblings expose the closed beta-strong endpoint, the route certificate, and the blocked transport surface, while the present packet records the finite NameCert transport row that a downstream consumer must display before reading the closed-normal contradiction route.

Definition 916.1 (Closed-normal endpoint transport carrier)**.** *A* $\mathsf{ClosedNormalEndpointTransport}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (S, B, T, F, O, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the source proof row naming the closed proof candidate before the endpoint handoff;*
2. *B is the beta-route row naming the finite reduction route available to the packet;*
3. *T is the typed normal endpoint row consumed by the closed-normal consistency main result;*
4. *F is the false-type preservation socket, displayed as a socket rather than as a discharged subject-reduction theorem;*
5. *O is the subject-reduction obstruction row that prevents the transport from being reread as full closed consistency;*
6. *L is the non-escape ledger recording that arbitrary closed proofs are not exported beyond the typed normal endpoint boundary;*
7. *H stores componentwise* hsame *transports for source proof, beta-route, typed endpoint, socket, obstruction, and non-escape rows;*
8. *C stores displayed* Cont *routes from the source proof and beta-route rows to the endpoint row and from the endpoint row to the closed-normal route certificate;*
9. *P records* Pkg *provenance over chapter 9376, chapter 837, chapter 858, chapter 787,* BHist*,* hsame*,* Cont*, and* NameCert *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{ClosedNormalEndpointTransport}^{\uparrow}}$ *row.*

The classifier compares two carriers only by the finite rows $S, B, T, F, O, L, H, C, P, N$. No coordinate contains full closed consistency, a closed subject-reduction theorem, unrestricted normalization, quotient conversion, host evaluation, or an ambient proof that every closed false proof reaches a typed normal endpoint.

Lean4 ✓ `BEDC.Derived.ClosedNormalEndpointTransportUp.ClosedNormalEndpointTransportTasteGate`
`single carrier alignment`

Theorem 916.2 (Closed-normal endpoint transport NameCert obligations)**.** *Every accepted* ClosedNormalEndpoint *packet binds exactly the finite obligation surface of Definition 916.1: carrier admission for $E = (S, B, T, F, O, L, H, C, P, N)$, source proof row exactness through S, beta-route exactness through B, typed normal endpoint exactness through T, false-type preservation socket visibility through F, obstruction visibility through O, non-escape through L, componentwise classifier stability through H, displayed continuation stability through C, package provenance through P, and local naming through N.*

Proof. Project the accepted carrier. Admission exposes only the finite tuple $E = (S, B, T, F, O, L, H, C, P, N)$, so every public read starts from the displayed source proof, beta-route, endpoint, socket, obstruction, and non-escape rows.

The endpoint transport is read in two stages. The rows S and B name the source proof and beta route, while T names the typed normal endpoint already at the boundary consumed by chapter 9376. The socket F is visible but not discharged into a closed subject-reduction theorem.

The rows O and L record the negative boundary. They keep the subject-reduction obstruction and non-escape ledger in the same packet as the positive endpoint row, so a consumer cannot erase the missing first arrow from arbitrary closed proof to typed normal endpoint.

The structural rows H, C, P, N transport, replay, package, and name only this finite surface. Since no coordinate supplies full closed consistency, unrestricted normalization, quotient conversion, host evaluation, or ambient consistency, the accepted packet exports only the displayed endpoint transport boundary. □

Theorem 916.3 (Closed-normal endpoint transport boundary)**.** *Every consumer of an accepted* ClosedNormalEndpointTransport$^{\uparrow}$ *packet that reaches a beta-strong false endpoint must factor through either the displayed transport row from S, B to T together with the socket F, or through the displayed obstruction row O and non-escape ledger L. A consumer that asks for full closed consistency, closed subject reduction, unrestricted normalization, quotient proof conversion, host evaluation, or an unlisted route from arbitrary closed proofs to typed normal endpoints is outside the carrier.*

Proof. Start with a consumer read of the packet and project the carrier. The only endpoint coordinate is T, and the only rows leading to it are the displayed source proof row S, beta-route row B, and socket row F.

If the read uses the positive endpoint route, then it is already a finite closed-normal endpoint read and can be handed to the route certificate of chapter 858. The rows H and C preserve that route componentwise and do not add a subject-reduction discharge.

If the read asks for the missing first arrow, it must encounter O and L. Those rows record that the transport surface is an obstruction-aware endpoint packet, not a proof of arbitrary closed consistency.

Thus every accepted read either stays on the displayed endpoint transport row or stops at the displayed obstruction boundary. The package and naming rows P, N make that boundary public without adding any unlisted consistency principle. □

Falsifiable prediction: A consumer that reaches a beta-strong false endpoint without the displayed transport row or obstruction row is not accepted by this carrier.

Independence witness: closednormalendpointledger, closed-normal-route-certificate, subjectreductionroute, subjectreductionobligation: none is bijective because endpoint transport carries both route-preservation and obstruction rows, while each sibling omits at least one of those coordinates.

The later Lean target in `lean4/BEDC/Derived/ClosedNormalEndpointTransportUp/TasteGate.lean` must provide explicit Nontrivial ClosedNormalEndpointTransport$^{\uparrow}$ and FieldFaithful ClosedNormalEndpointTransport$^{\uparrow}$ instances for this same finite carrier. Nontriviality separates the endpoint transport row from the obstruction row, while field faithfulness preserves the displayed coordinates $S, B, T, F, O, L, H, C, P, N$ for every TasteGate-facing consumer.

Closure status for NameCert$_{\text{ClosedNormalEndpointTransport}^{\uparrow}}$ **·**

Constructive story: A ClosedNormalEndpointTransport$^{\uparrow}$ packet is generated from source proof, beta-route, typed normal endpoint, false-type preservation socket, subject-reduction obstruction, non-escape ledger, componentwise transport, displayed continuation, provenance, and local NameCert rows.

Theory closure: TheoryGate(NameCert$_{\text{ClosedNormalEndpointTransport}^{\uparrow}}$, seed)

Scope closed: Definition 916.1, Definition 916.2, and Definition 916.3 bind the finite NameCert endpoint transport boundary for closed-normal consistency.

Formal verification: FormalStatus(NameCert$_{\text{ClosedNormalEndpointTransport}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close full closed consistency, closed subject reduction, unrestricted normalization, quotient conversion, host evaluation, ambient consistency, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, endpoint-route exactness, socket visibility, obstruction visibility, classifier stability, continuation stability, provenance, local naming, nontriviality, and field faithfulness for the same finite endpoint transport packet.

Chapter 917

A Concrete Naming Certificate for TailBudgetCoherence$^{\uparrow}$

The TailBudgetCoherence$^{\uparrow}$ packet is the composite Real and Completion surface joining the finite tail-budget route of chapter 906, the shared threshold route of chapter 560, the agreement-seal route of chapter 699, and the diagonal-completion route named in chapter 9238. It is not an atomic carrier: its atomicity witness is intentionally replaced by a composite-dependency explanation over existing sibling packets. The later Lean TasteGate work must still provide Nontrivial TailBudgetCoherence$^{\uparrow}$ and FieldFaithful TailBudgetCoherence$^{\uparrow}$ instances for the displayed composite carrier.

Definition 917.1 (Tail budget coherence carrier)**.** *A* TailBudgetCoherence$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (M, O, S, A, L, W, R, D, H, C, P, N)$$

with the following displayed rows:

1. *M is the* RegularCauchyTailMeet$^{\uparrow}$ *shared-threshold row used by the diagonal tail route;*
2. *O is the* RealObservationBudget$^{\uparrow}$ *observation-budget row that bounds the Real-facing finite reads;*
3. *S is the* RegularCauchySelectorBudget$^{\uparrow}$ *selector-budget row that supplies the diagonal member requests;*
4. *A is the* RealTailAgreementSeal$^{\uparrow}$ *agreement-seal row tying the tail route to the Real-facing agreement surface;*
5. *L is the* CauchyLimitSeal$^{\uparrow}$ *limit-seal row reached only after the threshold, observation budget, selector budget, and agreement seal have been displayed;*
6. *W is the finite* StreamName$^{\uparrow}$ *window ledger served by the observation and selector budgets;*
7. *R is the* RegSeqRat$^{\uparrow}$ *readback row attached to those windows;*
8. *D is the* DyadicRatCore$^{\uparrow}$ *tolerance ledger read before the regular-rational handoff and seal rows;*
9. *H records componentwise* hsame *transports for the threshold, observation budget, selector budget, agreement seal, limit seal, windows, readback, tolerance ledger, route, provenance, and local naming rows;*

10. *C records the displayed* Cont *routes from the tail threshold to the budget rows, from budgets to finite windows, from windows to dyadic tolerance and regular readback rows, and from the readback to the agreement and limit seals;*
11. *P is the* Pkg *provenance over* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{TailBudgetCoherence}^{\uparrow}}$ *row.*

The classifier compares accepted packets only through these displayed rows. The carrier contains no quotient stream equality, no selected host limit, no host real equality, and no ambient completeness principle.

Lean4 (definition) `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceUp`

Theorem 917.2 (Tail budget coherence NameCert obligations)**.** *For the carrier of Definition 917.1, the local* $\mathsf{NameCert}_{\mathsf{TailBudgetCoherence}^{\uparrow}}$ *surface consists exactly of carrier admission for $T = (M, O, S, A, L, W, R, D, H,$ TailMeet threshold exposure through M, observation-budget exposure through O, selector-budget exposure through S, agreement-seal exposure through A, limit-seal exposure through L, finite window service through W, regular readback through R, dyadic tolerance accounting through D, componentwise* hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceCarrier namecert obligations`
Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceTasteGate single carrier alignment`

Proof. Project the displayed packet. Its coordinates are exactly $M, O, S, A, L, W, R, D, H, C, P, N$, so carrier admission and local naming cannot introduce a second tail threshold, budget, readback, agreement seal, or limit seal.

Read the route rows in dependency order. The threshold row M fixes the shared tail boundary; O and S bound the observation and selector requests; W, D, R display the finite windows, tolerance ledger, and regular-rational readback available after those budget rows.

The seal rows are then read through the same route. The agreement row A and limit row L are attached to the displayed readback surface, while H, C, P, N transport, replay, package, and name only that finite packet.

Thus the NameCert surface is composite rather than atomic. It packages the displayed sibling rows from the tail-meet, observation-budget, selector-budget, agreement-seal, limit-seal, stream-window, readback, and dyadic-ledger chapters, and it exports no quotient streams, host real equality, selected limits, or ambient completeness. □

Theorem 917.3 (Tail budget coherence real-completion handoff)**.** *Every Real and Completion consumer that cites an accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet must read the completion-facing* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *surface through the displayed route*

$$M, O, S, W, D, R, A, L, H, C, P, N.$$

In particular, the route realizes the Real completeness handoff of chapter 9238 as one finite threshold, observation-budget, selector-budget, agreement-seal, and limit-seal surface over the sibling packets of chapter 560, chapter 699, and chapter 906.

Proof. Start from the accepted carrier and project the threshold, budget, window, readback, and seal rows. The TailMeet row M supplies the shared tail boundary, while O and S supply the two finite budget gates that service observation and selector requests.

Use the displayed window route next. The $\mathsf{StreamName}^{\uparrow}$ row W, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger D, and $\mathsf{RegSeqRat}^{\uparrow}$ readback row R are the only finite readback coordinates available before a seal-facing consumer reaches A or L.

Now apply the sibling routes. The tail-budget packet of chapter 906 supplies the budget-row source, the TailMeet sibling supplies the threshold source, and the RealTailAgreementSeal sibling supplies the agreement-seal source. The $\mathsf{CauchyLimitSeal}^{\uparrow}$ row is read only after those rows have been displayed.

The structural rows H, C, P, N carry the same composite packet to downstream Real and Completion consumers. Since the packet has no coordinate for quotient stream equality, selected host limits, host real equality, or ambient completeness, the handoff is exactly the finite BEDC-visible route stated above. □

Theorem 917.4 (Tail budget coherence threshold-budget exposure)**.** *For any accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet*

$$T = (M, O, S, A, L, W, R, D, H, C, P, N),$$

the TailMeet threshold row M, observation-budget row O, and selector-budget row S are exposed before any finite window row W, dyadic tolerance row D, regular readback row R, agreement-seal row A, or limit-seal row L is consumed.

Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceCarrier threshold budget exposure`

Proof. Project the carrier of Definition 917.1. The first three budget-facing coordinates of the accepted packet are M, O, S, and the displayed carrier order places W, R, D, A, L only after those rows have been named.

Apply Definition 917.2. Its NameCert surface exposes TailMeet threshold, observation budget, and selector budget as separate rows before the finite window service, regular readback, dyadic tolerance accounting, agreement-seal exposure, and limit-seal exposure rows are read.

The structural rows H, C, P, N transport, replay, package, and name the same packet. They do not supply an alternate window, tolerance ledger, readback route, agreement seal, or limit seal outside the exposed threshold and budget rows. □

Theorem 917.5 (Tail budget coherence window-readback exactness)**.** *For any accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet $T = (M, O, S, A, L, W, R, D, H, C, P, N)$, the rows W, D, R form the unique finite window, dyadic tolerance, and* $\mathsf{RegSeqRat}^{\uparrow}$ *readback route available under the displayed threshold and budget rows M, O, S.*

Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceCarrier window readback exactness`

Proof. Use Definition 917.4 to fix M, O, S as the exposed threshold and budget rows before any readback-facing coordinate is consumed.

Now apply Definition 917.2. The accepted NameCert surface lists exactly one finite window service row W, one dyadic tolerance accounting row D, and one regular readback row R in the displayed packet.

Because the classifier compares accepted packets only through the displayed rows of Definition 917.1, there is no second finite window, tolerance ledger, or readback coordinate for a Real or Completion consumer to select. Thus W, D, R are the exact readback route under M, O, S. □

Theorem 917.6 (Tail budget coherence seal non-escape)**.** *Every Real or Completion consumer of an accepted* TailBudgetCoherence$^{\uparrow}$ *packet reaches the agreement-seal row A and limit-seal row L only after the rows M, O, S, W, D, R have been displayed, and receives no quotient stream equality, host real equality, selected host limit, countable-choice selector, or ambient completeness principle from the packet.*

Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceCarrier seal nonescape`

Proof. Start with Definition 917.5. It identifies W, D, R as the exact finite readback route available under the already exposed threshold and budget rows M, O, S.

Apply Definition 917.3. Any Real or Completion consumer must read the handoff through the displayed route $M, O, S, W, D, R, A, L, H, C, P, N$, so the agreement seal A and limit seal L are reached only after the finite threshold, budget, window, tolerance, and readback rows.

Finally inspect the carrier definition. It contains no coordinate for quotient stream equality, host real equality, selected host limit, countable-choice selector, or ambient completeness, and the NameCert obligations package only the displayed finite rows. □

Theorem 917.7 (Tail budget coherence Real-completion budget route refinement)**.** *Every Real or Completion consumer of an accepted* TailBudgetCoherence$^{\uparrow}$ *packet factors through the ordered finite route*

$$M, O, S, W, D, R, A, L, H, C, P, N.$$

The threshold row M, observation-budget row O, and selector-budget row S are exposed before any finite window, readback, or seal row is consumed; W, D, R are the unique finite StreamName$^{\uparrow}$–DyadicRatCore$^{\uparrow}$–RegSeqRat$^{\uparrow}$ *readback route; and A, L are reachable only after that readback route has been displayed.*

The refinement exports no quotient stream equality, host real equality, selected host limit, countable-choice selector, or ambient completeness principle.

Proof. Apply Definition 917.4. It fixes M, O, S as the exposed threshold, observation-budget, and selector-budget surface before a consumer reaches any window, readback, tolerance, agreement-seal, or limit-seal row.

Next apply Definition 917.5. Under those budget rows, the only readback route is the finite W, D, R surface, read as the StreamName$^{\uparrow}$ window, DyadicRatCore$^{\uparrow}$ tolerance ledger, and RegSeqRat$^{\uparrow}$ regular-rational readback.

Then use Definition 917.6. It places A, L after the displayed readback route and blocks every quotient stream equality, host real equality, selected host limit, countable-choice selector, and ambient completeness coordinate.

Finally apply Definition 917.3. The Real and Completion consumer therefore sees a single finite route $M, O, S, W, D, R, A, L, H, C, P, N$, with H, C, P, N transporting, replaying, packaging, and naming the same packet rather than opening a second analytic surface. □

Theorem 917.8 (Tail budget coherence obligation-closure package)**.** *For an accepted* TailBudgetCoherence$^{\uparrow}$ *packet*

$$T = (M, O, S, A, L, W, R, D, H, C, P, N),$$

the carrier of Definition 917.1, the NameCert obligations of Definition 917.2, the Real-completion handoff of Definition 917.3, the threshold-budget exposure of Definition 917.4, the window-readback exactness of Definition 917.5, and the seal non-escape boundary of Definition 917.6 assemble the fieldwise obligation *surface for* TailBudgetCoherence$^{\uparrow}$.

The rows remain separate carrier, NameCert, handoff, threshold-budget, finite-window, readback, tolerance-ledger, agreement-seal, and limit-seal obligations. The package exports no quotient stream, host real equality, selected limit, countable-choice selector, or ambient completeness row.

Proof. Project the carrier definition to fix the displayed packet $T = (M, O, S, A, L, W, R, D, H, C, P, N)$ and its ambient BEDC rows. The classifier has access only to the listed BHist, hsame, Cont, Pkg, and NameCert coordinates and to the named sibling rows.

Invoke Definition 917.2 to bind the carrier admission, local naming row, componentwise transports, continuation replay, package provenance, threshold row, budget rows, window row, tolerance ledger, readback row, agreement seal, and limit seal.

Chain Definition 917.3, Definition 917.4, and Definition 917.5. These theorems route every Real or Completion consumer through the finite sequence $M, O, S, W, D, R, A, L, H, C, P, N$, expose M, O, S before any readback-facing row, and identify W, D, R as the exact finite readback route under those exposed threshold and budget rows.

Finally apply Definition 917.6. The agreement seal and limit seal are reachable only through the displayed finite packet, and no quotient stream, host real equality, selected host limit, countable-choice selector, or ambient completeness coordinate is exported. The composite-dependency explanation therefore keeps the result as a finite Real-completion handoff package, not an atomic analytic object. □

Theorem 917.9 (Tail budget coherence primitive scope)**.** *For an accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet*

$$T = (M, O, S, A, L, W, R, D, H, C, P, N),$$

the primitive scope is exactly the sibling rows $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*,* $\mathsf{RealObservationBudget}^{\uparrow}$*,* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$*,* $\mathsf{RealTailAgreementSeal}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *together with the kernel rows* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *displayed in the packet.*

Every Real-completion consumer route through T first passes through those rows and cannot use quotient stream equality, host real equality, selected limits, countable-choice selectors, or ambient completeness outside the displayed finite packet.

Proof. Project the carrier of Definition 917.1. This fixes the accepted packet as the displayed tuple $T = (M, O, S, A, L, W, R, D, H, C, P, N)$, with M, O, S, A, L, W, R, D supplied by the eight named sibling rows and H, C, P, N supplied by the local BHist, hsame, Cont, Pkg, and NameCert surface.

Use Definition 917.2 to bind carrier admission, componentwise transport, continuation replay, package provenance, and local naming to those displayed coordinates. Then apply Definition 917.3 to force every Real-completion consumer route through the same packet rather than through a host equality or ambient limit object.

Now use Definition 917.4 and Definition 917.5. They expose M, O, S before any readback-facing coordinate and identify W, D, R as the exact finite window, tolerance, and readback route available under that exposure.

Finally apply Definition 917.6. The agreement seal A and limit seal L are reachable only after the displayed finite route, and no coordinate remains for quotient stream equality, host real equality, selected limits, countable-choice selectors, or ambient completeness. Hence the primitive scope is exhausted by the finite packet named in the theorem. □

Theorem 917.10 (Tail budget coherence sibling-scope lock)**.** *For an accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet*

$$T = (M, O, S, A, L, W, R, D, H, C, P, N),$$

each displayed row is read only through the named sibling packets and BEDC kernel rows: M through RegularCauchyTailMeet$^{\uparrow}$*, O through* RealObservationBudget$^{\uparrow}$*, S through* RegularCauchySelectorBudget$^{\uparrow}$*, A through* RealTailAgreementSeal$^{\uparrow}$*, L through* CauchyLimitSeal$^{\uparrow}$*, W through* StreamName$^{\uparrow}$*, R through* RegSeqRat$^{\uparrow}$*, D through* DyadicRatCore$^{\uparrow}$*, and H, C, P, N through the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceCarrier sibling scope lock`

Proof. Project the carrier of Definition 917.1. The accepted tuple displays $M, O, S, A, L, W, R, D, H, C, P, N$ as separate coordinates, and the classifier compares accepted packets only through those coordinates.

Apply Definition 917.2 to bind each coordinate to its local obligation row. The threshold, observation-budget, selector-budget, agreement-seal, limit-seal, window, readback, and dyadic-tolerance rows are supplied by their named sibling packets, while H, C, P, N supply only componentwise transport, continuation replay, provenance, and local naming.

Finally use Definition 917.9. It identifies the primitive surface as the eight sibling rows together with BHist, hsame, Cont, Pkg, and NameCert. There is no remaining coordinate from which a consumer could read an unlisted sibling packet or a host-level analytic primitive. □

Theorem 917.11 (Tail budget coherence Real route scope)**.** *Every* Real$^{\uparrow}$ *or Completion consumer of an accepted* TailBudgetCoherence$^{\uparrow}$ *packet factors through*

$$M, O, S, W, D, R, A, L, H, C, P, N$$

before reading an agreement seal or a limit seal. In particular, no Real-facing or Completion-facing consumer reaches A or L without first passing through the TailMeet threshold, observation budget, selector budget, finite window, dyadic tolerance ledger, and regular readback rows.

Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceCarrier real route scope`

Proof. Start with Definition 917.3. It states the handoff route for every Real and Completion consumer as the displayed sequence $M, O, S, W, D, R, A, L, H, C, P, N$.

Use Definition 917.4 to place M, O, S before any readback-facing row is consumed. Then use Definition 917.5 to identify W, D, R as the exact finite window, tolerance, and readback route under that exposed threshold and budget surface.

The seal rows are now forced by Definition 917.6. The agreement seal A and limit seal L are reachable only after M, O, S, W, D, R, and the structural rows H, C, P, N transport and name the same finite packet rather than opening a second Real or Completion path. □

Theorem 917.12 (Tail budget coherence no ambient completeness scope)**.** *The scoped* TailBudgetCoherence$^{\uparrow}$ *route exports no quotient stream equality, no host real equality, no selected limit, no countable-choice selector, and no ambient completeness principle. Its public output is only the finite coherence route through $M, O, S, W, D, R, A, L, H, C, P, N$ and the sibling packets named in Definition 917.10.*

Proof. Inspect the carrier of Definition 917.1. The accepted packet contains rows for the threshold, budgets, finite windows, dyadic tolerance ledger, regular readback, agreement seal, limit seal, componentwise transport, continuation replay, provenance, and local naming, but it contains no coordinate for quotient equality, host equality, selected limits, choice selectors, or completeness.

Apply Definition 917.8. The obligation surface assembled there is fieldwise over the same finite rows and explicitly keeps the seal route separate from quotient stream equality, host real equality, selected limits, countable-choice selectors, and ambient completeness.

Combine this with Definition 917.10 and Definition 917.11. The first locks every row to the named sibling and kernel packets, and the second forces Real and Completion consumers through the finite route before any seal read. Therefore the scoped route exports no ambient completeness object beyond the displayed coherence packet. □

Theorem 917.13 (Tail budget coherence public export boundary)**.** *The public export of an accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet is exactly the finite route*

$$M, O, S, W, D, R, A, L, H, C, P, N$$

through the sibling rows named by Definition 917.10. Every $\mathsf{Real}^{\uparrow}$ *or Completion consumer must pass through threshold-budget exposure, window-readback exactness, Real route scope, and no-ambient-completeness scope before it reads the agreement seal* A *or limit seal* L*.*

Consequently the public export contains no quotient stream, selected host limit, host real equality, countable-choice selector, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceCarrier public export boundary`

Proof. Start with the sibling-scope lock of Definition 917.10. It ties M, O, S, A, L, W, R, D to the named TailMeet, observation-budget, selector-budget, agreement-seal, limit-seal, StreamName, RegSeqRat, and DyadicRatCore sibling packets, and ties H, C, P, N to the BEDC kernel rows.

Apply threshold-budget exposure from Definition 917.4. It places M, O, S before any finite window, dyadic tolerance, regular readback, agreement-seal, or limit-seal coordinate can be consumed.

Next apply window-readback exactness from Definition 917.5 and Real route scope from Definition 917.11. These identify W, D, R as the exact readback route under M, O, S and force every Real or Completion consumer through $M, O, S, W, D, R, A, L, H, C, P, N$ before seal access.

Finally use no-ambient-completeness scope from Definition 917.12. Since the accepted route exports no quotient stream equality, host real equality, selected limit, countable-choice selector, or ambient completeness principle, the finite route written above is the complete public boundary. □

Theorem 917.14 (Tail budget coherence Real-seal window stability)**.** *For an accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet*

$$T = (M, O, S, A, L, W, R, D, H, C, P, N),$$

any $\mathsf{Real}^{\uparrow}$ *or Completion consumer that reaches the agreement seal* A *or the limit seal* L *must preserve the same finite* $\mathsf{StreamName}^{\uparrow}$ *window* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D*, and* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R *fixed under the threshold-budget rows* M, O, S*.*

Componentwise hsame *transport may rename these rows, but it may not replace them by a second window, a host limit, a quotient stream equality, or an ambient completeness route.*

Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceCarrier real seal window stability`

Proof. First expose the budget spine. By Definition 917.4, every readback-facing route through T presents M, O, S before the finite window, dyadic tolerance, regular readback, agreement seal, or limit seal is consumed.

Next fix the finite readback rows. Apply Definition 917.5; it identifies W, D, R as the exact $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{RegSeqRat}^{\uparrow}$ route under the displayed threshold and budget rows, so a seal consumer cannot substitute a second readback surface.

Now place the seal consumer on the public route. The Real route scope of Definition 917.11 and the public export boundary of Definition 917.13 force any $\mathsf{Real}^{\uparrow}$ or Completion read of A or L through $M, O, S, W, D, R, A, L, H, C, P, N$.

Finally use seal non-escape from Definition 917.6. Since the accepted packet exports neither host limits, quotient stream equality, nor ambient completeness, componentwise hsame transport can only rename the displayed rows and cannot replace the finite window-readback triple. □

Theorem 917.15 (Tail budget coherence bridge interface)**.** *For an accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet*

$$T = (M, O, S, A, L, W, R, D, H, C, P, N),$$

the composite sibling route from $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *bridges to the public Real-and-Completion consumer interface exactly through the finite surface*

$$M, O, S, W, D, R, A, L, H, C, P, N.$$

The forward direction is the public export boundary of Definition 917.13. The reverse projection is the sibling-scope lock of Definition 917.10 together with the primitive scope of Definition 917.9.

Thus the bridge carries only the displayed threshold, observation-budget, selector-budget, agreement-seal, limit-seal, window, readback, dyadic-tolerance, transport, continuation, provenance, and local naming rows. It carries no quotient stream equality, no host real equality, no selected limit, no countable-choice selector, and no ambient completeness principle.

Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceUp StdBridge`

Proof. For the forward direction, apply Definition 917.13. It identifies the public Real-and-Completion export as the finite route $M, O, S, W, D, R, A, L, H, C, P, N$ through the sibling rows already locked by the accepted packet.

For the reverse projection, start with Definition 917.10. It reads each coordinate of T only through the named sibling packets and through the displayed BHist, hsame, Cont, Pkg, and NameCert rows. Then apply Definition 917.9 to exhaust the primitive surface by those same sibling and kernel rows.

The consumer side is controlled by Definition 917.11. Every Real or Completion consumer factors through $M, O, S, W, D, R, A, L, H, C, P, N$ before reading an agreement seal or a limit seal.

Finally apply Definition 917.12. Since the route exports no quotient stream equality, host real equality, selected limit, countable-choice selector, or ambient completeness principle, the two projections describe a bridge only for the finite public surface and not for any stronger analytic equality or completeness object. □

Theorem 917.16 (Tail budget coherence finite-route determinacy)**.** *For an accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet*

$$T = (M, O, S, A, L, W, R, D, H, C, P, N),$$

any two $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumers that read the same TailMeet threshold, observation budget, selector budget, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, agreement seal, limit seal, and structural rows determine the same public finite route*

$$M, O, S, W, D, R, A, L, H, C, P, N.$$

No second window, quotient stream equality, selected limit, host real equality, countable-choice selector, or ambient completeness row can distinguish the two routes.

Proof. Begin with threshold-budget exposure from Definition 917.4. It fixes the TailMeet threshold, observation-budget, and selector-budget rows before any consumer can read the finite window or either seal.

Next apply window-readback exactness from Definition 917.5. The shared window, dyadic ledger, and regular readback are exactly W, D, R, so two consumers with the same displayed readback data cannot separate into two finite-window routes.

The Real route scope and public export boundary, Definition 917.11 and Definition 917.13, place both consumers on $M, O, S, W, D, R, A, L, H, C, P, N$ before either Real or Completion endpoint sees the agreement or limit seal.

Finally use the sibling-scope lock, bridge interface, and no-ambient-completeness scope of Definition 917.10, Definition 917.15, and Definition 917.12. These exhaust the structural rows and exclude quotient stream equality, selected limits, host real equality, choice selectors, and ambient completeness rows, so the two reads are the same public finite route. □

Theorem 917.17 (Tail budget coherence synchronizer comparison)**.** *For an accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet*

$$T = (M, O, S, A, L, W, R, D, H, C, P, N),$$

the $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *packet on the same consumer route is the window-to-seal projection of* T*: it reads the shared StreamName window* W*, RegSeqRat readback* R*, threshold-budget spine* M, O, S*, CauchyLimitSeal row* L*, transport, continuation, provenance, and local naming rows, and then exposes only the corresponding Real-window seal surface. The projection discards no hidden completion coordinate because* T *carries none.*

Lean4 ✓ `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceCarrier synchronizer comparison`

Proof. Begin with the TailBudgetCoherence bridge interface of Definition 917.15. It presents the public consumer route as $M, O, S, W, D, R, A, L, H, C, P, N$.

Compare this route with the RealWindowSynchronizer carrier and obligation package from Definition 979.1 and Definition 979.7. The synchronizer reads the same window W, readback R, threshold spine, limit seal L, transport, continuation, provenance, and naming rows when it exposes its Real-window seal.

The TailBudgetCoherence no-ambient-completeness scope ensures that the larger packet has no quotient stream, selected limit, host real equality, or ambient completeness coordinate to hide from the projection. Hence the synchronizer packet is exactly the window-to-seal projection of the public tail-budget packet. □

Theorem 917.18 (Tail budget coherence diagonal-selection dependency)**.** *Every Completion-facing* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *route consumes the finite diagonal-selection row of chapter 4080 before it reads the* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{RealTailAgreementSeal}^{\uparrow}$*, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows. The dependency is only a finite-route order: the packet does not choose a host diagonal sequence, assert quotient stream equality, or supply an ambient completeness principle.*

Proof. Start from threshold-budget exposure. The TailMeet threshold, observation budget, and selector budget rows M, O, S are visible before any finite window, tolerance, readback, or seal row is consumed.

The Cauchy diagonal-selection row is the selector-facing sibling that turns those displayed requests into the finite diagonal window service. Reading it first fixes the window requests that the $\mathsf{StreamName}^{\uparrow}$ row W may serve.

Then apply window-readback exactness and seal non-escape. The only downstream readback path is W, D, R followed by the agreement and limit seals A, L, and no row in the packet adds a host-selected diagonal, quotient equality, or ambient completeness object. □

Theorem 917.19 (Tail budget coherence shared-window refinement)**.** *In an accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet* $T = (M, O, S, A, L, W, R, D, H, C, P, N)$*, the shared window and refinement rows* W, D, R *agree under the threshold-budget rows* M, O, S*. Any RealWindowSynchronizer consumer that reads* W *and* R *through this packet also reads the dyadic tolerance ledger* D *as the displayed refinement witness for the same shared threshold-budget spine.*

Proof. Apply threshold-budget exposure from Definition 917.4. It places the TailMeet threshold, observation budget, and selector budget rows M, O, S before the finite window, dyadic tolerance ledger, and regular readback are consumed.

Then use window-readback exactness from Definition 917.5. It identifies W, D, R as the exact StreamName, DyadicRatCore, and RegSeqRat route under those same threshold-budget rows.

A RealWindowSynchronizer consumer reading through the TailBudgetCoherence packet therefore cannot choose a second window or readback row. It receives W and R together with D as the refinement witness for the shared M, O, S spine. □

Theorem 917.20 (Tail budget coherence Real-window consumer route)**.** *Any* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *consumer that uses an accepted* $\mathsf{TailBudgetCoherence}^{\uparrow}$ *packet follows the public route*

$$M, O, S, W, D, R, A, L, H, C, P, N.$$

The route carries the TailMeet threshold, observation budget, selector budget, shared StreamName window, DyadicRatCore tolerance ledger, RegSeqRat readback, agreement seal, CauchyLimitSeal row, transport, continuation, provenance, and local naming rows, and it exports no quotient stream or ambient completeness coordinate.

Proof. Use the synchronizer comparison of Definition 917.17 to place the RealWindowSynchronizer consumer as a projection of the TailBudgetCoherence public packet.

Apply shared-window refinement from Definition 917.19. The window, dyadic ledger, and readback rows are the displayed W, D, R rows under the same threshold-budget spine M, O, S.

Finally use the public export boundary and no-ambient-completeness scope of Definition 917.13 and Definition 917.12. The consumer route is exactly $M, O, S, W, D, R, A, L, H, C, P, N$, with no quotient stream or ambient completeness coordinate. □

Falsifiable prediction: If a completion-facing consumer reads the limit seal without a displayed TailMeet threshold, observation budget, selector budget, finite window ledger, dyadic tolerance ledger, regular readback, and agreement-seal row, that read is not accepted by $\mathsf{TailBudgetCoherence}^{\uparrow}$.

The composite-dependency explanation is the replacement for an atomic independence witness. The carrier is deliberately assembled from existing $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ rows; its content is the coherence of those rows at the Real-completion handoff, not a new primitive analytic object.

Closure status for $\mathsf{NameCert}_{\mathsf{TailBudgetCoherence}^{\uparrow}}$**.**

Constructive story: A $\mathsf{TailBudgetCoherence}^{\uparrow}$ packet is generated from TailMeet threshold, Real observation-budget, regular Cauchy selector-budget, RealTailAgreementSeal, CauchyLimitSeal, finite StreamName window, RegSeqRat readback, DyadicRatCore tolerance, componentwise transport, displayed continuation, provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TailBudgetCoherence}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 917.1, Definition 917.2, Definition 917.3, Definition 917.4, Definition 917.5, Definition 917.6, Definition 917.8, Definition 917.9, Definition 917.13, Definition 917.14, Definition 917.10, Definition 917.11, Definition 917.12, and Definition 917.15 give the mature treatment of the public export boundary, Real-seal window stability, bridge interface, sibling-scope lock, Real route scope, and no-ambient-completeness scope for the finite Real-completion tail-budget handoff.

Formal verification: FormalStatus(NameCert$_{\mathsf{TailBudgetCoherence}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.TailBudgetCoherenceUp.TailBudgetCoherenceUp\_StdBridge`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not prove Real completeness, quotient equality of regular streams, selected-limit existence, host real equality, or bridge checking for TailBudgetCoherence$^{\uparrow}$.

Chapter 918

A Concrete Naming Certificate for $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$

The $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ packet realizes the Real and Completion handoff requested by chapter 9238. It sits immediately downstream of the bounded monotone Cauchy witness surface of chapter 535: the witness still supplies the finite monotone source, tail window, Cauchy modulus, dyadic tolerance, and located trap rows, while the seal packages the public convergence handoff to $\mathsf{Real}^{\uparrow}$ without adding a selected limit or quotient equality.

Definition 918.1 (Bounded monotone convergence seal carrier)**.** *A* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$$

with the following displayed rows:

1. *W is the accepted* $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$ *row that supplies the bounded source, tail witness, dyadic ledger, located trap, and real-seal precursor;*
2. *M is the public* $\mathsf{MonotoneCauchy}^{\uparrow}$ *tail-window certificate through which the bounded monotone source is read;*
3. *K is the public* $\mathsf{CauchyCriterion}^{\uparrow}$ *packet through which tolerance requests, tail windows, and dyadic bounds are read;*
4. *F is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row exported by the witness and criterion packets;*
5. *σ is the finite* $\mathsf{StreamName}^{\uparrow}$ *window ledger used by the tail and seal reads;*
6. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance and upper-bound ledger consumed before any convergence seal is visible;*
7. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *compatibility row tying the witnessed Cauchy route to the completion-facing seal boundary;*
8. *R is the* $\mathsf{Real}^{\uparrow}$ *convergence seal row reached only after W, M, K, F, σ, D, L have been displayed;*
9. *H records componentwise* hsame *transports for all displayed rows;*
10. *C records the displayed* Cont *routes by which consumers read the witness, monotone tail, criterion, regular-rational, stream-window, dyadic, limit-seal, and Real rows;*

11. *P is the* Pkg *provenance over* BoundedMonotoneCauchyWitness$^{\uparrow}$, MonotoneCauchy$^{\uparrow}$, CauchyCriterion$^{\uparrow}$, CauchyLimitSeal$^{\uparrow}$, RegSeqRat$^{\uparrow}$, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
12. *N is the local* NameCert$_{\text{BoundedMonotoneConvergenceSeal}^{\uparrow}}$ *row.*

The carrier contains no selected limit representative, quotient stream equality, host real equality, trichotomy row, open-cover compactness row, detached tail oracle, or ambient completeness theorem.

Lean4 (definition) `BEDC.Derived.BoundedMonotoneConvergenceSealUp.BoundedMonotoneConvergenceSealUp`

Theorem 918.2 (Bounded monotone convergence seal NameCert obligations)**.** *The local* NameCert$_{\text{BoundedMonotoneC}}$ *surface for Definition 918.1 consists exactly of carrier admission for $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$, bounded witness exposure through W, public monotone tail-window exposure through M, public Cauchy criterion exposure through K, regular-rational handoff through F, finite stream-window exposure through σ, dyadic tolerance and upper-bound accounting through D, Cauchy-limit seal compatibility through L, Real convergence seal handoff through R, componentwise transport through H, displayed route replay through C, package provenance through P, and local naming through N.*

Proof. Project the carrier. Its displayed rows are exactly the bounded witness, public monotone tail-window, public Cauchy criterion, regular-rational handoff, finite stream-window, dyadic ledger, limit-seal compatibility, Real seal, transport, route, provenance, and local naming rows.

Use Definition 535.31. It routes the bounded source through the public MonotoneCauchy$^{\uparrow}$ tail-window certificate and routes the witness rows through the public CauchyCriterion$^{\uparrow}$ packet before the Real-facing seal is read.

Finally attach the completion-facing rows $F, \sigma, D, L, R, H, C, P, N$. Since the carrier has no coordinate for a selected limit, quotient stream, host equality, trichotomy, open-cover compactness, detached tail oracle, or ambient completeness, the listed rows are the complete local naming surface. □

Theorem 918.3 (Bounded monotone convergence seal public handoff)**.** *Every* Real$^{\uparrow}$ *or completion-facing consumer of an accepted* BoundedMonotoneConvergenceSeal$^{\uparrow}$ *packet factors first through the bounded monotone Cauchy witness row W, then through the public* MonotoneCauchy$^{\uparrow}$ *and* CauchyCriterion$^{\uparrow}$ *rows M and K, and only then through the displayed route*

$$F, \sigma, D, L, R, H, C, P, N.$$

The consumer receives a finite Real convergence handoff assembled from BoundedMonotoneCauchyWitness$^{\uparrow}$, MonotoneCauchy$^{\uparrow}$, CauchyCriterion$^{\uparrow}$, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *and* Real$^{\uparrow}$ *rows, with the* CauchyLimitSeal$^{\uparrow}$ *row L acting only as the compatibility boundary for the sealed route. It receives no route that bypasses W or K to a selected limit, quotient stream, host real equality, ambient completeness witness, detached tail oracle, trichotomy row, or open-cover compactness row.*

Proof. Begin with the bounded monotone witness surface. By Definition 535.19, every witness read is already scoped by the displayed regular-rational, stream-window, Cauchy witness, dyadic, located-trap, Real seal, transport, route, provenance, and naming rows.

Next use the bridge to public tail and criterion packets. The MonotoneCauchy$^{\uparrow}$ row supplies the public tail-window certificate, while the CauchyCriterion$^{\uparrow}$ row supplies the explicit tolerance, tail, dyadic, regular-rational, and seal route.

The remaining rows $F, \sigma, D, L, R, H, C, P, N$ carry the public convergence handoff to the Real-facing boundary. The limit-seal row records compatibility with the sealed completion route, but it does not add a selected representative or a host equality coordinate.

Thus every consumer route is exhausted by the displayed packet. A route that omits W or K has no access to the bounded witness or Cauchy criterion rows, and a route that asks for selected limits, quotient streams, host equality, ambient completeness, detached tail oracles, trichotomy, or compactness asks for data absent from the carrier. □

Theorem 918.4 (Bounded monotone convergence seal witness consumption)**.** *Every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$$

consumes the witness row W through $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$ *before any public* $\mathsf{Real}^{\uparrow}$ *or completion-facing seal row is available. A completion-facing consumer therefore receives the bounded source, tail witness, dyadic ledger, located trap, and Real-seal precursor from W before it reads $M, K, F, \sigma, D, L,$ or R.*

Lean4 ✓ `BEDC.Derived.BoundedMonotoneConvergenceSealUp.BoundedMonotoneConvergenceSealUp witness consumption`

Proof. Start with Definition 918.1. The first displayed coordinate of the accepted packet is W, and the carrier names it as the accepted $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$ row that supplies the bounded source, tail witness, dyadic ledger, located trap, and Real-seal precursor.

The sibling surface chapter 535 and the bridge theorem Definition 535.31 say that the bounded witness is the source from which the public $\mathsf{MonotoneCauchy}^{\uparrow}$ and $\mathsf{CauchyCriterion}^{\uparrow}$ rows are read. The same public route is later continued through chapter 438, chapter 392, chapter 126, chapter 291, chapter 301, chapter 386, and chapter 38.

Finally apply Definition 918.3. Every $\mathsf{Real}^{\uparrow}$ or completion-facing consumer factors through W before it reaches the public rows M, K and the route $F, \sigma, D, L, R, H, C, P, N$. Thus the witness row is exposed first and no direct completion read is available. □

Theorem 918.5 (Bounded monotone convergence seal criterion route)**.** *After the witness row W has been consumed, every tolerance-facing* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *read routes through the public rows M, K, F, σ, D, L before it reaches the Real seal row R. Such a read cannot bypass the public* $\mathsf{MonotoneCauchy}^{\uparrow}$ *row M or the public* $\mathsf{CauchyCriterion}^{\uparrow}$ *row K when it asks for a tail window, dyadic tolerance ledger, stream window, regular-rational handoff, or CauchyLimitSeal compatibility boundary.*

Lean4 ✓ `BEDC.Derived.BoundedMonotoneConvergenceSealUp.BoundedMonotoneConvergenceSealUp criterion route`

Proof. Project Definition 918.1. The carrier places M and K immediately after the bounded witness row W and before the regular-rational, stream, dyadic, CauchyLimitSeal, and Real rows.

The public tail and criterion rows are the sibling surfaces of chapter 438 and chapter 392. The bounded-witness source is supplied by chapter 535, and the later finite route is read through chapter 126, chapter 291, chapter 301, chapter 386, and chapter 38.

Now use Definition 918.2 together with Definition 918.3. The NameCert surface names public monotone tail-window exposure through M and public Cauchy criterion exposure through K, and the handoff theorem forces every completion-facing route through W, M, K before $F, \sigma, D, L, R, H, C, P, N$ can be consumed. □

Theorem 918.6 (Bounded monotone convergence seal Real handoff)**.** *For every accepted* BoundedMonotoneConver *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N),$$

the Real-facing handoff reaches R only after the finite route

$$W, M, K, F, \sigma, D, L, R, H, C, P, N$$

has displayed the witness, criterion, stream, dyadic, limit-seal, transport, route, package, and NameCert rows. The row R is exactly the $\mathsf{Real}^{\uparrow}$ *handoff at the end of this displayed route and not a selected limit, quotient stream equality, host real equality, ambient completeness row, or metric-completeness row.*

Lean4 ✓ `BEDC.Derived.BoundedMonotoneConvergenceSealUp.BoundedMonotoneConvergenceSealUp real handoff`

Proof. Read the displayed order in Definition 918.1. The route reaches R only after W, M, K, F, σ, D, L have appeared, and the rows F, σ, D, L are the regular-rational, stream-window, dyadic-ledger, and CauchyLimitSeal compatibility coordinates.

The sibling surfaces certify the same ordering: chapter 535 provides the witness source, chapter 438 and chapter 392 provide the public tail and criterion gates, chapter 301, chapter 126, and chapter 291 provide the finite name and tolerance route, chapter 386 provides only the compatibility boundary, and chapter 38 provides the terminal seal surface.

Finally apply Definition 918.3. It identifies L as compatibility only and R as the Real convergence handoff after the displayed route. Since the carrier contains no coordinate for selected limits, quotient stream equality, host real equality, ambient completeness, or metric-completeness rows, the handoff is exact at the listed Real seal boundary. □

Theorem 918.7 (Bounded monotone convergence seal limit-seal compatibility)**.** *For every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N),$$

the row L is only the $\mathsf{CauchyLimitSeal}^{\uparrow}$ *compatibility boundary reached after W, M, K, F, σ, D. It cannot itself expose a selected limit, quotient stream equality, host real equality, ambient completeness theorem, or a* $\mathsf{Real}^{\uparrow}$ *seal read.*

Proof. Project the carrier of Definition 918.1. The displayed route reaches L only after the bounded witness row, the public monotone and Cauchy rows, the regular-rational row, the stream-window row, and the dyadic ledger row.

Apply Definition 918.5. It identifies every tolerance-facing read of L as a read of the CauchyLimitSeal compatibility boundary after W, M, K, F, σ, D.

The sibling $\mathsf{CauchyLimitSeal}^{\uparrow}$ surface of chapter 386 is therefore used only as the boundary surface, while the $\mathsf{Real}^{\uparrow}$ surface of chapter 38 is read only at the terminal row R. The carrier has no coordinate for selected limits, quotient stream equality, host real equality, ambient completeness, or an early Real seal read, so coordinate exhaustion gives the stated nonescape. □

Theorem 918.8 (Bounded monotone convergence seal tail-window consumption)**.** *For every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N),$$

every seal read consumes the bounded witness row W, public monotone tail-window row M, public Cauchy criterion row K, regular-rational handoff row F, stream-window row σ, and dyadic tolerance ledger row D before it may read the CauchyLimitSeal boundary L or the Real handoff row R.

Proof. Project the carrier of Definition 918.1. The displayed tuple places W, M, K, F, σ, D before L, R, so no coordinate order exposes L or R ahead of the bounded witness, public tail, public criterion, regular-rational, stream-window, and dyadic rows.

Apply Definition 918.3 and Definition 918.5. These route the public consumer through W, M, K and then through F, σ, D before the CauchyLimitSeal boundary can be read.

Finally use Definition 918.6. The Real handoff R is available only after the same finite prefix and the compatibility row L, so every seal read consumes the six displayed rows before either terminal seal coordinate is inspected. □

Theorem 918.9 (Bounded monotone convergence seal limit refusal exhaustion)**.** *For every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet* $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$*, the row L is only the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *compatibility boundary. It exports no selected limit, quotient stream, host equality, trichotomy, open-cover compactness, or ambient completeness datum to any seal consumer.*

Proof. Use Definition 918.7. It identifies L as the CauchyLimitSeal compatibility boundary reached after the finite prefix W, M, K, F, σ, D.

The excluded data are not carrier rows. The packet has rows for the bounded witness, public monotone tail window, public Cauchy criterion, regular-rational handoff, stream window, dyadic ledger, compatibility boundary, Real handoff, transports, continuations, package provenance, and local NameCert provenance, but it has no coordinate for a selected limit, quotient stream, host equality, trichotomy, open-cover compactness, or ambient completeness principle.

Therefore a consumer that reads L receives compatibility only. Coordinate exhaustion blocks every listed limit or completeness datum from being exported through the limit-seal row. □

Theorem 918.10 (Bounded monotone convergence seal Real threshold route)**.** *For every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet* $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$*, the Real threshold row R is reached only through the finite route*

$$W, M, K, F, \sigma, D, L, R.$$

This route is consumed through the sibling surfaces $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$*,* $\mathsf{MonotoneCauchy}^{\uparrow}$*,* $\mathsf{CauchyCriterion}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*.*

Proof. Start with the carrier order. The route to R passes through W, M, K, F, σ, D, L before the Real threshold coordinate is available.

Attach the sibling surfaces to the finite prefix. The bounded source is read through chapter 535; the public monotone and Cauchy gates are read through chapter 438 and chapter 392; the finite naming and tolerance rows are read through chapter 126, chapter 291, and chapter 301.

Now apply Definition 918.7 and Definition 918.6. They place the $\mathsf{CauchyLimitSeal}^{\uparrow}$ compatibility boundary at L and the $\mathsf{Real}^{\uparrow}$ handoff at R, so the displayed sibling route is the only route to the Real threshold row. □

Theorem 918.11 (Bounded monotone convergence seal Real boundary nonescape)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing consumer of an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet reaches* R *only through the displayed route*

$$W \to (M, K) \to (F, \sigma, D, L) \to R.$$

It cannot recover an ambient completeness theorem, metric-completeness row, trichotomy row, open-cover compactness row, or detached tail oracle from that Real boundary.

Proof. First use Definition 918.3. It forces every Real-facing or completion-facing consumer to pass through the bounded witness row W before the public rows and finite route are available.

Next apply Definition 918.5 and Definition 918.6. These theorems place the public monotone and Cauchy rows M, K before F, σ, D, L and place the Real handoff row R only after the same route.

Finally use Definition 918.13. The excluded ambient completeness theorem, metric-completeness row, trichotomy row, open-cover compactness row, and detached tail oracle have no coordinate in $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$, so the displayed Real boundary cannot export them. □

Theorem 918.12 (Bounded monotone convergence seal obligation package)**.** *The obligation surface of an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet is the ordered package*

$$W \to (M, K) \to (F, \sigma, D, L) \to R$$

together with the transport, route, provenance, and naming rows H, C, P, N*. It exposes the bounded witness first, then the public* $\mathsf{MonotoneCauchy}^{\uparrow}$ *and* $\mathsf{CauchyCriterion}^{\uparrow}$ *handoff, then the finite* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route, and only then the* $\mathsf{Real}^{\uparrow}$ *row. The package closes no Real completeness theorem, no selected-limit theorem, no quotient-stream equality, and no host-real equality.*

Proof. The carrier definition Definition 918.1 gives the finite packet $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$. The local NameCert theorem Definition 918.2 reads the same coordinates as carrier admission, witness exposure, public tail and criterion exposure, finite route exposure, Real handoff, transport, continuation, provenance, and local naming.

The sibling surfaces determine the displayed route. The witness part is chapter 535; the public tail and criterion gates are chapter 438 and chapter 392; the finite route is chapter 301, chapter 126, chapter 291, and chapter 386; the terminal seal surface is chapter 38.

Apply Definition 918.3. It forces every Real or completion consumer through W, then M, K, then F, σ, D, L, and only then R, H, C, P, N. Therefore the ordered package is the complete obligation surface for the current seal, while completeness, selected limits, quotient stream equality, and host real equality remain outside the carrier. □

Theorem 918.13 (Bounded monotone convergence seal terminal budget exhaustion)**.** *For every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N),$$

every terminal $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of* S *is exhausted by the ordered route*

$$W \to (M, K) \to (F, \sigma, D, L) \to R$$

together with the structural rows H, C, P, N*. After that route has been read, the packet cannot recover a selected limit, quotient stream equality, host real equality, trichotomy row, open-cover compactness row, detached tail oracle, ambient completeness theorem, or metric-completeness datum.*

Proof. Start with the carrier of Definition 918.1. Its only terminal-facing coordinates are the witness row W, the public monotone and Cauchy rows M, K, the finite stream, dyadic, regular-rational, and limit-seal route F, σ, D, L, the Real handoff row R, and the structural rows H, C, P, N.

Apply Definition 918.3, Definition 918.5, and Definition 918.6. These results force the terminal consumer through the displayed route before any Real-facing read is available.

Use Definition 918.12 to collect the same rows as the complete obligation surface. The carrier has no coordinate for the excluded completion or compactness data, so exhausting the displayed route also exhausts every completion-facing read available from the packet. □

Theorem 918.14 (Bounded monotone convergence seal scoped handoff package)**.** *Every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$$

binds the witness, public monotone tail, Cauchy criterion, regular-rational row, stream name, dyadic ledger, CauchyLimitSeal compatibility row, Real handoff, componentwise transport, displayed route, package provenance, and local name to the primitive BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows. The sibling surfaces* $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$*,* $\mathsf{MonotoneCauchy}^{\uparrow}$*,* $\mathsf{CauchyCriterion}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *are read only through the displayed route*

$$W \to (M, K) \to (F, \sigma, D, L) \to R \to (H, C, P, N).$$

The handoff exports no selected limit, quotient stream equality, host real equality, ambient completeness, trichotomy, or detached tail oracle.

Proof. Start with the carrier of Definition 918.1. It supplies exactly the tuple $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N$ and makes H, C, P, N the only transport, continuation, package, and naming rows available to the packet.

Apply the NameCert obligations of Definition 918.2. They bind each displayed coordinate to the same primitive BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ surface rather than to an external Real-completion principle.

Use the public handoff of Definition 918.3 together with the criterion route recorded in Definition 918.5 and the Real handoff recorded in Definition 918.6. These theorems force every sibling read through the bounded witness, public monotone and Cauchy gates, finite rational-stream route, CauchyLimitSeal compatibility row, and terminal Real row.

Finally apply Definition 918.12. The package theorem collects those rows into one scoped obligation surface, so selected limits, quotient stream equality, host real equality, ambient completeness, trichotomy, and detached tail oracles remain outside the accepted packet. □

Theorem 918.15 (Bounded monotone convergence seal provenance and local naming)**.** *For every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N),$$

the provenance row P *and the local naming row* N *name exactly the ordered package*

$$W \to (M, K) \to (F, \sigma, D, L) \to R$$

together with the componentwise transport and displayed route rows H, C*. The rows* P *and* N *cannot add a selected limit, quotient stream equality, host real equality, trichotomy row, ambient completeness row, detached tail oracle, or open-cover compactness row.*

Proof. Project the carrier of Definition 918.1. Its final coordinates are the package provenance row P and local $\mathsf{NameCert}_{\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}}$ row N, after the displayed witness, public tail, criterion, finite route, Real seal, transport, and route rows.

Apply Definition 918.2. The obligation list names package provenance through P and local naming through N only as rows over the same displayed carrier inventory. Use Definition 918.3 and Definition 918.12 to identify the ordered package as $W \to (M, K) \to (F, \sigma, D, L) \to R$ together with H, C.

It remains to exclude escaping data. The carrier has no coordinate for a selected limit, quotient stream equality, host real equality, trichotomy, ambient completeness, detached tail oracle, or open-cover compactness. Since P and N only name provenance and local naming for the listed carrier coordinates, they cannot introduce any unlisted row. □

Theorem 918.16 (Bounded monotone convergence seal checked obligation route)**.** *For every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N),$$

the obligation route required for later checked Real-completion work is exactly

$$W \to (M, K) \to (F, \sigma, D, L) \to R \to (H, C, P, N).$$

The witness row W, monotone-tail row M, Cauchy-criterion row K, regular-rational row F, stream-name row σ, dyadic row D, CauchyLimitSeal row L, Real row R, transport row H, route row C, provenance row P, and local NameCert row N are supplied by the existing carrier, NameCert-obligation, public-handoff, obligation-package, scoped-handoff, and provenance/local-naming theorems of this chapter. The route excludes selected limits, quotient stream equality, host real equality, trichotomy, detached tail oracles, open-cover compactness, and ambient completeness.

Proof. Start with the carrier definition Definition 918.1. It supplies exactly the finite packet $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$ and has no coordinate for selected limits, quotient stream equality, host real equality, trichotomy, detached tail oracles, open-cover compactness, or ambient completeness.

Apply Definition 918.2 and Definition 918.3. These results expose the witness, public monotone-tail, Cauchy-criterion, finite rational-stream route, CauchyLimitSeal boundary, and Real handoff in the required order.

Now use Definition 918.12, Definition 918.14, and Definition 918.15. They package the same route as $W \to (M, K) \to (F, \sigma, D, L) \to R$ together with H, C, P, N, bind it to the primitive BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, and prevent the provenance or local name from adding any unlisted Real-completion content. □

Theorem 918.17 (Bounded monotone convergence seal witness scope)**.** *For every accepted* BoundedMonotoneConv *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N),$$

the row W is the unique bounded-witness entry point into the L10 Real-completion chain. Every subsequent public row of the packet depends on the $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$ *surface exposed by W: the monotone-tail gate M, the Cauchy-criterion gate K, the finite route F, σ, D, L, the Real handoff R, and the bookkeeping rows H, C, P, N have no independent entry route that avoids W.*

Proof. Begin with Definition 918.1. It places W as the first displayed row and identifies it as the accepted $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$ row carrying the bounded source, tail witness, dyadic ledger, located trap, and Real-seal precursor.

Apply Definition 918.4. It states that a completion-facing consumer consumes W before any of M, K, F, σ, D, L, or R is available.

Now use Definition 918.16. The checked route is exactly $W \to (M, K) \to (F, \sigma, D, L) \to R \to (H, C, P, N)$, so every later row is downstream of the witness surface and no second witness entry point is exported. □

Theorem 918.18 (Bounded monotone convergence seal witness-scope public factorization)**.** *Every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *completion-facing consumer factors through the ordered public route*

$$W \to (M, K) \to (F, \sigma, D, L) \to R \to (H, C, P, N),$$

where W is supplied by $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$*, M by* $\mathsf{MonotoneCauchy}^{\uparrow}$*, K by* $\mathsf{CauchyCriterion}^{\uparrow}$*, F by* $\mathsf{RegSeqRat}^{\uparrow}$*, σ by* $\mathsf{StreamName}^{\uparrow}$*, D by* $\mathsf{DyadicRatCore}^{\uparrow}$*, L by* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and R by* $\mathsf{Real}^{\uparrow}$*. The route excludes selected limits, quotient stream equality, host real equality, trichotomy, detached tail oracle, open-cover compactness, and ambient completeness.*

Proof. First apply Definition 918.17. It makes W the unique bounded-witness entry point into the public L10 chain and places every later row downstream of that witness surface.

Next use Definition 918.3 and Definition 918.5. These theorems force the completion-facing consumer from W through the public monotone-tail row M, the Cauchy-criterion row K, and the finite route F, σ, D, L before the Real-facing handoff can be read.

Then apply Definition 918.6. It identifies R as the terminal $\mathsf{Real}^{\uparrow}$ handoff after the displayed finite route, not as a selected limit, quotient stream equality, host real equality, or ambient completeness row.

Finally use Definition 918.16 together with Definition 918.15. The checked route appends exactly H, C, P, N as transport, route replay, provenance, and local naming for the same packet, while provenance and naming cannot add trichotomy, detached tail oracles, open-cover compactness, selected limits, quotient stream equality, host real equality, or ambient completeness. □

Theorem 918.19 (Bounded monotone convergence seal criterion scope)**.** *Within an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N),$$

the rows M and K are mandatory public gates before the L10 route reaches F, σ, D, L, or R. The row M is the $\mathsf{MonotoneCauchy}^{\uparrow}$ *tail-window gate and the row K is the* $\mathsf{CauchyCriterion}^{\uparrow}$ *tolerance gate; no StreamName, RegSeqRat, DyadicRatCore, CauchyLimitSeal, or Real handoff row is readable as a public convergence route until both gates have been consumed after W.*

Proof. Project the carrier in Definition 918.1. The rows M and K occur immediately after W and before the finite route rows F, σ, D, L and the Real row R.

Apply Definition 918.5. It prevents a tolerance-facing read from bypassing M or K when it asks for a tail window, dyadic tolerance ledger, stream window, regular-rational handoff, or CauchyLimitSeal boundary.

Finally use Definition 918.16. Since the displayed route is $W \to (M, K) \to (F, \sigma, D, L) \to R \to (H, C, P, N)$, the public criterion surface is a gate in the L10 chain rather than optional explanatory data. □

Theorem 918.20 (Bounded monotone convergence seal stream and Real scope)**.** *After the witness and criterion gates of an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet have been consumed, the finite L10 route consumes the rows in the displayed order*

$$\mathsf{StreamName}^{\uparrow},\ \mathsf{DyadicRatCore}^{\uparrow},\ \mathsf{RegSeqRat}^{\uparrow},\ \mathsf{CauchyLimitSeal}^{\uparrow},\ \mathsf{Real}^{\uparrow}$$

as the public surfaces named by the packet rows σ, D, F, L, R*. These surfaces are read from the carrier's finite block*

$$W \to (M, K) \to (F, \sigma, D, L) \to R \to (H, C, P, N),$$

so the StreamName, dyadic, regular-rational, limit-seal, and Real rows are consumed as one finite completion chain rather than as detached analytic endpoints.

Proof. Read the rows in Definition 918.1. The finite completion-facing part of the packet contains the regular-rational row F, the stream-window row σ, the dyadic row D, the CauchyLimitSeal boundary L, and the Real handoff R.

Use Definition 918.6. It places R after W, M, K, F, σ, D, L and identifies R as the terminal $\mathsf{Real}^{\uparrow}$ handoff rather than a selected limit or host equality. Thus the public consumption order of the finite L10 surfaces is read from the same finite block, not from an external analytic route.

The StreamName, dyadic, regular-rational, CauchyLimitSeal, and Real rows are therefore the finite L10 route named by Definition 918.16. The theorem's route order supplies the public consumption order for the chain, while the theorem statement records the sibling surfaces consumed by those rows. □

Theorem 918.21 (Bounded monotone convergence seal ledger exclusion scope)**.** *The ledger of an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet excludes selected limits, quotient stream equality, host real equality, trichotomy, detached tail oracles, open-cover compactness, and ambient completeness. Its only completion-facing rows are the bounded witness* W*, public gates* M, K*, finite route rows* F, σ, D, L, R*, transport and route rows* H, C*, provenance row* P*, and local naming row* N*.*

Proof. Start with Definition 918.1. The definition explicitly lists the rows of $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$ and states that the carrier contains no selected limit representative, quotient stream equality, host real equality, trichotomy row, open-cover compactness row, detached tail oracle, or ambient completeness theorem.

Apply Definition 918.29. It identifies P and N as provenance and local naming rows for exactly the displayed packet and prevents them from importing any excluded analytic object.

Finally use Definition 918.16. The route already accounts for every witness, criterion, finite completion, Real, transport, provenance, and naming row, so the exclusions are part of the scoped obligation surface rather than a separate side condition. □

Theorem 918.22 (Bounded monotone convergence seal obligation scope package)**.** *The four scoped rows Definition 918.17, Definition 918.19, Definition 918.20, and Definition 918.21 form the obligation package for the L10 completion-chain reading of* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$*. Together they bind the unique witness entry, mandatory public criterion gates, finite StreamName–DyadicRatCore–RegSeqRat–CauchyLimitSeal–Real route, and non-escape ledger for any* $\mathsf{obligation}$ *treatment of this packet.*

Proof. The witness-scope row identifies W as the only bounded-witness entry point. The criterion-scope row then forces M and K to be consumed as public $\mathsf{MonotoneCauchy}^{\uparrow}$ and $\mathsf{CauchyCriterion}^{\uparrow}$ gates before any completion-facing route can proceed.

The stream-and-Real scope row records the finite L10 consumption chain through σ, D, F, L, R, and the ledger-exclusion scope row removes selected limits, quotient equality, host equality, trichotomy, detached tail oracles, open-cover compactness, and ambient completeness from the packet.

Combining these rows with Definition 918.16 gives exactly the package $W \to (M, K) \to (F, \sigma, D, L) \to R \to (H, C, P, N)$. Hence the packet has a concrete obligation surface ready for a closure-grade reading without adding any Lean marker in this chapter. □

Theorem 918.23 (Bounded monotone convergence seal carrier admission)**.** *Every accepted* BoundedMonotoneConv *packet projects exactly the displayed carrier rows*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N).$$

Every $\mathsf{Real}^{\uparrow}$ *or completion-facing read of the packet must pass through the witness row W, public monotone-tail row M, public Cauchy-criterion row K, finite* $\mathsf{StreamName}^{\uparrow}$ *row σ, dyadic* $\mathsf{DyadicRatCore}^{\uparrow}$ *row D, regular-rational* $\mathsf{RegSeqRat}^{\uparrow}$ *row F,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *compatibility row L, and terminal* $\mathsf{Real}^{\uparrow}$ *row R, with H, C, P, N recording transport, displayed route, provenance, and local naming.*

Proof. Project Definition 918.1. Its coordinates are exactly $W, M, K, F, \sigma, D, L, R, H, C, P, N$, and no other coordinate is available for a selected limit, quotient stream, host equality, ambient completeness witness, trichotomy, or detached tail oracle.

Apply Definition 918.4 and Definition 918.5. They force the witness read through W and then the public monotone-tail and Cauchy-criterion reads through M and K before the finite route rows can be consumed.

Use Definition 918.6 together with Definition 918.15. The Real-facing row R is reached only after F, σ, D, L, while H, C, P, N only record transport, route replay, provenance, and local naming for the same displayed packet. □

Theorem 918.24 (Bounded monotone convergence seal nontriviality)**.** *The* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *carrier admits two distinguishable finite packet shapes. In one shape the Real seal row is still blocked at the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *compatibility boundary L; in the other shape the Real seal row R is displayed after the public route through W, M, K, F, σ, D, L. Hence the chapter does not present a one-element carrier.*

Proof. The carrier definition exposes both the compatibility boundary row L and the Real seal row R as separate coordinates. The sibling $\mathsf{CauchyLimitSeal}^{\uparrow}$ chapter supplies the sealed completion boundary, while the $\mathsf{Real}^{\uparrow}$ chapter supplies the public Real-facing seal surface.

For the boundary packet shape, read the displayed route only up to L. By Definition 918.5, tolerance-facing reads may reach the CauchyLimitSeal compatibility row after W, M, K, F, σ, D without thereby receiving a selected Real limit or host equality.

For the public seal packet shape, continue through Definition 918.3 and Definition 918.6. The row R is then displayed after the same public criterion route. Since one shape has no displayed R read and the other does, the two finite packet shapes are distinguishable by the consumer route. □

Theorem 918.25 (Bounded monotone convergence seal field faithfulness)**.** *For accepted* BoundedMonotoneConverg *packets*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$$

and

$$S' = (W', M', K', F', \sigma', D', L', R', H', C', P', N'),$$

equality of all displayed fields forces equality of the public seal read. Conversely, changing any one of W, K, F, σ, D, L, R *changes the corresponding consumer route through the witness, criterion, regular-rational, stream, dyadic, limit-seal, or Real-facing row.*

Proof. Assume the displayed fields of S and S' agree. By Definition 918.23, every public seal read is a read of the same ordered carrier rows, and by Definition 918.3 the Real-facing consumer factors through those rows in the displayed order.

The equality of $W, M, K, F, \sigma, D, L, R, H, C, P, N$ therefore transports the same witness, public tail, criterion, finite route, CauchyLimitSeal boundary, Real seal, route replay, provenance, and local name. The public seal read is equal because it has no coordinate outside that carrier inventory.

Now change one of W, K, F, σ, D, L, R. The witness-consumption theorem detects a change of W; the criterion-route theorem detects changes of K, F, σ, D, L; and the Real-handoff theorem detects a change of R. Each changed field is on the unique consumer route to the corresponding public read, so the corresponding route changes. □

Theorem 918.26 (Bounded monotone convergence seal route determinacy)**.** *Two accepted* BoundedMonotoneConv *seal-facing consumer routes with the same displayed rows*

$$W, M, K, F, \sigma, D, L, R, H, C, P, N$$

determine the same $\mathsf{Real}^{\uparrow}$ *handoff route. Conversely, changing any one of* W, K, F, σ, D, L, R *changes the corresponding witness, criterion, regular-rational, stream, dyadic, limit-seal, or Real-facing read.*

Proof. Start with carrier admission and the public handoff theorem. They make every seal-facing consumer route a read of the ordered carrier $W, M, K, F, \sigma, D, L, R, H, C, P, N$ and require the route to pass through the public completion-facing handoff before the Real row is exposed.

Next apply the criterion route and Real handoff. These rows force W to feed the witness surface, M, K to feed the public monotone-tail and Cauchy-criterion gates, F, σ, D to feed the regular-rational, stream, and dyadic route, L to feed the CauchyLimitSeal compatibility boundary, and R to feed the Real-facing read.

The obligation package and scoped handoff package then remove alternate route choices. With the same displayed rows, the route replay C, componentwise transport H, provenance P, and local name N can only certify the same finite passage through the same rows.

Finally use field faithfulness. A changed W, K, F, σ, D, L, or R is a changed field on the unique consumer route to its corresponding surface, so the affected witness, criterion, regular-rational, stream, dyadic, limit-seal, or Real-facing read changes as well. □

Theorem 918.27 (Bounded monotone convergence seal stability envelope)**.** *For accepted* BoundedMonotoneConver *packets* $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$ *and* $S' = (W', M', K', F', \sigma', D', L', R', H', C', P', N')$*, componentwise* hsame *transport recorded by* H *preserves the displayed route*

$$W \to (M, K) \to (F, \sigma, D, L) \to R \to (H, C, P, N).$$

Thus a transported consumer still reads the bounded witness, public monotone-tail and Cauchy-criterion rows, finite rational-stream route, $\mathsf{CauchyLimitSeal}^{\uparrow}$ *boundary,* $\mathsf{Real}^{\uparrow}$ *handoff, continuation replay, provenance, and local name in that order.*

Proof. Start with the carrier admission of Definition 918.23. It fixes the only coordinates available to a consumer as $W, M, K, F, \sigma, D, L, R, H, C, P, N$.

Apply the local NameCert obligations of Definition 918.2. These obligations make H the componentwise hsame transport row for the displayed packet rather than a second route.

The public and scoped handoff rows of Definition 918.3 and Definition 918.14 then preserve the route through W, (M, K), (F, σ, D, L), and R. Finally, Definition 918.15, Definition 918.24, and Definition 918.25 keep the transport attached to the same finite provenance, local name, distinguishable boundary rows, and faithful public seal fields. □

Theorem 918.28 (Bounded monotone convergence seal exactness envelope)**.** *Within an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet, the row L is exactly the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *compatibility boundary reached after W, M, K, F, σ, D, and the row R is exactly the* $\mathsf{Real}^{\uparrow}$ *handoff reached only after that finite route. No consumer may read L as a selected Real limit, or read R before the displayed bounded-witness, public-criterion, stream, dyadic, and regular-rational rows have been exposed.*

Proof. Use Definition 918.5. It places L after the witness, public monotone-tail, public Cauchy-criterion, regular-rational, stream, and dyadic rows, so L is only the compatibility boundary for that route.

Next apply Definition 918.6 and Definition 918.3. Together they put R after the same finite route and keep the Real-facing read from bypassing W, M, K, F, σ, D, L.

The carrier, obligation package, scoped handoff package, provenance-local-naming row, non-triviality row, and field-faithfulness row then rule out any alternate coordinate for a selected limit, an early Real handoff, or a second completion boundary. □

Theorem 918.29 (Bounded monotone convergence seal ledger exhaustion)**.** *For an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet, the provenance row P and local naming row N name exactly the displayed packet $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$. They cannot add selected limits, quotient stream equality, host real equality, trichotomy, compactness, or ambient completeness.*

Proof. Read the carrier and NameCert obligation rows from Definition 918.1 and Definition 918.2. The provenance and naming coordinates are P and N for the listed packet, with no extra coordinate for limit selection or ambient completeness.

Apply Definition 918.15. It identifies P as source provenance and N as the local NameCert row for the same route.

Finally combine Definition 918.23, Definition 918.3, Definition 918.14, Definition 918.24, and Definition 918.25. The route remains finite and field-faithful, so P, N exhaust the ledger rather than importing quotient equality, host equality, trichotomy, compactness, or a completeness principle. □

Theorem 918.30 (Bounded monotone convergence seal obligation closure package)**.** *For an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$, the paper obligation surface is exactly the carrier admission row, bounded-witness exposure row, public monotone-tail and Cauchy-criterion route, regular-rational stream route, dyadic tolerance ledger, stability envelope, exactness envelope, and provenance-local naming ledger. Equivalently, the obligation package is generated by carrier admission, witness exposure, criterion routing, stability, exactness, and ledger exhaustion over the displayed rows $W, M, K, F, \sigma, D, L, R, H, C, P, N$.*

Proof. Start from carrier admission. By Definition 918.23, every accepted packet exposes only the displayed rows $W, M, K, F, \sigma, D, L, R, H, C, P, N$.

The witness and criterion routes are supplied by Definition 918.4 and Definition 918.5. These place the bounded witness, monotone-tail row, Cauchy-criterion row, regular-rational handoff, stream window, dyadic ledger, limit-seal boundary, and Real-facing read in the stated order.

Next apply Definition 918.27 and Definition 918.28. They keep componentwise transport on the same route and make L and R exact terminal rows for the displayed convergence surface.

Finally use Definition 918.29. The provenance and local naming rows close the obligation package without importing selected limits, quotient stream equality, host real equality, trichotomy, compactness, or ambient completeness. □

Theorem 918.31 (Bounded monotone convergence seal obligation-upgrade scope)**.** *The paper obligation surface for* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *is ready only as a scope package over the displayed rows* $W, M, K, F, \sigma, D, L, R, H, C, P, N$*. Its dependency surface is the finite route through* $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$*,* $\mathsf{MonotoneCauchy}^{\uparrow}$*,* $\mathsf{CauchyCriterion}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. This theorem prepares the* $\mathsf{obligation}$ *route, but it does not change the chapter closurestatus, add a Lean marker, or claim Real completeness, selected limits, quotient stream equality, host real equality, trichotomy, compactness, or ambient completeness.*

Proof. Start with Definition 918.30. It already generates the paper obligation package from carrier admission, witness exposure, criterion routing, stability, exactness, and ledger exhaustion over $W, M, K, F, \sigma, D, L, R, H, C, P, N$.

The named dependencies are exactly the rows consumed by that route. $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$ supplies W, $\mathsf{MonotoneCauchy}^{\uparrow}$ supplies M, $\mathsf{CauchyCriterion}^{\uparrow}$ supplies K, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ supply F, σ, D, while $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ supply L, R.

The primitive BEDC rows BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ supply carrier formation, transport, replay, provenance, and local naming. These are sufficient to state the paper scope package.

Finally inspect the excluded claims in Definition 918.32. The route still does not select a limit, identify quotient streams, assert host real equality, or import a completeness principle, so the closurestatus and Lean verification axis remain unchanged. □

Theorem 918.32 (Bounded monotone convergence seal public route totality)**.** *Every public* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet reads through exactly the route*

$$W, M, K, F, \sigma, D, L, R, H, C, P, N.$$

No such consumer can instead read a selected limit, quotient stream, host real equality, trichotomy, open-cover compactness row, or ambient completeness coordinate.

Proof. First apply Definition 918.30. The public surface is already generated by carrier admission, witness exposure, criterion routing, stability, exactness, and ledger exhaustion over $W, M, K, F, \sigma, D, L, R, H, C, P, N$.

Use Definition 918.3 and Definition 918.14. They identify the $\mathsf{Real}^{\uparrow}$ and $\mathsf{Completion}^{\uparrow}$ reads with the displayed finite route rather than with a separate analytic completion object.

Finally combine Definition 918.28 with Definition 918.29. Exactness forces L and R to remain the terminal seal and Real handoff rows, while ledger exhaustion excludes selected limits, quotient stream equality, host real equality, trichotomy, open-cover compactness, and ambient completeness. □

Theorem 918.33 (Bounded monotone convergence seal finite-limit interface obligations)**.** *For every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet* $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$*, the finite-limit interface obligation is exactly the displayed route through* $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$*,* $\mathsf{MonotoneCauchy}^{\uparrow}$*,* $\mathsf{CauchyCriterion}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*:*

$$W, M, K, \sigma, D, F, L, R, H, C, P, N.$$

The public consumer receives only this finite route and receives no selected limit, quotient stream equality, host real equality, trichotomy, open-cover compactness, or ambient completeness principle.

Proof. Project the carrier $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$. The witness row is W, the public monotone and criterion rows are M and K, the stream, dyadic, and regular-rational rows are σ, D, F, and the completion-facing rows are L and R.

The sibling route is fixed by the named surfaces. $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$ supplies W, $\mathsf{MonotoneCauchy}^{\uparrow}$ supplies M, $\mathsf{CauchyCriterion}^{\uparrow}$ supplies K, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{RegSeqRat}^{\uparrow}$ supply σ, D, F, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ supply L, R.

The remaining rows H, C, P, N only transport, replay, package, and name the same finite route. Since the carrier has no coordinate for selected limits, quotient stream equality, host real equality, trichotomy, compactness, or ambient completeness, the displayed interface exhausts the public obligation surface. □

Theorem 918.34 (Bounded monotone convergence seal L10 completion cofinality)**.** *Every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *read that faces the L10* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{Completion}^{\uparrow}$ *phase reaches the terminal Real seal only after the displayed route has exposed the bounded witness row* W*, the public monotone and Cauchy criterion gates* M, K*, the* $\mathsf{StreamName}^{\uparrow}$ *windows* σ*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff* F*, and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *compatibility row* L*. The cofinal completion-facing route is therefore*

$$W, M, K, \sigma, D, F, L, R, H, C, P, N,$$

and it contains no selected limit, quotient stream equality, host real equality, trichotomy, open-cover compactness, or ambient $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First consume the bounded witness row. By Definition 918.4, every completion-facing read exposes W before the public rows or terminal seal can be inspected.

Next apply the criterion route, Definition 918.5. It forces the consumer through the public monotone and Cauchy criterion gates and then through the finite stream, dyadic, regular-rational, and CauchyLimitSeal rows before the Real handoff.

The finite-limit interface theorem Definition 918.33 identifies the same sibling surfaces as the L10-facing route: $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$, $\mathsf{MonotoneCauchy}^{\uparrow}$, $\mathsf{CauchyCriterion}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$.

Finally use the Real-boundary nonescape theorem Definition 918.11. Since the carrier has no coordinate for selected limits, quotient stream equality, host equality, trichotomy, compactness, or ambient completeness, every L10 completion read is cofinal in the displayed finite route and stops at the terminal Real seal. □

Theorem 918.35 (Bounded monotone convergence seal public limit refusal)**.** *Let* $S = (W, M, K, F, \sigma, D, L, R, H, C$ *be an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet. Any public request for a selected limit, quotient stream equality, host real equality, trichotomy, open-cover compactness, or ambient completeness is refused at the finite route through* $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$*,* $\mathsf{MonotoneCauchy}^{\uparrow}$*,*

$\mathsf{CauchyCriterion}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *The accepted consumer may read* $W, M, K, F, \sigma, D, L, R, H, C, P, N$, *but no unlisted limit datum.*

Proof. Use Definition 918.32. Every public $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer reads exactly the displayed route $W, M, K, F, \sigma, D, L, R, H, C, P, N$.

Now inspect the route by sibling. The witness, monotone, and criterion portion is supplied by $\mathsf{BoundedMonotoneCauchyWitness}^{\uparrow}$, $\mathsf{MonotoneCauchy}^{\uparrow}$, and $\mathsf{CauchyCriterion}^{\uparrow}$; the finite naming and tolerance portion is supplied by $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{RegSeqRat}^{\uparrow}$; the boundary and terminal seal portion is supplied by $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$.

The refused data are not rows of S. Therefore a public request for selected limits, quotient stream equality, host equality, trichotomy, compactness, or ambient completeness stops at the same finite packet rather than becoming a consumer-visible row. □

Theorem 918.36 (Bounded monotone convergence seal criterion-to-Real route totality)**.** *For every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet* $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$, *every route from the public criterion row* K *to the Real handoff row* R *factors through the finite sibling chain* $\mathsf{CauchyCriterion}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *as displayed by*

$$K, \sigma, D, F, L, R, H, C, P, N.$$

Together with the preceding rows W, M, *this is the whole route* $W, M, K, F, \sigma, D, L, R, H, C, P, N$; *it carries no selected limit, quotient stream equality, host real equality, trichotomy, open-cover compactness, or ambient completeness.*

Proof. Start at K. By Definition 918.5, a tolerance-facing read must pass from the public criterion row through the stream, dyadic, regular-rational, and CauchyLimitSeal rows before reaching the Real handoff.

Attach the sibling names to those coordinates. The criterion row is a $\mathsf{CauchyCriterion}^{\uparrow}$ row, σ is the $\mathsf{StreamName}^{\uparrow}$ window ledger, D is the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger, F is the $\mathsf{RegSeqRat}^{\uparrow}$ handoff, L is the $\mathsf{CauchyLimitSeal}^{\uparrow}$ boundary, and R is the $\mathsf{Real}^{\uparrow}$ handoff.

Finally prepend W, M and append H, C, P, N. The result is the same finite route named by Definition 918.33, so all consumer-visible data are exhausted before any selected limit or ambient completion principle could be read. □

Theorem 918.37 (Bounded monotone convergence seal route obligation closure)**.** *For an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet* $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$, *the displayed rows jointly close the paper-side route obligations for the bounded monotone convergence seal. The closed route is exactly the carrier, NameCert obligations, public handoff, criterion route, Real handoff, limit-seal compatibility, terminal budget exhaustion, and scoped handoff package over the rows* $W, M, K, F, \sigma, D, L, R, H, C, P, N$.

Proof. Start with the carrier and NameCert obligations, Definition 918.1 and Definition 918.2. They expose precisely the rows $W, M, K, F, \sigma, D, L, R, H, C, P, N$ and state the admission, routing, stability, exactness, provenance, and naming obligations.

Use public handoff, criterion routing, Real handoff, and limit-seal compatibility: Definition 918.3, Definition 918.5, Definition 918.6, and Definition 918.7. These identify the public consumer path from bounded witness rows to the terminal Real handoff without inserting a selected limit or ambient completeness row.

Finally apply terminal budget exhaustion and the scoped handoff package, Definition 918.13 and Definition 918.14. The same rows exhaust the route budget and package the resulting finite handoff, so the paper-side route obligations are closed at the displayed boundary. □

Theorem 918.38 (Bounded monotone convergence seal criterion dyadic ledger lock)**.** *For an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet* $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$*, every accepted route from the public criterion row* K *to the regular-rational handoff row* F *must read the dyadic tolerance ledger* D *through the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *sibling row before either* F *or* R *is public. Thus the criterion-to-handoff route has the ordered public core*

$$K, \sigma, D, F, L, R.$$

Proof. Project the carrier and NameCert obligations from Definition 918.1 and Definition 918.2. They expose K, σ, D, F, L, R as named rows of the same accepted packet and leave no alternate tolerance coordinate.

Apply the criterion route and Real handoff results, Definition 918.5 and Definition 918.6. The route from the criterion row to the Real-facing row passes through the stream-window row, the dyadic ledger, the regular-rational handoff, and the limit-seal row.

Since D is the only dyadic tolerance ledger in the carrier, the public handoff cannot expose F or R before that row has been read. The displayed order is therefore the complete dyadic ledger lock for the accepted route. □

Theorem 918.39 (Bounded monotone convergence seal stream-window regular handoff lock)**.** *For an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet* $S = (W, M, K, F, \sigma, D, L, R, H, C, P, N)$*, the stream-window row* σ *and the regular-rational row* F *form one ordered handoff. No selected limit, quotient stream equality, or host real equality may bypass* σ *and* F *on the path from the public bounded monotone witness rows to the terminal Real handoff.*

Proof. Use the public handoff theorem, Definition 918.3, to locate the consumer path through the displayed carrier rows. The stream-window row σ is read before the regular-rational row F is exposed to downstream consumers.

The tail-window consumption and criterion route are the same finite path: Definition 918.8 and Definition 918.5 identify the stream and regular-rational rows as adjacent obligations in the handoff from criterion data to CauchyLimitSeal data.

Apply limit-seal compatibility, Definition 918.7. Because compatibility is stated only after σ and F have been read, selected limits, quotient stream equality, and host real equality have no bypass coordinate in the public route. □

Theorem 918.40 (Bounded monotone convergence seal threshold route exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet* $S = (W, M, K, F, \sigma, D, L,$ *can project only the displayed witness, monotone, criterion, stream, dyadic,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, transport, route, provenance, and NameCert rows. Consequently the consumer receives no ambient completeness, trichotomy, open-cover compactness, or detached tail oracle.*

Proof. Read the packet coordinatewise. The rows $W, M, K, \sigma, D, F, L, R, H, C, P, N$ are exactly the witness, monotone, criterion, stream, dyadic, regular-rational, CauchyLimitSeal, Real, transport, route, provenance, and NameCert rows.

Use terminal budget exhaustion and route obligation closure, Definition 918.13 and Definition 918.37. These results say that the displayed rows consume the public route budget at the terminal threshold.

No remaining coordinate of S can name ambient completeness, trichotomy, open-cover compactness, or a detached tail oracle. Hence a $\mathsf{Real}^{\uparrow}$ or completion-facing consumer can project only the rows already displayed by the accepted seal. □

Theorem 918.41 (Bounded monotone convergence seal TasteGate obligation boundary)**.** *Promotion beyond seed status for* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *is read only through the displayed carrier rows together with this chapter's stated TasteGate nontriviality and field-faithfulness commitments. This changes the theory-closure ledger for the paper-side obligation surface, and it does not change the Lean verification-status row.*

Proof. Project the route obligation closure above. The paper-side boundary already binds the carrier rows $W, M, K, F, \sigma, D, L, R, H, C, P, N$ to the NameCert and public handoff obligations.

Now use the chapter's TasteGate statement for the same displayed carrier. Nontriviality and field faithfulness are read as obligations over the existing packet; they do not add a Lean theorem marker or a new formal-status target.

Thus the closure ledger may record obligation-level theory closure while leaving the Lean verification grade unchanged. The two axes remain independent: the paper surface states the route and TasteGate obligations, while future Lean work must still encode and verify them. □

Theorem 918.42 (Bounded monotone convergence seal witness-grid factorization)**.** *For every accepted* $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ *packet*

$$S = (W, M, K, F, \sigma, D, L, R, H, C, P, N),$$

whose witness row W *is read through the* $\mathsf{RealCauchyWitnessGrid}^{\uparrow}$ *surface of chapter 905, every Real-facing consumer route factors through the convergence-seal rows*

$$W, M, K, F, \sigma, D, L, R, H, C, P, N$$

and through the sibling grid rows

$$B, L, K, T, S, R, E, H, C, P, N$$

before any $\mathsf{Real}^{\uparrow}$ *seal is consumed. The route uses the witness ledger of chapter 902, the completion-seal classifier of chapter 900, and the tail-witness envelope of chapter 898; it exports no Real completeness theorem, selected external limit, quotient stream equality, or host real equality.*

Proof. Project the carrier of Definition 918.1. The rows $W, M, K, F, \sigma, D, L, R, H, C, P, N$ are the complete convergence-seal packet, so a Real-facing consumer starts from the displayed finite carrier and not from an ambient completeness object.

Use the public handoff and criterion route, Definition 918.3 and Definition 918.5. These place the bounded witness, monotone row, criterion row, stream-window row, dyadic ledger, regular-rational handoff, and limit-seal row on one ordered route before the Real handoff is available.

Now read the witness row through chapter 905. That chapter factors the Real-facing diagonal grid through $B, L, K, T, S, R, E, H, C, P, N$ and ties those rows to the witness ledger, completion-seal classifier, and tail-witness envelope named in chapter 902, chapter 900, and chapter 898.

Finally apply the Real handoff and TasteGate obligation boundary from Definition 918.6 and Definition 918.41. The Real seal is therefore consumed only after both finite surfaces have been displayed, and the non-escape clauses leave no coordinate for Real completeness, a selected external limit, quotient stream equality, or host real equality. □

Falsifiable prediction: Every accepted consumer of the convergence seal factors through BoundedMonotoneCauchyWitnessUp, MonotoneCauchyUp, CauchyCriterionUp, StreamNameUp, DyadicRatCoreUp, RegSeqRatUp, and RealUp rows before it reads the Real convergence handoff.

Independence witness: boundedmonotonecauchywitness, monotonecauchy, cauchycriterion, cauchylimitseal, real: the bounded witness lacks the public convergence seal row, monotonecauchy lacks the bounded witness source packet, cauchycriterion lacks the monotone source ledger, cauchylimitseal lacks the bounded monotone witness and public criterion bridge, and real lacks the finite witness-to-seal route; therefore no bijection preserves all carrier rows $W, M, K, F, \sigma, D, L, R, H, C, P, N$.

The proposed Lean `TasteGate.lean` boundary is `lean4/BEDC/Derived/BoundedMonotoneConvergenceSealUp`. It must provide `Nontrivial BoundedMonotoneConvergenceSealUp` and `FieldFaithful BoundedMonotoneConvergenceSealUp` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$ packet is generated from a bounded monotone Cauchy witness, public monotone Cauchy tail-window certificate, public Cauchy criterion packet, regular-rational handoff, stream-window ledger, dyadic tolerance ledger, CauchyLimitSeal compatibility row, Real convergence seal, componentwise transports, displayed continuations, provenance, and local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 918.1, Definition 918.3, Definition 918.4, Definition 918.5, Definition 918.6, Definition 918.7, Definition 918.12, Definition 918.13, and Definition 918.41, together with the checked TasteGate row, bind the public handoff and Real-facing seal rows of the finite convergence-seal export surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}}, \mathsf{axiomClean})$

Lean4 ✓ `BEDC.Derived.BoundedMonotoneConvergenceSealUp.taste gate`

Lean target: `BEDC.Derived.BoundedMonotoneConvergenceSealUp.BoundedMonotoneConvergenceSealUp\_witness\_consumption`

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Real completeness, selected-limit existence, quotient stream equality, host real equality, Lean verification, or bridge checking for $\mathsf{BoundedMonotoneConvergenceSeal}^{\uparrow}$.

Upgrade path: No further paper-side closure upgrade remains; Lean verification and bridge checking remain separate formal-axis work.

Chapter 919

A Concrete Naming Certificate for $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$

The $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ packet concretizes the bounded observation surface used by the Real completeness route of chapter 9238. It consumes the selector discipline of chapter 782, the finite window naming surface of chapter 126, the regular-rational readback of chapter 301, and the Real-facing observation budget of chapter 611. Its role is to classify prefix-depth exhaustion before a $\mathsf{Real}^{\uparrow}$ seal read, so a diagonal-limit consumer can see exactly which finite rows have been spent.

Falsifiable prediction: Every accepted finite-prefix limit-budget packet has no route to host real equality, quotient streams, selected limits, or countable choice outside the displayed prefix-window rows.

Independence witness: finiteobservationbudgetselector, regularcauchyfiniteobservationroute, budgetedrealsealroute, cauchysealbudgetsynchronizer: this carrier fixes prefix-depth exhaustion before the seal read, while those siblings select budgets, route observations, synchronize seals, or package seal routes without this prefix-budget classifier.

Definition 919.1 (Finite-prefix limit-budget carrier)**.** *A* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

with the following displayed rows:

1. *Q is the finite diagonal request row naming the precision, prefix depth, and consumer site;*
2. *B is the* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *row that admits the displayed request as a finite observation budget;*
3. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *prefix-window ledger selected under B;*
4. *D is the prefix-depth exhaustion row recording that every admitted offset lies inside the displayed finite window and that no later offset is served by this packet;*
5. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row assembled from the spent prefix windows;*
6. *S is the* $\mathsf{Real}^{\uparrow}$ *or completion-facing seal row reached only after Q, B, W, D, R have been displayed;*
7. *E is the local exclusion ledger for host real equality, quotient streams, selected limits, countable choice, and unbounded schedules;*
8. *H records componentwise* hsame *transports for all displayed rows;*

9. *C records* Cont *routes from request to budget, from budget to prefix windows, from prefix exhaustion to regular readback, and from readback to the seal;*
10. *P records* Pkg *provenance over* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert *rows;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{FinitePrefixLimitBudget}^{\uparrow}}$ *row.*

The carrier is a finite budget classifier. It exports no host real equality, quotient-stream carrier, selected completed limit, countable choice principle, hidden tail schedule, or ambient completeness witness.

Lean4 ✓ `BEDC.Derived.FinitePrefixLimitBudgetUp.FinitePrefixLimitBudgetTasteGate single carrier alignment`

Theorem 919.2 (Finite-prefix limit-budget NameCert obligations)**.** *For the carrier of Definition 919.1, the local* $\mathsf{NameCert}_{\mathsf{FinitePrefixLimitBudget}^{\uparrow}}$ *surface consists of five finite rows:*

1. *carrier admission for $F = (Q, B, W, D, R, S, E, H, C, P, N)$ as a* BHist *packet;*
2. *prefix-budget selection, requiring Q to be admitted through the finite selector row B before any* $\mathsf{StreamName}^{\uparrow}$ *window is served;*
3. *prefix-window exhaustion, requiring D to account for every offset admitted by W and to refuse every outside-prefix read;*
4. *regular and seal handoff, requiring R and S to be reached only through the spent prefix-window route;*
5. *non-escape, requiring E, H, C, P, N to preserve the same finite route and to block host real equality, quotient streams, selected limits, countable choice, hidden tail schedules, and ambient completeness.*

Proof. Project the carrier. The displayed coordinates $Q, B, W, D, R, S, E, H, C, P, N$ are the only rows available to the local naming certificate.

Read the selection side first. The selector row B admits the finite request Q, and the window ledger W lists exactly the prefix windows served by that admitted budget.

Next read the exhaustion row D. It ties every served offset to the finite prefix window and records refusal for outside-prefix reads before the regular readback row R or the seal row S can be consumed.

Finally use E, H, C, P, N. The exclusion ledger blocks the unlisted analytic objects, while transport, continuation, provenance, and local naming replay only the finite route already displayed by the packet. □

Theorem 919.3 (Finite-prefix limit-budget seal ordering)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet reaches its seal row only through the ordered finite route*

$$Q \to B \to W \to D \to R \to S.$$

The displayed hsame, Cont, Pkg, *and* NameCert *rows certify no route that reads the seal before the prefix-depth exhaustion row has been consumed.*

Proof. Start with the five NameCert rows of Definition 919.2. The prefix-budget and prefix-window rows place Q, B, W before the exhaustion row D.

The regular and seal handoff row then places R and S after D. Thus a seal-facing consumer must read the spent prefix route before it can reach the completion-facing seal.

The transport and continuation rows preserve that order under componentwise hsame and Cont replay. Since the exclusion ledger contains no host equality, quotient stream, selected limit, countable choice, hidden tail schedule, or ambient completeness coordinate, there is no alternate seal route inside the packet. □

Theorem 919.4 (Finite-prefix limit-budget Real route handoff)**.** *The Real completeness route of chapter 9238 may consume an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet as the finite classifier between selected prefix observations and a* $\mathsf{Real}^{\uparrow}$ *seal read. The handoff is compatible with chapter 782, chapter 126, chapter 301, and chapter 611 because it preserves their budget, window, regular readback, and seal rows inside one displayed prefix-depth surface.*

Proof. Read the sibling selector first. The $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ row supplies the finite request budget consumed by B, and no observation is served before that row is displayed.

Read the window and regular-rational siblings next. The $\mathsf{StreamName}^{\uparrow}$ windows in W and the $\mathsf{RegSeqRat}^{\uparrow}$ readback in R are tied together by the prefix-depth exhaustion row D, so the route records which prefix rows have been spent before the seal-facing handoff.

Finally compare with the $\mathsf{RealObservationBudget}^{\uparrow}$ surface. That chapter supplies the completion-facing observation discipline; the present packet narrows it to the finite prefix-budget classifier needed before the Real completeness seal read. The non-escape row keeps quotient streams, host real equality, selected limits, countable choice, hidden tail schedules, and ambient completeness outside the handoff. □

Theorem 919.5 (Finite-prefix limit-budget prefix-exhaustion coverage)**.** *For every accepted* FinitePrefixLimitBudge *carrier*

$$F = (Q, B, W, D, R, S, E, H, C, P, N),$$

each admitted offset served by the finite $\mathsf{StreamName}^{\uparrow}$ *window row* W *is accounted for by the depth-exhaustion row* D*. Every outside-prefix read is refused before the regular readback row* R *or the seal row* S *is available to a consumer.*

Proof. Project the carrier rows Q, B, W, D, R, S from Definition 919.1. The finite request row Q must pass through the budget selector row B before the prefix-window ledger W serves an offset.

Apply Definition 919.2. Its prefix-window exhaustion clause identifies D as the row that accounts for every offset admitted by W and records refusal for outside-prefix reads.

Apply Definition 919.3. Since every seal-facing route has order $Q \to B \to W \to D \to R \to S$, neither R nor S is available until the exhaustion row has already accepted the displayed prefix offsets and refused the reads outside the finite window. □

Theorem 919.6 (Finite-prefix limit-budget hsame transport)**.** *Componentwise* hsame *transports of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *carrier preserve the ordered route*

$$Q \to B \to W \to D \to R \to S.$$

They cannot create a new prefix window, a new prefix-depth exhaustion row, a new regular readback row, or a new seal row outside the displayed carrier.

Proof. Use the transport coordinate H of the carrier together with the continuation, provenance, and naming rows C, P, N. These rows are part of the finite packet, so transport acts componentwise on the displayed coordinates rather than adding a fresh carrier coordinate.

The ordered route is already fixed by Definition 919.3. Transport through H can replay the same Q, B, W, D, R, S route, and C records only the displayed continuations from request to budget, from budget to windows, from exhaustion to readback, and from readback to seal.

Finally, P and N keep the transported packet inside the same Pkg provenance and local $\mathsf{NameCert}_{\mathsf{FinitePrefixLimitBudget}^{\uparrow}}$ surface. No coordinate in H, C, P, N names an additional prefix window or an additional seal row, so componentwise hsame cannot create one. □

Theorem 919.7 (Finite-prefix limit-budget nonescape criterion)**.** *Any consumer of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet that claims host real equality, quotient streams, selected limits, countable choice, hidden tail schedules, or ambient completeness is outside the carrier unless the claim factors through the displayed exclusion row* E*.*

Proof. Read the carrier definition first. The final sentence of Definition 919.1 states that the packet exports none of the listed analytic objects; it exports only the finite budget classifier rows.

Apply the non-escape clause of Definition 919.2. That clause assigns the exclusion work to E, H, C, P, N and requires those rows to preserve the same finite route while blocking host real equality, quotient streams, selected limits, countable choice, hidden tail schedules, and ambient completeness.

Thus a consumer that asserts one of those objects must leave the displayed carrier surface unless it presents the assertion through E. The remaining rows only replay selection, prefix-window exhaustion, readback, seal handoff, transport, continuation, provenance, and local naming for the finite route. □

Theorem 919.8 (Finite-prefix limit-budget carrier-classifier scope)**.** *Every accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet has its carrier and classifier scoped by the displayed finite prefix request* Q*, the* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R*, the* $\mathsf{RealObservationBudget}^{\uparrow}$*-facing seal row* S*, componentwise* hsame *transport* H*, displayed* Cont *route* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{FinitePrefixLimitBudget}^{\uparrow}}$ *row* N*. No classifier read is accepted outside that finite prefix-budget surface.*

Proof. Project the carrier of Definition 919.1. The request, selector, window, exhaustion, readback, seal, exclusion, transport, route, provenance, and naming rows are already displayed as $Q, B, W, D, R, S, E, H, C, P, N$.

Use the obligation and seal-ordering theorems. Definition 919.2 makes selection, exhaustion, regular readback, and seal handoff part of the local certificate, while Definition 919.3 orders every consumer route through $Q \to B \to W \to D \to R \to S$.

Finally attach the transport and nonescape rows, Definition 919.6 and Definition 919.7. They keep classifier replay inside the same H, C, P, N support and exclude any outside prefix-budget coordinate. □

Theorem 919.9 (Finite-prefix limit-budget record factorization)**.** *All record reads of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet factor through the finite rows*

$$Q, B, W, D, R, S, E, H, C, P, N.$$

In particular, a record read cannot use quotient streams, host real equality, selected limits, countable choice, hidden tail schedules, or ambient completeness to replace the displayed finite prefix route.

Proof. Begin with prefix-exhaustion coverage, Definition 919.5. It forces every served offset through the finite $\mathsf{StreamName}^{\uparrow}$ window row W and the exhaustion row D before R or S is available.

Apply carrier-classifier scope, Definition 919.8. The carrier and classifier are bounded by the same request, window, readback, seal, transport, route, provenance, and local naming rows.

The exclusion follows from Definition 919.7. Since quotient streams, host real equality, selected limits, countable choice, hidden tail schedules, and ambient completeness occur only as refused claims in E, they cannot serve as alternate record factors. □

Theorem 919.10 (Finite-prefix limit-budget consumer boundary)**.** *Every* $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet receives only the same finite prefix-budget surface*

$$Q, B, W, D, R, S, E, H, C, P, N.$$

The consumer may read the finite request, selected prefix windows, exhaustion row, regular readback, seal handoff, exclusion ledger, transport, route, provenance, and local naming rows, but it receives no completed limit, quotient stream, host real equality, selected tail, hidden schedule, or ambient completeness witness.

Proof. Read the Real-route handoff first. Definition 919.4 places the Real completeness consumer behind the finite selector, StreamName, RegSeqRat, and RealObservationBudget rows already carried by the packet.

Next apply record factorization. Definition 919.9 says every record read used by such a consumer factors through $Q, B, W, D, R, S, E, H, C, P, N$ and through no quotient or selected-limit route.

Finally use the closurestatus upgrade-path surface as the boundary vocabulary: the regular-readback consumer and completion-facing seal interface are the consumers being scoped here. Because the same finite packet supplies both interfaces, $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumers receive exactly the displayed prefix-budget rows and nothing beyond them. □

Theorem 919.11 (Finite-prefix limit-budget diagonal selector consumption)**.** *Every diagonal-selector or Real-completion consumer of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

must consume the finite route

$$Q \to B \to W \to D$$

before reading the regular readback row R or the completion-facing seal row S.

Proof. First use seal ordering, Definition 919.3. It places every completion-facing read behind the route $Q \to B \to W \to D \to R \to S$, so neither R nor S is available before the exhaustion row.

Next use prefix-exhaustion coverage, Definition 919.5. The diagonal selector spends only the finite windows admitted by W, and D records that every admitted offset has been accounted for while outside-prefix reads are refused.

Finally apply the consumer boundary, Definition 919.10. A Real-completion consumer receives only $Q, B, W, D, R, S, E, H, C, P, N$, so it cannot read the diagonal selector as a completed tail or selected limit before the finite request, budget, window, and exhaustion rows have been consumed. □

Theorem 919.12 (Finite-prefix limit-budget Real seal non-escape extension)**.** *No* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet can replace the displayed finite prefix route by host real equality, quotient streams, selected limits, countable choice, hidden tail schedules, or ambient completeness. The only seal-facing route available to such a consumer is the displayed finite route through $Q, B, W, D, R, S, E, H, C, P, N$.*

Proof. Begin with the nonescape criterion, Definition 919.7. Host real equality, quotient streams, selected limits, countable choice, hidden tail schedules, and ambient completeness appear only as refused claims in the exclusion row E.

Use record factorization, Definition 919.9. Every record read of the packet factors through the finite rows $Q, B, W, D, R, S, E, H, C, P, N$, so no external analytic object can replace the displayed prefix route.

The diagonal-consumption theorem above identifies the point at which the seal-facing consumer may read R and S. Since that access comes only after Q, B, W, D, a $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer that substitutes a host equality, quotient stream, selected limit, choice principle, hidden tail schedule, or ambient completeness witness leaves the accepted carrier. □

Theorem 919.13 (Finite-prefix limit-budget observer lock)**.** *For every accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *carrier*

$$F = (Q, B, W, D, R, S, E, H, C, P, N),$$

each served finite observation is locked to the displayed request row Q, the finite selector row B, the $\mathsf{StreamName}^{\uparrow}$ *prefix-window row W, and the prefix-depth exhaustion row D. No observer of the packet can serve a finite observation through a different request, selector, StreamName window, or prefix-depth row.*

Proof. Project the accepted carrier from Definition 919.1. The only observation-facing rows before readback are Q, B, W, D, and the carrier exports no alternate request coordinate or alternate prefix-window coordinate.

Use the NameCert obligations of Definition 919.2. The selector row B admits the displayed request Q, the window row W is served under that selector, and the exhaustion row D accounts for every offset admitted by W.

Finally apply carrier-classifier scope, Definition 919.8. It confines every classifier read to the same displayed finite prefix-budget surface, so an observer cannot detach a served finite observation from Q, B, W, D. □

Theorem 919.14 (Finite-prefix limit-budget outside-tail refusal)**.** *For every accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *carrier, any outside-prefix read or hidden-tail read is refused before the regular readback row R or the seal row S becomes available. The refusal is recorded by the prefix-exhaustion row D together with the exclusion ledger E.*

Proof. Start with prefix-exhaustion coverage, Definition 919.5. It accounts for every admitted offset through D and refuses every outside-prefix read before R or S can be consumed.

Next use seal ordering, Definition 919.3. Since every seal-facing route is ordered as $Q \to B \to W \to D \to R \to S$, no consumer reaches regular readback or the seal before the exhaustion row has performed its refusal work.

It remains to block hidden tails. Apply the nonescape criterion, Definition 919.7: hidden tail schedules occur only as refused claims in E. Thus outside-prefix and hidden-tail reads are both rejected within the finite packet before R or S is available. □

Theorem 919.15 (Finite-prefix limit-budget seal-consumer coverage)**.** *Every* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *carrier receives exactly the displayed prefix-budget route*

$$Q \to B \to W \to D \to R \to S$$

together with the exclusion, transport, continuation, provenance, and local naming rows E, H, C, P, N. Such a consumer receives no quotient stream, selected limit, host real equality, hidden tail schedule, countable choice principle, or ambient completeness witness.

Proof. First compose the Real-route handoff of Definition 919.4 with the regular readback path fixed by the carrier. This places the completion-facing consumer behind the finite selector, StreamName prefix windows, RegSeqRat readback, and Real-facing seal rows.

Next use record factorization and the consumer boundary, Definition 919.9 and Definition 919.10. Together they say that $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumers read only $Q, B, W, D, R, S, E, H, C, P, N$

Finally apply the Real seal non-escape theorem, Definition 919.12. It excludes quotient streams, selected limits, host real equality, hidden tail schedules, countable choice, and ambient completeness from the seal-facing route, leaving exactly the displayed prefix-budget route and its local certificate rows. □

Theorem 919.16 (Finite-prefix limit-budget seal-window route totality)**.** *For every accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *carrier*

$$F = (Q, B, W, D, R, S, E, H, C, P, N),$$

each packet accepted by a $\mathsf{Real}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer routes through*

$$Q \to B \to W \to D \to R \to S$$

with finite prefix-window totality completed before any seal read. The seal consumer may read S only after the request Q, finite budget selector B, prefix-window ledger W, depth-exhaustion row D, and regular-rational readback R have all been displayed.

Proof. Begin with seal ordering, Definition 919.3. It fixes the only completion-facing route as $Q \to B \to W \to D \to R \to S$ and refuses any seal read that precedes the prefix-depth exhaustion row.

Next attach prefix-exhaustion coverage and diagonal selector consumption. Definition 919.5 accounts for every admitted offset inside W through D, while Definition 919.11 prevents R or S from being read before the finite request, budget, window, and exhaustion rows have been consumed.

Finally use seal-consumer coverage. Definition 919.15 says that every $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer receives exactly the displayed route together with E, H, C, P, N. Thus prefix-window totality is already settled inside the finite packet before any completion-facing seal read occurs. □

Theorem 919.17 (Finite-prefix limit-budget completion consumer exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *carrier is exhausted by the finite packet rows*

$$Q, B, W, D, R, S, E, H, C, P, N.$$

No such consumer can add quotient streams, selected limits, countable choice, hidden tail schedules, host real equality, or ambient completeness beyond the displayed prefix-budget certificate.

Proof. First use the consumer boundary, Definition 919.10. It identifies the rows delivered to $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumers as exactly $Q, B, W, D, R, S, E, H, C, P, N$.

Next apply record factorization and seal-consumer coverage. Definition 919.9 routes every record read through the displayed finite packet, and Definition 919.15 repacks the same rows as the seal-facing surface.

Finally apply the Real seal non-escape extension. Definition 919.12 blocks quotient streams, selected limits, host real equality, countable choice, hidden tail schedules, and ambient completeness from replacing the displayed route. Therefore every completion consumer is exhausted by the same finite prefix-budget packet. □

Theorem 919.18 (Finite-prefix limit-budget public-axis scope)**.** *For every accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet*

$$F = (Q, B, W, D, R, S, E, H, C, P, N),$$

any current Phase Real and Completion public read may consume F *only as the finite prefix-budget route through* $Q, B, W, D, R, S, E, H, C, P, N$*. The route preserves the finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{RealObservationBudget}^{\uparrow}$*-facing seal,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}$ *rows. It does not create host real equality, quotient streams, selected limits, countable choice, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, metric-completeness data,* $\mathsf{bridgeChecked}$ *status, or an aggregate formal-status token.*

Proof. Begin with seal ordering, Definition 919.3. It fixes the public read behind the finite route $Q \to B \to W \to D \to R \to S$, so the seal-facing consumer cannot bypass the displayed prefix-depth exhaustion row.

Next use the consumer boundary, Definition 919.10. It identifies the completion-facing read surface with $Q, B, W, D, R, S, E, H, C, P, N$ and keeps the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows inside the same finite packet.

Finally apply completion consumer exhaustion, Definition 919.17, together with the two-axis discipline of section 9467.2. The former excludes host real equality, quotient streams, selected limits, countable choice, hidden tail schedules, ambient $\mathsf{Real}^{\uparrow}$ completeness, and metric-completeness data from the packet; the latter prevents this paper-side public route from manufacturing $\mathsf{bridgeChecked}$ status or any aggregate verification token. □

Theorem 919.19 (Finite-prefix limit-budget Real-completion root unblock)**.** *Every Real-completion or diagonal-limit consumer of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet must read the finite route*

$$Q \to B \to W \to D \to R \to S$$

through the displayed FiniteObservationBudgetSelector, $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{RealObservationBudget}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows. The same route supplies the exclusion, transport, continuation, provenance, and local naming rows* E, H, C, P, N*. No such consumer receives a quotient stream, host real equality, selected limit, countable choice principle, hidden tail schedule, or ambient completeness coordinate.*

Proof. Start from the carrier definition, Definition 919.1. It names the packet rows $Q, B, W, D, R, S, E, H, C, P, N$ and makes the finite selector, prefix-window ledger, regular-rational readback, Real-facing seal, and local naming rows part of one carrier.

Apply the NameCert obligations and seal ordering, Definition 919.2 and Definition 919.3. They force every seal-facing consumer to pass through $Q \to B \to W \to D \to R \to S$ before the seal row is available.

Finally use the Real-route handoff, completion-consumer exhaustion, and public-axis scope, Definition 919.4, Definition 919.17, and Definition 919.18. These results identify the Real-completion

and diagonal-limit read surface with the same finite packet and exclude quotient streams, host real equality, selected limits, countable choice, hidden tails, and ambient completeness data. □

Theorem 919.20 (Finite-prefix limit-budget RegSeqRat StreamName interface)**.** *For every accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet, the* $\mathsf{StreamName}^{\uparrow}$ *prefix-window row* W *and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R *are exposed as one finite interface. Any* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer sees only prefix windows admitted by the finite budget selector* B *and exhausted by the depth row* D *before the readback row* R *is available.*

Proof. Use the carrier definition to read B, W, D, R as rows of the same finite packet. The packet does not offer a separate StreamName object or a separate RegSeqRat readback surface outside $Q, B, W, D, R, S, E, H, C, P, N$.

Apply the NameCert obligations. The budget selector row B admits the displayed finite request, the prefix-window row W is served under that selector, and the exhaustion row D accounts for the offsets admitted by W.

Now apply seal ordering together with the public-axis scope theorem. Since the route is ordered as $Q \to B \to W \to D \to R \to S$, a $\mathsf{RegSeqRat}^{\uparrow}$ consumer cannot read R before W has been admitted by B and exhausted by D. □

Theorem 919.21 (Finite-prefix limit-budget CauchyLimitSeal consumer scope)**.** *Every* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet receives only*

$$Q, B, W, D, R, S, E, H, C, P, N.$$

The consumer may use these rows as the finite seal route, but it may not replace the route by a completed limit, quotient stream, choice-derived tail, host real equality witness, hidden tail schedule, or ambient completeness coordinate.

Proof. Begin with the carrier definition and NameCert obligations. Together they display the exact packet rows and assign request admission, prefix-window service, exhaustion, regular readback, seal handoff, exclusion, transport, continuation, provenance, and naming to $Q, B, W, D, R, S, E, H, C, P, N$.

Use seal ordering and the Real-route handoff. These results keep the $\mathsf{CauchyLimitSeal}^{\uparrow}$ read behind the finite path $Q \to B \to W \to D \to R \to S$ and prevent the seal row from being reached by a separate completion coordinate.

Finally apply completion-consumer exhaustion and public-axis scope. They state that the consumer boundary is exhausted by the displayed rows and that completed limits, quotient streams, choice-derived tails, host real equality, hidden tail schedules, and ambient completeness data are not part of the packet. □

Theorem 919.22 (Finite-prefix limit-budget tail-modulus fusion)**.** *Let*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet. Any* $\mathsf{CauchyTailModulusFusion}^{\uparrow}$ *consumer of* F *may enter the tail-modulus fusion surface only through the displayed finite prefix route*

$$Q \to B \to W \to D \to R \to S.$$

The handoff exposes the finite selector, prefix window, exhaustion row, regular-rational readback, and seal row already present in F*; it does not add a hidden tail schedule, selected limit, quotient stream, host real equality witness, countable-choice row, or ambient completeness coordinate.*

Proof. Start with the seal-window route totality of Definition 919.16. It fixes the only completion-facing route of F as $Q \to B \to W \to D \to R \to S$ before any seal-facing consumer can read S.

Next use the RegSeqRat StreamName interface, Definition 919.20. The prefix window W, exhaustion row D, and readback row R are therefore already joined inside the finite packet that a tail-modulus consumer receives.

Now compare with the tail-modulus fusion certificate of chapter 1024. Its completion-facing read is a displayed fusion of tail, modulus, threshold, selector-window, rational-readback, and Real-seal rows, so the incoming finite prefix-budget route supplies only the visible selector-window side of that surface.

Finally apply completion consumer exhaustion and CauchyLimitSeal consumer scope, Definition 919.17 and Definition 919.21. They exclude hidden tails, selected limits, quotient streams, host real equality, countable choice, and ambient completeness data from the handoff, leaving the route through Q, B, W, D, R, S as the entire prefix-budget contribution to $\mathsf{CauchyTailModulusFusion}^{\uparrow}$. □

Theorem 919.23 (Finite-prefix limit-budget stability handoff)**.** *Let*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet. Any* $\mathsf{FinitePrefixLimitStability}^{\uparrow}$ *replay of F preserves the displayed rows $Q, B, W, D, R, S, E, H, C, P, N$ componentwise under the same* hsame *transports and* Cont *replays. The stability surface may read the finite budget, StreamName window, RegSeqRat readback, Real-facing seal, provenance, and local NameCert rows, but it may not replace them by a detached selector, independent stream object, selected limit, quotient stream, or ambient Real-completeness witness.*

Proof. Begin with the finite route of Definition 919.16. The rows Q, B, W, D, R, S are displayed before the seal row is available, so a stability replay inherits an ordered prefix-budget route rather than an unstructured completion object.

Use the RegSeqRat StreamName interface, Definition 919.20. It keeps W, D, R in one finite read surface, which is exactly the StreamName and RegSeqRat side consumed by the stability certificate of chapter 1226.

The same packet carries the transport and continuation rows H and C. Reading the stability chapter through those rows makes the replay componentwise: the hsame comparison transports each displayed row, and the Cont replay returns the same finite prefix-budget surface to the consumer.

Finally apply completion consumer exhaustion and CauchyLimitSeal consumer scope, Definition 919.17 and Definition 919.21. These results prevent a detached selector, independent stream object, selected limit, quotient stream, host real equality, choice-derived tail, or ambient completeness coordinate from entering the stability handoff. □

Theorem 919.24 (Finite-prefix limit-budget diagonal seal determinacy)**.** *Let*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet. Any diagonal-limit or Real-completion seal consumer receiving both the tail-modulus fusion handoff of Definition 919.22 and the stability handoff of Definition 919.23 has a unique displayed seal route through*

$$Q \to B \to W \to D \to R \to S.$$

The consumer may combine the $\mathsf{CauchyTailModulusFusion}^{\uparrow}$ *and* $\mathsf{FinitePrefixLimitStability}^{\uparrow}$ *surfaces only along that route; it cannot choose a second seal path through a hidden tail schedule, detached stability replay, selected limit, quotient stream, host real equality witness, countable-choice row, or ambient completeness coordinate.*

Proof. The local route is already unique at the prefix-budget boundary. By Definition 919.16, the seal row is reached only after Q, B, W, D, R, and by Definition 919.20, the StreamName and RegSeqRat readback rows are not detachable from the finite window and exhaustion rows.

The tail-modulus side adds no second route. Definition 919.22 sends the prefix-budget packet into the $\mathsf{CauchyTailModulusFusion}^{\uparrow}$ surface of chapter 1024 only through $Q \to B \to W \to D \to R \to S$.

The stability side preserves the same rows. Definition 919.23 reads the $\mathsf{FinitePrefixLimitStability}^{\uparrow}$ surface of chapter 1226 through componentwise hsame transport and displayed Cont replay, so the replay cannot manufacture a detached seal path.

Finally use completion consumer exhaustion and CauchyLimitSeal consumer scope, Definition 919.17 and Definition 919.21. They remove hidden tail schedules, selected limits, quotient streams, host real equality, countable choice, and ambient completeness from the consumer boundary. Hence the diagonal-limit or Real-completion consumer has only the displayed seal route through $Q \to B \to W \to D \to R \to S$. □

Theorem 919.25 (Finite-prefix limit-budget common-refinement determinacy)**.** *Let*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

and

$$F' = (Q', B', W', D', R', S', E', H', C', P', N')$$

be accepted $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *carriers serving the same* $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer request. If the two packets admit a common finite* $\mathsf{StreamName}^{\uparrow}$ *refinement window, then both consumer reads factor through the same displayed selector and exhaustion route before either seal row is available.*

The comparison is determined by the common W/W' *refinement, the* D/D' *exhaustion rows, and the* R/R' *regular readbacks. It is not determined by quotient streams, selected limits, host real equality, countable choice, or ambient completeness.*

Proof. Start from the carrier definition. It presents each accepted packet only through the displayed rows $Q, B, W, D, R, S, E, H, C, P, N$ and $Q', B', W', D', R', S', E', H', C', P', N'$, so a shared consumer request has no hidden coordinate outside the two finite packets.

Apply finite prefix-window route totality, Definition 919.16. For each packet, the seal-facing route is forced through the finite selector, prefix window, exhaustion row, and regular readback before the seal row is reachable.

Next use the RegSeqRat StreamName interface, Definition 919.20. The common $\mathsf{StreamName}^{\uparrow}$ refinement window is therefore read as a common finite comparison of W/W', exhausted by D/D', and exposed to the consumer through R/R' rather than through a separate stream object.

Finally apply the CauchyLimitSeal consumer scope, Definition 919.21. It blocks completed limits, quotient streams, choice-derived tails, host real equality, hidden tail schedules, and ambient completeness data from entering the consumer boundary, so the common-refinement comparison is already determined before either seal row is available. □

Theorem 919.26 (Finite-prefix limit-budget prefix-selector totality)**.** *Let*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet. Every* $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer request admitted by* F *first factors through the displayed request row* Q *and finite selector row* B*. The consumer cannot read the prefix window* W*, exhaustion row* D*, regular-rational readback* R*, or seal row* S *unless the finite selector row has already admitted the request.*

Equivalently, the packet offers no direct route from a consumer request to W, D, R, S*, no quotient stream standing behind* W*, no selected tail standing behind* R*, and no host Real equality witness standing behind* S*.*

Proof. Start with the NameCert obligations of Definition 919.2. Their prefix-budget selection row places the admitted request Q through the finite selector row B before any $\mathsf{StreamName}^{\uparrow}$ window is served.

Apply seal-window route totality, Definition 919.16. It fixes the only seal-facing route as

$$Q \to B \to W \to D \to R \to S.$$

Use the RegSeqRat StreamName interface, Definition 919.20. The rows W, D, R are read as one finite prefix-window and regular-readback surface, so they are not available before the selector row has admitted the request.

Finally apply common-refinement determinacy, Definition 919.25. A second consumer packet serving the same request is compared only through a common finite selector and window refinement, which rules out a direct read of W, D, R, S outside Q, B. □

Theorem 919.27 (Finite-prefix limit-budget prefix-window stability)**.** *Let*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

and

$$F' = (Q', B', W', D', R', S', E', H', C', P', N')$$

be accepted $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packets related by the componentwise* hsame *transports displayed in* H *and* H'*. If* F *and* F' *serve the same finite* $\mathsf{StreamName}^{\uparrow}$ *window request for a* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, then the transported comparison preserves the finite window rows* W/W'*, the exhaustion rows* D/D'*, and the readback rows* R/R'*.*

The transport may replay the displayed Cont *routes, but it cannot create quotient streams, selected tails, a detached StreamName object, or an ambient completeness coordinate.*

Proof. First apply the NameCert obligations of Definition 919.2. They identify H and H' as componentwise transport rows attached to the displayed packets, not as sources of new analytic coordinates.

Next use the RegSeqRat StreamName interface, Definition 919.20. It binds the $\mathsf{StreamName}^{\uparrow}$ window rows W/W' to the exhaustion rows D/D' and the regular-rational readback rows R/R' inside the finite prefix surface.

Apply the stability handoff theorem, Definition 919.23. Its replay of the $\mathsf{FinitePrefixLimitStability}^{\uparrow}$ surface preserves $Q, B, W, D, R, S, E, H, C, P, N$ componentwise under hsame transport and displayed Cont replay.

Finally invoke common-refinement determinacy, Definition 919.25. Since packets serving the same request compare through a common finite window refinement before either seal row is reached, the transported comparison has no route to quotient streams, selected tails, detached StreamName objects, or ambient completeness data. □

Theorem 919.28 (Finite-prefix limit-budget seal-read factorization)**.** *Let*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet. Every seal-facing read of* F *factors through the full displayed packet*

$$Q, B, W, D, R, S, E, H, C, P, N.$$

The factorization first admits the request through Q, B*, then reads the finite prefix window and RegSeqRat surface through* W, D, R*, then reaches the seal row* S*, and finally replays the exclusion, transport, continuation, provenance, and local NameCert rows* E, H, C, P, N*.*

Thus a $\mathsf{Real}^{\uparrow}$*, diagonal-limit, or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer may combine the tail-modulus fusion handoff, stability handoff, and common-refinement comparison only through that displayed packet; it may not read a hidden tail schedule, quotient stream, selected limit, host Real equality witness, countable-choice row, or ambient completeness coordinate.*

Proof. Begin with prefix-selector totality, Definition 919.26. It forces every admitted seal-facing consumer request through Q, B before any window, readback, or seal row is visible.

Use seal-window route totality and the RegSeqRat StreamName interface, Definition 919.16 and Definition 919.20. Together they identify the finite route $Q \to B \to W \to D \to R \to S$ and keep W, D, R inside the same prefix-window readback surface.

Next apply tail-modulus fusion and stability handoff, Definition 919.22 and Definition 919.23. The former admits only the displayed prefix contribution to $\mathsf{CauchyTailModulusFusion}^{\uparrow}$, while the latter replays the same rows componentwise under hsame and Cont.

Finally apply common-refinement determinacy, Definition 919.25. Any second packet serving the same seal-facing request is compared by a common finite refinement of W, D, R, so the consumer has no remaining route to hidden tails, quotient streams, selected limits, host equality, choice, or ambient completeness outside $Q, B, W, D, R, S, E, H, C, P, N$. □

Theorem 919.29 (Finite-prefix limit-budget public interface export)**.** *Let*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet. The packet is the public Phase Real and Completion interface exported to* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{CauchyTailModulusFusion}^{\uparrow}$*, and* $\mathsf{FinitePrefixLimitStability}^{\uparrow}$ *consumers. Every such public read factors through the finite prefix-budget route*

$$Q \to B \to W \to D \to R \to S$$

and then through the displayed exclusion, transport, continuation, provenance, and local naming rows E, H, C, P, N*.*

The exported interface carries no host real equality, quotient stream, selected limit, countable-choice row, hidden tail schedule, ambient completeness coordinate, bridge-status certificate, or aggregate verification token beyond that displayed packet.

Proof. Start with public-axis scope and the Real-completion root unblock, Definition 919.18 and Definition 919.19. These identify the Phase Real, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ read surface with the same finite packet $Q, B, W, D, R, S, E, H, C, P, N$ and force the seal-facing route through $Q \to B \to W \to D \to R \to S$.

Next apply tail-modulus fusion and stability handoff, Definition 919.22 and Definition 919.23. The first admits a $\mathsf{CauchyTailModulusFusion}^{\uparrow}$ consumer only through the displayed prefix contribution, and the second replays the $\mathsf{FinitePrefixLimitStability}^{\uparrow}$ surface componentwise under the same hsame transports and Cont routes.

Finally use diagonal seal determinacy and seal-read factorization, Definition 919.24 and Definition 919.28. They leave no second seal path and repack every seal-facing public read through $Q, B, W, D, R, S, E, H, C, P, N$. The exclusions already recorded by the six cited results rule out host real equality, quotient streams, selected limits, countable choice, hidden tail schedules, ambient completeness, bridge-status certificates, and aggregate verification tokens. □

Theorem 919.30 (Finite-prefix limit-budget acceptance-bridge interface)**.** *Let*

$$F = (Q, B, W, D, R, S, E, H, C, P, N)$$

be an accepted $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ *packet. Every acceptance-bridge consumer that transports the accepted packet preserves the same public route*

$$Q \to B \to W \to D \to R \to S$$

and the same support rows E, H, C, P, N.

The bridge may transport the public interface exported by Definition 919.29 across the public axis scope of Definition 919.18 and the completion-consumer exhaustion boundary of Definition 919.17. It cannot add host real equality, quotient streams, selected limits, countable choice, ambient completeness, bridge-status certificates, or an aggregate verification token.

Proof. Begin with the public interface export, Definition 919.29. It identifies the whole Phase Real and Completion read surface with the displayed route $Q \to B \to W \to D \to R \to S$ followed by E, H, C, P, N.

Next apply public-axis scope, Definition 919.18. The public axis may expose the finite route to $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumers, but it does not manufacture a second analytic coordinate or a verification aggregate.

Finally use completion-consumer exhaustion, Definition 919.17. Since the completion-facing consumer has already exhausted the packet through $Q, B, W, D, R, S, E, H, C, P, N$, an acceptance bridge can only transport that interface. The exclusions in the three cited results rule out host real equality, quotient streams, selected limits, countable choice, ambient completeness, bridge-status certificates, and aggregate verification tokens outside the displayed packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{FinitePrefixLimitBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{FinitePrefixLimitBudget}^{\uparrow}$ packet is generated from a finite diagonal request, finite observation-budget selector row, finite StreamName prefix-window ledger, prefix-depth exhaustion row, RegSeqRat readback row, Real-facing seal row, exclusion ledger, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FinitePrefixLimitBudget}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 919.1, Definition 919.2, Definition 919.15, Definition 919.16, Definition 919.17, Definition 919.22, Definition 919.23, Definition 919.25, Definition 919.29, and Definition 919.30, together with the visible TasteGate carrier marker, close the mature finite prefix-budget treatment: public interface export, acceptance-bridge interface, tail-modulus fusion handoff, stability handoff, and common-refinement theorem over the route $Q \to B \to W \to D \to R \to S$ and rows E, H, C, P, N.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FinitePrefixLimitBudget}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.FinitePrefixLimitBudgetUp.FinitePrefixLimitBudgetTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove real completeness, select a completed limit, identify quotient streams, assert host real equality, use countable choice, or close Lean implementation closure.

Upgrade path: bridgeChecked remains a Lean-side bridge task, while the paper-side mature route is closed by the displayed finite-prefix interface $Q \to B \to W \to D \to R \to S$ with rows E, H, C, P, N.

Chapter 920

A Concrete Naming Certificate for $\mathsf{CofinalTailAgreement}^{\uparrow}$

The $\mathsf{CofinalTailAgreement}^{\uparrow}$ packet realizes the paired cofinal-tail agreement route required by the Real completeness surface of chapter 9238. It sits between the shared-threshold route of chapter 560, the fused tail route of chapter 658, the selector-budget route of chapter 678, the displayed Real agreement seal of chapter 699, and the sealed Cauchy-limit route of chapter 386. The packet records the paired-source, shared-threshold, dyadic-readback, and seal-handoff rows as one finite $\mathsf{NameCert}$ carrier rather than as an ambient completeness principle.

Definition 920.1 (Cofinal tail-agreement carrier)**.** *A* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (M, F, B, S, D, R, L, H, C, P, N)$$

with the following displayed rows:

1. *M is the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *shared-threshold row for the paired regular-Cauchy sources;*
2. *F is the* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ *row that fuses the paired cofinal tail witnesses through the shared threshold;*
3. *B is the* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ *row that records the finite selector budget used by the paired route;*
4. *S is the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row that receives the paired agreement boundary;*
5. *D is the dyadic readback row consumed before the seal handoff is visible;*
6. *R records the regular-rational source readbacks visible to the paired route;*
7. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row consumed by completion-facing readers;*
8. *H records componentwise* hsame *transport for all displayed rows;*
9. *C records the* Cont *routes by which consumers read the shared threshold, fusion, budget, dyadic readback, Real agreement seal, and Cauchy-limit handoff;*
10. *P is the* Pkg *provenance over* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RegularCauchyTailFusion}^{\uparrow}$, $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{CofinalTailAgreement}^{\uparrow}}$ *row.*

The carrier contains no quotient stream equality, selected host limit, external tail oracle, countable-choice row, or ambient Real-completeness theorem.

Lean4 ✓ `BEDC.Derived.CofinalTailAgreementUp.CofinalTailAgreementTasteGate single carrier alignment`

Theorem 920.2 (Cofinal tail-agreement NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CofinalTailAgreement}^{\uparrow}}$ *surface for Definition 920.1 consists of six obligation rows: carrier admission for* $A = (M, F, B, S, D, R, L, H, C, P, N)$*, shared-threshold exactness through* M*, fused cofinal-tail exactness through* F*, selector-budget readback through* B*, dyadic agreement readback through* D, R, S*, Cauchy-limit seal handoff through* L*, and non-escape through* H, C, P, N*.*

Proof. Carrier admission is projection from the displayed packet. The rows already expose the shared threshold, fused tail route, selector budget, dyadic readback, regular source readbacks, Real agreement seal, Cauchy-limit handoff, transports, routes, provenance, and local naming.

The dependency rows are read in order. The shared threshold M supplies the common tail bound, F fuses the paired cofinal witnesses through that bound, and B records the finite selector budget that the paired route may use.

The consumer-facing rows are then forced. The dyadic readback D and regular readbacks R feed the Real agreement seal S, and the completion-facing reader reaches the Cauchy-limit handoff L only through the same displayed route. Since H, C, P, N name all transports, continuations, provenance, and local certificate rows, no hidden tail selector or ambient completeness principle is exported. □

Theorem 920.3 (Cofinal tail-agreement carrier admission)**.** *Every accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *packet admits the displayed* BHist *carrier*

$$A = (M, F, B, S, D, R, L, H, C, P, N)$$

before any public Real-completion consumer may read a tail-agreement result. The admission row exposes M, F, B, D, R, S, L *as source, budget, readback, seal, and handoff data, while* H, C, P, N *expose componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{CofinalTailAgreement}^{\uparrow}}$ *row.*

Proof. Project the carrier of Definition 920.1. Its rows are already a finite BHist packet rather than quotient-stream or host-limit data.

Apply the obligation surface of Definition 920.2. Carrier admission is the first obligation, and the same surface names shared-threshold exactness, fused-tail exactness, selector-budget readback, dyadic readback, seal handoff, and non-escape.

The TasteGate marker following Definition 920.1 records the same single-carrier alignment. Thus a public consumer starts from $A = (M, F, B, S, D, R, L, H, C, P, N)$ and cannot bypass the hsame, Cont, Pkg, or $\mathsf{NameCert}$ support rows. □

Theorem 920.4 (Cofinal tail-agreement tail readback)**.** *Every public tail readback of an accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *packet factors through the full row route*

$$M, F, B, D, R, S, L, H, C, P, N.$$

The readback first uses the shared threshold and fused cofinal tail rows M, F*, then the finite selector budget* B*, then the dyadic and regular source readbacks* D, R*, then the Real agreement seal* S *and Cauchy-limit handoff* L*, with* H, C, P, N *preserving the same route.*

Proof. Begin with carrier admission, Definition 920.3. It makes the full row set visible before any consumer-facing agreement read.

Use Definition 920.2. The obligations place shared-threshold exactness before fused-tail exactness, selector-budget readback before dyadic and regular readback, and seal handoff after those readback rows.

Finally apply the consumer factorization pattern established by Definition 920.6. The rows H, C, P, N do not select a new tail; they transport, replay, package, and name the already displayed route. □

Theorem 920.5 (Cofinal tail-agreement cofinal nonescape)**.** *No accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier exports quotient stream equality, a selected host limit, countable choice, or ambient Real completeness as a substitute for the displayed cofinal route* $M, F, B, D, R, S, L, H, C, P, N$*. Any Completion-facing consumer that omits one of these rows cannot be repacked as a public read of the accepted packet.*

Proof. Read the admitted carrier from Definition 920.3. The finite packet supplies exactly the displayed rows and no quotient-stream, selected-limit, choice, or ambient-completeness coordinate.

Apply tail readback, Definition 920.4. The public route to the Real and Completion handoff passes through M, F, B, D, R, S, L and then through the support rows H, C, P, N.

Use the existing non-escape theorem, Definition 920.8. A route omitting the shared threshold, fused tail, budget, readbacks, seal, handoff, transport, continuation, provenance, or local name is outside the packet, so none of the refused host objects can be exported as the cofinal tail agreement. □

Theorem 920.6 (Cofinal tail-agreement consumer factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *packet factors through the shared-threshold row* M*, the fused tail row* F*, the selector-budget row* B*, the dyadic readback row* D*, the regular readback row* R*, the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row* S*, and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* L *before it can read a completion-facing agreement result. The consumer receives the paired route*

$$M, F, B, D, R, S, L, H, C, P, N$$

and receives no quotient stream, selected limit, host equality, hidden tail oracle, or ambient completeness theorem.

Proof. Start from the accepted carrier. Its only consumer-facing rows are $M, F, B, D, R, S, L, H, C, P, N$, so any public read begins with the displayed finite packet.

Use the sibling tail surfaces in order. The $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ row fixes the shared threshold, the $\mathsf{RegularCauchyTailFusion}^{\uparrow}$ row fuses the paired cofinal witnesses through that threshold, and the $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$ row records the finite selector budget used by the paired read.

Now route the seal handoff. The dyadic and regular readbacks feed the $\mathsf{RealTailAgreementSeal}^{\uparrow}$ row, and the completion-facing side then consumes the $\mathsf{CauchyLimitSeal}^{\uparrow}$ row through the same H, C, P, N provenance. No carrier coordinate remains for a second tail selector or a separate completion route. □

Theorem 920.7 (Cofinal tail-agreement Real and Completion handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer that reaches the paired agreement result of an accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier must pass through the route*

$$M, F, B, D, R, S, L, H, C, P, N,$$

with the $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row* S *consumed before the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* L*. The consumer cannot replace this route by quotient stream equality, host stream equality, a selected limit, or an ambient completeness theorem.*

Proof. Begin with the local NameCert obligations. The carrier admission row exposes only $M, F, B, S, D, R, L, H, C$ while the shared-threshold, fused-tail, selector-budget, dyadic-readback, and Cauchy-limit handoff obligations force the same displayed rows to be consumed by any public reader.

Apply Definition 920.6. A $\mathsf{Real}^{\uparrow}$ or $\mathsf{Completion}^{\uparrow}$ consumer reaches the paired agreement only through $M, F, B, D, R, S, L, H, C, P, N$, so the agreement result is not available before the shared threshold, fused tail, budget, dyadic readback, regular readback, and seal rows have been read.

Use Definition 920.9 and Definition 920.10. The shared threshold and selector budget are single displayed rows, and the handoff has exactly one $\mathsf{RealTailAgreementSeal}^{\uparrow}$ row before exactly one $\mathsf{CauchyLimitSeal}^{\uparrow}$ row.

Finally apply Definition 920.11. Quotient stream equality, host stream equality, selected limits, and ambient completeness all bypass the displayed route, so none can be repacked as the Real or Completion handoff of the accepted $\mathsf{CofinalTailAgreement}^{\uparrow}$ carrier. □

Theorem 920.8 (Cofinal tail-agreement non-escape)**.** *An accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *packet exports only the paired-source, shared-threshold, dyadic-readback, Real-agreement-seal, and Cauchy-limit handoff rows of Definition 920.1. A route that omits the shared threshold* M*, the fused tail row* F*, the selector budget* B*, the dyadic readback* D*, the Real agreement seal* S*, or the Cauchy-limit handoff* L *is outside the packet and cannot be repacked as the paired cofinal-tail agreement route.*

Proof. Inspect the carrier inventory. The packet has exactly the displayed rows $M, F, B, S, D, R, L, H, C, P, N$ and no coordinate for quotient streams, host equality, selected limits, hidden tail oracles, or external completeness data.

Apply Definition 920.2. Its obligation rows make the shared threshold, fused tail, selector budget, dyadic readback, Real agreement seal, and Cauchy-limit handoff mandatory for the public route.

Finally apply Definition 920.6. Every Real or Completion consumer reaches the agreement result through the same displayed rows, so an attempted route omitting any of the mandatory rows has no continuation that can export the packet. □

Theorem 920.9 (Cofinal tail-agreement shared threshold budget)**.** *For every accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier* $A = (M, F, B, S, D, R, L, H, C, P, N)$*, the paired cofinal-tail route has a single shared threshold row* M *and a single finite selector-budget row* B*. Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer that reads the agreement through* S *or* L *must first factor through* M, F, B *and the same transport, replay, provenance, and naming rows* H, C, P, N*.*

Proof. Project the accepted carrier. The only threshold coordinate is M, and the only selector-budget coordinate is B; the fused paired route is the row F between them.

Use Definition 920.2. Shared-threshold exactness, fused cofinal-tail exactness, and selector-budget readback are separate obligation rows, so no consumer can replace M, F, B by an external threshold or a second selector budget.

Finally apply Definition 920.6. Both Real and Completion reads reach the seal handoff through the same $M, F, B, D, R, S, L, H, C, P, N$ route, so the shared threshold and finite budget are not optional decorations of the packet. □

Theorem 920.10 (Cofinal tail-agreement seal handoff determinacy)**.** *In an accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier* $A = (M, F, B, S, D, R, L, H, C, P, N)$*, the handoff from the paired cofinal-tail route to* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *and then to* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *is determined by the displayed rows* $M, F, B, D, R, S, L, H, C, P$*. A consumer preserving those rows cannot choose a second Real agreement seal, a second Cauchy-limit seal, or a selected host limit.*

Proof. The carrier has exactly one Real agreement seal row S and exactly one Cauchy-limit handoff row L. The dyadic and regular readbacks D, R are the only displayed rows feeding the seal handoff.

Read the obligation surface of Definition 920.2. It names dyadic agreement readback through D, R, S and Cauchy-limit seal handoff through L as mandatory local certificate rows.

Transport and replay do not introduce another seal. The rows H, C, P, N only preserve and expose the same displayed packet, so any consumer preserving $M, F, B, D, R, S, L, H, C, P, N$ has no coordinate from which to select a second host limit or an alternate seal path. □

Theorem 920.11 (Cofinal tail-agreement quotient stream refusal)**.** *No accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier* $A = (M, F, B, S, D, R, L, H, C, P, N)$ *exports quotient-stream equality, host stream equality, a selected limit, or an ambient completeness theorem. Every attempted consumer of such data factors through the refusal already expressed by the missing carrier coordinate and therefore cannot be repacked as a* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *read.*

Proof. Inspect the definition of the carrier. Its public coordinates are $M, F, B, S, D, R, L, H, C, P, N$, and the definition explicitly excludes quotient stream equality, selected host limits, external tail oracles, countable-choice rows, and ambient Real-completeness data.

Apply the non-escape theorem, Definition 920.8. A route that omits the shared threshold, fused tail, selector budget, dyadic readback, Real agreement seal, or Cauchy-limit handoff is outside the packet.

The refused data omit the displayed route by construction. Quotient-stream equality and host equality bypass M, F, B, D, R, S, L; selected limits bypass the finite budget B and handoff row L; ambient completeness bypasses the local $\mathsf{NameCert}$ row N. Hence none of them can be repacked as an accepted paired cofinal-tail agreement route. □

Theorem 920.12 (Cofinal tail-agreement shared-threshold exposure)**.** *For every accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier* $A = (M, F, B, S, D, R, L, H, C, P, N)$*, every public* $\mathsf{NameCert}_{\mathsf{CofinalTailAgreement}^{\uparrow}}$ *read exposes the shared-threshold row* M *before it can read the fused cofinal-tail row* F*, the finite selector-budget row* B*, the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row* S*, or the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* L*. The row* M *is therefore a displayed* BHist *coordinate of the packet, not a threshold recovered from quotient streams, host limits, or ambient completeness.*

Proof. Apply Definition 920.2. Its obligation surface separates shared-threshold exactness through M from fused-tail exactness through F, selector-budget readback through B, dyadic agreement readback through D, R, S, and Cauchy-limit handoff through L.

Next use Definition 920.6. Every public Real or Completion consumer reads the agreement through $M, F, B, D, R, S, L, H, C, P, N$, so no later seal row is available before the shared threshold has been displayed.

Finally apply Definition 920.8. A route omitting M lies outside the accepted packet, and Definition 920.11 prevents quotient stream equality, host equality, selected limits, or ambient completeness from replacing that missing row. □

Theorem 920.13 (Cofinal tail-agreement selector-budget readback)**.** *For every accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier* $A = (M, F, B, S, D, R, L, H, C, P, N)$*, the row* B *is the finite selector-budget coordinate*

through which the dyadic readback D, the regular-source readback R, the Real agreement seal S, and the Cauchy-limit handoff L are publicly read. No consumer of the accepted packet receives a second selector budget, hidden selector oracle, selected host limit, or budget-free path from D, R to S, L.

Proof. Read the carrier and the obligation rows of Definition 920.2. The selector-budget obligation names B separately from M, F, D, R, S, L, so the budget is a finite row of the same BHist packet rather than a property inferred after the seal.

Apply Definition 920.6. The displayed consumer route places B before D, R, S, L, and every Real or Completion-facing read of those rows proceeds through the same transport, continuation, provenance, and local naming rows H, C, P, N.

Use Definition 920.7 and Definition 920.11. The handoff never exports a selected limit, hidden selector, host equality, or ambient completeness coordinate, so no budget-free route can be repacked as an accepted $\mathsf{CofinalTailAgreement}^{\uparrow}$ read. □

Theorem 920.14 (Cofinal tail-agreement seal handoff coverage)**.** *For every accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier $A = (M, F, B, S, D, R, L, H, C, P, N)$, every Completion-facing consumer reaches the handoff row L only after passing through the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row S on the same $M, F, B, D, R, H, C, P, N$ route. The consumer receives no quotient-stream equality, host limit, selected-limit coordinate, or ambient completeness row as part of that handoff.*

Proof. Begin with Definition 920.7. It states that every Real or Completion consumer reaching the paired agreement result passes through $M, F, B, D, R, S, L, H, C, P, N$, with S consumed before L.

Then apply Definition 920.6. The same route is the whole public consumer surface, so Completion-facing use of L remains tied to the Real agreement seal S and to the displayed carrier rows.

Finally use Definition 920.8 together with Definition 920.11. Quotient stream equality, host limits, selected limits, and ambient completeness each require an absent coordinate, hence none is delivered by the Completion handoff. □

Theorem 920.15 (Cofinal tail-agreement eventual selector exactness)**.** *For every accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *packet $A = (M, F, B, S, D, R, L, H, C, P, N)$, the selector-budget row B is the unique public route from the shared-threshold row M and fused-tail row F to the dyadic readback row D and regular readback row R. No accepted Real or Completion consumer can read D, R, S, L from M, F by a second selector, hidden tail oracle, quotient stream equality, or ambient completeness row.*

Proof. Begin with the carrier and NameCert obligations. The packet displays exactly one shared-threshold row M, one fused-tail row F, and one selector-budget row B, and the obligation surface reads shared-threshold exposure, fused-tail exactness, and selector-budget readback as separate rows of the same finite certificate.

Use Definition 920.12 and Definition 920.13. They place M before F and force the public read of D, R, S, L through B, with H, C, P, N preserving the same packet rather than supplying an alternate selector.

Finally apply Definition 920.14 and Definition 920.11. The Real and Cauchy-limit handoffs consume the route already built from M, F, B, D, R, while quotient stream equality, selected limits, hidden tail oracles, and ambient completeness require absent coordinates. Thus B is the unique public selector route from the shared threshold and fused tail to the readback rows. □

Theorem 920.16 (Cofinal tail-agreement tail-filter stability)**.** *Componentwise* hsame *transport of an accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *packet preserves the cofinal tail filter represented by the rows $M, F, B, D, R, S, L, H, C, P, N$. The transported read cannot replace that finite filter by quotient*

stream equality, host stream equality, a selected limit, or any equality of completed streams outside the displayed packet.

Proof. Read the transport row H in the carrier. It transports the shared threshold, fused tail, selector budget, dyadic readback, regular readback, Real agreement seal, Cauchy-limit handoff, continuation, provenance, and local naming rows componentwise.

Apply Definition 920.6 and Definition 920.21. Every public consumer route uses the same finite sequence $M, F, B, D, R, S, L, H, C, P, N$, so transporting the packet preserves the filter as a displayed row sequence rather than as a quotient of streams.

The replacement cases are excluded by Definition 920.11. Quotient stream equality, host stream equality, selected limits, and equality of completed streams ask for data the carrier explicitly omits, so no hsame transport can turn them into the accepted tail-filter read. □

Theorem 920.17 (Cofinal tail-agreement completion-window coherence)**.** *The* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *handoff row S and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row L of an accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *packet consume the same finite selector window. In particular, both handoffs read the same shared-threshold row M, fused-tail row F, selector-budget row B, dyadic readback row D, regular readback row R, and support rows H, C, P, N.*

Proof. Start from Definition 920.14. It places every Completion-facing use of L after the Real agreement seal S on the same $M, F, B, D, R, H, C, P, N$ route.

Use Definition 920.15. The selector-budget row B is the unique public route from M, F to the dyadic and regular readback rows, so the Real seal cannot consume one selector window while the Cauchy-limit seal consumes another.

Finally apply Definition 920.19 and Definition 920.20. They identify the terminal handoff with the same source route and exclude quotient streams, selected host limits, countable choice, and ambient Real completeness. Hence S and L share one finite selector window. □

Theorem 920.18 (Cofinal tail-agreement modulus seal route)**.** *Every accepted paired agreement route consumed by* $\mathsf{CofinalModulusSeal}^{\uparrow}$ *from a* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier $A = (M, F, B, S, D, R, L, H, C, P, N)$ preserves the same shared-threshold row M, fused tail row F, selector-budget row B, dyadic readback row D, regular readback row R, seal row S, terminal handoff row L, transport row H, continuation row C, provenance row P, and local naming row N. A* $\mathsf{CofinalModulusSeal}^{\uparrow}$ *consumer cannot read the paired cofinal agreement through S while changing any of the upstream M, F, B, D, R rows or any of the support rows H, C, P, N.*

Proof. Start from the carrier of Definition 920.1. Its displayed packet is exactly $M, F, B, S, D, R, L, H, C, P, N$, so the modulus-seal consumer has no coordinate outside that finite carrier.

Apply the NameCert obligations of Definition 920.2. They bind shared-threshold exactness through M, fused cofinal-tail exactness through F, selector-budget readback through B, dyadic and regular readback through D, R, S, and terminal handoff through L.

Now use consumer factorization and the Real/Completion handoff, Definition 920.6 and Definition 920.7. Any accepted consumer that reaches the seal row reads the route $M, F, B, D, R, S, L, H, C, P, N$, and the support rows only transport, replay, package, and name that same route.

Finally combine shared-threshold budget, seal-handoff determinacy, quotient-stream refusal, and non-escape, Definition 920.9, Definition 920.10, Definition 920.11, and Definition 920.8. They rule out a second threshold, second budget, altered readback, alternate seal, quotient-stream equality, selected limit, or ambient completeness route for the same $\mathsf{CofinalModulusSeal}^{\uparrow}$ read. □

Theorem 920.19 (Cofinal tail-agreement terminal seal compatibility)**.** *For an accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier* $A = (M, F, B, S, D, R, L, H, C, P, N)$*, the handoff* $S \to L$ *is compatible with the terminal* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row only when the same source route* M, F, B, D, R *is displayed before the seal and preserved by* H, C, P, N*. A terminal consumer that reaches* L *without the same* M, F, B, D, R *route is not reading the* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *handoff.*

Proof. Project the accepted packet. The only terminal handoff coordinate is L, and Definition 920.10 makes its predecessor the displayed seal row S fed by D, R on the same M, F, B source route.

The route into Completion is already forced by Definition 920.7. It places S before L and keeps the same $M, F, B, D, R, H, C, P, N$ support around the handoff.

Use Definition 920.14 and Definition 920.18. They show that Completion-facing consumption of L and modulus-seal consumption of S preserve one displayed source route rather than two separately chosen routes.

If a consumer omits or changes M, F, B, D, R, then Definition 920.8 and Definition 920.11 apply. The attempted handoff would require an absent coordinate such as a quotient stream, host limit, selected limit, or ambient completeness row, so it is outside the terminal seal compatibility surface. □

Theorem 920.20 (Cofinal tail-agreement completion source exhaustion)**.** *No Completion-facing consumer of an accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *carrier can replace the route* $M, F, B, D, R, S, L, H, C, P, N$ *by quotient stream equality, host limits, selected limits, countable choice, or ambient Real completeness. The accepted source for the terminal agreement is exhausted by the displayed shared-threshold, fused-tail, selector-budget, dyadic-readback, regular-readback, seal, handoff, transport, continuation, provenance, and naming rows.*

Proof. Read the carrier and NameCert obligations. The packet lists $M, F, B, S, D, R, L, H, C, P, N$ and explicitly excludes quotient stream equality, selected host limits, external tail oracles, countable-choice rows, and ambient Real-completeness data.

Consumer factorization, Real/Completion handoff, and seal-handoff coverage force every Completion-facing read through the same displayed route. Thus L is not a free limit coordinate; it is the terminal row reached after M, F, B, D, R, S and preserved by H, C, P, N.

Apply the modulus-seal route and terminal compatibility theorems above. They identify the same M, F, B, D, R source route as the one seen by the modulus seal and by the terminal Cauchy-limit seal.

Finally use quotient-stream refusal and non-escape. Each replacement source asks for data that the carrier has refused or omitted, so none can be repacked as a Completion-facing consumer of the accepted $\mathsf{CofinalTailAgreement}^{\uparrow}$ route. □

Theorem 920.21 (Cofinal tail-agreement route coverage)**.** *For every accepted public read of a* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *packet* $A = (M, F, B, S, D, R, L, H, C, P, N)$*, the visible route covers the rows* $M, F, B, D, R, S, L, H, C, P, N$ *and factors through the* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*,* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$*,* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$*,* $\mathsf{RealTailAgreementSeal}^{\uparrow}$*, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *surfaces. No accepted Real- or Completion-facing read may consume* S *or* L *while omitting any upstream row among* M, F, B, D, R *or any support row among* H, C, P, N*.*

Proof. Start with the carrier and NameCert obligations. They expose the shared threshold M, fused tail route F, selector budget B, dyadic and regular readbacks D, R, Real agreement seal S, Cauchy-limit handoff L, and the support rows H, C, P, N in one finite BHist packet.

The factorization is supplied by the existing consumer route. Use Definition 920.6, Definition 920.7, and Definition 920.14: together they place the RegularCauchyTailMeet, RegularCauchyTailFusion, RegularCauchySelectorBudget, RealTailAgreementSeal, and CauchyLimitSeal readings on the same displayed route.

It remains to exclude partial public reads. The non-escape and quotient-stream refusal theorems, Definition 920.8 and Definition 920.11, say that an omitted row would have to be replaced by host equality, a selected limit, quotient-stream equality, countable choice, or ambient completeness, none of which is a coordinate of the accepted packet. □

Theorem 920.22 (Cofinal tail-agreement dependency lock)**.** *The sibling rows named in the* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *route are mandatory* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *coordinates of the accepted packet, not prose dependencies. In particular, the RegularCauchyTailMeet threshold, RegularCauchyTailFusion tail route, RegularCauchySelectorBudget budget, RealTailAgreementSeal row, and CauchyLimitSeal handoff remain locked to the same* H, C, P, N *support rows throughout every accepted consumer read.*

Proof. Read Definition 920.1. The sibling data enter the packet as displayed coordinates rather than as external chapter names or informal prerequisites.

The NameCert obligations then assign those coordinates their transport, continuation, provenance, and local naming roles. They bind BHist membership, componentwise hsame stability, Cont replay, Pkg provenance, and $\mathsf{NameCert}$ locality to the same finite route.

Consumer factorization and the handoff theorems preserve that lock downstream. The Real/Completion handoff, modulus-seal route, terminal seal compatibility, and completion source exhaustion results together prevent a consumer from changing a sibling row while keeping the public $\mathsf{CofinalTailAgreement}^{\uparrow}$ name. □

Theorem 920.23 (Cofinal tail-agreement completion boundary)**.** *Every Completion-facing consumer of an accepted* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *packet receives only the finite route* $M, F, B, D, R, S, L, H, C, P, N$*. The consumer cannot substitute quotient streams, selected host limits, countable choice, or ambient Real completeness for the displayed shared threshold, fused tail, selector budget, dyadic readback, regular readback, Real seal, Cauchy-limit handoff, transport, continuation, provenance, and local naming rows.*

Proof. The boundary begins at the Real/Completion handoff. By Definition 920.7 and Definition 920.14, the handoff into L is reached only through the displayed $M, F, B, D, R, S, H, C, P, N$ route.

The terminal compatibility and completion source exhaustion results identify this as the whole Completion-facing source. They leave no hidden quotient stream, selected limit, choice-selected tail, or ambient completeness coordinate behind L.

Finally, quotient-stream refusal and non-escape close the boundary. Any attempted replacement asks for data outside the carrier and therefore cannot be repacked as a $\mathsf{CofinalTailAgreement}^{\uparrow}$ consumer read. □

Theorem 920.24 (Cofinal tail-agreement scoped kernel route)**.** *Every accepted public* $\mathsf{CofinalTailAgreement}^{\uparrow}$ *read factors through the displayed route* $M, F, B, D, R, S, L, H, C, P, N$*. This route is scoped exactly by the carrier's* BHist *rows, componentwise* hsame *transports, displayed* Cont *continuation,* Pkg *provenance, local* $\mathsf{NameCert}$ *row, and the named* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$*,* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$*,* $\mathsf{RegularCauchySelectorBudget}^{\uparrow}$*,* $\mathsf{RealTailAgreementSeal}^{\uparrow}$*, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *surfaces. No accepted read may replace any part of the route by quotient*

stream equality, host stream equality, a selected limit, countable choice, or ambient Real completeness.

Proof. Start from Definition 920.1 and Definition 920.2. They present $M, F, B, D, R, S, L, H, C, P, N$ as one finite packet, with H supplying componentwise hsame transport, C supplying the displayed Cont replay, P supplying Pkg provenance, and N supplying local NameCert naming over the StreamName, dyadic, regular, Real, and tail-handoff rows.

Next apply Definition 920.6, Definition 920.21, and Definition 920.22. These results put every public read on the same $M, F, B, D, R, S, L, H, C, P, N$ route and lock the shared threshold, fused tail, selector budget, dyadic readback, regular readback, Real agreement seal, and Cauchy-limit handoff to the same H, C, P, N support.

Definition 920.23 supplies the final exclusion. A reader that asks for quotient stream equality, host stream equality, a selected limit, countable choice, or ambient Real completeness asks for a coordinate not present in the accepted packet. Hence the public read is scoped by exactly the displayed BEDC kernel rows and the listed completion-route surfaces. □

Falsifiable prediction: Deleting the shared cofinal threshold row breaks the Real/Completion consumer route while leaving the one-sided tail-fusion route intact.

Independence witness: The nearest siblings regularcauchytailmeet, regularcauchytailfusion, regularcauchyselectorbudget, realtailagreementseal, and cauchylimitseal share individual rows with $\mathsf{CofinalTailAgreement}^{\uparrow}$, but no bijection preserves all paired-source, shared-threshold, dyadic-readback, and seal-handoff rows at once: the tail-meet packet lacks the selector-budget and seal-handoff rows, the tail-fusion packet lacks the terminal Cauchy-limit handoff, the selector-budget packet lacks the paired agreement seal, the Real tail-agreement seal lacks the upstream fusion budget, and the Cauchy-limit seal lacks the paired-source threshold route.

The Lean `TasteGate.lean` boundary for this carrier must include `Nontrivial CofinalTailAgreementUp` and `FieldFaithful CofinalTailAgreementUp` instances, so the paired shared-threshold route is represented by a nonempty and field-faithful carrier rather than by a vacuous type.

Closure status for $\mathsf{NameCert}_{\mathsf{CofinalTailAgreement}^{\uparrow}}$.

Constructive story: A $\mathsf{CofinalTailAgreement}^{\uparrow}$ packet is generated from a shared RegularCauchyTailMeet threshold, RegularCauchyTailFusion paired tail route, RegularCauchySelectorBudget finite selector budget, dyadic and regular readbacks, RealTailAgreementSeal handoff, CauchyLimitSeal handoff, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CofinalTailAgreement}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 920.24 binds every accepted public read of the finite paired cofinal-tail agreement carrier to the displayed BEDC kernel rows and Real/Completion route surfaces.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CofinalTailAgreement}^{\uparrow}}$, axiomClean)

Lean4 ✓ `BEDC.Derived.CofinalTailAgreementUp.taste gate`

Lean target: `BEDC.Derived.CofinalTailAgreementUp.CofinalTailAgreementTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close public-object closure, quotient stream equality, selected host limits, countable choice, ambient Real completeness, or bridge checking.

Upgrade path: Public closure requires exhibiting the route as a stable public object surface rather than only a scoped finite kernel route.

Chapter 921

A Concrete Naming Certificate for $\mathsf{FiniteTailFiberSchedule}^{\uparrow}$

The $\mathsf{FiniteTailFiberSchedule}^{\uparrow}$ packet realizes the finite tail route behind the Real-completeness target of chapter 9238. It sits after the stream-name surface of chapter 126, the regular rational source of chapter 301, the dyadic readback core of chapter 291, the RealUp seal of chapter 38, and the shared tail-meet route of chapter 560. The packet records one finite tail fiber, its schedule row, and its seal handoff without claiming quotient reals, ambient completeness, or an unrestricted diagonal theorem.

Definition 921.1 (Finite tail-fiber schedule carrier)**.** *A* $\mathsf{FiniteTailFiberSchedule}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (T, F, S, D, R, E, H, C, P, N)$$

with the following visible rows:

1. *T is the displayed tail index at which the finite Real-completeness route is read;*
2. *F is the finite fiber row over that tail index, recording the stream observations available at the selected tail;*
3. *S is the schedule row that binds the tail index and finite fiber to the selected RealUp seal route;*
4. *D is the dyadic radius ledger consumed by the finite tail readback;*
5. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row used to interpret the scheduled fiber as regular rational data;*
6. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row reached by the scheduled tail-fiber route;*
7. *H records componentwise* hsame *transport for the tail index, fiber row, schedule row, dyadic radius ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and* $\mathsf{Real}^{\uparrow}$ *seal;*
8. *C records the displayed* Cont *routes for stream-name readback, dyadic-radius use, regular-rational readback, tail-meet comparison, and seal consumption;*
9. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and local naming rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteTailFiberSchedule}^{\uparrow}}$ *row.*

The classifier compares two carriers only by the displayed rows $T, F, S, D, R, E, H, C, P, N$. It has no coordinate for quotient stream equality, an infinite tail oracle, a selected host limit, countable choice, or an ambient real-completeness theorem.

Lean4 ✓ `BEDC.Derived.FiniteTailFiberScheduleUp.FiniteTailFiberScheduleTasteGate single carrier alignment`

Theorem 921.2 (FiniteTailFiberSchedule NameCert obligations)**.** *Every accepted* $\mathsf{FiniteTailFiberSchedule}^{\uparrow}$ *packet with carrier Definition 921.1 carries the standard five local naming obligations:*

1. *carrier habitation: the tuple* $Q = (T, F, S, D, R, E, H, C, P, N)$ *is admitted as one finite* BHist *packet;*
2. *classifier transport: the componentwise* hsame *rows in* H *and the displayed* Cont *routes in* C *preserve the tail index, finite fiber, schedule, dyadic ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{Real}^{\uparrow}$ *seal, package, and naming rows;*
3. *schedule-to-fiber exactness: every accepted schedule read passes through the displayed tail index* T *and finite fiber row* F *before it can cite a RealUp seal;*
4. *dyadic and regular readback exactness: every seal-facing radius and regular-rational read passes through the dyadic ledger* D *and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R*;*
5. *non-escape: accepted carriers export no quotient real, selected host limit, infinite tail oracle, countable-choice row, or ambient Real-completeness theorem.*

Thus the local $\mathsf{NameCert}_{\mathsf{FiniteTailFiberSchedule}^{\uparrow}}$ *surface is exactly the finite schedule from a displayed tail fiber to a displayed* $\mathsf{Real}^{\uparrow}$ *seal.*

Proof. Carrier habitation is the displayed finite tuple $Q = (T, F, S, D, R, E, H, C, P, N)$. Each coordinate is a visible history row or a finite route between such rows, so admission does not require an external stream space or a host real carrier.

For classifier transport, read the structural rows componentwise. The hsame data in H preserve each displayed coordinate, and the Cont routes in C replay the stream-name, dyadic-radius, regular-rational, tail-meet, and seal-consumption reads without introducing another tail object.

Schedule-to-fiber exactness follows from the shape of S. A schedule row is accepted only when it binds the displayed tail index T to the finite fiber row F, and the seal row E is reachable only along that same route.

Dyadic and regular readback exactness then projects D and R. The radius information used at the scheduled tail is precisely the finite dyadic ledger, and the regular-rational data are precisely the displayed $\mathsf{RegSeqRat}^{\uparrow}$ readback for that fiber.

Non-escape is carrier inspection. Since no coordinate stores quotient equality, a host-selected limit, an infinite tail oracle, countable choice, or an ambient completeness theorem, every consumer of the packet must remain inside the displayed tail-fiber schedule and RealUp seal rows. □

Falsifiable prediction: Any accepted finite tail-fiber schedule consumer reaches the RealUp seal only after the displayed tail index, finite fiber, dyadic radius, RegSeqRat readback, hsame, Cont, Pkg, and local NameCert rows are present.

Independence witness: Compare StreamName, RegSeqRat, DyadicRatCore, RealUp, and RegularCauchyTailMeet: this packet is not bijective with any of them because it carries a schedule row binding one finite tail fiber to a RealUp seal; each sibling lacks at least the schedule-to-seal obligation or the tail-fiber ledger.

The later Lean `TasteGate.lean` boundary for this carrier must provide `Nontrivial FiniteTailFiberSchedul` and `FieldFaithful FiniteTailFiberScheduleUp` instances with explicit witness pairs and field projections. The nontrivial witness separates a scheduled tail-fiber packet from a carrier with no

seal route, while field faithfulness preserves the tail index, finite fiber, schedule row, dyadic ledger, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal, hsame transport, Cont routes, package provenance, and local naming row.

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteTailFiberSchedule}^{\uparrow}}$.

Constructive story: A $\mathsf{FiniteTailFiberSchedule}^{\uparrow}$ packet is generated from a displayed tail index, finite fiber row, schedule row, dyadic radius ledger, RegSeqRat readback, RealUp seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FiniteTailFiberSchedule}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 921.1 and Definition 921.2 bind the finite tail-fiber schedule and RealUp seal handoff route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FiniteTailFiberSchedule}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, quotient reals, host real completeness, selected limits, countable choice, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, schedule-to-fiber exactness, dyadic and regular readback exactness, RealUp seal handoff, transport closure, and TasteGate nontriviality with field faithfulness.

Lemma 921.3 (FiniteTailFiberSchedule seal-route determinacy)**.** *Let*

$$Q = (T, F, S, D, R, E, H, C, P, N)$$

and

$$Q' = (T', F', S', D', R', E', H', C', P', N')$$

be accepted $\mathsf{FiniteTailFiberSchedule}^{\uparrow}$ *packets. Suppose the displayed non-seal rows agree componentwise through the packet classifier:*

$$T = T', \quad F = F', \quad S = S', \quad D = D', \quad R = R', \quad H = H', \quad C = C', \quad P = P', \quad N = N'.$$

Then the $\mathsf{Real}^{\uparrow}$ *seal rows* E *and* E' *are classified along the same finite tail-fiber route. More explicitly, any accepted read of* E *and any accepted read of* E' *both factor through the common route*

$$T, F, S, D, R, H, C, P, N,$$

so the seal comparison has no independent coordinate from which to distinguish two RealUp seal routes under the same displayed tail index, finite fiber, schedule, dyadic ledger, RegSeqRat readback, transport, continuation, provenance, and local naming rows.

Proof. Project both packets to the carrier of Definition 921.1. The only row that can expose a RealUp seal is the seal coordinate attached to the same tuple as the displayed tail index, finite fiber, schedule row, dyadic ledger, RegSeqRat readback, componentwise transports, continuation routes, package provenance, and local name.

Apply the schedule-to-fiber obligation from Definition 921.2. In each accepted packet, a seal-facing schedule read must first pass through the displayed tail index and finite fiber row. Since $T = T'$, $F = F'$, and $S = S'$, the two packets present one scheduled tail-fiber route before either seal row can be cited.

Apply the dyadic and regular readback obligation from the same theorem. A seal-facing radius read is the displayed dyadic ledger D, and the regular-rational read is the displayed $\mathsf{RegSeqRat}^{\uparrow}$ row R. Since $D = D'$ and $R = R'$, the readback portion of the two seal routes is the same finite ledger rather than two separate regular-rational sources.

The transport and continuation rows now identify the remaining route data. The common rows $H = H'$ and $C = C'$ replay the same componentwise hsame transport and the same displayed Cont

route through the stream-name readback, dyadic-radius use, regular-rational readback, tail-meet comparison, and seal consumption. The common rows $P = P'$ and $N = N'$ attach the same package provenance and local naming surface to that replay.

Finally use non-escape from Definition 921.2. The packet has no coordinate for a quotient real, selected host limit, infinite tail oracle, countable-choice row, ambient completeness theorem, or second seal selector. Therefore an alleged distinct seal route would need an unlisted coordinate, while every accepted seal read is already forced through the common finite route $T, F, S, D, R, H, C, P, N$. Hence E and E' classify together along that route. $\square$

Chapter 922

A Concrete Naming Certificate for MetaCICTypedExamplesApplicationRoute$^{\uparrow}$

The MetaCICTypedExamplesApplicationRoute$^{\uparrow}$ packet realizes the application and beta-redex rows of chapter 9382 as a finite route certificate. It sits beside the MetaCIC gallery of chapter 775, the worked-example seal of chapter 753, the typed-example gallery of chapter 756, and the audit budget of chapter 880: those siblings expose gallery entries, checker rows, seal rows, and regression-spend rows, while this chapter isolates the route by which application-form examples and identity redex examples are carried to downstream MetaCIC audit consumers.

Definition 922.1 (MetaCIC typed-examples application-route carrier)**.** *A* MetaCICTypedExamplesApplicationRoute *carrier is a finite* BHist *packet*

$$R = (S, T, A, B, Z, H, C, P, N)$$

with the following displayed rows:

1. *S is the typed source-term row, recording the displayed function, argument, context, and sort information for application-form examples such as* app_id_sort_in_empty_ctx *and dependent identity application rows;*
2. *T is the typed target-term row, recording the displayed result term and its type after application or beta replay;*
3. *A is the application spine row, listing the finite head, argument, binder, context, and instantiation packets consumed by the route;*
4. *B is the beta and checker row, recording the selected redex endpoint, local checker acceptance, and named beta replay for rows such as* id_sort_redex *and* id_sort_redex_typed*;*
5. *Z is the closedness row, recording the finite closed-term, closed-context, and well-scoped inputs needed by S, T, A, B;*
6. *H records componentwise* hsame *transports for source terms, target terms, application spines, beta and checker rows, closedness rows, provenance, and local naming;*
7. *C records the displayed* Cont *routes by which a downstream consumer reaches the source row, target row, application spine, beta or checker row, closedness row, and sibling handoff rows;*
8. *P is the* Pkg *provenance over chapter 9382, chapter 775, chapter 753, chapter 756, and chapter 880;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{MetaCICTypedExamplesApplicationRoute}^{\uparrow}}$ *row.*

The carrier has no coordinate for arbitrary subject reduction, strong normalization, confluence, global checker completeness, unrestricted beta closure, or a host evaluator.

Theorem 922.2 (MetaCIC typed-examples application-route NameCert obligations)**.** *For the carrier of Definition 922.1, the local* $\mathsf{NameCert}_{\mathsf{MetaCICTypedExamplesApplicationRoute}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission for $R = (S, T, A, B, Z, H, C, P, N)$;*
2. *source-target exposure through S and T for typed application examples and typed beta-redex endpoints named by chapter 9382;*
3. *application-spine exactness through A, including the displayed head, argument, binder, context, and instantiation packets;*
4. *beta, checker, and closedness visibility through B and Z for exactly the selected application and identity-redex rows;*
5. *transport, continuation, provenance, and local naming through H, C, P, N, with sibling handoff restricted to the four concrete TypedExamples packets cited above.*

Proof. Project the finite packet. The source row S and target row T expose the endpoints of the application route, while the spine row A records the finite head, argument, binder, context, and instantiation data that make the route inspectable.

The beta and checker row B is read only together with the closedness row Z. Thus a consumer can replay the selected identity-redex and application examples, but it cannot replace them by an arbitrary represented term or by an unrestricted beta closure.

Finally route the read through H, C, P, N. The transport and continuation rows keep the same displayed source, target, spine, beta, checker, and closedness coordinates, and the provenance row limits sibling access to the existing gallery, seal, typed-gallery, and audit-budget packets. Since no other coordinate is present, the listed obligations exhaust the local NameCert surface. □

Theorem 922.3 (MetaCIC typed-examples application-route soundness)**.** *Every consumer of an accepted* $\mathsf{MetaCICTypedExamplesApplicationRoute}^{\uparrow}$ *packet reaches a typed application or beta-redex example through the displayed rows*

$$S, T, A, B, Z, H, C, P, N.$$

The consumer may use the packet as a finite route from a typed source term through an application spine to a typed target term, with beta, checker, closedness, transport, continuation, provenance, and local naming evidence. It receives no theorem about all MetaCIC applications, no unrestricted subject-reduction principle, no normalization endpoint selector, no confluence principle, and no global checker-completeness witness.

Proof. Begin with an accepted route packet. The only public endpoints are the typed source row S and the typed target row T, and the only path between them is the finite application spine A together with the beta and checker row B.

Closedness is supplied by Z, so the checker and beta reads are tied to the displayed source, target, and spine rows rather than to an ambient term space. Componentwise transport through H preserves those same rows before any comparison is made.

The continuation row C supplies the consumer path, while P and N record provenance and local naming. Because the carrier contains no coordinate for arbitrary applications, unrestricted

beta closure, subject reduction, normalization, confluence, or checker completeness, every accepted consumer read remains the finite application route described in the statement. □

Closure status for $\mathsf{NameCert}_{\mathsf{MetaCICTypedExamplesApplicationRoute}^{\uparrow}}$ ·

Constructive story: A $\mathsf{MetaCICTypedExamplesApplicationRoute}^{\uparrow}$ packet is generated from finite BHist rows for typed source terms, typed target terms, application spines, beta and checker rows, closedness rows, transports, continuations, provenance, and local naming. The route to a typed application or beta-redex example is replayed by Cont through the displayed source, spine, beta/checker, closedness, and target rows. Componentwise hsame preserves the same term, spine, checker, and closedness inventory, while Pkg records the typed-examples audit map and sibling gallery, seal, typed-gallery, and audit-budget packets. The packet certifies selected examples only.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{MetaCICTypedExamplesApplicationRoute}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the MetaCIC typed-examples application-route carrier, NameCert obligations, route soundness theorem, and finite consumer path.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{MetaCICTypedExamplesApplicationRoute}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim arbitrary applications, unrestricted beta closure, subject reduction, normalization, confluence, host evaluation, or checker completeness.

Upgrade path: Obligation closure requires Lean encodings of the application-route carrier, source-target exposure, beta/checker route, closedness row, and soundness theorem.

Chapter 923

A Concrete Naming Certificate for $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$

The $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ packet realizes the TypedExamples audit-map vision of chapter 9382 as a finite coverage matrix. It sits beside the MetaCIC gallery of chapter 775, the typed-example gallery of chapter 756, the worked-example seal of chapter 753, the regression-spend budget of chapter 880, and the beta-step boundary of chapter 754. Those siblings expose gallery rows, checker rows, seal rows, budget rows, and beta-boundary rows; this chapter binds them as one finite row-indexed coverage object for checker-audit consumers.

Definition 923.1 (Typed example coverage matrix carrier)**.** *A* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (F, G, C, B, R, E, H, K, P, N)$$

with the following displayed rows:

1. *F is the finite family index for accepted typed-example families;*
2. *G records, for each row of F, the paired gallery cells inherited from the MetaCIC and typed-example gallery packets;*
3. *C records the checker cells attached to the same rows;*
4. *B records the beta-boundary cells attached to the same rows;*
5. *R records the regression-spend cells and their accepted coverage budget;*
6. *E is the exactness row asserting that every accepted family in F has the displayed G, C, B, R cells and no extra coverage cell;*
7. *H records componentwise* hsame *transports for the family, gallery, checker, beta, regression-spend, exactness, provenance, and local naming rows;*
8. *K records the displayed* Cont *routes by which checker-audit consumers read exactly the cells F, G, C, B, R, E;*
9. *P is the* Pkg *provenance over the sibling gallery, seal, budget, beta-boundary, transport, continuation, and exactness rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{TypedExampleCoverageMatrix}^{\uparrow}}$ *row.*

The carrier has no coordinate for checker completeness, subject reduction, normalization, arbitrary beta closure, or unindexed regression spending.

Definition 923.2 (Typed example coverage matrix row family)**.** *For an accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *carrier* $M = (F, G, C, B, R, E, H, K, P, N)$*, the* coverage row family *is the finite subfamily of* F *whose displayed cells name the boolean, natural-number, pair, option, list, sum, and dependent-function gallery examples. The row family is read only through the paired matrix coordinates* G, C, B, R, E*:* G *names the example cell,* C *names its checker cell,* B *names the beta-boundary cell available for that example,* R *names the regression-spend cell, and* E *records that all four cells belong to the same family row.*

Theorem 923.3 (Typed example coverage matrix NameCert obligations)**.** *For the carrier of Definition 923.1, the local* $\mathsf{NameCert}_{\mathsf{TypedExampleCoverageMatrix}^{\uparrow}}$ *surface consists exactly of five finite obligation rows:*

1. *carrier admission for* $M = (F, G, C, B, R, E, H, K, P, N)$*;*
2. *family-index exactness through* F *against the accepted typed-example family rows;*
3. *paired gallery, checker, beta, and regression-spend cell exposure through* G, C, B, R*;*
4. *matrix exactness through* E*, requiring each accepted row to carry all four cell kinds and no unindexed cell;*
5. *transport, continuation, provenance, and local naming through* H, K, P, N*.*

Proof. Carrier admission is projection of the displayed packet. The row F supplies the finite family index before any coverage cell is read.

The rows G, C, B, R are paired by position. A consumer can inspect a gallery cell, checker cell, beta cell, or regression-spend cell only as the cell attached to the same family row.

The exactness row E records that the four cell kinds are jointly present for every accepted family and that no extra coverage coordinate exists outside the matrix. The rows H, K, P, N then transport, route, name, and package only the displayed rows. □

Theorem 923.4 (Typed example coverage matrix regression exactness)**.** *Every regression-spend cell in an accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *packet is paired with the unique displayed family row and with the corresponding gallery, checker, and beta cells. Conversely, every accepted family row has a displayed regression-spend cell in* R*.*

Proof. Project the accepted packet to F, G, C, B, R, E. The exactness row E is read against the common family index F, so each regression-spend entry is indexed before it is exposed to a checker-audit consumer.

For a displayed spend cell, E supplies the matching gallery, checker, and beta cells in the same row. For a displayed family row, E supplies the corresponding regression-spend cell in R.

Since the carrier has no unindexed spend coordinate, these two readings exhaust regression coverage for the packet. □

Theorem 923.5 (Typed example coverage matrix non-escape)**.** *Every checker-audit consumer of an accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *carrier reads coverage only through the displayed matrix rows* $F, G, C, B, R, E, H, K, P, N$*. The consumer cannot replace a missing gallery, checker, beta, or regression-spend cell by a sibling packet alone, an ambient checker theorem, or an unindexed budget row.*

Proof. Let a checker-audit consumer route be given. The route must pass through the displayed continuation row K and therefore reaches only the family, cell, exactness, transport, provenance, and local naming rows.

The sibling packets provide provenance for the cell contents, but the matrix pairing is carried by F and E. A sibling gallery, seal, budget, or beta-boundary packet alone does not store the combined cell row.

No coordinate in the carrier names an ambient checker theorem or an unindexed budget row. Hence the accepted consumer surface is exactly the finite coverage matrix. □

Theorem 923.6 (Typed example coverage matrix spend boundary)**.** *If a checker-audit consumer spends a regression budget from an accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *packet, the spend is licensed only for the family row whose gallery, checker, beta, and regression-spend cells are all displayed in the same matrix row.*

Proof. A regression spend is read from R through the continuation route K. The exactness row E identifies the family row in F and the paired gallery, checker, and beta cells in G, C, B.

The transport row H preserves the same row identity under componentwise hsame movement, while P and N record provenance and local naming only. They do not create a second spend endpoint.

Therefore a spend is confined to the displayed matrix row that carries all four cell kinds. □

Theorem 923.7 (Typed example coverage matrix gallery rows)**.** *The coverage row family of Definition 923.2 contains displayed rows for the boolean, natural-number, pair, option, list, sum, and dependent-function gallery examples. For each such row, the* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *packet exposes the same-family gallery cell in G, checker cell in C, beta-boundary cell in B, regression-spend cell in R, and exactness witness in E.*

Proof. Project the accepted carrier to F, G, C, B, R, E. The row family is a finite subfamily of F, so each listed gallery example is named before any checker-audit cell is read.

Read E at each of the boolean, natural-number, pair, option, list, sum, and dependent-function rows. The exactness row displays the matching G, C, B, R cells at the same family index.

Because the cells are paired inside the same carrier, coverage of these examples is matrix coverage. It is not a claim that an external checker proves every term in the surrounding type system. □

Theorem 923.8 (Typed example coverage matrix boundary rows)**.** *The accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *row family does not claim total dependent coverage, polymorphic total coverage, subject reduction, normalization, or checker completeness. Any consumer that needs those properties must add a separate carrier and NameCert surface; they are not obtained from the boolean, natural-number, pair, option, list, sum, or dependent-function gallery rows alone.*

Proof. Inspect the carrier inventory of Definition 923.1. The only coverage coordinates are the finite family index F, the displayed cells G, C, B, R, and the exactness row E.

The row family of Definition 923.2 selects named gallery examples from F. It does not add a coordinate for arbitrary dependent typing, polymorphic instantiation, subject reduction, normalization, or checker completeness.

The support rows H, K, P, N transport, replay, source, and name the same matrix. They cannot manufacture a global type-system theorem outside the displayed coverage rows. □

Theorem 923.9 (Typed example coverage matrix public export)**.** *Every MetaCIC audit consumer of an accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *packet receives only the family-indexed gallery, checker, beta-boundary, and regression-spend rows* $F, G, C, B, R, E, H, K, P, N$*. The export may cite the MetaCIC typed-examples gallery of chapter 775, the typed-example audit budget of chapter 880, and the beta-step boundary of chapter 754, but it does not export checker completeness, subject reduction, normalization, arbitrary beta closure, or gallery soundness beyond the displayed family rows.*

Proof. Project the accepted matrix carrier. The public rows are the family index F, the paired gallery, checker, beta-boundary, and regression-spend cells G, C, B, R, the exactness row E, and the structural rows H, K, P, N.

Read the cited sibling chapters through provenance. The MetaCIC typed-examples gallery supplies gallery cells, the audit-budget packet supplies regression-spend cells, and the beta-step boundary supplies beta-boundary cells; the coverage matrix is the place where those cells share one family index.

Apply the boundary-row theorem above. Since the exported rows do not contain subject reduction, normalization, checker completeness, arbitrary beta closure, or gallery soundness coordinates, a MetaCIC audit consumer receives only the displayed row-indexed matrix surface. □

Theorem 923.10 (Typed example coverage matrix critical-path spend exhaustion)**.** *Any checker-audit spend from an accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *packet must expose the same family row in* F*, gallery cell in* G*, checker cell in* C*, beta-boundary cell in* B*, regression spend in* R*, exactness row in* E*, and structural rows* H, K, P, N*. Therefore the matrix cannot be used as subject-reduction evidence, normalization evidence, or checker-completeness evidence.*

Proof. Project the accepted carrier of Definition 923.1. The only spend coordinate is R, and it is indexed by the same finite family row F as the gallery, checker, beta-boundary, and exactness cells.

Use regression exactness, the spend boundary, and checker-cell locality. These theorems keep every spend attached to the displayed G, C, B, R, E cells at one row and prevent a consumer from moving the checker cell or budget cell to a different family.

Finally apply non-escape and family exhaustion. The structural rows H, K, P, N preserve and replay the same packet, while the carrier has no coordinate for subject reduction, normalization, or checker completeness. The critical-path spend is therefore exhausted by the displayed matrix row. □

Theorem 923.11 (Typed example coverage matrix row totality)**.** *Every accepted family row in* F *has displayed gallery, checker, beta-boundary, and regression-spend cells in* G, C, B, R*, with the exactness row* E *recording that the four cells belong to the same row.*

Proof. Project the accepted carrier to F, G, C, B, R, E. A family row is accepted only as an element of the finite index F, so the row is named before any coverage cell is consumed.

Read the exactness row E at that family index. The row-totality clause in E displays the corresponding gallery cell in G, checker cell in C, beta-boundary cell in B, and regression-spend cell in R.

Because E is part of the same carrier, the four cells are not imported independently from sibling chapters. They are the displayed cells of the accepted matrix row. □

Theorem 923.12 (Typed example coverage matrix checker-cell locality)**.** *A checker cell from* C *may be consumed only at the family row whose gallery cell in* G*, beta-boundary cell in* B*, and regression-spend cell in* R *are paired with it through* E*.*

Proof. Let a checker-audit consumer read a checker cell. The read is routed through K, hence it reaches C only through the displayed matrix rows.

The exactness row E identifies the family row in F attached to that checker cell. At the same index it displays the paired gallery, beta-boundary, and regression-spend cells in G, B, R.

The transport row H preserves this row identity under componentwise hsame movement. Thus a checker cell cannot be moved to a different family row or paired with unrelated sibling data. □

Theorem 923.13 (Typed example coverage matrix family exhaustion)**.** *The accepted family index F exhausts the matrix surface of an accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *carrier: no ambient checker theorem, sibling gallery row, beta-boundary row, or unindexed budget row can add a hidden family outside F.*

Proof. Inspect the carrier inventory. The only family coordinate is F, and the only coverage-cell coordinates are G, C, B, R paired by E.

The provenance row P records sibling ancestry, but provenance is not a second family index. Likewise, the continuation row K only replays reads from the displayed matrix; it does not allocate another row.

Since the carrier has no coordinate for an ambient checker theorem or unindexed budget row, every accepted family is already one of the rows of F. □

Theorem 923.14 (Typed example coverage matrix carrier admission)**.** *For an accepted packet $M = (F, G, C, B, R, E, H, K, P, N)$, carrier admission is exactly the finite matrix row M together with the family index F and the displayed checker-audit rows $G, C, B, R, E, H, K, P, N$. The carrier admission row does not replace the matrix by a sibling gallery packet, a checker packet, or a budget packet.*

Proof. Project the accepted packet of Definition 923.1. The family index F is the first displayed row, so the carrier is admitted before any checker-audit consumer reads a cell.

Apply the NameCert obligations of Definition 923.3. They keep the displayed matrix together with the paired gallery, checker, beta, regression-spend, exactness, transport, continuation, provenance, and local naming rows. No sibling packet can supply the same combined row. □

Theorem 923.15 (Typed example coverage matrix context coverage)**.** *Every accepted* TypedExampleCoverageMatri *carrier covers its typed-example context exactly through the family rows in F and the paired gallery, checker, beta, and regression-spend rows in G, C, B, R. The context coverage row is therefore the displayed matrix row, not an ambient parameter-transport theorem.*

Proof. Read the row-totality theorem and the checker-cell locality theorem. Together they force each family row in F to carry all four displayed cell kinds in the same matrix row.

Then use family exhaustion. It rules out hidden family rows outside the matrix surface, so the accepted context is exhausted by the displayed F, G, C, B, R rows and their exactness row E. □

Theorem 923.16 (Typed example coverage matrix ledger non-escape)**.** *The local ledger row of an accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *packet cannot escape the matrix surface: every regression-spend read, checker read, gallery read, or beta-boundary read remains tied to the same family row and its paired exactness data. In particular, the ledger does not leave a residual unindexed budget row behind the displayed packet.*

Proof. Project the carrier and read the continuation row K. It routes every read through the displayed matrix rows, so a ledger read reaches only $F, G, C, B, R, E, H, P, N$.

Now apply regression exactness and non-escape. They keep the spend row paired with the family row and rule out replacement by a sibling packet or an unindexed budget row. The ledger therefore stays inside the accepted matrix surface. □

Theorem 923.17 (TypedExampleCoverageMatrix component route)**.** *Any checker, beta-boundary, gallery, or regression-spend consumer of an accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *carrier must read the gallery row, checker row, beta-step row, regression-spend row, row-totality evidence, checker-locality evidence, family-exhaustion evidence, componentwise* hsame*, displayed* Cont*,* Pkg*, and local* $\mathsf{NameCert}_{\mathsf{TypedExampleCoverageMatrix}^{\uparrow}}$ *rows as one packet.*

Proof. Project the carrier of Definition 923.1. The accepted packet already displays the family row F, the gallery row G, the checker row C, the beta-boundary row B, the regression-spend row R, the exactness row E, and the structural rows H, K, P, N.

Apply the NameCert obligations of Definition 923.3. They force a consumer to read the family index, paired cell exposure, matrix exactness, transport, continuation, provenance, and local naming as one finite matrix packet.

The regression exactness, non-escape, spend boundary, row-totality, checker-cell locality, and family-exhaustion theorems keep every checker, beta-boundary, gallery, or regression-spend read on the same accepted row. Therefore the consumer cannot split the packet into independent cells. □

Theorem 923.18 (Typed example coverage matrix TasteGate obligation surface)**.** *Before any closure promotion, the coverage-matrix obligation surface of an accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *packet is exactly the finite family index F, the paired gallery, checker, beta, and regression-spend cells G, C, B, R, the exactness row E, and the nonescape route through H, K, P, N. A TasteGate witness for this chapter must expose those rows as field-faithful carrier evidence and must not replace the displayed matrix by a sibling gallery, checker theorem, beta route, regression budget, or ambient audit object.*

Proof. Project the carrier $M = (F, G, C, B, R, E, H, K, P, N)$ of Definition 923.1. The family index F is named before any coverage cell can be inspected.

Use row totality Definition 923.11 and checker-cell locality Definition 923.12. They bind each gallery, checker, beta, and regression-spend cell to the same family row through E.

Finally apply family exhaustion Definition 923.13 and non-escape Definition 923.5. The remaining rows H, K, P, N transport, replay, source, and name only the displayed matrix, so a TasteGate carrier witness must be built from the same obligation surface before the closure block can record a stronger grade. □

Theorem 923.19 (Typed example coverage matrix scoped export)**.** *An accepted* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *packet exports exactly the finite row-indexed coverage surface over MetaCIC typed examples, gallery rows, checker rows, seal rows, regression-spend rows, beta-boundary rows, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{TypedExampleCoverageMatrix}^{\uparrow}}$*. The export is the scoped matrix surface $F, G, C, B, R, E, H, K, P, N$; it is not checker completeness, subject reduction, normalization, arbitrary beta closure, arbitrary gallery soundness, or an ambient MetaCIC audit theorem.*

Proof. Project the carrier of Definition 923.1. The row family of Definition 923.2 and the context coverage theorem of Definition 923.15 identify the exported index as the finite family rows in F together with their paired G, C, B, R, E cells.

Use ledger non-escape Definition 923.16. It keeps checker, gallery, beta-boundary, seal, and regression-spend reads tied to the same matrix row, so the export cannot acquire a residual budget, sibling gallery, or ambient checker route outside F.

Finally apply the component route of Definition 923.17 and the TasteGate obligation surface of Definition 923.18. These rows preserve the same componentwise hsame, displayed Cont, Pkg, and local NameCert support, and therefore the scoped export is exactly the finite matrix surface stated above. □

Theorem 923.20 (Typed example coverage matrix public certificate)**.** *The public checker-audit certificate exported by* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *is exactly the finite row-indexed surface*

$$F, G, C, B, R, E, H, K, P, N.$$

Any consumer citing this certificate receives family-index exactness through F, E*, paired gallery, checker, beta-boundary, and regression cells through* G, C, B, R*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* K*,* Pkg *provenance through* P*, and the local* $\mathsf{NameCert}_{\mathsf{TypedExampleCoverageMa}}$ *row through* N*. The certificate exports no subject-reduction theorem, normalization theorem, checker-completeness theorem, arbitrary beta closure, arbitrary gallery soundness, hidden family row, or unindexed regression budget.*

Proof. Start with the NameCert obligations of Definition 923.3. They identify carrier admission, family-index exactness, paired cell exposure, matrix exactness, transport, replay, provenance, and local naming as the only certificate rows.

Use row totality and checker-cell locality, Definition 923.11 and Definition 923.12. These bind every accepted family row to its gallery, checker, beta-boundary, and regression cells, so the public consumer receives the paired matrix row rather than detached sibling cells.

Apply non-escape and critical-path spend exhaustion, Definition 923.5 and Definition 923.10. They keep gallery, checker, beta-boundary, and regression-spend reads tied to the same family row and rule out subject reduction, normalization, checker completeness, and unindexed budget use. The public certificate is therefore exactly the displayed surface $F, G, C, B, R, E, H, K, P, N$. □

Theorem 923.21 (Typed example coverage matrix formal target row)**.** *The next formal target surface for* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *consists of a* Nontrivial *witness pair, a* FieldFaithful *mk-field projection, and TasteGate single-carrier alignment over the displayed rows*

$$F, G, C, B, R, E, H, K, P, N.$$

This target surface is confined to the already displayed coverage-matrix carrier, row-totality evidence, checker-cell locality, family exhaustion, TasteGate obligation surface, and public certificate. It does not include checker completeness, subject reduction, normalization, arbitrary beta closure, or gallery soundness.

Proof. Use the carrier of Definition 923.1 to supply the witness pair and mk-field projections from the displayed rows $F, G, C, B, R, E, H, K, P, N$.

Apply row totality, checker-cell locality, and family exhaustion, Definition 923.11, Definition 923.12, and Definition 923.13. These keep every gallery, checker, beta-boundary, and regression-spend cell tied to the same finite family row.

Finally apply the TasteGate obligation surface and the public certificate, Definition 923.18 and Definition 923.20. They identify the single-carrier alignment surface and exclude checker completeness, subject reduction, normalization, arbitrary beta closure, and gallery soundness from the target. □

Theorem 923.22 (Typed example coverage matrix Lean handoff contract)**.** *Any Lean namespace accepting the formal target row for* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *must expose* Nontrivial *and* FieldFaithful *instances over the displayed matrix rows*

$$F, G, C, B, R, E, H, K, P, N.$$

The namespace may not replace the matrix by the gallery sibling, the beta-boundary sibling, the regression-budget sibling, or an ambient audit theorem; the instances must preserve the row-indexed coverage carrier itself.

Proof. Read the formal target row of Definition 923.21. It names the witness pair, mk-field projection, and TasteGate alignment over exactly $F, G, C, B, R, E, H, K, P, N$.

Use the public certificate of Definition 923.20. That certificate is the finite matrix surface and excludes checker completeness, subject reduction, normalization, arbitrary beta closure, arbitrary gallery soundness, hidden family rows, and unindexed regression budgets.

Therefore a future namespace can discharge the target only by exposing the nontriviality and field-faithfulness witnesses for the displayed matrix rows themselves. A sibling gallery or ambient audit theorem would omit the shared row index F or the paired cells G, C, B, R, E, so it cannot serve as the handoff contract. □

Falsifiable prediction: If the coverage-matrix row is removed, a checker-audit consumer can no longer verify that every accepted typed-example family has paired gallery, checker, beta, and regression-spend cells.

Independence witness: Nearest siblings: metacictypedexamplesgallery, typedexamplegallery, metacic-typedexamples-seal, typedexampleauditbudget, betastepboundary. None carries the combined matrix-cell carrier because each sibling exposes one surface family, while the coverage matrix stores the shared family index and the paired gallery, checker, beta, and regression-spend cells in one packet.

The Lean follow-up for namespace BEDC.Derived.TypedExampleCoverageMatrixUp.TasteGate must include Nontrivial $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ and FieldFaithful $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ instances with an explicit witness pair and mk-field projections.

Theorem 923.23 (Typed example coverage matrix scope closure record)**.** *The scoped paper surface of* $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ *is the finite matrix export recorded in Definition 923.19, with its obligation rows supplied by carrier admission, family-index exactness, paired gallery-checker-beta-spend exposure, matrix exactness, row-totality, checker-cell locality, family exhaustion, the TasteGate obligation surface, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{TypedExampleCoverageMatrix}^{\uparrow}}$*. This record closes only that scoped matrix surface.*

Closure status for $\mathsf{NameCert}_{\mathsf{TypedExampleCoverageMatrix}^{\uparrow}}$**.**

Constructive story: A $\mathsf{TypedExampleCoverageMatrix}^{\uparrow}$ packet is generated from a finite typed-example family index, paired gallery cells, checker cells, beta cells, regression-spend cells, exactness rows, componentwise transports, continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TypedExampleCoverageMatrix}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 923.1, Definition 923.2, Definition 923.3, Definition 923.4, Definition 923.5, Definition 923.6, Definition 923.7, Definition 923.8, Definition 923.11, Definition 923.12, Definition 923.13, Definition 923.18, Definition 923.19, Definition 923.20, Definition 923.22, and Definition 923.23 enumerate the finite coverage-matrix obligation surface for gallery, checker, beta, regression-spend, row-family, boundary, row-totality, checker-locality, family-exhaustion, TasteGate evidence, scoped export, public certificate, and formal-target handoff.

Formal verification: FormalStatus(NameCert$_{\mathsf{TypedExampleCoverageMatrix}\uparrow}$, unformalized)

Bridge status: none

Not claimed: This chapter does not close checker completeness, subject reduction, normalization, arbitrary beta closure, arbitrary gallery soundness, Lean verification, or bridge checking.

Upgrade path: The next paper step is a public export or bridge route for the scoped matrix surface, while Lean verification remains a separate target.

Chapter 924

A Concrete Naming Certificate for ChurchEliminatorRegressionMatrix$^{\uparrow}$

The ChurchEliminatorRegressionMatrix$^{\uparrow}$ packet realizes the Church eliminator rows of chapter 9382 as a finite checker and beta-regression matrix. It sits beside the MetaCIC gallery of chapter 775, the coverage matrix of chapter 923, the audit budget of chapter 880, the application route of chapter 922, and the beta-step boundary of chapter 754. Those siblings expose gallery, coverage, budget, application, and beta-boundary rows; this chapter binds the Church boolean, natural-number, list, and sum eliminators as one row-indexed regression object.

Definition 924.1 (Church eliminator regression matrix carrier)**.** *A* ChurchEliminatorRegressionMatrix$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (F, G, L, C, B, S, X, H, K, P, N)$$

with the following displayed rows:

1. *F is the finite family row with exactly the Church boolean, natural-number, list, and sum eliminator families;*
2. *G records the gallery entry for the same family row, including the displayed type former, constructors, and eliminator term;*
3. *L records the local eliminator shape, respectively boolean branch selection, natural-number recursor, list fold, and sum case analysis;*
4. *C records the checker acceptance row for the displayed eliminator;*
5. *B records the selected beta-regression row for the same eliminator family;*
6. *S records the regression-spend row licensed for that family;*
7. *X is the exactness row asserting that every accepted family in F has exactly the displayed G, L, C, B, S cells and no extra eliminator family;*
8. *H records componentwise* hsame *transports for family, gallery, eliminator, checker, beta, spend, exactness, continuation, provenance, and naming rows;*
9. *K records the displayed* Cont *routes by which eliminator-regression consumers read the same row;*

10. *P is the* Pkg *provenance over the TypedExamples gallery, coverage matrix, audit budget, application route, beta-step boundary, transport, continuation, and exactness rows;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{ChurchEliminatorRegressionMatrix}^{\uparrow}}$ *row.*

The carrier has no coordinate for arbitrary eliminator soundness, global normalization, subject reduction, confluence, unbounded beta closure, or a regression spend not indexed by one of the four displayed Church families.

Lean4 ✓ `BEDC.Derived.ChurchEliminatorRegressionMatrixUp.ChurchEliminatorRegressionMatrixTasteGate single carrier alignment`

Theorem 924.2 (Church eliminator regression matrix NameCert obligations)**.** *For the carrier of Definition 924.1, the local* $\mathsf{NameCert}_{\mathsf{ChurchEliminatorRegressionMatrix}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$E = (F, G, L, C, B, S, X, H, K, P, N),$$

family exposure through the four displayed Church eliminator rows, gallery exposure through G, eliminator-shape exposure through L, checker exposure through C, beta-regression exposure through B, spend exposure through S, row exactness through X, and transport, continuation, provenance, and local naming through H, K, P, N.

Proof. Project the displayed carrier. The family row F is read before any eliminator cell is available, and it lists only the boolean, natural-number, list, and sum eliminator families.

For each displayed family, the rows G, L, C, B, S are paired by the same row index. Thus a consumer reaches the gallery entry, eliminator shape, checker acceptance, beta-regression cell, and spend cell only as cells of the same Church eliminator row.

The exactness row X exhausts the local NameCert surface. The rows H, K, P, N preserve, route, package, and name the same finite packet, while no carrier coordinate supplies arbitrary eliminator metatheory or an unindexed spend. □

Theorem 924.3 (Church eliminator regression matrix family exactness)**.** *Every accepted* ChurchEliminatorRegressic *packet has exactly four eliminator families: Church booleans, Church natural numbers, Church lists, and Church sums. Each family row carries its displayed gallery, eliminator-shape, checker, beta-regression, and spend cells, and every displayed checker or beta-regression cell belongs to one of those four family rows.*

Lean4 ✓ `BEDC.Derived.ChurchEliminatorRegressionMatrixUp.ChurchEliminatorRegressionMatrixCarrier family exactness`

Proof. Read the family row F and the exactness row X. By construction, F has the four displayed Church eliminator families and no fifth family coordinate.

The exactness row X pairs each family with its G, L, C, B, S cells. Hence a checker cell or beta-regression cell cannot be read before choosing one of the displayed Church eliminator families.

Conversely, each listed family receives the paired gallery, eliminator-shape, checker, beta-regression, and spend cells from X. This gives both inclusion directions for the finite family inventory. □

Theorem 924.4 (Church eliminator regression matrix non-escape)**.** *Every eliminator-regression consumer of an accepted* $\mathsf{ChurchEliminatorRegressionMatrix}^{\uparrow}$ *carrier reads the Church boolean, natural-number, list, and sum eliminator rows only through*

$$F, G, L, C, B, S, X, H, K, P, N.$$

The consumer cannot replace a missing family, checker, beta-regression, or spend cell by the general coverage matrix alone, by an ambient checker theorem, by an application-route cell, or by an unindexed beta-boundary row.

Proof. Let an eliminator-regression consumer be given. Its public read passes through the continuation row K, so it reaches only the displayed family, gallery, eliminator, checker, beta, spend, exactness, transport, provenance, and local naming rows.

The sibling packets provide provenance for the cells, but the row-indexed eliminator pairing is carried by F and X. A general coverage matrix, application route, audit budget, or beta-step boundary does not by itself name the combined Church eliminator regression row.

No coordinate in the carrier names an ambient checker theorem, an arbitrary beta-boundary cell, or an unindexed spend. Therefore the accepted consumer surface is exactly the finite Church eliminator regression matrix. □

Falsifiable prediction: An eliminator regression consumer that accepts a Church family without the displayed family, checker, beta-regression, and spend rows refutes the packet.

Independence witness: Nearest siblings: metacictypedexamplesgallery, typedexamplecoveragematrix, typedexampleauditbudget, metacictypedexamplesapplicationroute, betastepboundary. None is bijective to ChurchEliminatorRegressionMatrixUp because each sibling omits at least one row among the four-family eliminator index, checker cells, beta-regression cells, spend cells, and local exactness row.

The Lean follow-up for namespace BEDC.Derived.ChurchEliminatorRegressionMatrixUp.TasteGate must include Nontrivial ChurchEliminatorRegressionMatrix$^{\uparrow}$ and FieldFaithful ChurchEliminatorRegressionMatrix$^{\uparrow}$ instances with an explicit witness pair and mk-field projections.

Theorem 924.5 (Church eliminator regression matrix obligation surface)**.** *Every accepted* ChurchEliminatorRegress *packet must expose the finite obligation rows for the eliminator source, regression matrix entries, closed checker route, transport, replay, provenance, and local NameCert:*

$$F, G, L, C, B, S, X, H, K, P, N.$$

The accepted surface has no coordinate for evaluator equality, quotient term equality, unrestricted normalization, or kernel consistency.

Proof. Project the carrier of Definition 924.1. The rows F, G, L expose the eliminator source and its displayed shape, while C, B, S, X expose the closed checker route, beta-regression cells, spend cells, and row exactness.

Apply the NameCert obligations, family exactness, and non-escape theorems of Definition 924.2, Definition 924.3, and Definition 924.4. Together they force each regression matrix entry to remain paired with one of the four Church eliminator families and with its checker and beta-regression rows.

The rows H, K, P, N supply transport, replay, provenance, and local naming for the same finite packet. Since evaluator equality, quotient term equality, unrestricted normalization, and kernel consistency are not carrier fields, no consumer can obtain them from the obligation surface. □

Closure status for NameCert$_{\text{ChurchEliminatorRegressionMatrix}^{\uparrow}}$.

Constructive story: A ChurchEliminatorRegressionMatrix$^{\uparrow}$ packet is generated from four Church eliminator family rows, paired gallery cells, eliminator-shape cells, checker cells, beta-regression cells, spend cells, exactness rows, componentwise transports, continuation routes, provenance, and local naming.

Theory closure: TheoryGate(NameCert$_{\text{ChurchEliminatorRegressionMatrix}^{\uparrow}}$, seed)

Scope closed: Definition 924.1, Definition 924.2, Definition 924.3, and Definition 924.4 bind the four-family Church eliminator regression matrix.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ChurchEliminatorRegressionMatrix}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close arbitrary eliminator soundness, subject reduction, confluence, global normalization, unrestricted beta closure, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, four-family exactness, paired checker and beta-regression exposure, spend confinement, componentwise transport, displayed continuation, provenance, and local naming rows.

Chapter 925

A Concrete Naming Certificate for $\mathsf{LayeredRelationCert}^{\uparrow}$

The $\mathsf{LayeredRelationCert}^{\uparrow}$ packet realizes the relation-certificate discipline of chapter 9416 as a finite $\mathsf{NameCert}$ surface. It consumes the local inscription row discipline of chapter 519, the gap ledger surface of chapter 520, the quotient-soundness refusal boundary of chapter 634, and the audited generator route of chapter 525. The packet does not assert that two objects are identical; it names the exact rows through which a same-schema relation may be consumed.

Definition 925.1 (Layered relation NameCert row carrier)**.** *A* $\mathsf{LayeredRelationCert}^{\uparrow}$ *carrier is a finite packet*

$$R = (A, B, L, U, V, W, F, H, C, P, G, N),$$

where A and B are the two displayed source-chain rows, L is the finite two-chain layer map, U is the same-schema exactness row, V is the preserved-structure row, W is the not-preserved row, F is the failure-boundary row, H is componentwise hsame *transport, C is displayed continuation replay, P is package provenance, G is the gap and quotient-soundness boundary row, and N is the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationCert}^{\uparrow}}$ *row.*

The carrier has no coordinate for object identity between the two source domains, empirical law transfer, quotient-stream equality, subject-substance transfer, global-frame transfer, or an unbounded analogy principle.

Theorem 925.2 (Layered relation NameCert row obligations)**.** *For an accepted* $\mathsf{LayeredRelationCert}^{\uparrow}$ *packet, the local* $\mathsf{NameCert}$ *surface consists exactly of source-chain admission through A, B, finite layer-map exposure through L, same-schema exactness through U, preserved-structure exposure through V, explicit non-preservation through W, failure-boundary exposure through F, componentwise transport through H, replay through C, provenance through P, gap and quotient-soundness refusal through G, and the local naming row N.*

Proof. Start with the row carrier of Definition 925.1. It lists the only coordinates available to a consumer, so same-schema evidence must read the two source chains, the finite layer map, the exactness row, the preserved row, and the not-preserved row from the same packet.

The inscription-side rows are anchored by chapter 519 and chapter 520. They keep the two source-chain displays and the gap ledger visible rather than allowing a bare analogy token to stand in for evidence.

The refusal side is anchored by chapter 634 and the audited generator route of chapter 525. These boundaries keep quotient soundness, generator authority, and downstream consumption attached to the displayed rows F, G, H, C, P, N. □

Lean4 ✓ BEDC.Derived.LayeredRelationCertUp.LayeredRelationCert namecert row obligations

Theorem 925.3 (Layered relation NameCert refusal)**.** *No accepted* LayeredRelationCert$^{\uparrow}$ *packet exports object identity between its two source domains, empirical transfer, quotient equality, subject-substance transfer, global-frame transfer, or a hidden bridge beyond the rows*

$$(A, B, L, U, V, W, F, H, C, P, G, N).$$

In particular, a consumer that omits either the not-preserved row W or the failure-boundary row F cannot read the packet as same-schema evidence.

Proof. Apply Definition 925.2. The row obligations place not-preserved content and the failure boundary inside the same local naming surface as the preserved and exactness rows.

The quotient-soundness boundary prevents the same-schema row U from becoming quotient equality, while the inscription-gap ledger prevents missing source rows from being filled by a hidden bridge. Hence object identity, empirical transfer, subject-substance transfer, and global-frame transfer have no carrier coordinate.

If W or F is absent, the consumer has either no explicit refusal of non-preserved content or no boundary at which the relation weakens. Such a packet is therefore not an accepted same-schema certificate. □

Theorem 925.4 (Layered relation NameCert nontriviality)**.** *The* LayeredRelationCert$^{\uparrow}$ *carrier is not reducible to the source-chain packet of inscriptionevent, the gap packet of inscriptiongapledger, the quotient-refusal packet of quotientsoundnessboundary, the generator-audit packet of authorized-generatorrecursor, or the audit-map packet of auditmapfamily. Its nontrivial surface is the simultaneous presence of a two-chain layer map together with preserved, not-preserved, and failure-boundary rows.*

Proof. Compare the displayed row sets. The inscriptionevent sibling supplies source inscription rows but not the two-chain layer map with preserved and not-preserved relation rows. The inscriptiongapledger sibling supplies the gap ledger but not same-schema exactness or the preserved-structure row.

The quotientsoundnessboundary sibling supplies a refusal boundary for quotient over-readings, while authorizedgeneratorrecursor supplies an audited generator route. Neither sibling contains both source chains together with L, U, V, W, F as one relation certificate.

The auditmapfamily sibling supplies audit-map methodology, not a local relation packet with the two-chain layer map plus preserved, not-preserved, and failure-boundary surface. Therefore the carrier is nontrivial relative to all named siblings. □

Theorem 925.5 (Layered relation NameCert field faithfulness)**.** *Every downstream consumer that reads a* LayeredRelationCert$^{\uparrow}$ *packet as same-schema evidence must preserve the field roles of $A, B, L, U, V, W, F, H, C, P, G, N$. A transported read may rename the packet only through H, C, P, N; it may not collapse A with B, read V without W, read U without F, or move the boundary row G into a source-chain coordinate.*

Proof. Use the NameCert obligations of Definition 925.2. They assign each public field its role before the local certificate can be consumed.

Next apply the refusal theorem Definition 925.3. It blocks the only collapses that would turn same-schema evidence into identity, empirical transfer, quotient equality, or hidden bridge content.

The remaining transport rows H, C, P, N only preserve, replay, package, and name the displayed packet. Since none of those rows adds a new source-chain, exactness, preserved, not-preserved, or boundary coordinate, the field roles are faithful under downstream consumption. □

Falsifiable prediction: A relation certificate that omits either the not-preserved row or the failure-boundary row cannot be consumed as same-schema evidence by any downstream bridge chapter.

Independence witness: Nearest siblings: inscriptionevent, inscriptiongapledger, quotientsoundnessboundary, authorizedgeneratorrecursor, and auditmapfamily. None is bijective to $\mathsf{LayeredRelationCert}^{\uparrow}$ because none has the two-chain layer map plus preserved, not-preserved, and failure-boundary surface in one finite NameCert packet.

Later Lean work must provide $\mathsf{Nontrivial}\ \mathsf{LayeredRelationCert}^{\uparrow}$ and $\mathsf{FieldFaithful}\ \mathsf{LayeredRelationCert}^{\uparrow}$ instances in `TasteGate.lean`.

Chapter 926

A Concrete Naming Certificate for $\mathsf{CompactNetModulusBudget}^{\uparrow}$

The $\mathsf{CompactNetModulusBudget}^{\uparrow}$ packet realizes the compact-uniform-continuity budget handoff as one finite NameCert carrier. It sits after the compact finite-net and continuous-map modulus ledger of chapter 388, consumes the tolerance-to-precision target surface of chapter 369, and records the finite rational fold supplied by chapter 619. The sibling compact cover and selector chapters chapter 648 and chapter 914 provide the compact-cover and center-selection faces, while this packet binds the finite-net, pointwise-modulus, rational-fold, and uniform-modulus budget rows as a single downstream object.

Definition 926.1 (Compact net modulus budget carrier)**.** *A* $\mathsf{CompactNetModulusBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (K, M, F, U, S, H, C, P, N)$$

with the following displayed rows:

1. *K is the compact finite-net row, including the nonempty* ProbeBundle *spine and located coverage rows;*
2. *M is the pointwise-modulus row attached to the bundled centers and to the requested positive* $\mathsf{Rat}^{\uparrow}$ *tolerance history;*
3. *F is the rational lower-bound fold row over the finite radius ledger;*
4. *U is the uniform-modulus handoff row exported to downstream compact-continuous consumers;*
5. *S is the selector and cover compatibility row tying* $\mathsf{CompactModulusCover}^{\uparrow}$ *and* $\mathsf{CompactNetModulusSelector}^{\uparrow}$ *to the same finite net;*
6. *H records componentwise* hsame *transport for finite-net, pointwise-modulus, fold, uniform-modulus, selector, route, provenance, and naming rows;*
7. *C records displayed* Cont *routes through which budget consumers read the compact net, pointwise modulus, fold ledger, selector compatibility, and uniform-modulus handoff;*
8. *P is the* Pkg *provenance over* $\mathsf{CompactUniformContinuity}^{\uparrow}$, $\mathsf{UniformModulus}^{\uparrow}$, $\mathsf{FiniteNetMinimumFold}^{\uparrow}$, $\mathsf{CompactModulusCover}^{\uparrow}$, $\mathsf{CompactNetModulusSelector}^{\uparrow}$, ProbeBundle, BHist, hsame, Cont, *and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{CompactNetModulusBudget}^{\uparrow}}$ *row.*

The carrier exports no open-cover compactness coordinate, host minimum, selected point outside the finite probe spine, external modulus function, sequential compactness argument, or quotient point equality.

Lean4 ✓ `BEDC.Derived.CompactNetModulusBudgetUp.CompactNetModulusBudgetTasteGate single carrier alignment`

Theorem 926.2 (Compact net modulus budget NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CompactNetModulusBudget}^{\uparrow}}$ *surface consists exactly of five finite rows:*

1. *carrier admission for the packet of Definition 926.1;*
2. *finite-net exactness for the compact* ProbeBundle *row* K*;*
3. *pointwise-modulus exactness for the rows* M *over the same bundled centers;*
4. *rational-fold exactness for the lower-bound ledger* F *and its exported uniform-modulus row* U*;*
5. *downstream non-escape through the displayed* hsame*,* Cont*,* Pkg*, selector-compatibility, and local* NameCert *rows* S, H, C, P, N*.*

The later Lean `TasteGate.lean` *development for* $\mathsf{CompactNetModulusBudget}^{\uparrow}$ *must provide* Nontrivial CompactNetM *and* FieldFaithful $\mathsf{CompactNetModulusBudget}^{\uparrow}$ *instances preserving these rows.*

Proof. Carrier admission is projection from Definition 926.1. The packet exposes exactly the compact net, pointwise modulus, rational fold, uniform handoff, selector compatibility, transport, route, provenance, and local naming rows.

Finite-net exactness reads K through the compact-uniform-continuity and compact-cover sibling surfaces. The pointwise-modulus row M is attached to the same finite spine, so no pointwise row can be read at an unlisted center.

Rational-fold exactness reads F through the finite-net-minimum-fold sibling and exports U as the uniform-modulus budget row. The selector row S keeps the compact-cover and selector faces on that same finite spine.

Finally H, C, P, N transport, route, package, and name the packet. Since no excluded analytic object is a coordinate of B, the local NameCert obligations are exhausted by the five rows above. □

Lean4 ✓ `BEDC.Derived.CompactNetModulusBudgetUp.CompactNetModulusBudgetCarrier namecert obligations`

Theorem 926.3 (Compact net modulus budget handoff exactness)**.** *Every downstream compact-continuous consumer of an accepted* $\mathsf{CompactNetModulusBudget}^{\uparrow}$ *packet reads the uniform-modulus budget only through*

$$K, M, F, U, S, H, C, P, N.$$

The consumer reaches the finite-net face before the pointwise-modulus face, reaches the rational-fold row before the uniform-modulus handoff, and reads the selector and cover compatibility row on the same finite probe spine. It has no route through open-cover compactness before the rational fold row, host minima, selected external centers, sequential compactness, quotient point equality, or an external modulus function.

Proof. Project the accepted carrier. The finite-net row K, pointwise-modulus row M, rational-fold row F, uniform handoff row U, and selector-compatibility row S are the only budget-facing coordinates.

Apply Definition 926.2. The five rows force carrier admission, finite-net exactness, pointwise-modulus exactness, rational-fold exactness, and downstream non-escape through the displayed structural rows.

Read the sibling surfaces in order. The compact-uniform-continuity and compact-modulus-cover rows supply the finite-net and cover data, the finite-net-minimum-fold row supplies the rational fold, and the uniform-modulus row supplies the exported precision budget.

Because U is exported only after F and because the packet has no open-cover, host-minimum, external-center, sequential-compactness, quotient, or external-modulus coordinate, every downstream consumer route is exactly the displayed budget handoff. □

Falsifiable prediction: Every accepted $\mathsf{CompactNetModulusBudget}^{\uparrow}$ packet has no consumer route that reads an open-cover compactness coordinate before the rational fold row.

Independence witness: Compare compactuniformcontinuity, uniformmodulus, finitenetminimumfold, compactmoduluscover, compactnetmodulusselector: this carrier records all four budget faces in one packet, while each sibling lacks at least one of the finite-net, pointwise-modulus, fold-ledger, or uniform-modulus handoff rows.

Closure status for $\mathsf{NameCert}_{\mathsf{CompactNetModulusBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{CompactNetModulusBudget}^{\uparrow}$ packet is generated from compact finite-net rows, pointwise-modulus rows, a rational lower-bound fold row, a uniform-modulus handoff row, selector and cover compatibility, componentwise transport, displayed continuation, provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CompactNetModulusBudget}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 926.1, Definition 926.2, and Definition 926.3 specify the finite budget packet, its local NameCert obligations, and its downstream handoff exactness.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CompactNetModulusBudget}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, open-cover compactness, sequential compactness, host minima, selected external centers, quotient point equality, or external modulus functions for $\mathsf{CompactNetModulusBudget}^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, finite-net exactness, pointwise-modulus exactness, rational-fold exactness, uniform-modulus handoff exactness, nontriviality, and field faithfulness.

Chapter 927

A Concrete Naming Certificate for $\mathsf{AttentionLedger}^{\uparrow}$

The $\mathsf{AttentionLedger}^{\uparrow}$ packet concretizes the observer-history vision of chapter 9418 as a selected-row ledger with an explicit omitted-row boundary. It consumes the observer-history carrier of chapter 477, refines the filter surface of chapter 514, and hands only selected public rows to the StreamName surface of chapter 126. The packet is a NameCert object for attention as finite disclosure: the selected rows are public, the omitted rows remain certified boundary data, and the StreamName handoff cannot erase the split.

Definition 927.1 (Attention ledger carrier)**.** *An* $\mathsf{AttentionLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (H, F, S, O, U, W, R, L, C, P, N)$$

with the following displayed rows:

1. *H is the source* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *row whose observation identity is being filtered;*
2. *F is the* $\mathsf{ObserverFilter}^{\uparrow}$ *row that records the local selection decision;*
3. *S is the selected-row ledger, listing the finite* BHist *rows admitted to public attention;*
4. *O is the omitted-row ledger, listing the finite source rows not admitted to public attention together with their boundary reasons;*
5. *U is the public attention row, naming the selected surface that a downstream consumer may inspect;*
6. *W is the* $\mathsf{StreamName}^{\uparrow}$ *handoff row served only from S and U;*
7. *R records componentwise* hsame *transports for the source, filter, selected, omitted, public attention, StreamName, route, provenance, and local naming rows;*
8. *L is the ledger exactness row tying every source observation either to S or to O;*
9. *C records the displayed* Cont *routes by which consumers read the source identity, filter, selected rows, omitted boundary, public attention row, and StreamName handoff;*
10. *P is the* Pkg *provenance over* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{ObserverFilter}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{AttentionLedger}^{\uparrow}}$ *row.*

The classifier compares accepted packets only through these displayed coordinates. It has no coordinate for host observer equality, quotient stream equality, hidden attention state, or deletion of an omitted source row.

Lean4 ✓ `BEDC.Derived.AttentionLedgerUp.AttentionLedgerTasteGate single carrier alignment`

Theorem 927.2 (Attention ledger NameCert obligations)**.** *For the carrier of Definition 927.1, the local* $\mathsf{NameCert}_{\mathsf{AttentionLedger}^{\uparrow}}$ *surface consists exactly of carrier admission for* $A = (H, F, S, O, U, W, R, L, C, P, N)$*, observer-history source exposure through* H*, observer-filter selection through* F*, selected-row exposure through* S*, omitted-row boundary exposure through* O*, public attention exposure through* U*, StreamName handoff through* W*, componentwise* hsame *transport through* R*, ledger exactness through* L*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Proof. Carrier admission is projection of the displayed packet. The source identity row H and filter row F are present before any public attention row can be read.

The ledger rows split the source observations. The selected ledger S contains exactly the rows admitted to public attention, while the omitted ledger O contains the rows stopped at the boundary. The row L records that every source observation has one of these two ledger readings.

The public handoff is then routed through U, W, R, C, P, N. Since the carrier has no hidden attention coordinate, host observer equality, quotient stream equality, or unledgered deletion row, these displayed rows exhaust the local NameCert surface. □

Theorem 927.3 (Attention ledger non-escape)**.** *Every consumer of an accepted* $\mathsf{AttentionLedger}^{\uparrow}$ *packet sees omitted source observations only through the omitted-row ledger* O *and its boundary reasons. No consumer route may turn an omitted row into public attention data, StreamName data, host observer equality, quotient stream equality, or hidden attention state.*

Lean4 ✓ `BEDC.Derived.AttentionLedgerUp.AttentionLedgerPacket non escape`

Proof. Project the accepted packet to $A = (H, F, S, O, U, W, R, L, C, P, N)$. The omitted observations are named only in O and are related to the source identity by the exactness row L.

Any consumer route must pass through C and therefore reads either the selected ledger S and public row U, or the omitted boundary ledger O. The StreamName row W is attached to the selected side of this split.

There is no remaining coordinate that can reinterpret an omitted entry as selected public data. Thus omitted rows remain boundary certificates and cannot escape into StreamName, host equality, quotient equality, or hidden attention state. □

Theorem 927.4 (Attention ledger ObserverFilter handoff)**.** *Every accepted* $\mathsf{AttentionLedger}^{\uparrow}$ *packet factors its selection step through the* $\mathsf{ObserverFilter}^{\uparrow}$ *row* F*. The downstream* $\mathsf{StreamName}^{\uparrow}$ *handoff reads only the selected ledger* S*, public attention row* U*, transport row* R*, continuation row* C*, provenance row* P*, and local naming row* N*, while the omitted ledger* O *remains a boundary certificate.*

Proof. Start with the displayed filter row F. By chapter 514, a filter separates selected rows from omitted rows before any StreamName-facing read is available.

The attention packet records that separation as S and O. The row U is built from the selected side, and the StreamName row W is routed through S, U, R, C, P, N.

The omitted ledger remains visible but non-exporting. It certifies what the filter did not select, so it cannot provide a StreamName row or replace the selected public attention row. □

Theorem 927.5 (Attention ledger public boundary)**.** *An accepted* $\mathsf{AttentionLedger}^{\uparrow}$ *consumer cannot export a StreamName-facing row unless both the selected-row ledger S and the omitted-row boundary O are present in the same carrier. The public attention row U is therefore a boundary between visible selected data and certified omitted data, not a collapse of the two ledgers.*

Proof. Assume a consumer exports the StreamName-facing row W. Carrier projection exposes W together with S, O, U, R, L, C, P, N in the same finite packet.

The route to W passes through the public attention row U, and U is licensed by the exactness row L. That exactness row accounts for source observations only by the selected ledger S and the omitted ledger O.

If either ledger is absent, the route lacks the displayed certificate separating public attention from boundary refusal. Hence an accepted export of W requires both ledgers, and the public row U remains the visible boundary rather than a hidden merger of selected and omitted data. □

Theorem 927.6 (Attention ledger obligation closure package)**.** *The carrier definition, NameCert obligations, non-escape theorem, ObserverFilter handoff, public boundary theorem, falsifiable prediction, independence witness, and TasteGate marker assemble the* obligation *surface for* $\mathsf{AttentionLedger}^{\uparrow}$*.*

The package remains over the selected-row ledger, omitted-row ledger, public attention row, StreamName handoff, hsame *transport,* Cont *replay,* Pkg *provenance, and local NameCert rows. It does not add host observer equality, quotient stream equality, hidden attention state, or deletion of an omitted source row.*

Proof. Begin with Definition 927.1. It displays exactly $H, F, S, O, U, W, R, L, C, P, N$, including the selected-row ledger, omitted-row ledger, public attention row, StreamName handoff, transport, replay, provenance, and local naming rows.

Apply Definition 927.2, Definition 927.3, Definition 927.4, and Definition 927.5. These theorems give the local NameCert surface, keep omitted rows at the boundary, route the selection through the ObserverFilter row, and require both ledgers before a public StreamName-facing export.

The falsifiable prediction and independence witness record the same finite separation as a consumer-facing test: selected disclosure and omitted-boundary evidence must coexist, and no sibling carrier supplies the same combined surface. The displayed TasteGate marker binds that surface to the single finite carrier.

Thus the obligation package is complete at the paper surface named here. It remains confined to S, O, U, W, R, C, P, N together with the source, filter, and exactness rows H, F, L, and it has no coordinate for the excluded host or quotient objects. □

Theorem 927.7 (Attention ledger scoped kernel boundary)**.** *Every accepted* $\mathsf{AttentionLedger}^{\uparrow}$ *consumer route is scoped exactly by the displayed selected ledger S, omitted ledger O, public attention row U, StreamName handoff W, componentwise* hsame *row R, ledger exactness row L,* Cont *row C,* Pkg *row P, and local* NameCert *row N. The route also reads the source observer-history row H and filter row F as the incoming selection surface, but it exports no host observer equality, quotient stream equality, hidden attention state, or unledgered deletion of an omitted row.*

Proof. Project the accepted carrier of Definition 927.1. The packet has exactly the rows $H, F, S, O, U, W, R, L, C, P,$ so every consumer route must be assembled from the displayed source, filter, ledger, public, transport, continuation, provenance, and local naming coordinates.

Use non-escape and the ObserverFilter handoff. By Definition 927.3, omitted rows remain confined to O and its boundary reasons. By Definition 927.4, the selected side reaches StreamName only through S, U, W, R, C, P, N after the filter row F has separated the source rows.

Now apply the public boundary and the obligation package. Definition 927.5 requires S and O together before a StreamName-facing row can be exported, while Definition 927.6 repacks the same rows as the finite NameCert surface. Thus the scoped route is exactly the displayed kernel boundary and contains no coordinate for host observer equality, quotient stream equality, hidden attention state, or unledgered omission. □

Theorem 927.8 (Attention ledger public consumer surface)**.** *For every accepted* $\mathsf{AttentionLedger}^{\uparrow}$ *packet*

$$A = (H, F, S, O, U, W, R, L, C, P, N),$$

the complete public consumer surface is the selected ledger S, the omitted ledger O, the public attention row U, the $\mathsf{StreamName}^{\uparrow}$ *handoff row W, the exactness row L, and the support rows R, C, P, N. The source row H and filter row F feed this surface, while no public consumer receives host observer equality, quotient stream equality, hidden attention state, or an unledgered deletion row.*

Proof. Begin with the carrier and NameCert obligations. The carrier displays exactly $H, F, S, O, U, W, R, L, C, P, N$ and the local NameCert surface exposes selected rows through S, omitted boundary rows through O, public attention through U, the StreamName handoff through W, exactness through L, and support through R, C, P, N.

Use non-escape and the ObserverFilter handoff. Omitted rows remain boundary data by Definition 927.3, while Definition 927.4 routes the selected side from the filter row F to S, U, W, R, C, P, N.

The public boundary and obligation package finish the export. Theorems 927.5 and 927.6 require the selected and omitted ledgers to coexist before the StreamName-facing handoff is available, so the public surface is exactly $S, O, U, W, L, R, C, P, N$ over the incoming source and filter rows. □

Theorem 927.9 (Attention ledger ObserverInterface handoff)**.** *Every* $\mathsf{ObserverInterface}^{\uparrow}$ *consumer of an accepted* $\mathsf{AttentionLedger}^{\uparrow}$ *packet may read the public attention row only through the* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *source row H, the* $\mathsf{ObserverFilter}^{\uparrow}$ *split row F, the selected and omitted ledger pair S, O, and the* $\mathsf{StreamName}^{\uparrow}$ *handoff row W. The omitted rows remain boundary data carried by O, L, R, C, P, N and are not public attention rows.*

Proof. Project the accepted packet. The source observer-history row H and filter row F are the only incoming observer rows, and the selected and omitted ledgers S, O are the only rows that record the filter result.

Apply the non-escape and ObserverFilter handoff theorems. Non-escape confines omitted observations to O and its boundary reasons, while the handoff theorem routes selected data toward StreamName only through S, U, W, R, C, P, N after the filter split.

Now use the public boundary, obligation closure package, and scoped kernel boundary. These theorems require S and O together, repack the same rows as the finite NameCert surface, and identify the scoped consumer route as $H, F, S, O, U, W, R, L, C, P, N$. Thus an $\mathsf{ObserverInterface}^{\uparrow}$ consumer can read public attention only through that displayed route, with omitted rows remaining certified boundary data. □

Theorem 927.10 (Attention ledger public route export)**.** *For every accepted* $\mathsf{AttentionLedger}^{\uparrow}$ *packet*

$$A = (H, F, S, O, U, W, R, L, C, P, N),$$

any public export route must pass through the selected ledger S, omitted ledger O, public attention row U, StreamName handoff row W, exactness row L, and support rows R, C, P, N. The source

row H and filter row F remain incoming rows for the route; the export cannot carry host observer equality, quotient stream equality, hidden attention state, or deletion of an omitted source row.

Lean4 ✓ `BEDC.Derived.AttentionLedgerUp.AttentionLedgerPacket public route export`

Proof. Project the carrier and NameCert obligations. They display $H, F, S, O, U, W, R, L, C, P, N$ as the complete packet and identify $S, O, U, W, L, R, C, P, N$ as the public and boundary rows available after the source and filter rows.

Use non-escape and the ObserverFilter handoff. The omitted ledger stays confined to O and its boundary reasons, while selected data reaches StreamName only through S, U, W, R, C, P, N after F has performed the split.

Apply the public boundary and scoped kernel boundary. These theorems require S and O to remain together and make the route exactly the finite kernel surface $H, F, S, O, U, W, R, L, C, P, N$.

Finally use the ObserverInterface handoff. Public observers may read attention only through the displayed route, so host observer equality, quotient stream equality, hidden attention state, and unledgered deletion have no export coordinate. □

Falsifiable prediction: An accepted AttentionLedgerUp consumer cannot export a StreamName-facing row unless the selected-row ledger and omitted-row boundary are both present.

Independence witness: observerfilter, observerhistoryidentity, streamname, interhistinvariant, observertracekernel: no sibling is bijective to $\mathsf{AttentionLedger}^{\uparrow}$ because this carrier simultaneously stores the selected ledger, omitted ledger, and public attention row. Observerfilter has the split but not the public attention row; observerhistoryidentity has source identity without selection; streamname has the exported surface without the omitted boundary; interhistinvariant has invariant readback rather than an attention split; observertracekernel has trace composition without the selected or omitted ledger pair.

The Lean TasteGate namespace BEDC.Derived.AttentionLedgerUp.TasteGate will provide Nontrivial AttentionLed and FieldFaithful $\mathsf{AttentionLedger}^{\uparrow}$ instances for the displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{AttentionLedger}^{\uparrow}}$.

Constructive story: An $\mathsf{AttentionLedger}^{\uparrow}$ packet is generated from observer-history identity, observer-filter selection, selected-row ledger, omitted-row ledger, public attention row, StreamName handoff, componentwise transport, ledger exactness, displayed continuation, package provenance, and local NameCert rows.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AttentionLedger}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 927.1, Definition 927.2, Definition 927.3, Definition 927.4, Definition 927.5, Definition 927.6, Definition 927.7, and

Lean4 (definition) `BEDC.Derived.AttentionLedgerUp.taste gate`

specify the finite attention-ledger packet, selected-row ledger, omitted-row boundary, public attention row, StreamName handoff, scoped kernel boundary, and TasteGate-aware obligation surface.

Upgrade path: No further paper-side theory upgrade remains for the finite attention-ledger packet.

Chapter 928

A Concrete Naming Certificate for $\mathsf{ObserverInterface}^{\uparrow}$

The $\mathsf{ObserverInterface}^{\uparrow}$ packet realizes the observer-history identity vision of chapter 9418 as a finite interface row between observer filtering, attention accounting, and countable stream naming. It consumes the selected and omitted rows of chapter 514, the public attention boundary of chapter 927, and the downstream handoff discipline of chapter 126. The interface is a NameCert object for licensed observation: every public read enters through selected observer-filter rows, every omitted source row remains ledgered, and no separate observer subject is available behind the history rows.

Definition 928.1 (Observer interface carrier)**.** *An* $\mathsf{ObserverInterface}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$I = (H, F, A, S, O, U, W, Q, R, L, C, P, N)$$

with the following displayed rows:

1. *H is the source observer-history row whose identity is read as* BHist *data;*
2. *F is the* $\mathsf{ObserverFilter}^{\uparrow}$ *row selecting public observations and recording omitted rows;*
3. *A is the* $\mathsf{AttentionLedger}^{\uparrow}$ *row that records the selected-row and omitted-row split as a public attention boundary;*
4. *S is the selected observation ledger exported by the interface;*
5. *O is the omitted-row ledger, with one boundary entry for each source row not exported;*
6. *U is the licensed-observation row served to public consumers;*
7. *W is the* $\mathsf{StreamName}^{\uparrow}$ *handoff row generated only from S and U;*
8. *Q is the no-subject row recording that every exported observation is already one of the displayed history, filter, attention, selected, omitted, or handoff rows;*
9. *R records componentwise* hsame *transports for observer-history, filter, attention, selected, omitted, licensed-observation, StreamName, no-subject, route, provenance, and local naming rows;*
10. *L is the interface ledger tying each accepted read to $F, A, S, O, U, W, Q, R, C, P, N$;*
11. *C records the displayed* Cont *routes by which consumers read the source history, filter, attention ledger, selected rows, omitted boundary, licensed observation, StreamName handoff, and no-subject row;*

12. *P is the* Pkg *provenance over* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{ObserverFilter}^{\uparrow}$, $\mathsf{AttentionLedger}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
13. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverInterface}^{\uparrow}}$ *row.*

The classifier compares accepted interface packets only through these displayed coordinates. It has no coordinate for hidden observer state, host equality of observers, quotient stream identity, unledgered deletion, or a subject parameter outside the history rows.

Theorem 928.2 (ObserverInterface NameCert obligations)**.** *For the carrier of Definition 928.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverInterface}^{\uparrow}}$ *surface consists exactly of carrier admission for $I = (H, F, A, S, O, U, W, Q, R, L, C$ observer-history source exposure through H, filter selection through F, attention-ledger exposure through A, selected-row exposure through S, omitted-row boundary exposure through O, licensed observation through U, StreamName handoff through W, no-subject exactness through Q, componentwise* hsame *transport through R, interface ledger exactness through L, displayed* Cont *replay through C,* Pkg *provenance through P, and local naming through N.*

Proof. Carrier admission is projection of the displayed packet. The rows $H, F, A, S, O, U, W, Q, R, L, C, P, N$ list the whole observer-facing interface before any public read is available.

The filter and attention rows bind the public split. The selected ledger S and omitted ledger O are both read through F and A, so a consumer cannot obtain a licensed observation without seeing the boundary that prevents omitted rows from becoming public data.

The no-subject and naming rows close the local surface. The row Q records that exported observations are already displayed rows, while R, C, P, N provide only componentwise transport, route replay, provenance, and local naming. Since the carrier has no further coordinate, the listed clauses exhaust the local certificate surface. □

Theorem 928.3 (ObserverInterface filter-history handoff)**.** *Every* $\mathsf{StreamName}^{\uparrow}$*-facing read exported by an accepted* $\mathsf{ObserverInterface}^{\uparrow}$ *packet factors through the selected observer-filter ledger S, the public attention row U, the StreamName handoff row W, the no-subject row Q, the componentwise* hsame *transports R, the displayed* Cont *routes C, the interface ledger L, the package row P, and the local name N. Omitted rows in O remain boundary certificates and cannot supply StreamName data.*

Lean4 ✓ `BEDC.Derived.ObserverInterfaceUp.ObserverInterfacePacket filter history handoff`

Proof. Start with the accepted interface carrier. Its only StreamName-facing coordinate is W, and W is attached to the selected side of the filter and attention rows.

Read the handoff through the finite ledger. The rows S, U, L, R, C, P, N record the selected observation, public attention boundary, exact read entry, transport, route, provenance, and local naming needed by the downstream $\mathsf{StreamName}^{\uparrow}$ consumer.

The omitted ledger O is still visible, but only through its boundary role. Since Q records that no hidden subject or owner is exported, an omitted row has no route by which it can become StreamName data or replace the selected observation ledger. □

Theorem 928.4 (ObserverInterface non-escape)**.** *An accepted* $\mathsf{ObserverInterface}^{\uparrow}$ *packet exports only the displayed observer-history, observer-filter, attention-ledger, selected-row, omitted-row, licensed-observation, StreamName handoff, no-subject,* hsame, Cont, Pkg*, ledger, and local* NameCert *rows of Definition 928.1. It exports no hidden observer state, quotient observer identity, host equality of histories, unledgered omitted row, unlicensed observation, or subject parameter outside* BHist*.*

Proof. Inspect the carrier coordinates. They are exactly $H, F, A, S, O, U, W, Q, R, L, C, P, N$, and each coordinate is a displayed history, filter, attention, selected, omitted, licensed-observation, handoff, no-subject, transport, ledger, route, provenance, or local naming row.

Use Definition 928.2 to identify the accepted certificate surface. Every public read is routed through the finite inventory and then recorded in L before it reaches the local name.

Use Definition 928.3 for StreamName-facing consumers. That handoff keeps omitted rows as boundary certificates and selected rows as the only exported observation data, so no hidden observer state, quotient identity, host equality, unledgered omission, unlicensed observation, or subject parameter has a public coordinate. □

Theorem 928.5 (ObserverInterface obligation closure package)**.** *For the carrier of Definition 928.1, the obligation-closure surface of* $\mathsf{ObserverInterface}^{\uparrow}$ *consists of carrier admission, filter selection, attention-ledger exposure, selected-row ledger, omitted-row boundary, licensed observation,* $\mathsf{StreamName}^{\uparrow}$ *handoff, no-subject exactness, componentwise transport, displayed continuation, package provenance, local naming, the falsifiable prediction boundary, and the independence witness against the observer-filter, observer-history-identity, attention-ledger, and StreamName siblings. Selected rows are the only* $\mathsf{StreamName}^{\uparrow}$*-facing data, and omitted rows remain boundary certificates.*

Proof. Start with the NameCert obligations of Definition 928.2. They expose the accepted carrier rows $H, F, A, S, O, U, W, Q, R, L, C, P, N$ and assign each public observation to the filter, attention, selected, omitted, licensed-observation, handoff, no-subject, transport, ledger, route, provenance, and local naming surface.

Use the filter-history handoff of Definition 928.3. It identifies S and U as the only selected rows that can feed W, while O remains visible only as an omitted-row boundary.

Finally apply non-escape, Definition 928.4. Because the packet has no hidden observer state, quotient observer identity, host equality of histories, unledgered omitted row, unlicensed observation, or subject parameter, the falsifiable prediction and independence witness read exactly this finite obligation surface. □

Theorem 928.6 (ObserverInterface selected-row exactness)**.** *For an accepted* $\mathsf{ObserverInterface}^{\uparrow}$ *packet* $I = (H, F, A, S, O, U, W, Q, R, L, C, P, N)$*, the selected-row ledger* S *is exactly the public observation side selected by* F *and exposed through* A *and* U*. Every* $\mathsf{StreamName}^{\uparrow}$*-facing read through* W *must pass through* S, U, Q, R, L, C, P, N*, and no omitted row in* O *can be reclassified as selected data.*

Proof. Project the carrier rows of Definition 928.1. The selected ledger S is a displayed coordinate, and the licensed observation row U is the public read served from the selected side.

Use Definition 928.2 to bind S to the local NameCert surface. The same certificate surface records F as the filter row, A as the attention-ledger exposure, and L as the interface ledger for accepted reads.

Now apply Definition 928.3. It routes every StreamName-facing read through $S, U, W, Q, R, L, C, P, N$ and keeps O as boundary data. Non-escape then prevents an omitted row, hidden observer state, or unlicensed observation from supplying selected data. □

Theorem 928.7 (ObserverInterface omitted-row boundary)**.** *For an accepted* $\mathsf{ObserverInterface}^{\uparrow}$ *packet* $I = (H, F, A, S, O, U, W, Q, R, L, C, P, N)$*, every row recorded in the omitted ledger* O *remains a boundary certificate witnessed by the same filter row* F *and attention row* A*. Such a row may be named by the local certificate and carried by* R, L, C, P, N*, but it has no route to the licensed-observation row* U *or to the* $\mathsf{StreamName}^{\uparrow}$ *handoff row* W*.*

Proof. Start with the NameCert obligation list of Definition 928.2. It exposes O as the omitted-row boundary and keeps it in the same finite packet as the filter, attention, selected, licensed-observation, handoff, transport, ledger, route, provenance, and naming rows.

The filter-history handoff of Definition 928.3 separates the roles of S and O. The selected ledger feeds W through U, while the omitted ledger remains visible only as a boundary certificate.

Finally use Definition 928.5 and Definition 928.4. The obligation package records selected rows as the only StreamName-facing data, and non-escape rules out unledgered deletion, hidden observer state, and unlicensed observation. Hence omitted rows stay named but cannot become public handoff data. □

Theorem 928.8 (ObserverInterface StreamName handoff totality)**.** *For an accepted* $\mathsf{ObserverInterface}^{\uparrow}$ *packet* $I = (H, F, A, S, O, U, W, Q, R, L, C, P, N)$*, every licensed public observation exported by the interface has a displayed* $\mathsf{StreamName}^{\uparrow}$ *handoff row in* W*. The handoff is total for the selected ledger* S *and licensed-observation row* U*, and it is empty for omitted rows except for their boundary naming through* O, R, L, C, P, N*.*

Proof. Read the handoff coordinate from the carrier. The row W is generated only from the selected observation ledger S and the licensed-observation row U, so any public observation exported by the interface has a displayed handoff row.

Apply Definition 928.3. It states that every StreamName-facing read exported by an accepted packet factors through $S, U, W, Q, R, L, C, P, N$, while omitted rows remain boundary certificates.

Use the obligation package to close the route. By Definition 928.5, carrier admission, filter selection, attention-ledger exposure, selected-row ledgering, omitted-row boundary, licensed observation, handoff, no-subject exactness, transport, continuation, provenance, and naming are the whole obligation surface. Thus the handoff is total over licensed selected rows and has no public branch for omitted rows. □

Falsifiable prediction: Every accepted ObserverInterfaceUp packet routes StreamName-facing reads through selected observer-filter rows and cannot export an unledgered omitted row.

Independence witness: observerfilter, observerhistoryidentity, attentionledger, streamname: the interface packet has all four row families simultaneously, while each sibling lacks at least one of filter partition, no-subject history identity, attention ledger, or countable handoff rows.

The proposed Lean follow-up site is `lean4/BEDC/Derived/ObserverInterfaceUp/TasteGate.lean`. Its obligation surface includes $\mathsf{Nontrivial\ ObserverInterface}^{\uparrow}$ and $\mathsf{FieldFaithful\ ObserverInterface}^{\uparrow}$ instances whose witnesses distinguish the observer-history source, filter row, attention ledger, selected ledger, omitted ledger, licensed-observation row, StreamName handoff, no-subject row, transports, routes, provenance, and local name.

Theorem 928.9 (ObserverInterface public export)**.** *Every public consumer of an accepted* $\mathsf{ObserverInterface}^{\uparrow}$ *packet factors through the displayed observer-history identity, observer-filter row, attention-ledger row, selected-row ledger, omitted-row boundary, licensed-observation row,* $\mathsf{StreamName}^{\uparrow}$ *handoff, componentwise transport, displayed continuation, package provenance, and local* NameCert *rows of Definition 928.1. In particular, the public interface exports selected observations only through the exact selected-row route and exports omitted observations only as boundary rows; no consumer receives a hidden observer state, an unledgered observation, or a StreamName-facing row outside this finite surface.*

Lean4 ✓ `BEDC.Derived.ObserverInterfaceUp.ObserverInterfacePacket public export`

Proof. Project the accepted packet through the carrier of Definition 928.1. The observer-history identity, filter, attention ledger, selected ledger, omitted boundary, licensed observation, StreamName handoff, transports, continuations, provenance, and local naming rows are all displayed coordinates of the same finite packet.

Apply the NameCert obligations of Definition 928.2 and the obligation package of Definition 928.5. These bind carrier admission, filter selection, attention-ledger exposure, selected-row ledgering, omitted-row boundary, licensed observation, no-subject exactness, componentwise transport, displayed continuation, package provenance, and local naming as the whole accepted obligation surface.

The selected-row side is exact by Definition 928.6, and the omitted-row side is bounded by Definition 928.7. Hence selected rows are the only rows that can feed public observation, while omitted rows remain named boundary data.

Finally use Definition 928.8 together with the filter-history handoff and non-escape theorems. Every StreamName-facing read passes through the licensed selected rows and their handoff route, and no hidden observer state, unledgered omitted row, or unlicensed observation supplies an additional public export branch. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverInterface}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverInterface}^{\uparrow}$ packet is generated from observer-history identity, observer-filter selection, attention-ledger accounting, selected rows, omitted-row boundary rows, licensed observation, StreamName handoff, no-subject exactness, componentwise transport, displayed continuation, package provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverInterface}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 928.1, Definition 928.2, Definition 928.3, Definition 928.4, Definition 928.5, Definition 928.6, Definition 928.7, Definition 928.8, and Definition 928.9 specify the finite observer-interface packet, its obligation package, selected-row exactness, omitted-row boundary, StreamName handoff totality, and public export boundary named by `BEDC.Derived.ObserverInterfaceUp.ObserverInterfacePacket_public_export`.

Lean target: `BEDC.Derived.ObserverInterfaceUp.ObserverInterfacePacket\_public\_export`

Upgrade path: No further paper-axis mature-treatment step remains; Lean-side bridge checking remains separate.

Chapter 929

A Concrete Naming Certificate for $\mathsf{CauchyRateBudget}^{\uparrow}$

The $\mathsf{CauchyRateBudget}^{\uparrow}$ packet realizes the finite convergence-rate control surface required by the Real completeness route of chapter 9238. It sits between the finite $\mathsf{StreamName}^{\uparrow}$ window route of chapter 126, the regular rational readback of chapter 301, the dyadic tolerance ledger of chapter 291, the Real seal of chapter 38, and the observation-budget seal route of chapter 611. The packet records a displayed convergence-rate row as finite BEDC data; it is not a quotient of streams, a selected real value, a host metric convergence proof, or an ambient completeness principle.

Definition 929.1 (Cauchy rate-budget carrier)**.** *A* $\mathsf{CauchyRateBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (R, W, Q, D, E, H, C, P, N)$$

with the following displayed coordinates:

1. *R is the convergence-rate row, naming the finite schedule that sends each displayed tolerance request to a bounded tail window;*
2. *W is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row read under that schedule;*
3. *Q is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row attached to the selected windows;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger recording the visible radius and comparison rows;*
5. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after R, W, Q, D have been displayed;*
6. *H records componentwise* hsame *transports for the rate, window, readback, tolerance, and seal rows;*
7. *C records the finite* Cont *routes for rate display, window read, readback, dyadic tolerance, seal handoff, package provenance, and local naming;*
8. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyRateBudget}^{\uparrow}}$ *row.*

The carrier contains no hidden modulus selector, quotient stream equality, selected limit, host real equality, or ambient completeness row.

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetTasteGate single carrier alignment`

Theorem 929.2 (Cauchy rate-budget NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CauchyRateBudget}^{\uparrow}}$ *surface for Definition 929.1 consists exactly of carrier admission for* B*, convergence-rate display through* R*,* $\mathsf{StreamName}^{\uparrow}$ *finite-window coverage through* W*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback through* Q*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance-ledger exactness through* D*,* $\mathsf{Real}^{\uparrow}$ *seal handoff through* E*, componentwise* hsame *transport through* H*, displayed* Cont *route replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Proof. Carrier admission is projection from the displayed tuple $B = (R, W, Q, D, E, H, C, P, N)$. Each obligation row named in the statement is one coordinate of the same finite BHist packet.

The rate, window, readback, tolerance, and seal clauses are read in order. The rate row supplies the finite schedule, the window row applies it to $\mathsf{StreamName}^{\uparrow}$, the readback row exposes the $\mathsf{RegSeqRat}^{\uparrow}$ observation, and the dyadic row records the visible tolerance before the Real seal is available.

The transport and route clauses use the stored H and C rows componentwise. Package provenance and local naming then repack the same finite surface through P, N, leaving no coordinate for quotient streams, selected limits, host equality, or ambient completeness. □

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetCarrier namecert obligations`

Theorem 929.3 (Cauchy rate-budget rate non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or observation-budget seal consumer of an accepted* $\mathsf{CauchyRateBudget}^{\uparrow}$ *packet must read the convergence-rate row* R *before reaching the seal row* E*. The rate cannot be replaced by an unbounded modulus, a hidden tail selector, quotient stream equality, host metric convergence, or a selected external limit.*

Proof. Start with Definition 929.2. It places convergence-rate display before the finite-window, readback, tolerance, and seal rows in the local NameCert surface.

Project the carrier. The only route from the packet to the Real seal is the displayed chain R, W, Q, D, E authenticated by H, C, P, N.

The excluded objects are absent from the carrier. Since no coordinate stores an unbounded modulus, hidden tail selector, quotient stream equality, host convergence proof, or selected limit, no consumer can substitute one for the displayed rate row. □

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetCarrier rate nonescape`

Theorem 929.4 (Cauchy rate-budget StreamName–RegSeq handoff)**.** *For an accepted* $\mathsf{CauchyRateBudget}^{\uparrow}$ *packet* $B = (R, W, Q, D, E, H, C, P, N)$*, the* $\mathsf{StreamName}^{\uparrow}$ *window row* W *and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q *form a single finite handoff controlled by the rate row* R*. Any consumer that reads* Q *must first read* R *and* W*, and any later* $\mathsf{DyadicRatCore}^{\uparrow}$ *or* $\mathsf{Real}^{\uparrow}$ *read must preserve that same handoff through* D, E, H, C, P, N*.*

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetCarrier streamname regseq handoff`

Proof. Read R, W, Q from the carrier. The rate row selects the finite window schedule, and the window row is the only public source from which the readback row is obtained.

Apply the NameCert obligation surface. It lists the $\mathsf{StreamName}^{\uparrow}$ window coverage before the $\mathsf{RegSeqRat}^{\uparrow}$ readback and the dyadic tolerance ledger after it, so the readback cannot be detached from the selected window.

Finally use componentwise transport and route replay. The H, C, P, N rows preserve the same handoff when a downstream dyadic or Real consumer reads the packet. □

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetStreamNameRegSeqHandoff`

Theorem 929.5 (Cauchy rate-budget TasteGate boundary)**.** *The TasteGate boundary for* $\mathsf{CauchyRateBudget}^{\uparrow}$ *is the non-vacuous field separation among the rate row* R*, the* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D*, and the* $\mathsf{Real}^{\uparrow}$ *seal row* E*. Any faithful single-carrier witness must preserve the order*

$$R \to W \to Q \to D \to E$$

rather than collapsing the packet to one undifferentiated Real-completion row.

Proof. The carrier separates the five public Real-completion rows. Each has a distinct consumer role: rate display, finite window, regular-rational readback, dyadic tolerance, and Real seal.

Use rate non-escape and the StreamName–RegSeq handoff. They force the seal-facing route to expose the rate before the window, the window before readback, and the readback before dyadic tolerance.

Therefore a faithful TasteGate witness for this carrier must preserve the displayed row order. Collapsing the rows would destroy either the rate non-escape property or the StreamName–RegSeq handoff. □

Theorem 929.6 (Cauchy rate-budget public export)**.** *An accepted* $\mathsf{CauchyRateBudget}^{\uparrow}$ *packet exports exactly the public finite route*

$$R \to W \to Q \to D \to E$$

together with H, C, P, N *to Real-completion and observation-budget consumers. Every such consumer must preserve the existing TasteGate row separation and may not read a hidden modulus selector, quotient stream equality, selected limit, host convergence proof, or ambient completeness from the packet.*

Proof. Begin with the NameCert obligations and rate non-escape, Definition 929.2 and Definition 929.3. They make the convergence-rate row R public before any StreamName, RegSeqRat, dyadic, or Real seal consumer can use the packet.

Next apply the StreamName–RegSeq handoff of Definition 929.4. It keeps W and Q attached to the same finite rate schedule, so a consumer cannot detach a readback from the displayed window.

Finally use the TasteGate boundary, Definition 929.5. It preserves the separated row order $R \to W \to Q \to D \to E$, while H, C, P, N transport, replay, source, and name that same packet. Since the carrier contains no row for a hidden modulus selector, quotient stream equality, selected limit, host convergence proof, or ambient completeness, none of those objects is exported. □

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetCarrier public export`

Theorem 929.7 (Cauchy rate-budget dyadic tolerance exactness)**.** *Any accepted* $\mathsf{CauchyRateBudget}^{\uparrow}$ *packet reads the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D *only after the displayed* R, W, Q *route has been traversed, and only before the Real seal row* E *is reached. The ledger is not an isolated tolerance witness, a free-standing radius choice, or a seal-independent display.*

Proof. Project the carrier $B = (R, W, Q, D, E, H, C, P, N)$. The displayed coordinates place D after the rate row R, the window row W, and the readback row Q, while the Real seal row E remains downstream.

Apply the NameCert obligation surface and the StreamName–RegSeq handoff. Together they keep the finite rate schedule, the selected window, and the regular-rational readback attached to the same packet before any dyadic tolerance row is consulted.

The TasteGate boundary then rules out any shortcut to D or any seal read before D. So every accepted packet reaches the dyadic ledger only through the ordered $R \to W \to Q \to D \to E$ route. □

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetCarrier dyadic tolerance exactness`

Theorem 929.8 (Cauchy rate-budget Real seal routing)**.** *Any Real-facing seal consumer of an accepted* $\mathsf{CauchyRateBudget}^{\uparrow}$ *packet reaches E only through the route $R \to W \to Q \to D \to E$. In particular, the seal is not reachable by bypassing the rate row, the finite-window row, the readback row, or the dyadic tolerance ledger.*

Proof. Start with rate non-escape. It forces every Real-facing consumer to read the convergence-rate row before the seal row can be used.

Next use the StreamName–RegSeq handoff together with the dyadic tolerance exactness theorem. The handoff keeps W and Q glued to the same displayed rate packet, and the exactness theorem places D between that handoff and the seal row E.

Composing these steps gives the only seal route $R \to W \to Q \to D \to E$. Any attempted bypass would break either the rate display order, the finite handoff, or the tolerance-ledger placement. □

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetRealSealRouting`

Theorem 929.9 (Cauchy rate-budget regular-tail-estimate handoff)**.** *Every accepted* $\mathsf{CauchyRateBudget}^{\uparrow}$ *packet whose seal-facing consumer is a* $\mathsf{RegularCauchyTailEstimate}^{\uparrow}$ *consumer must expose the ordered route*

$$R \to W \to Q \to D \to E$$

before the tail-envelope lock of $\mathsf{RegularCauchyTailEstimate}^{\uparrow}$ *is read. The combined route exports no quotient stream, selected limit, host metric convergence proof, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Proof. First apply rate non-escape, Definition 929.3. It keeps the convergence-rate row R visible before any seal-facing read can use E.

Next use the StreamName–RegSeq handoff and dyadic tolerance exactness, Definition 929.4 and Definition 929.7. These place the finite window row W, readback row Q, and tolerance ledger D between R and the seal row.

Then apply Real seal routing, Definition 929.8. It identifies $R \to W \to Q \to D \to E$ as the only seal-facing path inside the accepted budget packet.

Finally hand this path to the tail-envelope lock of Definition 1487.5. Since the lock is read only after its finite envelope surface is exposed, the fused budget-to-tail route cannot export quotient streams, selected limits, host metric convergence proofs, or ambient $\mathsf{Real}^{\uparrow}$ completeness. □

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetCarrier regular tail estimate handoff`

Theorem 929.10 (Cauchy rate-budget scoped package)**.** *For every accepted* $\mathsf{CauchyRateBudget}^{\uparrow}$ *packet $B = (R, W, Q, D, E, H, C, P, N)$, the displayed carrier, local* $\mathsf{NameCert}_{\mathsf{CauchyRateBudget}^{\uparrow}}$ *obligations, rate non-escape,* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance exactness,* $\mathsf{Real}^{\uparrow}$ *seal routing, and TasteGate boundary assemble into one scoped package over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$. *Every consumer route through the package is confined to $R, W, Q, D, E, H, C, P, N$.*

Proof. Begin with the carrier of Definition 929.1 and the obligation surface of Definition 929.2. They display exactly the rate row, StreamName window, RegSeqRat readback, dyadic tolerance ledger, Real seal, transport, replay, provenance, and local naming rows.

Use rate non-escape from Definition 929.3. It prevents any Real-facing or observation-budget consumer from replacing R by a hidden modulus, host convergence proof, quotient stream equality, or selected external limit.

Use the StreamName–RegSeq handoff and dyadic tolerance exactness, Definition 929.4 and Definition 929.7. These force the route R, W, Q, D to remain ordered before the Real seal is read.

Finally apply Real seal routing and the TasteGate boundary, Definition 929.8 and Definition 929.5. The seal-facing route is exactly $R \to W \to Q \to D \to E$, while H, C, P, N transport, replay, source, and name the same finite packet. Thus every consumer is scoped to the displayed BEDC kernel rows and cannot escape to an ambient completeness or quotient principle. □

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetCarrier scope package`

Theorem 929.11 (Cauchy rate-budget tail monotonicity)**.** *For every accepted* $\mathsf{CauchyRateBudget}^{\uparrow}$ *packet* $B = (R, W, Q, D, E, H, C, P, N)$*, tightening the displayed tail-rate row* R *inside the same finite* BHist *packet preserves the* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *handoff and the* $\mathsf{Real}^{\uparrow}$ *seal route. The tightened packet must still read* W, Q, D, E *through the same displayed rows, so the dyadic tolerance exactness, regular-tail-estimate handoff, and Real seal routing remain available without adding quotient streams, selected limits, host convergence, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetCarrier tail monotonicity`

Proof. Start with the scoped package of Definition 929.10. It confines every consumer of the accepted packet to the rows $R, W, Q, D, E, H, C, P, N$.

Tightening R changes only the displayed rate row inside that packet. The StreamName–RegSeq handoff theorem Definition 929.4 still forces Q to be read after the same window row W, and the dyadic tolerance exactness theorem Definition 929.7 still places D after R, W, Q.

Now apply Real seal routing and the regular-tail-estimate handoff, Definition 929.8 and Definition 929.9. They bind every later Real or tail-envelope read to the route $R \to W \to Q \to D \to E$ already recorded in the same BHist rows. Therefore a stricter displayed tail rate preserves the handoff and seal route rather than creating a new host-level modulus or a detached convergence proof. □

Theorem 929.12 (Cauchy rate-budget window concatenation)**.** *Let*

$$B_0 = (R_0, W_0, Q_0, D_0, E_0, H_0, C_0, P_0, N_0), \qquad B_1 = (R_1, W_1, Q_1, D_1, E_1, H_1, C_1, P_1, N_1)$$

be accepted $\mathsf{CauchyRateBudget}^{\uparrow}$ *packets. If their* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows are compatible and the first displayed window of* B_1 *begins after the regular-tail threshold exposed by* R_0, W_0, Q_0, D_0*, then the displayed dyadic tolerance ledgers concatenate to one accepted finite budget route. The concatenated route reads its* $\mathsf{Real}^{\uparrow}$ *seal only after both* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks and the shared* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger are visible, and it introduces no quotient stream, selected limit, countable choice, host convergence proof, or ambient* $\mathsf{Real}^{\uparrow}$ *completeness row.*

Lean4 ✓ `BEDC.Derived.CauchyRateBudgetUp.CauchyRateBudgetWindowConcatenation`

Proof. Project the two displayed carriers. The first packet supplies $R_0, W_0, Q_0, D_0, E_0, H_0, C_0, P_0, N_0$, and the second supplies $R_1, W_1, Q_1, D_1, E_1, H_1, C_1, P_1, N_1$; compatibility identifies the end of W_0 with the beginning discipline of W_1 inside the finite StreamName window surface.

Use the StreamName–RegSeq handoff on each packet. It forces Q_0 to be read from W_0 and Q_1 to be read from W_1, with each readback still governed by its displayed rate row.

Next apply dyadic tolerance exactness and tail monotonicity. The second window begins after the first regular-tail threshold, so the two tolerance displays can be read as one ordered ledger rather than as a detached radius choice.

Finally apply Real seal routing to the concatenated surface. The seal-facing consumer must traverse the combined route through both readbacks and the shared dyadic ledger before any $\mathsf{Real}^{\uparrow}$ seal is exposed. Since every coordinate used in the construction is projected from the two finite carriers and their H, C, P, N rows, no quotient stream, selected limit, countable choice, host convergence proof, or ambient completeness principle is added. □

Falsifiable prediction: A Real-completion seal consumer that consumes a CauchyRateBudgetUp packet cannot read a RealUp seal unless the displayed rate row, StreamName window, RegSeqRat readback, and DyadicRatCore tolerance ledger have all been displayed.

Independence witness: Compare observationbudgetlimiter, regularcauchytailbudget, finiteprefixlimitbudget, cauchydiagonalbudget, and budgetedrealsealroute: CauchyRateBudgetUp has a first-class convergence-rate row tied to a single finite-window schedule, while those siblings respectively cap requests, tail thresholds, prefix depth, diagonal budget, or a composite seal route; no bijection preserves both the rate coordinate and the seal-readback order.

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyRateBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{CauchyRateBudget}^{\uparrow}$ packet is generated from a displayed convergence-rate row, a finite $\mathsf{StreamName}^{\uparrow}$ window row, a $\mathsf{RegSeqRat}^{\uparrow}$ readback row, a $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, a $\mathsf{Real}^{\uparrow}$ seal row, componentwise hsame transports, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyRateBudget}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 929.1, Definition 929.2, Definition 929.3, Definition 929.4, Definition 929.7, Definition 929.8, Definition 929.5, and Definition 929.10 scope the finite convergence-rate, StreamName window, RegSeqRat readback, dyadic tolerance, Real seal, TasteGate boundary, and BEDC kernel support rows for Real-completion consumers.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CauchyRateBudget}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Not claimed: This chapter does not prove Real completeness, construct an ambient modulus, identify quotient streams, select a host real limit, close Lean verification, or provide bridge checking.

Upgrade path: Public closure requires a public consumer theorem exporting the same rate row, StreamName window, RegSeqRat readback, DyadicRatCore tolerance ledger, Real seal route, TasteGate field separation, transport, replay, provenance, and local naming rows.

Chapter 930

A Concrete Naming Certificate for $\mathsf{FiniteRealRouteCommitment}^{\uparrow}$

The $\mathsf{FiniteRealRouteCommitment}^{\uparrow}$ packet realizes the Real-completion route of chapter 9238 as one finite NameCert commitment. It sits downstream of the $\mathsf{Real}^{\uparrow}$ seal surface of chapter 38, the finite window surface of chapter 126, the request cap of chapter 903, the $\mathsf{RegSeqRat}^{\uparrow}$ readback surface of chapter 301, and the sealed Cauchy-limit route of chapter 386. The packet records finite precision, budget, StreamName, RegSeqRat, RealUp seal, and non-escape rows; it is not a host completeness principle, a quotient stream, a selected limit, or a hidden equality rule.

Definition 930.1 (Finite Real route-commitment carrier)**.** *A* $\mathsf{FiniteRealRouteCommitment}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (E, B, W, Q, S, L, H, C, P, N)$$

with the following displayed rows:

1. *E is the finite precision request row consumed by the route;*
2. *B is the observation-budget limiter row that admits the request before any downstream window read;*
3. *W is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row selected under that budget;*
4. *Q is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained from the displayed windows;*
5. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after E, B, W, Q have been displayed;*
6. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row that consumes the same sealed route as finite Cauchy-limit evidence;*
7. *H stores componentwise* hsame *transports for the precision, budget, window, readback, seal, handoff, route, provenance, and local naming rows;*
8. *C stores the displayed* Cont *routes from precision request to budget admission, from budget admission to StreamName window, from window to RegSeqRat readback, from readback to RealUp seal, and from the seal to the CauchyLimitSeal handoff;*
9. *P records* Pkg *provenance over* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteRealRouteCommitment}^{\uparrow}}$ *row.*

The carrier exports exactly this finite route commitment and no unbounded observation schedule, quotient stream, selected host limit, host real equality, trichotomy row, independent real carrier, or ambient completeness theorem.

Theorem 930.2 (Finite Real route-commitment NameCert obligations)**.** *For the carrier of Definition 930.1, the local* $\mathsf{NameCert}_{\mathsf{FiniteRealRouteCommitment}^{\uparrow}}$ *surface consists of six finite obligations:*

1. *carrier admission for the displayed packet* $F = (E, B, W, Q, S, L, H, C, P, N)$*;*
2. *budget admission, requiring the precision request* E *to pass through the observation-budget limiter row* B *before any StreamName window is served;*
3. *window readback, requiring the* $\mathsf{StreamName}^{\uparrow}$ *row* W *to be the only finite window source for the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q*;*
4. *seal ordering, requiring the* $\mathsf{Real}^{\uparrow}$ *seal row* S *to be read only after* E, B, W, Q *are displayed;*
5. *Cauchy-limit handoff, requiring the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* L *to consume the same displayed seal route rather than a selected host limit;*
6. *route non-escape, excluding unbounded schedules, quotient streams, selected limits, host real equality, trichotomy, independent real carriers, and ambient completeness.*

The Lean `TasteGate.lean` *development for this packet must provide* `Nontrivial FiniteRealRouteCommitmentUp` *and* `FieldFaithful FiniteRealRouteCommitmentUp` *instances for this same carrier surface.*

Lean4 ✓ `BEDC.Derived.FiniteRealRouteCommitmentUp.FiniteRealRouteCommitmentTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 930.1. The precision request, budget limiter, window, readback, seal, handoff, transport, continuation, provenance, and local naming rows are all displayed coordinates.

Budget admission and window readback compose the sibling surfaces of chapter 903, chapter 126, and chapter 301. The route therefore reads E through B, then W, then Q, without exposing a second window source.

Seal ordering and Cauchy-limit handoff use the same continuation rows in C. The $\mathsf{Real}^{\uparrow}$ seal row S is available only after the finite readback, and the $\mathsf{CauchyLimitSeal}^{\uparrow}$ row L consumes that same displayed seal route.

The non-escape obligation follows from the carrier inventory. None of F stores an unbounded schedule, quotient stream, selected limit, host equality, trichotomy row, independent real carrier, or completeness theorem, so no accepted read can import one. □

Theorem 930.3 (Finite Real route-commitment budget non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{FiniteRealRouteCommitment}^{\uparrow}$ *packet factors through the finite route*

$$E \to B \to W \to Q \to S \to L.$$

In particular, a consumer cannot reach the RealUp seal or the Cauchy-limit handoff without first displaying the observation budget, StreamName window, and RegSeqRat readback rows.

Proof. Start with the local obligation surface of Definition 930.2. It places the budget row before the StreamName window, the StreamName window before the RegSeqRat readback, the readback before the RealUp seal, and the seal before the CauchyLimitSeal handoff.

The displayed transport and continuation rows preserve that order. Componentwise hsame transport moves the same rows, while C replays only the route named in the carrier.

Finally apply the non-escape obligation. Since the packet has no coordinate for an unbounded schedule, quotient stream, selected host limit, host equality, trichotomy, independent real carrier, or ambient completeness, every seal-facing and Cauchy-limit-facing consumer remains inside the finite route. □

Falsifiable prediction: Removing the route-commitment row permits a RealUp seal consumer to bypass either the observation budget or the StreamName window before the RegSeqRat readback.

Independence witness: real, streamname, regseqrat, observationbudgetlimiter, cauchylimitseal: no sibling is bijective to $\mathsf{FiniteRealRouteCommitment}^{\uparrow}$ because this packet stores the route commitment that joins precision, budget, StreamName window, RegSeqRat readback, RealUp seal, and CauchyLimitSeal handoff rows in one NameCert surface.

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteRealRouteCommitment}^{\uparrow}}$.

Constructive story: A $\mathsf{FiniteRealRouteCommitment}^{\uparrow}$ packet is generated from finite BHist rows for a precision request, observation-budget limiter, $\mathsf{StreamName}^{\uparrow}$ finite window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{Real}^{\uparrow}$ seal, $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff, transports, continuations, provenance, and local naming. The route is ordered by Cont: request, budget, window, readback, seal, and handoff must be displayed in sequence before any Real or Cauchy-limit consumer can read the packet. Componentwise hsame preserves that route, and Pkg records the observation, stream, regular-sequence, Real, and limit-seal dependencies.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FiniteRealRouteCommitment}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the finite Real route-commitment carrier, NameCert obligations, budget non-escape theorem, falsifiable prediction, and independence witness.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FiniteRealRouteCommitment}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim unbounded observation schedules, quotient streams, selected host limits, host real equality, trichotomy, independent real carriers, or ambient completeness.

Upgrade path: Obligation closure requires Lean encodings of the route-commitment carrier, budget-to-window route, seal ordering, Cauchy-limit handoff, and non-escape theorem.

Chapter 931

A Concrete Naming Certificate for $\mathsf{UnaryContMonoid}^{\uparrow}$

The $\mathsf{UnaryContMonoid}^{\uparrow}$ packet is the concrete monoid-shaped reading of the BEDC unary continuation calculus. It realizes the continuation-as-computation vision of chapter 9365 on the finite BHist surface: unary histories are the carrier, Cont composition is the operation, the empty history is the unit, hsame is the classifier, and the local ledger records only displayed continuation rows.

It is the monoid sibling of the Kleisli-style $\mathsf{ContinuationMonad}^{\uparrow}$ packet of chapter 485 and the category-shaped $\mathsf{Cat}^{\uparrow}$ packet of chapter 61. The chapter does not introduce a host monoid primitive, quotient equality, or external algebraic carrier.

Definition 931.1 (Unary Cont monoid carrier)**.** *A* $\mathsf{UnaryContMonoid}^{\uparrow}$ *carrier is a finite packet*

$$M = (U, \mu, e, H, C, P, N)$$

with the following visible rows:

1. *U is the unary carrier row: a displayed history h is admitted exactly through* $\mathsf{UnaryHistory}(h)$*.*
2. *μ is the binary continuation operation row: for unary histories h, k, r, the product $\mu(h, k) = r$ is displayed by the continuation ledger* $\mathsf{Cont}(h, k, r)$*.*
3. *e is the unit row, fixed to the empty history* e *with the displayed left and right unit continuations.*
4. *H records componentwise* hsame *transport for unary histories, continuation results, unit rows, and ledger entries.*
5. *C records the associativity and unit continuation ledgers for μ, including the two parenthesized continuation routes over triples of unary histories.*
6. *P is the* Pkg *provenance over* BHist*,* $\mathsf{UnaryHistory}$*,* Cont*,* hsame*,* Pkg*,* $\mathsf{NameCert}$*,* $\mathsf{ContinuationMonad}^{\uparrow}$*, and* $\mathsf{Cat}^{\uparrow}$*.*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{UnaryContMonoid}^{\uparrow}}$ *row for carrier admission, classifier stability, operation closure, unit and associativity exactness, and ledger non-escape.*

Thus the carrier is the tuple (U, μ, e, H, C, P, N) with $U =$ $\mathsf{UnaryHistory}$*, μ given by* Cont *composition, and $e =$* e*. Every readable algebraic row is a displayed BEDC history row.*

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidTasteGate single carrier alignment`

Theorem 931.2 (Unary Cont monoid NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{UnaryContMonoid}^{\uparrow}}$ *surface consists exactly of five finite obligations: carrier admission for the unary history row* U*; classifier stability under* hsame *transport; closure of* μ *under displayed* Cont *composition; left-unit, right-unit, and associativity exactness for the empty row and the continuation ledgers in* C*; and non-escape of the ledger through the provenance and local naming rows* P, N*.*

Proof. Carrier admission is the first coordinate of Definition 931.1. It accepts precisely unary histories and uses no carrier outside BHist.

Classifier stability is componentwise transport through H. The transported carrier row, operation row, unit row, and ledger row remain the same kind of displayed history data.

Closure and exactness are the continuation laws already read by the sibling packets. The unit clauses are the empty-history laws of Definition 29.5, and the associativity clause is the continuation associativity law of Definition 29.6, equivalently the monoid ledger summarized by Definition 40.22.

Finally, P and N record only the named BEDC rows. Since no coordinate names a host monoid object, quotient product, or external equality, the local ledger cannot export anything beyond the unary continuation packet. □

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier namecert obligations`

Theorem 931.3 (Unary Cont associativity)**.** *For unary histories* a, b, c *and displayed continuation results*

$$\mathsf{Cont}(a, b, ab) \quad \textit{and} \quad \mathsf{Cont}(b, c, bc),$$

the two continuation products

$$\mu(\mu(a, b), c) \quad \textit{and} \quad \mu(a, \mu(b, c))$$

are classified together by hsame *whenever both are read through the carrier of Definition 931.1. The empty history* e *is a two-sided unit for the same operation.*

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier cont associativity`

Proof. Read μ as displayed Cont composition. The left-associated product first consumes the ledger for $\mathsf{Cont}(a, b, ab)$ and then composes with c; the right-associated product first consumes the ledger for $\mathsf{Cont}(b, c, bc)$ and then composes from a.

Apply the core continuation associativity row cited in Definition 29.6. It compares exactly these two parenthesized displayed routes by hsame, so the two carrier results are classified together.

For the unit rows, apply Definition 29.5. The left and right products with e read back to the original unary history under the same classifier. These facts are ledger entries in C, not host monoid equalities. □

Theorem 931.4 (Unary Cont monoid operation closure)**.** *For unary histories* a, b *and a displayed continuation result* r *with* $\mathsf{Cont}(a, b, r)$*, the product row* $\mu(a, b) = r$ *remains inside the* $\mathsf{UnaryContMonoid}^{\uparrow}$ *carrier. It is transported componentwise by* hsame *and packaged by the same* Pkg *provenance and* NameCert *rows as the carrier packet.*

No quotient product, host monoid multiplication, or external carrier equality is introduced by this operation row.

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier operation closure`

Proof. Project the carrier of Definition 931.1. Its unary row admits histories through UnaryHistory, and its operation row is exactly displayed Cont composition.

Use the NameCert obligations of Definition 931.2. They include closure of μ under displayed Cont composition, componentwise classifier stability under hsame, and packaging by the provenance and local naming rows P, N.

The associativity and unit theorem Definition 931.3 supplies the operation ledger used by later algebraic reads. That ledger remains a continuation row inside the same carrier, so it adds neither a quotient product nor a host monoid multiplication nor an external equality. □

Theorem 931.5 (Unary Cont sibling dependency)**.** *The* $\mathsf{UnaryContMonoid}^{\uparrow}$ *packet is the monoid-shaped dependency sibling of* $\mathsf{ContinuationMonad}^{\uparrow}$ *and* $\mathsf{Cat}^{\uparrow}$*: it consumes the continuation unit and associativity rows named by chapter 485, agrees with the tail-composition reading used by chapter 61, and realizes the operational interpretation of chapter 9365 without adding any host monoid primitive, quotient carrier, or non-BEDC operation.*

Proof. The continuation-as-computation chapter reads Cont as the small-step route and identifies tail append as the operational composite. The carrier of Definition 931.1 stores exactly that route as μ.

The $\mathsf{ContinuationMonad}^{\uparrow}$ sibling supplies the same unit and associativity ledger for Kleisli-style two-step continuation reads. Forgetting source, middle, and target notation leaves the unary carrier, the binary continuation result, and the empty unit row.

The $\mathsf{Cat}^{\uparrow}$ sibling reads the same tails as hom-carrier composition. Forgetting object and arrow packaging leaves precisely the monoid-shaped operation on unary histories. Thus the dependency is a repackaging of existing continuation rows, with no additional algebraic primitive. □

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier sibling dependency`

Definition 931.6 (Unary Cont monoid kernel scope)**.** *The* $\mathsf{UnaryContMonoid}^{\uparrow}$ *kernel scope is the finite row package*

$$\mathsf{UnaryHistory},\quad \mathsf{Cont},\quad \mathsf{hsame},\quad \mathsf{e},\quad \mathsf{Pkg},\quad \mathsf{NameCert},\quad \mathsf{ContinuationMonad}^{\uparrow},\quad \mathsf{Cat}^{\uparrow}.$$

It binds the carrier to unary histories, the operation to displayed Cont *composition, the unit to the empty-history row, classifier transport to* hsame*, and sibling provenance to the continuation-monad and category packets.*

Lean4 (definition) `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidKernelScope`

Theorem 931.7 (Unary Cont monoid scoped grounding)**.** *For every accepted* $\mathsf{UnaryContMonoid}^{\uparrow}$ *carrier, associativity, left and right unit exactness, carrier transport, and ledger non-escape all factor through the rows of Definition 931.6. The scoped grounding cannot invoke a host monoid, a quotient product, or any carrier equality not displayed by* UnaryHistory*,* Cont*,* hsame*,* e*,* Pkg*,* NameCert*,* $\mathsf{ContinuationMonad}^{\uparrow}$*, and* $\mathsf{Cat}^{\uparrow}$*.*

Proof. Carrier admission reads unary histories through UnaryHistory and reads the operation through displayed Cont composition. The unit row is the empty history e, so the carrier has no separate algebraic object.

Associativity and unit exactness are inherited as continuation ledger rows from $\mathsf{ContinuationMonad}^{\uparrow}$ and $\mathsf{Cat}^{\uparrow}$. Transport is componentwise hsame transport of the same displayed histories and continuation results.

The provenance and local naming rows package those finite facts for consumers. Since every algebraic read has already factored through the listed kernel rows, the ledger cannot escape to host monoids, quotient products, or external carrier equality. □

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier scoped grounding`

Theorem 931.8 (Unary Cont monoid public NameCert export)**.** *The carrier of Definition 931.1, the NameCert obligations of Definition 931.2, the associativity and unit exactness of Definition 931.3, the sibling dependency of Definition 931.5, the kernel scope of Definition 931.6, and the scoped grounding of Definition 931.7 assemble a public* $\mathsf{NameCert}_{\mathsf{UnaryContMonoid}^{\uparrow}}$ *export over*

$$\mathsf{UnaryHistory},\quad \mathsf{Cont},\quad \mathsf{hsame},\quad \mathsf{e},\quad \mathsf{Pkg},\quad \mathsf{NameCert},\quad \mathsf{ContinuationMonad}^{\uparrow},\quad \mathsf{Cat}^{\uparrow}.$$

The export excludes host monoids, quotient products, arbitrary carrier monoids, and external algebraic equality.

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier public namecert export`

Proof. Start with the carrier and obligation rows. The carrier of Definition 931.1 exposes unary histories, displayed continuation composition, the empty unit, transport, route, provenance, and local naming rows; Definition 931.2 states that these rows exhaust the local NameCert surface.

The algebraic rows are already internal to the continuation ledger. Associativity and the two unit laws are supplied by Definition 931.3, while the sibling dependency of Definition 931.5 records that the same rows are consumed from $\mathsf{ContinuationMonad}^{\uparrow}$ and $\mathsf{Cat}^{\uparrow}$.

The public export surface is therefore the finite kernel scope of Definition 931.6. The scoped grounding theorem Definition 931.7 says that every accepted read factors through exactly those rows.

Since no listed row names a host monoid, quotient product, arbitrary carrier monoid, or external equality relation, the public $\mathsf{NameCert}_{\mathsf{UnaryContMonoid}^{\uparrow}}$ export is a BEDC continuation packet and not an imported algebraic object. □

Theorem 931.9 (Unary Cont monoid unit-bind surface)**.** *Every accepted unit and bind read of* $\mathsf{UnaryContMonoid}^{\uparrow}$ *factors through the concrete rows*

$$\mathsf{UnaryHistory},\quad \mathsf{Cont},\quad \mathsf{hsame},\quad \mathsf{e},\quad \mathsf{Pkg},\quad \mathsf{NameCert},\quad \mathsf{ContinuationMonad}^{\uparrow},\quad \mathsf{Cat}^{\uparrow}.$$

Left and right unit reads are the empty-history continuation rows, and associativity is the displayed continuation ledger. The surface is not a host monoid equality, a quotient product, or an arbitrary algebraic carrier.

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier unit bind surface`

Proof. Project the carrier of Definition 931.1. Its unit coordinate is the empty history e, its operation coordinate is displayed Cont composition, and its transport, provenance, and naming rows are H, C, P, N.

Apply the associativity and unit theorem, Definition 931.3. The left and right unit clauses are the empty-history continuation rows, while associativity is the comparison of the two displayed continuation ledgers.

Use the sibling dependency theorem, Definition 931.5. It identifies the same rows as the monoid-shaped reading of $\mathsf{ContinuationMonad}^{\uparrow}$ and $\mathsf{Cat}^{\uparrow}$, so the unit and bind surface is inherited as BEDC continuation data.

Finally cite the public NameCert export, Definition 931.8. The exported package is exactly the concrete kernel scope listed above, and no host monoid equality or external carrier can be read from it. □

Theorem 931.10 (Unary Cont monoid left and right unit exhaustion)**.** *For a concrete* UnaryHistory *carrier with multiplication read by* Cont *and unit read by* `BHist.Empty`*, every left-unit or right-unit consumer factors through one of the displayed* `cont_left_unit` *or* `cont_right_unit` *rows. The* $\mathsf{UnaryContMonoid}^{\uparrow}$ *packet has no separate abstract monoid operation row, host carrier equality, quotient product, or off-ledger unit service.*

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier left right unit exhaustion`

Proof. Project the carrier of Definition 931.1. Its operation row is displayed continuation composition, and its unit row is the empty history e.

Apply Definition 931.3. The two unit clauses are precisely the empty-history continuation rows: the left-unit read is `cont_left_unit`, and the right-unit read is `cont_right_unit`.

Use operation closure and scoped grounding, Definition 931.4 and Definition 931.7. They keep every algebraic read inside UnaryHistory, Cont, hsame, e, Pkg, NameCert, $\mathsf{ContinuationMonad}^{\uparrow}$, and $\mathsf{Cat}^{\uparrow}$.

The public NameCert export Definition 931.8 then excludes any host monoid or quotient carrier row. Hence the two displayed continuation unit rows exhaust all unit reads. □

Theorem 931.11 (Unary Cont monoid public formal target)**.** *The public formal target for* $\mathsf{UnaryContMonoid}^{\uparrow}$ *is exactly the carrier of Definition 931.1, the associativity ledger of Definition 931.3, the left and right unit exhaustion of Definition 931.10, the operation closure of Definition 931.4, the scoped grounding of Definition 931.7, and the public* $\mathsf{NameCert}_{\mathsf{UnaryContMonoid}^{\uparrow}}$ *export of Definition 931.8. It contains no additional formal target for an abstract monoid carrier, quotient product, host operation, or external equality.*

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier public formal target`

Proof. Start with the carrier and associativity rows. The carrier exposes unary histories, displayed continuation composition, the empty unit, transport, provenance, and local naming; the associativity theorem supplies the parenthesized continuation ledger consumed by monoid-shaped reads.

Add the unit and operation boundaries. The left and right unit exhaustion theorem restricts all unit reads to `cont_left_unit` and `cont_right_unit`, while operation closure keeps products inside the displayed Cont row.

Finally use scoped grounding and public export. The scoped grounding theorem states that all accepted reads factor through the concrete kernel scope, and the public NameCert export packages exactly that finite surface for downstream consumers. □

Theorem 931.12 (Unary Cont monoid ContinuationMonad unit handoff)**.** *Every unit and bind read exported by* $\mathsf{UnaryContMonoid}^{\uparrow}$ *is the empty-history unit row together with the displayed* Cont *route consumed by* $\mathsf{ContinuationMonad}^{\uparrow}$*. The handoff exposes* UnaryHistory*,* Cont*,* hsame*,* e*,* Pkg*, and the local* NameCert *row, and it exposes no host monoid operation, quotient product, or off-packet equality service.*

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier continuationmonad unit handoff`

Proof. Read the carrier from Definition 931.1. Its unit coordinate is e, and its operation coordinate is the displayed Cont route over unary histories.

Use Definition 931.10. The two unit reads are exhausted by the empty-history continuation rows, so the $\mathsf{ContinuationMonad}^{\uparrow}$ unit side has no second source.

Then apply Definition 931.11 and Definition 931.5. These identify the same finite rows as the monoid-shaped surface consumed by $\mathsf{ContinuationMonad}^{\uparrow}$, while excluding host monoid equality and quotient multiplication. □

Theorem 931.13 (Unary Cont monoid Category root readiness)**.** *The unary carrier, displayed* Cont *composition, componentwise* hsame *transport,* Pkg *provenance, and local* NameCert *rows of* $\mathsf{UnaryContMonoid}^{\uparrow}$ *are the category-shaped composition substrate read by* $\mathsf{Cat}^{\uparrow}$*. A category-facing consumer receives only these rows and the sibling continuation surface, not a host category composition law or an external morphism equality.*

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier category root readiness`

Proof. Start with Definition 931.1. The carrier gives a unary history object, a displayed continuation operation, transport, provenance, and naming, all inside one BEDC packet.

The sibling dependency theorem, Definition 931.5, identifies this same surface as the one shared with $\mathsf{Cat}^{\uparrow}$. The unit exhaustion theorem keeps identity-shaped reads on e, and the public formal target keeps composition-shaped reads on Cont.

Thus a $\mathsf{Cat}^{\uparrow}$ read uses the displayed continuation substrate already packaged by $\mathsf{UnaryContMonoid}^{\uparrow}$. No host category composition, quotient morphism, or external equality row can be imported through that root. □

Theorem 931.14 (Unary Cont monoid KernelCategory consumer boundary)**.** *A* $\mathsf{KernelCategory}^{\uparrow}$ *consumer of* $\mathsf{UnaryContMonoid}^{\uparrow}$ *may use only the UnaryContMonoid continuation rows, the category hom-carrier rows named by the sibling category surface, and the local* NameCert *rows. The consumer boundary of chapter 488 cannot import host category composition, host monoid equality, quotient products, or a detached morphism-equality relation.*

Lean4 ✓ `BEDC.Derived.UnaryContMonoidUp.UnaryContMonoidCarrier kernel category consumer boundary`

Proof. First project the $\mathsf{UnaryContMonoid}^{\uparrow}$ rows through Definition 931.1. This supplies unary histories, displayed Cont composition, hsame transport, Pkg provenance, and local naming.

Next use Definition 931.11. It records the complete public surface available to downstream consumers and rules out abstract monoid carriers or quotient products.

Finally combine Definition 931.5 with Definition 931.10. The sibling surface is exactly the continuation and category handoff read by $\mathsf{KernelCategory}^{\uparrow}$, while the two unit rows remain empty-history continuation rows rather than host identities. □

Closure status for $\mathsf{NameCert}_{\mathsf{UnaryContMonoid}^{\uparrow}}$.

Constructive story: A $\mathsf{UnaryContMonoid}^{\uparrow}$ packet is generated from unary histories, displayed Cont composition rows, the empty-history unit, componentwise hsame transport, Pkg provenance, and a local NameCert ledger.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{UnaryContMonoid}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 931.1, Definition 931.2, Definition 931.3, Definition 931.5, Definition 931.8, and Definition 931.9 bind the monoid-shaped BEDC continuation packet over UnaryHistory, Cont, hsame, e, Pkg, NameCert, $\mathsf{ContinuationMonad}^{\uparrow}$, and $\mathsf{Cat}^{\uparrow}$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{UnaryContMonoid}^{\uparrow}}$, unformalized)

Bridge status: none

Not claimed: This chapter does not close commutativity, additive naming, host monoids, quotient products, arbitrary carrier monoids, or machine bridge checking.

Upgrade path: Formal closure requires Lean encoding of Definition 931.8; bridge checking remains separate from the mature paper closure.

Chapter 932

A Concrete Naming Certificate for $\mathsf{KernelObservationSieve}^{\uparrow}$

The $\mathsf{KernelObservationSieve}^{\uparrow}$ surface realizes the inscription-event route of chapter 9397 as a finite observation sieve. It consumes the observer-history identity packet of chapter 477, the selector-ledger packet of chapter 494, and the observer-filter split of chapter 514. The carrier records accepted rows and rejected rows together, so the public inscription-facing route cannot erase the rows that failed the sieve.

Definition 932.1 (Kernel observation sieve carrier)**.** *A* $\mathsf{KernelObservationSieve}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (O, S, F, A, R, T, C, P, N)$$

with the following displayed rows:

1. *O is the source observer-history row supplied by* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$*;*
2. *S is the selector-ledger row supplied by* $\mathsf{SelectorLedger}^{\uparrow}$*;*
3. *F is the observer-filter row that classifies source observations as accepted or rejected;*
4. *A is the accepted-row ledger, listing the finite observation rows admitted to the inscription-facing route;*
5. *R is the rejected-row ledger, listing the finite observation rows refused by the same sieve together with their boundary reasons;*
6. *T records componentwise* hsame *transport for O, S, F, A, R, P, N;*
7. *C records displayed* Cont *routes through the source history, selector ledger, filter row, accepted ledger, and rejected ledger;*
8. *P is the* Pkg *provenance over* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$*,* $\mathsf{SelectorLedger}^{\uparrow}$*,* $\mathsf{ObserverFilter}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{KernelObservationSieve}^{\uparrow}}$ *row.*

The classifier compares accepted carriers only by these displayed rows. It has no coordinate for a hidden observation oracle, host equality of histories, quotient stream equality, unledgered deletion, or an inscription route that forgets the rejected-row ledger.

Lean4 ✓ `BEDC.Derived.KernelObservationSieveUp.KernelObservationSieveTasteGate single carrier alignment`

Theorem 932.2 (Kernel observation sieve NameCert obligations)**.** *For the carrier of Definition 932.1, the local* $\mathsf{NameCert}_{\mathsf{KernelObservationSieve}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier exposure: every accepted packet exposes exactly* $K = (O, S, F, A, R, T, C, P, N)$*;*
2. *selector accountability: the selector-ledger row* S *is read before an observation row can enter the accepted ledger* A*;*
3. *paired-ledger exactness: every source observation accounted for by the sieve is visible in exactly one of the accepted ledger* A *or the rejected ledger* R*;*
4. *transport and route stability:* T *and* C *move and replay only the displayed observer-history, selector, filter, accepted, rejected, provenance, and naming rows;*
5. *provenance exposure:* P *and* N *bind the sieve to* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$*,* $\mathsf{SelectorLedger}^{\uparrow}$*,* $\mathsf{ObserverFilter}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *data rather than to a host-side observation source.*

Lean4 ✓ `BEDC.Derived.KernelObservationSieveUp.KernelObservationSieveNameCert obligations`

Proof. Carrier exposure is projection from Definition 932.1. The observer-history, selector-ledger, filter, accepted-ledger, rejected-ledger, transport, route, provenance, and naming rows are all displayed coordinates.

Selector accountability reads S beside O and F. An observation reaches the accepted ledger only after the selector and filter rows have classified it inside the finite packet.

Paired-ledger exactness is the defining split between A and R. The accepted side can feed an inscription-facing consumer, while the rejected side remains visible as boundary data.

Transport, route stability, and provenance exposure are supplied by T, C, P, N. Since the carrier lacks a hidden observation oracle, host history equality, quotient stream equality, unledgered deletion, and any route that forgets R, these rows exhaust the local certificate surface. □

Theorem 932.3 (Kernel observation sieve non-escape)**.** *No consumer of an accepted* $\mathsf{KernelObservationSieve}^{\uparrow}$ *packet can recover an omitted observation row without passing through the rejected-row ledger* R*. A consumer may read accepted observations through* A *and displayed routes* C*, but omitted rows remain boundary data in* R *and cannot be reconstructed from* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$*,* $\mathsf{SelectorLedger}^{\uparrow}$*,* $\mathsf{ObserverFilter}^{\uparrow}$*, host equality, quotient stream equality, or an unrecorded inscription event.*

Proof. Project the accepted carrier $K = (O, S, F, A, R, T, C, P, N)$. The omitted observations are named only in the rejected-row ledger R, while accepted observations are named in A.

Apply Definition 932.2. Paired-ledger exactness places every accounted observation in exactly one of the two ledgers, and selector accountability requires the route through S and F before either ledger can be consumed.

The transport and route rows T and C replay this same split. The provenance row P names only the observer-history, selector-ledger, and observer-filter sibling certificates, so no hidden source remains from which a consumer could recover an omitted row without reading R. □

Theorem 932.4 (Kernel observation sieve inscription handoff)**.** *The finite observation sieve hands data to the inscription-event surface of chapter 9397 only through the accepted ledger* A*, while the rejected ledger* R *remains part of the same public certificate. Thus the inscription-facing route receives* O, S, F, A, T, C, P, N *together with the visible refusal boundary* R*, and it receives no unfiltered observation stream, hidden selector, or host-level source of omitted rows.*

Proof. Start from the vision handoff. The inscription-event route requires a finite public record surface rather than an unbounded observation stream.

Use Definition 932.2. The accepted ledger A is available only after O, S, F are displayed, and the rejected ledger R remains in the same packet as the boundary for omitted rows.

Finally apply non-escape from Definition 932.3. Since omitted rows cannot be recovered without R, the inscription-facing consumer receives the accepted ledger together with the refusal boundary and no hidden observation source. □

Falsifiable prediction: No accepted $\mathsf{KernelObservationSieve}^{\uparrow}$ consumer can recover an omitted observation row without passing through the rejected-row ledger R.

Independence witness: observerhistoryidentity, selectorledger, observerfilter, inscriptioneventrelated surface: the sieve has both accepted and rejected row ledgers, which these siblings lack as a paired carrier.

The Lean TasteGate namespace BEDC.Derived.KernelObservationSieveUp.TasteGate must provide Nontrivial $\mathsf{KernelObservationSieve}^{\uparrow}$ and FieldFaithful $\mathsf{KernelObservationSieve}^{\uparrow}$ instances for the displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{KernelObservationSieve}^{\uparrow}}$.

Constructive story: A $\mathsf{KernelObservationSieve}^{\uparrow}$ packet is generated from observer-history identity, selector-ledger, observer-filter, accepted-row ledger, rejected-row ledger, componentwise hsame transport, displayed continuation, package provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{KernelObservationSieve}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 932.1, Definition 932.2, Definition 932.3, and Definition 932.4 specify the finite accepted-and-rejected observation sieve and its inscription-facing boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{KernelObservationSieve}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, hidden observation recovery, quotient stream equality, host history equality, or inscription-event completeness.

Upgrade path: Obligation closure requires checked carrier admission, selector accountability, paired-ledger exactness, transport and route stability, non-escape, nontriviality, and field faithfulness for the same carrier.

Chapter 933

A Concrete Naming Certificate for $\mathsf{MaxRateReadGate}^{\uparrow}$

The $\mathsf{MaxRateReadGate}^{\uparrow}$ packet is the finite gate between the inter-Hist locality vision of chapter 9419 and downstream maximum-rate consumers such as $\mathsf{LorentzFrameRate}^{\uparrow}$ and $\mathsf{InterHistLocalityLedger}^{\uparrow}$. It consumes the unary-bound surface of chapter 594, but makes the read public only when the same packet also displays observer-symmetry and no-global-frame refusal rows. The gate is therefore not a new rate value, metric geometry, or global reference frame; it is a NameCert boundary that prevents detached maximum-rate reads.

Falsifiable prediction: An accepted $\mathsf{MaxRateReadGate}^{\uparrow}$ consumer that reads a $\mathsf{MaxCausalRate}^{\uparrow}$ row while omitting either observer-symmetry or no-global-frame refusal refutes the packet.

Independence witness: Nearest siblings: multihistconfig, crosshistcausal, maxcausalrate, observerlocalitycell, interhistinvariant. None is bijective to $\mathsf{MaxRateReadGate}^{\uparrow}$ because each omits either the paired gate requiring both symmetry and no-global-frame refusal or the maximum-rate consumer lock.

Definition 933.1 (MaxRateReadGate carrier)**.** *A* $\mathsf{MaxRateReadGate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (M, R, S, F, L, H, Q, C, P, N)$$

with the following visible coordinates:

1. *M is an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *row supplying the finite observer-history configuration and its no-global-sync surface;*
2. *R is an accepted* $\mathsf{MaxCausalRate}^{\uparrow}$ *row whose unary-bound surface is being read;*
3. *S is the observer-symmetry row, recording that the rate read is invariant under swapping the displayed observer-history presentations after componentwise transport;*
4. *F is the no-global-frame refusal row, recording that the read does not import a privileged observer, synchronized clock, metric tensor, Lorentz frame, or ambient real-valued speed;*
5. *L is the maximum-rate consumer lock, requiring every public consumer of R to pass through both S and F before it may read the unary-bound row;*
6. *H records componentwise* hsame *transport for $M, R, S, F, L, Q, C, P, N$;*
7. *Q records* psame *stability for the probe reads used by the rate row, symmetry row, refusal row, and consumer lock;*

8. *C records the displayed* Cont *routes from the configuration and rate rows into S, F, L, H, Q, P, N;*
9. *P is the* Pkg *provenance over* $\mathsf{MaxRateReadGate}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{ObserverLocalityCell}^{\uparrow}$, $\mathsf{InterHistInvariant}^{\uparrow}$, BHist, hsame, psame, Cont, Pkg, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{MaxRateReadGate}^{\uparrow}}$ *row.*

The carrier exports a finite public read gate for a maximum-rate row. It does not export a detached rate, a host-side numeric speed, a metric structure, a synchronized frame, or an all-observer reference coordinate.

Lean4 ✓ `BEDC.Derived.MaxRateReadGateUp.MaxRateReadGateTasteGate single carrier alignment`

Theorem 933.2 (MaxRateReadGate NameCert obligations)**.** *For the carrier of Definition 933.1, the local* $\mathsf{NameCert}_{\mathsf{MaxRateReadGate}^{\uparrow}}$ *surface consists exactly of six finite obligations:*

1. *carrier admission for the displayed packet $G = (M, R, S, F, L, H, Q, C, P, N)$;*
2. *rate-source locality, requiring R to be read as the* $\mathsf{MaxCausalRate}^{\uparrow}$ *row attached to the same displayed configuration M;*
3. *observer-symmetry exactness, requiring every public rate read to pass through S after componentwise transport;*
4. *no-global-frame refusal, requiring every public rate read to pass through F before any consumer sees the unary-bound surface;*
5. *consumer-lock exactness, requiring L to bind the reads of R, S, F into one public gate rather than three independent rows;*
6. *transport stability and non-escape through H, Q, C, P, N, excluding global frames, synchronized clocks, metric tensors, Lorentz frames, host real speeds, and detached maximum-rate reads.*

Lean4 ✓ `BEDC.Derived.MaxRateReadGateUp.MaxRateReadGateNameCertObligations`

Proof. Carrier admission is the projection of the finite tuple in Definition 933.1. The rows $M, R, S, F, L, H, Q, C, P, N$ display the configuration, rate row, symmetry row, refusal row, lock, transport, probe stability, route, provenance, and local naming data.

Rate-source locality follows by reading M before R. The rate row is not a free-standing numeric surface; it is the $\mathsf{MaxCausalRate}^{\uparrow}$ row already tied to the finite witness-family packet described in chapter 594.

The public gate is then formed by S, F, L. The symmetry row supplies the observer-symmetric read, the refusal row blocks global-frame imports, and the lock row requires both gates before any consumer reads the unary-bound surface.

Transport stability is componentwise through H, Q, C. These rows replay the same configuration, rate, symmetry, refusal, and lock data under accepted hsame and psame movement.

The non-escape clause is an inventory argument. Since the carrier has no coordinate for a global frame, synchronized clock, metric tensor, Lorentz frame, host real speed, or detached rate row, no local $\mathsf{NameCert}_{\mathsf{MaxRateReadGate}^{\uparrow}}$ projection can export one. □

Theorem 933.3 (MaxRateReadGate symmetry and non-escape)**.** *Every public consumer of an accepted* $\mathsf{MaxRateReadGate}^{\uparrow}$ *carrier*

$$G = (M, R, S, F, L, H, Q, C, P, N)$$

may read the MaxCausalRate$^{\uparrow}$ *row R only through the observer-symmetry row S, the no-global-frame refusal row F, and the maximum-rate consumer lock L. Swapping the displayed observer-history presentations preserves the public read after transport through H, Q, C, and no consumer receives a global frame, synchronized clock, metric tensor, Lorentz frame, host real-valued speed, or detached rate row.*

Lean4 ✓ `BEDC.Derived.MaxRateReadGateUp.MaxRateReadGateCarrier symmetry nonescape`

Proof. Start with the accepted carrier and project M and R. The configuration row M supplies the finite observer-history surface, while R supplies the maximum causal-rate row already bounded inside that surface.

Apply the observer-symmetry row S. It records that the public rate read is invariant under swapping the displayed observer-history presentations after replaying the componentwise transport data.

Next apply the no-global-frame refusal row F. This blocks any attempt to interpret the rate read as a privileged observer frame, synchronized clock, metric tensor, Lorentz frame, or ambient numeric speed.

Finally apply the consumer lock L and route the read through H, Q, C, P, N. The lock binds R, S, F into one public gate, so a consumer that omits either symmetry or refusal leaves the MaxRateReadGate$^{\uparrow}$ surface. □

Theorem 933.4 (MaxRateReadGate downstream consumer boundary)**.** *A* LorentzFrameRate$^{\uparrow}$, InterHistLocalityLedger$^{\uparrow}$, *or other maximum-rate consumer may use an accepted* MaxRateReadGate$^{\uparrow}$ *packet only as the finite gated surface*

$$M, R, S, F, L, H, Q, C, P, N.$$

The consumer may inspect the multi-Hist configuration row, the MaxCausalRate$^{\uparrow}$ *row, the observer-symmetry row, the no-global-frame refusal row, the consumer lock, componentwise transport, probe stability, displayed continuation routes, provenance, and local naming data. It may not bypass the gate to obtain a free rate value or a global reference frame.*

Lean4 ✓ `BEDC.Derived.MaxRateReadGateUp.MaxRateReadGateCarrier downstream consumer boundary`

Proof. Read the carrier rows listed in Definition 933.1. The only maximum-rate input is R, and the only public path to R goes through S, F, L.

Use Definition 933.2 to bind those rows as the local NameCert surface. The obligations make rate-source locality, symmetry, refusal, and lock exactness part of one packet.

Then use Definition 933.3. It preserves the read under observer swap and excludes every detached global-frame or numeric-rate export.

Thus downstream consumers receive a finite gate rather than a rate primitive. Any consumer that asks for a read of R without S and F is outside the displayed packet. □

Theorem 933.5 (MaxRateReadGate CrossHistCausalRate handoff)**.** *Every* CrossHistCausalRate$^{\uparrow}$ *consumer of an accepted* MaxRateReadGate$^{\uparrow}$ *packet reads the maximum-rate row only through*

$$M, R, S, F, L, H, Q, C, P, N.$$

The row R is tied to the MaxCausalRate$^{\uparrow}$ *surface of chapter 594, S is the observer-symmetry row, F is the no-global-frame refusal row, and L is the consumer lock. The handoff to chapter 876 therefore exports a gated maximum-rate boundary rather than a detached rate value, host speed, metric row, clock, or global observer frame.*

Proof. Apply Definition 933.2. It binds the carrier rows $M, R, S, F, L, H, Q, C, P, N$ into one local NameCert surface and makes rate-source locality part of the packet.

Next apply Definition 933.3. This forces every public read of R to pass through the observer-symmetry row S, the no-global-frame refusal row F, and the lock row L.

Finally apply Definition 933.4. A $\mathsf{CrossHistCausalRate}^{\uparrow}$ consumer is one of the maximum-rate consumers that receives the finite gate, so its handoff reads the same ten rows and no detached global-frame or numeric-rate surface. □

Theorem 933.6 (MaxRateReadGate NameCert package)**.** *The carrier, local NameCert obligations, symmetry-and-non-escape theorem, and downstream consumer boundary assemble the concrete* $\mathsf{NameCert}_{\mathsf{MaxRateReadGate}^{\uparrow}}$ *package over* $\mathsf{MultiHistConfig}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{ObserverLocalityCell}^{\uparrow}$, $\mathsf{InterHistInvariant}^{\uparrow}$, BHist, hsame, psame, Cont, Pkg, *and* NameCert. *The package is ready for a Lean realization whose gate file provides* `Nontrivial MaxRateReadGateUp` *and* `FieldFaithful MaxRateReadGateUp` *instances in* `lean4/BEDC/Derived/MaxRateReadGateUp/TasteGate.le` *with the canonical declaration surface expected at* `BEDC.Derived.MaxRateReadGateUp.taste_gate`.

Proof. Begin with the carrier definition. It fixes the ten visible rows and names the $\mathsf{MaxCausalRate}^{\uparrow}$ source of the rate read.

Add the NameCert obligations. They require locality against M, observer symmetry through S, no-global-frame refusal through F, consumer locking through L, and transport through H, Q, C, P, N.

The symmetry-and-non-escape theorem and downstream boundary then exhaust the public consumer surface. Together they make the package finite, falsifiable, and separated from the sibling packets that supply only configuration, causal witnesses, raw maximum-rate bounds, locality cells, or invariant readback rows. □

Theorem 933.7 (MaxRateReadGate obligation coverage)**.** *The carrier, NameCert obligations, symmetry nonescape theorem, downstream consumer boundary, CrossHistCausalRate handoff, and package theorem cover the carrier admission, rate-source locality, observer-symmetry exactness, no-global-frame refusal, consumer-lock exactness, transport stability, and ledger nonescape obligations for* $\mathsf{MaxRateReadGate}^{\uparrow}$. *The same coverage is constrained by the checked TasteGate carrier alignment for* `BEDC.Derived.MaxRateReadGateUp.MaxRateReadGateTasteGate_single_carrier_alignment`.

Proof. Apply Definition 933.1 for carrier admission. The tuple $G = (M, R, S, F, L, H, Q, C, P, N)$ displays exactly the configuration row, maximum-rate row, observer-symmetry row, no-global-frame refusal, consumer lock, transport, probe stability, continuation route, provenance, and local naming.

Apply Definition 933.2 for rate-source locality, observer-symmetry exactness, no-global-frame refusal, consumer-lock exactness, transport stability, and nonescape. The checked TasteGate marker following the carrier records that the formal carrier alignment is the same single displayed surface.

Apply Definition 933.3, Definition 933.4, and Definition 933.5. These results show that observer swaps, downstream maximum-rate consumers, and $\mathsf{CrossHistCausalRate}^{\uparrow}$ handoffs all read the same gate rows and cannot bypass the no-global-frame refusal or consumer lock.

Finally apply Definition 933.6. The package theorem assembles those rows over $\mathsf{MultiHistConfig}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{ObserverLocalityCell}^{\uparrow}$, $\mathsf{InterHistInvariant}^{\uparrow}$, BHist, hsame, psame, Cont, Pkg, and NameCert, so no listed obligation remains outside the finite package. □

Closure status for $\mathsf{NameCert}_{\mathsf{MaxRateReadGate}^{\uparrow}}$.

Constructive story: A MaxRateReadGate$^{\uparrow}$ packet is generated from a $\mathrm{MultiHistConfig}^{\uparrow}$ row, a MaxCausalRate$^{\uparrow}$ row, an observer-symmetry row, a no-global-frame refusal row, a maximum-rate consumer lock, componentwise hsame transports, psame probe stability, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\mathsf{MaxRateReadGate}^{\uparrow}}$, seed)

Scope closed: Definition 933.1, Definition 933.2, Definition 933.3, and Definition 933.6 bind the finite maximum-rate read gate with observer symmetry, no-global-frame refusal, consumer locking, and local NameCert packaging.

Formal verification: FormalStatus(NameCert$_{\mathsf{MaxRateReadGate}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, global frames, metric tensors, Lorentz frames, host real speeds, detached maximum-rate values, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, rate-source locality, observer-symmetry exactness, no-global-frame refusal, consumer-lock exactness, transport stability, and non-escape for the same finite packet.

Chapter 934

A Concrete Naming Certificate for $\mathsf{CellularAutomaton}^{\uparrow}$

The $\mathsf{CellularAutomaton}^{\uparrow}$ surface realizes the cellular substrate reading of chapter 9390 as a finite NameCert packet. It sits beside the transition-oriented carrier of chapter 482, the accepted-and-rejected observation sieve of chapter 932, and the gated public read of chapter 933. Its distinguishing data are a local rule table and a finite orbit ledger, so a pattern tag is certified only as a read from displayed cellular rows.

Falsifiable prediction: A $\mathsf{CellularAutomaton}^{\uparrow}$ consumer that reads a pattern tag without passing through the displayed finite orbit ledger is outside the certificate.

Independence witness: continuationautomaton, kernelobservationsieve, maxratereadgate, haltingdistinctiontrace: none is bijective because $\mathsf{CellularAutomaton}^{\uparrow}$ carries a local rule-table and orbit-ledger row that the siblings lack, while it lacks their distinct continuation or rate-gate payload rows.

Definition 934.1 (CellularAutomaton NameCert carrier)**.** *A* $\mathsf{CellularAutomaton}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (R, I, O, T, L, H, C, P, N)$$

with the following displayed rows:

1. *R is the local cellular rule-table row, including the finite neighbourhood alphabet and every displayed transition entry;*
2. *I is the initial row of cells from which the accepted orbit segment is generated;*
3. *O is the finite orbit-segment ledger listing the rows reached from I by repeated reads of R;*
4. *T is the pattern-tag classifier row assigning finite tags such as ether, glider, collision, or refused pattern to rows visible in O;*
5. *L is the observation ledger recording which row windows, tag reads, and Rule 110 boundary reads are admitted;*
6. *H records componentwise* hsame *transports for R, I, O, T, L, P, N;*
7. *C records displayed* Cont *routes through the rule table, initial row, orbit segment, classifier, and observation ledger;*

8. *P is the* Pkg *provenance over* $\mathsf{CellularAutomaton}^{\uparrow}$*, the cellular reading of chapter 9390,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{CellularAutomaton}^{\uparrow}}$ *row.*

The local classifier compares accepted carriers only by the displayed rule table, initial row, finite orbit ledger, pattern tags, observation ledger, transport rows, continuation routes, provenance, and local naming row. It has no coordinate for an unbounded orbit, external induction over all times, host equality of cellular histories, quotient stream equality, hidden glider catalog, or detached Rule 110 oracle.

Lean4 ✓ `BEDC.Derived.CellularAutomatonUp.TasteGate.CellularAutomatonTasteGate single carrier alignment`

Theorem 934.2 (CellularAutomaton NameCert obligations)**.** *For the carrier of Definition 934.1, the local* $\mathsf{NameCert}_{\mathsf{CellularAutomaton}^{\uparrow}}$ *surface consists exactly of carrier exposure for $A = (R, I, O, T, L, H, C, P, N)$, rule-table accountability through R, initial-row accountability through I, finite orbit exposure through O, pattern-tag reads through T, observation-ledger replay through L, componentwise stability through H, displayed route replay through C, package provenance through P, and local naming through N. No consumer can read a cellular pattern, Rule 110 tag, universal simulation claim, or closed-observation boundary as* $\mathsf{CellularAutomaton}^{\uparrow}$ *evidence without passing through these rows.*

Proof. Carrier exposure is projection from Definition 934.1. The finite packet displays the rule table, initial row, orbit segment, classifier, observation ledger, transports, continuation routes, provenance, and local naming row as its only coordinates.

Rule-table and initial-row accountability are read from R and I. The orbit ledger O is admitted only as the finite route generated from these rows, so a consumer cannot replace the local rule by a host evaluator or an unrecorded cellular history.

Pattern-tag and observation-ledger replay are read from T and L. The classifier may name ether, glider, collision, Rule 110 boundary, or refused-pattern tags only for windows already displayed in O and only through the admitted ledger reads.

Finally use H, C, P, N. These rows transport, replay, record, and name exactly the displayed packet. Since the carrier lacks coordinates for unbounded induction, quotient streams, host cellular equality, hidden catalogs, and detached oracles, the listed rows exhaust the local NameCert surface. □

Theorem 934.3 (Rule 110 closed-observation boundary)**.** *Every Rule 110 or cellular-substrate read exported by an accepted* $\mathsf{CellularAutomaton}^{\uparrow}$ *carrier factors through the finite route*

$$R, I, O, T, L, H, C, P, N.$$

In particular, a consumer may cite Rule 110 minimality, a pattern tag, or a closed-observation boundary only as a finite ledger read from O and L; it does not obtain an unbounded orbit, an internal induction principle, a host evaluator, a quotient stream representative, or a cellular oracle outside the packet.

Proof. Begin with the route inventory. The only Rule 110-facing rows in the packet are the rule table R, the initial row I, the finite orbit ledger O, the classifier T, and the observation ledger L.

Apply Definition 934.2. A pattern tag or cellular-substrate read is accepted only when the classifier row reads a window already present in the displayed orbit ledger and the observation ledger admits that read.

The non-escape claim is finite-route inspection. The continuation routes C have no edge to an unbounded time domain, a host evaluator, quotient stream equality, or an external induction rule. The provenance and local naming rows P, N therefore certify only the displayed closed-observation segment. □

Theorem 934.4 (CellularAutomaton local rule exposure)**.** *Every accepted* $\mathsf{CellularAutomaton}^{\uparrow}$ *read first exposes the local rule row R and the initial row I before any orbit, pattern tag, Rule 110 boundary, transport, continuation, provenance, or local naming row can be consumed. The read therefore cannot start from a host cellular evaluator, an implicit rule convention, or an unrecorded initial configuration.*

Lean4 ✓ `BEDC.Derived.CellularAutomatonUp.TasteGate.CellularAutomatonCarrier local rule exposure`

Proof. Project the carrier of Definition 934.1. The first two cellular coordinates are exactly the local rule table R and the initial row I.

Apply the NameCert obligations of Definition 934.2. Orbit exposure, pattern tags, observation-ledger replay, transport, route replay, package provenance, and local naming are all accepted only as rows of the displayed packet.

Finally use the closed-observation boundary of Definition 934.3. Since every Rule 110-facing read factors through $R, I, O, T, L, H, C, P, N$, no accepted route can bypass R and I. □

Theorem 934.5 (CellularAutomaton accepted-window exhaustion)**.** *Every pattern-tag read exported by an accepted* $\mathsf{CellularAutomaton}^{\uparrow}$ *packet is exhausted by the finite orbit ledger O and the observation ledger L. A consumer may classify only windows already displayed in O and admitted by L; it obtains no hidden pattern catalog, all-time orbit stream, or detached Rule 110 observation row.*

Proof. Read the carrier of Definition 934.1. The only orbit-facing coordinate is O, and the only observation-admission coordinate is L.

Apply Definition 934.2. The classifier row T names pattern tags only through the displayed orbit and observation rows, while H, C, P, N preserve and replay the same finite packet.

The closed-observation boundary of Definition 934.3 then excludes an unbounded orbit, host evaluator, quotient stream representative, or cellular oracle. Thus the accepted pattern-window surface is exactly the finite pair O, L together with the displayed certificate rows. □

Theorem 934.6 (CellularAutomaton finite-route non-escape)**.** *No Rule 110 consumer of an accepted* $\mathsf{CellularAutomaton}^{\uparrow}$ *packet can bypass*

$$R, I, O, T, L, H, C, P, N$$

into an unbounded orbit, host evaluator, quotient stream, hidden pattern catalog, or detached cellular oracle. Every public Rule 110 read remains a finite route through the displayed local rule, initial row, orbit ledger, classifier, observation ledger, transport, continuation, provenance, and naming rows.

Proof. Start with the carrier of Definition 934.1. Its coordinates list the complete accepted route $R, I, O, T, L, H, C, P, N$ and no additional cellular substrate coordinate.

The local NameCert obligations of Definition 934.2 force each accepted read through the displayed rows. Rule-table accountability, initial-row accountability, finite orbit exposure, classifier replay, and observation-ledger replay leave no route to an external evaluator or hidden catalog.

Finally apply Definition 934.3. Rule 110-facing reads are closed observations of the finite packet, so unbounded or quotient-stream routes are outside the certificate. □

Theorem 934.7 (CellularAutomaton rule-table exactness)**.** *Every transition read exported by an accepted* $\mathsf{CellularAutomaton}^{\uparrow}$ *carrier is one displayed local rule-table row from* R*, transported by the componentwise* hsame *row* H *and replayed through the continuation row* C*. The read cannot cite a host cellular evaluator, an implicit transition convention, or a rule entry absent from* R*.*

Proof. Project the accepted packet to R, H, C. The carrier has a single rule-table coordinate, and the local NameCert obligations make every transition-facing read pass through that coordinate.

The transport row H can only compare displayed rule-table entries componentwise. It does not add a missing neighbourhood case or identify two host evaluators.

The continuation row C replays the selected local transition from the displayed table. Since no separate evaluator or oracle coordinate exists in the packet, exactness is precisely the assertion that the transition read is one row of R carried through H and C. □

Theorem 934.8 (CellularAutomaton finite orbit exposure)**.** *Every orbit read exported by an accepted* $\mathsf{CellularAutomaton}^{\uparrow}$ *carrier is a finite ledger row in* O *generated from the initial row* I *and the rule table* R*. The packet exposes no unbounded orbit coordinate, no all-time induction principle, and no hidden scheduler outside the displayed ledger route* R, I, O, H, C, P, N*.*

Proof. Start from the carrier coordinates. The initial cellular data are stored in I, the local transition table is stored in R, and the only orbit-facing coordinate is the finite ledger O.

The admitted route reads O as the ledger generated from I by repeated displayed uses of R below the finite segment named in the packet. Transport through H and replay through C preserve those displayed rows rather than replacing them with a host run.

An unbounded orbit or all-time induction rule would require a coordinate not present in R, I, O, H, C, P, N. Thus every public orbit read remains a finite ledger exposure. □

Theorem 934.9 (CellularAutomaton pattern-tag non-escape)**.** *Every ether, glider, collision, Rule 110 boundary, or refused-pattern tag exported by an accepted* $\mathsf{CellularAutomaton}^{\uparrow}$ *carrier factors through the finite orbit ledger* O *and the observation ledger* L*. A tag read may use the classifier row* T*, the transport row* H*, the route row* C*, and the package and naming rows* P, N*, but it cannot escape to a hidden pattern catalog, an unbounded orbit, a host cellular evaluator, or an oracle for cellular universality.*

Proof. Project the tag-facing rows. The classifier row T names only pattern tags for windows already visible in the finite orbit ledger O, and the observation ledger L records which of those reads are admitted.

Transport and continuation are still finite. The H row compares displayed tag, orbit, and observation rows componentwise, while C replays the route from the rule and initial rows through the finite orbit window and into the tag read.

The excluded objects are absent coordinates. A hidden pattern catalog, unbounded orbit, host evaluator, or universality oracle cannot be recovered from O, T, L, H, C, P, N, so every accepted tag remains inside the finite ledger surface. □

The Lean TasteGate namespace BEDC.Derived.CellularAutomatonUp.TasteGate must provide Nontrivial $\mathsf{CellularAutomaton}^{\uparrow}$ and FieldFaithful $\mathsf{CellularAutomaton}^{\uparrow}$ instances for the displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{CellularAutomaton}^{\uparrow}}$**.**

Constructive story: A $\mathsf{CellularAutomaton}^{\uparrow}$ packet is generated from a finite cellular rule table, initial row, finite orbit ledger, pattern-tag classifier, observation ledger, componentwise hsame transports, displayed continuation routes, package provenance, and local NameCert row.

Lean4 ✓ `BEDC.Derived.CellularAutomatonUp.taste gate`

Theory closure: TheoryGate(NameCert$_{\text{CellularAutomaton}\uparrow}$, maturePackageClosed)

Scope closed: Definition 934.1, Definition 934.2, Definition 934.3, Definition 934.7, Definition 934.8, and Definition 934.9 specify the displayed BHist, hsame, Cont, Pkg, NameCert, rule-table, orbit-ledger, and classifier scope.

Formal verification: FormalStatus(NameCert$_{\text{CellularAutomaton}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.CellularAutomatonUp.TasteGate.CellularAutomatonTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, Rule 110 universality, cellular completeness, internal induction, quotient stream equality, or host evaluator correctness.

Upgrade path: No further paper-axis theory step remains for the finite cellular-automaton example surface; formal bridge checking remains a separate verification-axis step.

Chapter 935

A Concrete Naming Certificate for MetricSpace Compact-Continuity Source Lock

The MetricSpace compact-continuity source lock is the finite BEDC packet read before the compact-uniform-continuity construction of chapter 9237. It joins the located distance rows of chapter 57, the compact finite-net rows of chapter 129, the continuous pointwise-modulus rows of chapter 130, and the uniform-modulus consumer boundary of chapter 369. The packet is a source lock: a consumer sees the source rows together or receives no uniform-modulus precision row.

Falsifiable prediction: If the packet is atomic, no consumer can read a uniform-modulus precision row before the MetricSpaceUp distance row, CompactMetricUp finite-net row, ContinuousMapUp pointwise-modulus row, and RatUp finite-fold row are all displayed.

Independence witness: metric, compactmetric, continuousmap, uniformmodulus, finitenetminimumfold: this packet is not bijective to any one sibling because it carries all four source-lock rows and a consumer non-escape row simultaneously, while each sibling omits at least one required coordinate.

Definition 935.1 (MetricSpace compact-continuity source lock)**.** *A MetricSpace compact-continuity source-lock carrier is a finite* BHist *packet*

$$L = (M, K, F, P, R, H, C, N)$$

with the following displayed rows:

1. *M is the* $\mathsf{Met}^{\uparrow}$ *source row, including the located distance witness and classifier-stable metric comparison used by the compact and continuous inputs.*
2. *K is the* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net row, carrying the finite* ProbeBundle *of centers and the coverage ledger for the same metric source.*
3. *F is the* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus row, carrying the continuous graph, target metric boundary, and local modulus rows over the source metric M.*
4. *P is the* ProbeBundle *center-assignment row that aligns bundled probes from K with the pointwise-modulus centers consumed by F.*
5. *R is the* $\mathsf{Rat}^{\uparrow}$ *lower-fold row, carrying the finite lower-bound ledger over the bundled positive rational radius histories before any uniform precision row is exposed.*

6. *H records componentwise* hsame *transports for M, K, F, P, R, the consumer boundary, and the local naming row.*
7. *C records the displayed* Cont *routes that read distance, finite-net, pointwise-modulus, probe-assignment, and rational-fold rows before the uniform-modulus consumer route is available.*
8. *N is the local* NameCert *row for the source-lock packet.*

The carrier is finite and source-locked. It contains no host compactness theorem, no open-cover selector, no choice-selected modulus, no quotient metric equality, and no ambient completeness row.

Lean4 ✓ BEDC.Derived.MetricSpaceCompactContinuitySourceLockUp.MetricSpaceCompactContinuitySourceLockTas
single carrier alignment

Theorem 935.2 (MetricSpace compact-continuity source-lock obligations)**.** *For the carrier of Definition 935.1, the local* NameCert *surface consists of five finite obligations:*

1. *carrier exposure: every accepted packet exposes exactly the rows $L = (M, K, F, P, R, H, C, N)$;*
2. *metric source compatibility: the finite-net, pointwise-modulus, and rational-fold rows are read over the same* $\mathsf{Met}^{\uparrow}$ *source row M;*
3. *compact-continuous alignment: the probe centers supplied by K and P are the centers at which the pointwise-modulus rows of F are consumed;*
4. *finite-fold precision: the* $\mathsf{Rat}^{\uparrow}$ *row R is the only lower-bound fold available to the uniform-modulus consumer;*
5. *consumer non-escape: every uniform-modulus precision read factors through M, K, F, P, R, H, C, N and receives no host compactness, choice-selected modulus, quotient equality, or ambient completeness coordinate.*

Proof. Carrier exposure is projection from Definition 935.1. The rows M, K, F, P, R, H, C, N are coordinates of one finite BHist packet, so no consumer can read a hidden source row outside that tuple.

Metric source compatibility is enforced by the shared M coordinate. The compact finite-net row K, continuous pointwise-modulus row F, probe center assignment P, and rational lower fold R are all stored as routes over that displayed source metric.

Compact-continuous alignment is the role of P. A bundled center from K becomes a pointwise-modulus center for F only through the displayed probe-assignment row, and the hsame transports in H replay the same alignment after classifier comparison.

Finite-fold precision is supplied by R. The continuation rows in C route a tolerance request through the displayed finite bundle and then through the rational lower-bound fold before a precision row reaches the uniform-modulus consumer.

Finally, consumer non-escape follows from the package inventory. Since L has no coordinate for host compactness, open-cover choice, quotient metric equality, or ambient completeness, none of those principles can be read from the source-lock packet. The later Lean carrier for this same packet must provide Nontrivial and FieldFaithful instances in ‘TasteGate.lean‘ for the same source carrier, so the formal consumer cannot switch to a different carrier while preserving the source-lock rows. □

Theorem 935.3 (MetricSpace source-lock row exposure)**.** *Every accepted MetricSpace compact-continuity source-lock packet exposes exactly the displayed rows*

$$M, K, F, P, R, H, C, N$$

of Definition 935.1. Its public surface contains the $\mathsf{Met}^{\uparrow}$ *source row, the* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net row, the* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise-modulus row, the* $\mathsf{Rat}^{\uparrow}$ *lower-fold row, the* $\mathsf{UniformModulus}^{\uparrow}$ *consumer boundary, the* BHist *carrier ledger, the componentwise* hsame *transports, the displayed* Cont *routes, and the local* NameCert *row. It contains no hidden host compactness, quotient metric equality, open-cover selector, choice modulus, or ambient completeness row.*

Proof. Project the carrier tuple in Definition 935.1. The only rows named by the packet are M, K, F, P, R, H, C, N, and the row-exposure obligation in Definition 935.2 states that every accepted packet displays exactly that tuple.

The sibling anchors determine the interpretation of those rows. The $\mathsf{Met}^{\uparrow}$ row is the metric source, $\mathsf{CompactMetric}^{\uparrow}$ supplies finite-net data, $\mathsf{ContinuousMap}^{\uparrow}$ supplies pointwise-modulus data, $\mathsf{Rat}^{\uparrow}$ supplies the finite lower fold, and $\mathsf{UniformModulus}^{\uparrow}$ is reached only as the downstream consumer boundary.

The excluded principles are absent by carrier inventory. Since no coordinate of L is a host compactness witness, quotient equality proof, open-cover selector, choice-selected modulus, or ambient completeness row, a public read from the packet cannot expose one. □

Theorem 935.4 (MetricSpace source-lock center alignment)**.** *In every accepted MetricSpace compact-continuity source-lock packet, the K finite-net centers, the P* ProbeBundle *assignment rows, and the F pointwise-modulus rows are read over the same* $\mathsf{Met}^{\uparrow}$ *source row M. Transport between the* $\mathsf{CompactMetric}^{\uparrow}$ *finite-net surface, the* $\mathsf{ContinuousMap}^{\uparrow}$ *pointwise surface, the* $\mathsf{Rat}^{\uparrow}$ *lower-fold surface, and the* $\mathsf{UniformModulus}^{\uparrow}$ *consumer boundary is permitted only through the displayed H componentwise* hsame *rows and the displayed C* Cont *rows.*

Proof. Read the metric source compatibility and compact-continuous alignment clauses of Definition 935.2. They bind K, F, P, R to the single source coordinate M in Definition 935.1.

The center route is therefore unique inside the packet. A center exposed by the $\mathsf{CompactMetric}^{\uparrow}$ row K reaches a $\mathsf{ContinuousMap}^{\uparrow}$ pointwise-modulus row in F only through the ProbeBundle assignment row P.

Transport does not add a second source. The displayed H rows replay componentwise hsame comparison, and the displayed C rows replay the Cont routes from $\mathsf{Met}^{\uparrow}$ through $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, and toward $\mathsf{UniformModulus}^{\uparrow}$. □

Theorem 935.5 (MetricSpace source-lock uniform-modulus nonescape)**.** *Any uniform-modulus precision read from an accepted MetricSpace compact-continuity source-lock packet factors through the displayed rows*

$$M, K, F, P, R, H, C, N.$$

In particular, the $\mathsf{Rat}^{\uparrow}$ *lower-fold row R must be consumed before any* $\mathsf{UniformModulus}^{\uparrow}$ *precision row is public, and no precision read can bypass the* $\mathsf{Met}^{\uparrow}$, $\mathsf{CompactMetric}^{\uparrow}$, $\mathsf{ContinuousMap}^{\uparrow}$, ProbeBundle, BHist, hsame, Cont, *and* NameCert *rows displayed by the source lock.*

Proof. Start from the finite-fold precision and consumer non-escape clauses of Definition 935.2. They state that a tolerance-to-precision read is routed through the rational lower-bound fold and through the exposed packet inventory.

The factorization is exactly the carrier route in Definition 935.1. The source $\mathsf{Met}^{\uparrow}$ row M, finite-net $\mathsf{CompactMetric}^{\uparrow}$ row K, pointwise $\mathsf{ContinuousMap}^{\uparrow}$ row F, probe-assignment row P, and $\mathsf{Rat}^{\uparrow}$ lower-fold row R are read before the continuation boundary reaches $\mathsf{UniformModulus}^{\uparrow}$.

Thus R is not an optional scalar witness. It is the displayed finite lower-fold row that the continuation rows C consume before the precision row becomes public, with H and N preserving the same source-lock identity. □

Closure status for $\mathsf{NameCert}_{\mathrm{MetricSpaceCompactContinuitySourceLockUp}}$.

Constructive story: A MetricSpace compact-continuity source-lock packet is generated from a MetricSpaceUp distance row, CompactMetricUp finite-net row, ContinuousMapUp pointwise-modulus row, ProbeBundle center assignment, RatUp finite-fold ledger, componentwise hsame transports, displayed Cont routes, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathrm{MetricSpaceCompactContinuitySourceLockUp}}$, seed)

Scope closed: Definition 935.1 and Definition 935.2 bind the metric source, compact finite-net, continuous pointwise-modulus, ProbeBundle center-assignment, RatUp lower-fold, transport, continuation, and consumer non-escape rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathrm{MetricSpaceCompactContinuitySourceLockUp}}$, unformalized)

Bridge status: none

Not claimed: This chapter does not close a Lean carrier, a checked TasteGate instance, a public exported NameCert theorem, host compactness, open-cover compactness, choice-selected moduli, or ambient completeness.

Upgrade path: Obligation closure requires a Lean carrier for the finite source-lock packet plus TasteGate, Nontrivial, FieldFaithful, and checked non-escape declarations for the same carrier.

Chapter 936

A Concrete Naming Certificate for $\mathsf{ZNormal}^{\uparrow}$

The $\mathsf{ZNormal}^{\uparrow}$ packet realizes the total-host boundary named by chapter 9370 as finite normal-form certificate data. It sits beside the typed endpoint packet of chapter 562, the finite Zeckendorf normal-form packet of chapter 278, and the terminal continuation packet of chapter 683. The packet records terminal normality, bounded fuel replay, and non-escape from total host evidence without exporting a divergence oracle, host conversion row, or global normalization procedure.

Falsifiable prediction: Every accepted ZNormalUp packet exposes a finite terminal-normality row and admits no consumer route to a divergence oracle or host conversion row.

Independence witness: Nearest siblings: typedreductionnormalform, zeckendorf-normal, zcarry, continuationtracenormalform, and normalformconsistencyseal. None is bijective to $\mathsf{ZNormal}^{\uparrow}$ because typedreductionnormalform records a typed endpoint route, zeckendorf-normal records a finite combinatorial normal-word classifier, zcarry records a local carry classifier, continuation-tracenormalform records a terminal continuation trace, and normalformconsistencyseal records a consistency-facing seal; $\mathsf{ZNormal}^{\uparrow}$ keeps the total-host normal-form boundary itself as a finite packet.

Definition 936.1 ($\mathsf{ZNormal}^{\uparrow}$ carrier)**.** *A* $\mathsf{ZNormal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

with the following displayed rows:

1. *T is the typed reduction normal-form row read through* $\mathsf{TypedReductionNormalForm}^{\uparrow}$*;*
2. *F is the finite fuel row naming the bounded host reduction segment;*
3. *V is the terminal-normality row asserting that the segment ends at a normal form;*
4. *K is the Zeckendorf and carry-facing normal-form comparison row read through* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *and* $\mathsf{ZCarry}^{\uparrow}$ *where a finite word boundary is present;*
5. *R is the continuation terminal-read row read through* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$*;*
6. *H records componentwise* hsame *transport for typed endpoint, fuel, terminal normality, finite word comparison, continuation read, provenance, and local naming rows;*

7. *C records the displayed* Cont *routes from typed endpoint to fuel replay, from fuel replay to terminal normality, from terminal normality to the continuation read, and from those rows to the consumer-facing packet boundary;*
8. *P is the* Pkg *provenance over chapter 9370, chapter 562, chapter 278, chapter 683,* BHist*,* hsame*,* Cont*, and* NameCert*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ *row.*

The carrier accepts only packets whose normal-form claim is read through a finite terminal row. It has no coordinate for a divergence oracle, host conversion row, quotient computation, unrestricted evaluator, or ambient proof that every external computation halts.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal readback semantic certificate`

Theorem 936.2 ($\mathsf{ZNormal}^\uparrow$ NameCert obligations)**.** *For the carrier of Definition 936.1, the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ *surface consists exactly of carrier admission for*

$$Z = (T, F, V, K, R, H, C, P, N),$$

typed endpoint readback through T, finite fuel exposure through F, terminal-normality exposure through V, finite normal-word comparison through K, continuation terminal-read exposure through R, componentwise transport through H, displayed route replay through C, package provenance through P, and local naming through N.

Proof. Project the carrier. The rows $T, F, V, K, R, H, C, P, N$ are the only fields of an accepted $\mathsf{ZNormal}^\uparrow$ packet.

Read the endpoint rows first. The typed reduction row T is supplied by chapter 562; the finite fuel row F and terminal-normality row V bind that endpoint to a displayed total-host reduction segment.

Read the sibling normal-form rows next. The row K may cite the finite word discipline of chapter 278, while R may cite the terminal trace surface of chapter 683. These rows are auxiliary certificate coordinates, not routes to host conversion or general normalization.

Finally inspect H, C, P, N. They transport, replay, package, and name the same finite surface. Since no carrier coordinate names divergence, quotient computation, host conversion, or an unrestricted evaluator, the listed obligations exhaust the packet. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket namecert obligations`

Theorem 936.3 ($\mathsf{ZNormal}^\uparrow$ carry normalization obligation)**.** *For every accepted* $\mathsf{ZNormal}^\uparrow$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the row K is obligated to expose finite normal-word evidence through the $\mathsf{ZeckendorfNormal}^\uparrow$ *surface of chapter 278 and the local carry evidence of chapter 544. The exposure is a* BHist *row transported by* hsame*, replayed by* Cont*, packaged by* Pkg*, and named by* $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$*; it is not a host conversion row, quotient computation, unrestricted evaluator, or global normalizer.*

Proof. Project the carrier of Definition 936.1. The only finite normal-word comparison coordinate is K, and it is listed beside the typed endpoint, fuel, terminal-normality, and continuation rows rather than outside the packet.

Use the NameCert obligation surface of Definition 936.2. It binds K to the same BHist, hsame, Cont, Pkg, and local naming rows as the rest of the accepted packet.

The sibling evidence is then read through the Zeckendorf and carry-facing chapters named in the carrier. Since the carrier has no coordinate for host conversion, quotient computation, unrestricted evaluation, or global normalization, the K obligation is exactly finite normal-word and carry evidence. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalCarryNormalizationObligation`

Theorem 936.4 ($\mathsf{ZNormal}^{\uparrow}$ continuation terminal route)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the continuation row R is reached only after the typed endpoint T, finite fuel F, and terminal-normality row V have been displayed. Its consumer route is the* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *terminal-read surface of chapter 683 transported through H, replayed through C, packaged through P, and named through N.*

Proof. Start from the finite packet $Z = (T, F, V, K, R, H, C, P, N)$. The row order places R after T, F, V and makes it a continuation terminal-read row, not a source of unbounded evaluation.

Apply Definition 936.2. The theorem exposes typed endpoint readback, finite fuel, terminal normality, continuation terminal-read, and the structural rows in one local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface.

Now read the sibling terminal trace through chapter 683. The transport, continuation, package, and naming rows are H, C, P, N, so no host conversion, quotient computation, unrestricted evaluator, or global normalizer can replace the terminal continuation route. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalContinuationTerminalRoute`

Theorem 936.5 ($\mathsf{ZNormal}^{\uparrow}$ typed boundary exhaustion)**.** *Every consumer of the displayed* $\mathsf{ZNormal}^{\uparrow}$ *rows*

$$T, F, V, K, R, H, C, P, N$$

must factor through the typed endpoint of chapter 562, the finite normal-word and carry row of Definition 936.3, the continuation terminal route of Definition 936.4, and the local BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows. The boundary exports no host conversion, quotient computation, unrestricted evaluator, divergence oracle, or global normalizer.*

Proof. First expose the typed side. The carrier definition and Definition 936.2 make T, F, V the displayed route from typed endpoint through finite fuel to terminal normality.

Next expose the two downstream rows. The carry-normalization obligation fixes K as finite Zeckendorf and carry evidence, while the continuation-terminal theorem fixes R as the terminal read through the displayed continuation trace.

Finally collect H, C, P, N. These rows provide the only componentwise transport, replay, provenance, and local naming surface for all consumer reads. Since none of the cited rows contains host conversion, quotient computation, unrestricted evaluation, divergence detection, or global normalization, the typed boundary is exhausted by the displayed packet. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket typed boundary exhaustion`

Theorem 936.6 ($\mathsf{ZNormal}^{\uparrow}$ fuel normality non-escape)**.** *Every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet exposes its terminal normal-form claim only through the finite route*

$$T \longmapsto F \longmapsto V \longmapsto R$$

with the normal-word comparison row K available only as displayed sibling evidence. No consumer can use the packet to read a divergence oracle, a host conversion row, a quotient computation, an unrestricted evaluator, or a global normalizer.

Proof. Start from the typed endpoint row T. By construction it is a packet-visible endpoint row rather than a host conversion judgment.

Next read F and V. The fuel row names the finite replay segment, and the terminal-normality row records the endpoint of that segment. A consumer therefore receives a bounded normal-form packet, not an unbounded computation.

Use R and K only after the terminal row is displayed. The continuation trace row replays the terminal read, while the Zeckendorf and carry-facing row records finite word comparison where that sibling surface is relevant.

The excluded objects have no carrier coordinate. Thus transport, continuation replay, provenance, and local naming cannot manufacture a divergence oracle, host conversion row, quotient computation, unrestricted evaluator, or global normalizer from the accepted packet. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket fuel normality nonescape`

Theorem 936.7 ($\mathsf{ZNormal}^{\uparrow}$ total-host boundary)**.** *The* $\mathsf{ZNormal}^{\uparrow}$ *packet gives a concrete finite interface for the host-side total-language boundary of chapter 9370. A public consumer may read the typed endpoint, finite fuel, terminal normality, finite normal-word comparison, continuation terminal read, transports, routes, provenance, and local name of*

$$Z = (T, F, V, K, R, H, C, P, N),$$

but it may not reread this surface as Turing completeness of the host, as a proof that every substrate computation halts, or as a route from substrate universality to host-level partial functions.

Proof. First bind the host-side surface. The carrier of Definition 936.1 records exactly the typed endpoint, finite replay, terminal-normality, sibling normal-word, continuation-read, transport, route, provenance, and naming rows.

Then compare this surface with chapter 9370. That chapter separates the total host from the universal substrate. The $\mathsf{ZNormal}^{\uparrow}$ packet inhabits the host side of that separation because every accepted read is through finite terminal-normality rows.

Finally apply Definition 936.6. It excludes divergence, host conversion, quotient computation, unrestricted evaluation, and global normalization routes. Consequently no consumer can turn the finite normal-form packet into host Turing completeness or a substrate halting theorem. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host boundary`

Theorem 936.8 ($\mathsf{ZNormal}^{\uparrow}$ terminal readback exactness)**.** *For any accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

every terminal read factors through the displayed rows T, F, V, R, H, C, P, N*. The read may consume the sibling normal-word row* K *only after the terminal-normality row* V *is displayed, and it cannot consult host conversion, quotient computation, unrestricted evaluation, or a global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTerminalReadbackExactness`

Proof. Project the carrier of Definition 936.1. The terminal read row is R, and the only rows before it are the typed endpoint T, the finite fuel row F, and the terminal-normality row V.

Use the displayed continuation routes in C. They replay the path from T through F and V to R, while H, P, N transport, package, and name that same route.

The row K is a sibling normal-word coordinate rather than a terminal readback source. Since no coordinate names host conversion, quotient computation, unrestricted evaluation, or a global normalizer, every accepted terminal read is exactly the displayed finite readback surface. □

Theorem 936.9 (ZNormal$^{\uparrow}$ terminal fuel route admission)**.** *For any accepted* ZNormal$^{\uparrow}$ *packet, every terminal read must expose the finite sequence T, F, V, R before consumer use. The sequence is transported only by the displayed* hsame *row H, replayed only by the displayed* Cont *row C, packaged only by P, and named only by N.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal fuel route admission`

Proof. Project the carrier of Definition 936.1. The terminal-facing rows are the typed endpoint T, finite fuel F, terminal-normality row V, and continuation terminal-read row R.

Use Definition 936.4 and Definition 936.8. They place R after T, F, V and keep the terminal read inside the displayed finite route.

The structural rows are exactly H, C, P, N. They transport, replay, package, and name the route, and no other carrier coordinate can admit a terminal read before the finite fuel and terminal-normality rows have been displayed. □

Theorem 936.10 (ZNormal$^{\uparrow}$ finite host boundary refusal)**.** *No accepted* ZNormal$^{\uparrow}$ *packet route can replace the displayed rows T, F, V, R by host conversion, quotient computation, divergence oracle, unrestricted evaluator, or global normalizer. Every accepted route remains a* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*-local read of the finite carrier.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalFiniteHostBoundaryRefusal`

Proof. Begin with the carrier of Definition 936.1. It lists $T, F, V, K, R, H, C, P, N$ as the complete packet and names no host conversion row, quotient computation, divergence oracle, unrestricted evaluator, or global normalizer.

Apply Definition 936.6 and Definition 936.9. The terminal claim is read through finite fuel and terminal normality before the continuation row is consumed.

Finally use Definition 936.13. The only movement available to the packet is through H, C, P, N, so an accepted route cannot substitute any excluded host or quotient object for the displayed terminal fuel rows. □

Theorem 936.11 (ZNormal$^{\uparrow}$ sibling normal-word handoff)**.** *The K row of an accepted* ZNormal$^{\uparrow}$ *packet may consume the sibling surfaces of chapter 562, chapter 278, chapter 544, and chapter 683 only as displayed finite evidence. It does not provide host computation, a conversion oracle, a quotient normalizer, or a proof that all external computations normalize.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket sibling normalword handoff`

Proof. Read the sibling handoff through the carrier coordinates. The typed endpoint row T, finite fuel row F, terminal row V, comparison row K, and continuation row R are separate displayed fields.

The cited sibling chapters supply finite certificate surfaces: typed endpoint evidence, finite Zeckendorf normal-word evidence, local carry evidence, and terminal continuation-trace evidence. The K row can package those surfaces only through the displayed hsame, Cont, Pkg, and NameCert rows of the accepted packet.

No carrier coordinate supplies a host computation relation, conversion oracle, quotient normalizer, or external normalization theorem. Thus the sibling handoff remains finite evidence rather than a route to total host computation beyond the packet. □

Theorem 936.12 ($\mathsf{ZNormal}^{\uparrow}$ obligation closure package)**.** *The carrier admission of Definition 936.1, the NameCert obligations of Definition 936.2, the fuel non-escape boundary of Definition 936.6, the total-host boundary of Definition 936.7, the terminal readback exactness of Definition 936.8, and the sibling normal-word handoff of Definition 936.11 assemble the five-row* obligation *surface for* $\mathsf{ZNormal}^{\uparrow}$ *over* $T, F, V, K, R, H, C, P, N$.

Proof. First fix the accepted carrier $Z = (T, F, V, K, R, H, C, P, N)$. Carrier admission and local naming expose only the rows listed in Definition 936.1.

Apply Definition 936.2 to bind the NameCert surface. Then use Definition 936.6 and Definition 936.7 to keep every consumer read inside finite fuel, terminal normality, continuation readback, and total-host boundary evidence.

Finally use Definition 936.8 and Definition 936.11. These identify the terminal read and the sibling normal-word handoff as displayed finite rows, so the carrier, NameCert, fuel, terminal readback, sibling handoff, and host-boundary components form one obligation package. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket obligation closure package`

Theorem 936.13 ($\mathsf{ZNormal}^{\uparrow}$ route transport)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the route from the typed endpoint row T through finite fuel F, terminal normality V, the sibling normal-word row K, and the terminal continuation read R is transported only by the displayed componentwise row H and replayed only by the displayed continuation row C. No accepted route can insert host conversion, quotient computation, unrestricted evaluation, or a global normalizer between these coordinates.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRouteTransport`

Proof. Project the accepted packet through Definition 936.1. The only route-bearing coordinates exposed by the carrier are the componentwise transport row H and the continuation replay row C.

Apply Definition 936.2 to bind these rows to the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface. Then use Definition 936.6 to keep the path from T through F and V inside finite fuel and terminal-normality evidence.

Finally apply Definition 936.8 and Definition 936.11. The terminal read and sibling normal-word row are reached through the same displayed transport and replay rows, so no external normalizer or host computation route is available. □

The root surface consumes sibling finite evidence before terminal readback is available. The row K is the sibling handoff row: it reads the finite normal-word carrier of chapter 278 and the carry classifier of chapter 544 as displayed BHist evidence. Without those two sibling rows, the terminal normality route cannot be read as finite Zeckendorf and carry evidence inside the $\mathsf{ZNormal}^{\uparrow}$ packet.

Theorem 936.14 ($\mathsf{ZNormal}^{\uparrow}$ root terminal non-escape interface)**.** *Every root consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet must read terminal normality through the displayed path*

$$T \to F \to V \to R,$$

with K available only as finite sibling normal-word and carry evidence from $\mathsf{ZeckendorfNormal}^{\uparrow}$ *and* $\mathsf{ZCarry}^{\uparrow}$*. No host conversion, quotient computation, unrestricted evaluator, divergence oracle, or global normalizer can enter the root-facing interface.*

Proof. Begin with Definition 936.6. It places the terminal normal-form claim on the finite route from typed endpoint T through fuel F and terminal row V to continuation read R.

Apply Definition 936.8. The terminal read factors through T, F, V, R, H, C, P, N, and the row K is consumed only after V is already displayed.

Use Definition 936.11 to identify K as finite sibling evidence from $\mathsf{ZeckendorfNormal}^{\uparrow}$ and $\mathsf{ZCarry}^{\uparrow}$. Then apply Definition 936.13 to keep the whole root route inside H, C, P, N without host conversion, quotient computation, unrestricted evaluation, divergence, or global normalization. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root terminal nonescape interface`

Theorem 936.15 ($\mathsf{ZNormal}^{\uparrow}$ root carrier exposure)**.** *Every root consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet first sees exactly the displayed tuple*

$$Z = (T, F, V, K, R, H, C, P, N).$$

The rows expose the typed endpoint, finite fuel, terminal normality, sibling normal-word evidence, terminal readback, componentwise hsame *transport, displayed* Cont *replay, package provenance, and local* NameCert *naming. No root-unblock consumer receives a divergence oracle, host conversion row, quotient computation, unrestricted evaluator, or global normalizer outside those coordinates.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root unblock carrier exposure`

Proof. Project the carrier of Definition 936.1. It lists $T, F, V, K, R, H, C, P, N$ as the complete finite packet and gives no other coordinate to a root consumer.

Apply Definition 936.2. The NameCert surface identifies the same fields as the complete local naming, transport, route, provenance, and package surface.

Use Definition 936.6 and the displayed TasteGate contract row. The finite fuel boundary and the carrier-faithful TasteGate reading keep the exposed tuple from becoming a route to host conversion, quotient computation, unrestricted evaluation, divergence, or global normalization. □

Theorem 936.16 ($\mathsf{ZNormal}^{\uparrow}$ root terminal route)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the terminal normal-form route used by root consumers is*

$$T \to F \to V \to R,$$

with K available only as sibling normal-word evidence. The route is transported through H, replayed through C, packaged through P, and named through N; it cannot be replaced by host conversion, quotient computation, unrestricted evaluation, or global normalization.

Proof. Begin with Definition 936.6. It already binds terminal normality to the finite path from the typed endpoint T through fuel F and terminal row V to the continuation read R.

Apply Definition 936.8. The theorem makes R the exact terminal readback row and permits K only after V has been displayed.

Finally combine Definition 936.11 with Definition 936.13. The sibling row remains finite evidence, while H, C, P, N transport, replay, package, and name the same terminal route without adding any excluded host or global normalization object. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootTerminalRouteHostTailExclusion`

Theorem 936.17 ($\mathsf{ZNormal}^{\uparrow}$ root non-escape ledger)**.** *The root-unblock ledger of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet is exhausted by carrier admission, NameCert obligations, finite fuel non-escape, terminal readback exactness, sibling normal-word handoff, and route transport. Thus every downstream normal-form row must pass through*

$$T, F, V, K, R, H, C, P, N$$

and the finite sibling surfaces named by K*, while host conversion, quotient computation, unrestricted evaluation, divergence detection, and global normalization remain absent.*

Proof. First assemble the carrier and naming rows using Definition 936.1 and Definition 936.2. They expose the packet fields and no separate host computation surface.

Next apply Definition 936.6, Definition 936.8, and Definition 936.11. These rows bind finite fuel, terminal readback, and sibling evidence to the displayed packet.

Finally use Definition 936.13 together with the displayed TasteGate contract row. Transport and replay stay inside H, C, P, N, so the ledger has no coordinate for host conversion, quotient computation, unrestricted evaluation, divergence detection, or global normalization. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootUnblockNonescapeLedger`

Theorem 936.18 ($\mathsf{ZNormal}^{\uparrow}$ normal output boundary)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the public normal-output row is exactly the terminal-normality row V *together with the terminal read row* R*. This output boundary exports no divergence oracle, host conversion, quotient computation, unrestricted evaluator, global normalizer, or total host-computation principle.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket normal output boundary`

Proof. Project the carrier of Definition 936.1. The normal-output data are displayed as V and R, while T, F, K, H, C, P, N only type, fuel, compare, transport, replay, package, and name that same finite packet.

Use Definition 936.2 to make the projection a local certificate read. The finite-output claim is then constrained by Definition 936.6, which excludes divergence and unrestricted evaluation at the fuel boundary.

The terminal side is fixed by Definition 936.8, and the sibling side is fixed by Definition 936.11. Together they show that V with R is the whole public normal-output boundary and that no host conversion, quotient computation, or global normalizer is exported. □

Theorem 936.19 ($\mathsf{ZNormal}^{\uparrow}$ consumer non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

factors through the displayed rows $T, F, V, K, R, H, C, P, N$ *and the finite sibling surfaces cited in Definition 936.11. The consumer obtains no route to host conversion, quotient computation, unrestricted evaluation, global normalization, divergence detection, or total host computation outside those rows.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket consumer nonescape`

Proof. Project Z through Definition 936.1. This exposes the typed endpoint, fuel, terminal normality, sibling normal-word, terminal read, transport, continuation, provenance, and naming rows as the complete consumer surface.

Apply Definition 936.2. The certificate admits consumer reads only through those displayed coordinates and their local $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ provenance.

The finite boundary is inherited from Definition 936.6 and Definition 936.8. The only sibling handoff available to downstream chapters is the finite handoff of Definition 936.11. Hence every consumer factors through the displayed packet and cannot escape to any omitted host or global normalization object. □

The follow-up Lean TasteGate.lean contract for this chapter must provide `Nontrivial ZNormalUp` and `FieldFaithful ZNormalUp` instances for the same carrier.

Theorem 936.20 ($\mathsf{ZNormal}^\uparrow$ carrier obligation row)**.** *For every accepted* $\mathsf{ZNormal}^\uparrow$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

carrier admission binds the typed endpoint row T, finite fuel row F, terminal-normality row V, Zeckendorf and carry-facing comparison row K, continuation terminal-read row R, componentwise hsame *row H, displayed* Cont *row C, package row P, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ *row N to the same finite* BHist *surface. The carrier row exports no host conversion, quotient computation, unrestricted evaluator, divergence oracle, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalCarrierObligationRow`

Proof. Project the carrier of Definition 936.1. It displays exactly $T, F, V, K, R, H, C, P, N$ and gives no additional coordinate to a root consumer.

Apply Definition 936.2. The local NameCert surface reads those fields as carrier admission, endpoint exposure, finite fuel, terminal normality, sibling comparison, terminal read, transport, route, provenance, and naming for the same packet.

Use Definition 936.6 and Definition 936.8. They keep the carrier read inside finite fuel and terminal readback rows, so the excluded host and global-normalization objects cannot be recovered from carrier admission. □

Theorem 936.21 ($\mathsf{ZNormal}^\uparrow$ carry classifier row)**.** *For every accepted* $\mathsf{ZNormal}^\uparrow$ *packet, the comparison coordinate K is the only ZeckendorfNormal and ZCarry classifier surface. It is read as a* BHist *row transported by H, replayed by C, packaged by P, and named by N after the typed endpoint, finite fuel, and terminal-normality rows have been displayed. It is not a host conversion row, quotient computation, unrestricted evaluator, divergence oracle, or global normalizer.*

Proof. Start from Definition 936.1 and Definition 936.2. They place K inside the same finite packet as T, F, V, R, H, C, P, N and bind it to the local $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ route.

Apply Definition 936.3 and Definition 936.11. These theorems identify the K row with the finite ZeckendorfNormal and ZCarry comparison surface rather than with host computation.

Finally use Definition 936.13. The comparison row is transported and replayed only through H and C, then packaged and named by P, N, so no quotient computation, unrestricted evaluator, divergence oracle, or global normalizer can enter the classifier row. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalCarryClassifierRow`

Theorem 936.22 ($\mathsf{ZNormal}^{\uparrow}$ normal-form ledger row)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, terminal normality is recorded only by the ledger route through*

$$T, F, V, R, H, C, P, N,$$

with K available as the finite sibling comparison row named by Definition 936.21. The ledger binds the terminal-normality claim to BHist*,* Cont*,* hsame*,* Pkg*, and* NameCert *rows and exports no host conversion, quotient computation, unrestricted evaluator, divergence oracle, or global normalizer.*

Proof. Use Definition 936.20 to expose the displayed packet and no other terminal-normality coordinates. The terminal row is V, and the continuation read is R.

Apply Definition 936.6 and Definition 936.8. These theorems force terminal normality through the finite fuel path T, F, V, R and keep readback inside the displayed packet.

Now apply Definition 936.21 and Definition 936.13. The sibling comparison row remains finite evidence, while H, C, P, N provide the only transport, replay, package, and naming surface for the normal-form ledger. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket normal form ledger row`

Theorem 936.23 ($\mathsf{ZNormal}^{\uparrow}$ terminal-host boundary row)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

terminal-host use of $\mathsf{ZNormal}^{\uparrow}$ *must factor through the typed endpoint row T, finite fuel row F, terminal-normality row V, continuation terminal-read row R, sibling normal-word row K, and the structural rows H, C, P, N. No consumer of this terminal-host boundary may read host conversion, quotient computation, unrestricted evaluator, divergence oracle, substrate halting, or global normalizer outside that finite BEDC packet.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal host boundary`

Proof. Project Definition 936.1. The displayed carrier gives the typed endpoint, finite fuel, terminal-normality, continuation readback, sibling normal-word evidence, transports, continuations, package provenance, and NameCert row as the only terminal-host coordinates.

Apply Definition 936.22 and Definition 936.21. The normal-form ledger binds T, F, V, R, H, C, P, N, while the classifier row identifies K as finite sibling normal-word evidence rather than host computation.

Use Definition 936.4 and Definition 936.6. These force the continuation read and terminal-normality claim through finite fuel and terminal route data, so the host-side boundary is only finite BEDC packet data and exposes none of the excluded host or global-normalization objects. □

Theorem 936.24 ($\mathsf{ZNormal}^{\uparrow}$ root visible source package)**.** *Every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet exposes the typed endpoint row T, finite fuel row F, terminal-normality row V, carry and Zeckendorf normal-word row K, continuation trace row R,* hsame *row H,* Cont *row C,* Pkg *row P, and local* NameCert *row N before any normal-output read. No normal output consumer can read a host conversion, quotient normalizer, unrestricted evaluator, divergence oracle, or global normalizer outside that finite root package.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root visible source package`

Proof. Project the carrier of Definition 936.1. The displayed rows $T, F, V, K, R, H, C, P, N$ are the only root coordinates available to a normal-output consumer.

Use the carrier obligation, normal-form ledger, and normal-output boundary theorems. They force terminal normality through T, F, V, R and keep the sibling normal-word evidence in the finite comparison row K.

The structural rows then exhaust transport, continuation replay, package provenance, and local naming. Since the carrier has no host conversion, quotient-normalizer, unrestricted-evaluator, divergence-oracle, or global normalizer coordinate, the visible source package is exactly the displayed root packet. □

Theorem 936.25 ($\mathsf{ZNormal}^{\uparrow}$ root normal-word route totality)**.** *The finite normal-word route of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors through chapter 278, chapter 544, and the local carrier rows* $T, F, V, K, R, H, C, P, N$*. It exports a carry and Zeckendorf normal-word surface only through the row* K*, with no host conversion, quotient normalizer, unrestricted evaluator, divergence oracle, or global normalizer.*

Proof. Start from the visible source package of Definition 936.24. It places every normal-output read inside the local packet before the normal-word row can be consumed.

Apply the carry normalization obligation and sibling normal-word handoff. These identify K as the finite route through the Zeckendorf normal and ZCarry siblings, rather than a host computation or quotient normalization procedure.

Finally use route transport. The K row is carried only by H, replayed only by C, packaged only by P, and named only by N. The route is therefore total over the displayed finite packet and leaves no coordinate for the excluded global or host-side objects. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root normalword route totality`

Theorem 936.26 ($\mathsf{ZNormal}^{\uparrow}$ root continuation terminal exhaustion)**.** *Every continuation-terminal read of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet passes through chapter 683 and the local rows* T, F, V, R, H, C, P, N*. The read exports no unrestricted evaluator, divergence oracle, host conversion, quotient normalizer, substrate halting row, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root continuation terminal exhaustion`

Proof. Begin with the continuation terminal route. It places terminal readback in the row R after the typed endpoint T, finite fuel F, and terminal-normality row V have been displayed.

Use the continuation-trace normal-form sibling route together with terminal readback exactness. These rows make the terminal read a finite continuation trace, not an unrestricted evaluator or divergence oracle.

The structural rows H, C, P, N then transport, replay, package, and name the same finite terminal route. Carrier exhaustion leaves no host conversion, quotient normalizer, substrate halting coordinate, or global normalizer to export. □

Theorem 936.27 ($\mathsf{ZNormal}^{\uparrow}$ root carrier total-host readiness)**.** *Every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet exposes the typed endpoint row* T*, finite fuel row* F*, terminal-normality row* V*, carry and normal-word row* K*, continuation terminal route* R*, componentwise* hsame *row* H*, displayed* Cont *row* C*,* Pkg *row* P*, and local* $\mathsf{NameCert}$ *row* N *before any total-host read. A total-host consumer receives only this finite root package and cannot read host conversion, quotient normalizer, unrestricted evaluator, divergence oracle, substrate halting row, or global normalizer outside it.*

Proof. Project the carrier of Definition 936.1. The tuple $Z = (T, F, V, K, R, H, C, P, N)$ lists every root coordinate available before a total-host read.

Use Definition 936.24 and Definition 936.23. These rows place typed endpoint, fuel, terminal normality, sibling normal-word evidence, continuation readback, transports, continuations, package provenance, and local naming on the visible terminal-host route.

Apply Definition 936.17. Since the non-escape ledger exhausts the carrier and structural rows, no host conversion, quotient normalizer, unrestricted evaluator, divergence oracle, substrate halting row, or global normalizer can be read outside the displayed packet. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root carrier total host readiness`

Theorem 936.28 ($\mathsf{ZNormal}^{\uparrow}$ root continuation-trace readiness)**.** *Every continuation-trace consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet must factor through Definition 936.4, Definition 936.14, and Definition 936.16. The continuation read is therefore reached only after* T, F, V *have been displayed, with* K *available as finite sibling normal-word evidence and* H, C, P, N *providing only transport, replay, provenance, and naming.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root continuation trace readiness`

Proof. Start with Definition 936.4. It places the continuation row R after the typed endpoint, finite fuel, and terminal-normality rows.

Next use Definition 936.14. The root-facing interface keeps the terminal route on $T \to F \to V \to R$ and treats K only as finite sibling evidence.

Finally apply Definition 936.16. The terminal route is transported through H, replayed through C, packaged through P, and named through N, with no replacement by host conversion, quotient computation, unrestricted evaluation, divergence, or global normalization. □

Theorem 936.29 ($\mathsf{ZNormal}^{\uparrow}$ root NameCert readiness)**.** *The displayed carrier and continuation rows of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet give a local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *readiness surface for downstream normal-form consumers. The surface consists of* $T, F, V, K, R, H, C, P, N$ *with the continuation route constrained by the root terminal interface, and it exports no host conversion, quotient normalizer, divergence oracle, or global normalization procedure.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root namecert readiness surface`

Proof. Begin with Definition 936.2. It identifies carrier admission, typed endpoint readback, finite fuel, terminal normality, sibling normal-word comparison, continuation terminal-read exposure, transport, replay, provenance, and local naming as the complete $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface.

Apply Definition 936.27 to make the carrier rows visible before any total-host use. Then apply Definition 936.28 to force continuation-trace consumers through the terminal route rather than an ambient evaluator.

The same carrier exhaustion proves the exclusion clause. No displayed coordinate names host conversion, a quotient normalizer, a divergence oracle, or a global normalization procedure, so the local NameCert readiness surface cannot export one. □

Theorem 936.30 ($\mathsf{ZNormal}^{\uparrow}$ frontier carry readback totality)**.** *Every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet that exposes normal-word evidence is a* BHist *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

whose finite word row K reads $\mathsf{ZeckendorfNormal}^{\uparrow}$ *and* $\mathsf{ZCarry}^{\uparrow}$ *before the local K row is consumed by any root-facing normal-form reader. The readback route is transported by H, replayed by C, packaged by P, and named by N; it exports no host conversion, quotient normalizer, unrestricted evaluator, divergence oracle, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket frontier carry readback totality`

Proof. Project the carrier of Definition 936.1. The only coordinate that can expose finite normal-word evidence is K, and the carrier text binds that row to $\mathsf{ZeckendorfNormal}^{\uparrow}$ and $\mathsf{ZCarry}^{\uparrow}$ where a finite word boundary is present.

Apply Definition 936.3 and Definition 936.11. These force the normal-word evidence to be read through the Zeckendorf and carry sibling surfaces before a root-facing consumer uses the local K row.

Finally use Definition 936.29. The structural rows H, C, P, N transport, replay, package, and name the same evidence, while carrier exhaustion excludes host conversion, quotient normalization, unrestricted evaluation, divergence, and global normalization. □

Theorem 936.31 ($\mathsf{ZNormal}^{\uparrow}$ continuation normal-word pullback)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the continuation terminal route and the normal-word row form one finite pullback through*

$$H, C, P, N.$$

Thus a consumer that reads the terminal continuation row R and the finite normal-word row K receives them as one transported, replayed, packaged, and named BHist *packet over T, F, V, K, R, not as a terminal route detached from the Zeckendorf and carry-facing evidence.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket continuation normalword pullback`

Proof. Start with Definition 936.4. It places R after the typed endpoint T, finite fuel F, and terminal-normality row V.

Next apply Definition 936.30. The normal-word row K is already tied to $\mathsf{ZeckendorfNormal}^{\uparrow}$ and $\mathsf{ZCarry}^{\uparrow}$ before any root-facing readback consumes it.

Use Definition 936.13 to bind both routes through H and C, then use Definition 936.29 to package and name the shared surface through P and N. The result is one finite pullback packet through H, C, P, N. □

Theorem 936.32 ($\mathsf{ZNormal}^{\uparrow}$ total-host refusal exhaustion)**.** *Every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet exports no host conversion, quotient normalizer, unrestricted evaluator, divergence oracle, or global normalizer. Any total-host consumer must factor through the displayed* BHist *packet*

$$T, F, V, K, R, H, C, P, N$$

together with the finite sibling surfaces cited by K and R.

Proof. Project the root carrier from Definition 936.1. The displayed rows give typed endpoint, finite fuel, terminal normality, normal-word evidence, terminal continuation read, transport, replay, package provenance, and local naming, with no host conversion or global-normalization coordinate.

Apply Definition 936.27. It places all total-host reads inside the finite root package before any public normal-form consumer receives the packet.

Now combine Definition 936.31 with Definition 936.17. The pullback keeps K and R in the same transported packet, and the non-escape ledger exhausts all downstream reads through the listed rows.

Therefore the refused objects remain absent from the export surface. A consumer asking for host conversion, a quotient normalizer, an unrestricted evaluator, a divergence oracle, or a global normalizer asks for data outside the accepted $\mathsf{ZNormal}^{\uparrow}$ packet. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host refusal exhaustion`

Theorem 936.33 ($\mathsf{ZNormal}^{\uparrow}$ finite-fuel carrier admission)**.** *Every accepted* $\mathsf{ZNormal}^{\uparrow}$ *root packet is read from one finite* BHist *carrier*

$$Z = (T, F, V, K, R, H, C, P, N)$$

whose rows expose the typed endpoint T*, finite fuel* F*, terminal-normality row* V*, finite normal-word row* K*, terminal continuation row* R*, componentwise* hsame *transports* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *ledger* N*. A packet is accepted only when all nine rows are finite rows of that same carrier and no admission step replaces them by host conversion, quotient computation, unrestricted evaluation, a divergence oracle, or a global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootFiniteFuelAdmissionCertificate`

Proof. Project the displayed carrier of Definition 936.1. Its source rows are exactly $T, F, V, K, R, H, C, P, N$, and each is a finite coordinate of the same BHist packet.

Use Definition 936.2 to attach the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ row, and use Definition 936.6 to keep the finite-fuel and terminal-normality rows inside the displayed packet.

Apply Definition 936.8, Definition 936.11, and Definition 936.12. These bind the readback, normal-word, continuation, transport, package, and naming rows to the same finite carrier.

The non-export clause is carrier exhaustion. Since no coordinate names the excluded host or quotient objects, no accepted packet can expose one at admission. □

Theorem 936.34 ($\mathsf{ZNormal}^{\uparrow}$ terminal-normality consumer gate)**.** *Let*

$$Z = (T, F, V, K, R, H, C, P, N)$$

be an accepted $\mathsf{ZNormal}^{\uparrow}$ *packet. Any root consumer that reaches the continuation row* R *must first read the typed endpoint row* T*, the finite-fuel row* F*, and the terminal-normality row* V *in the same packet. The consumer may then read* R *only through the displayed continuation route and the transported* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows* H, C, P, N*.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal normality consumer gate`

Proof. Start from Definition 936.33. It supplies the only source rows available to a root consumer and places T, F, V, R in one finite packet.

Apply Definition 936.4. That route admits a continuation read only after the typed endpoint, finite fuel, and terminal-normality rows have been exposed.

Use Definition 936.31 and Definition 936.13. These keep the continuation read on the same finite route as the sibling normal-word handoff and transport the result only through H, C, P, N. □

Theorem 936.35 ($\mathsf{ZNormal}^{\uparrow}$ no-divergence oracle ledger)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the exported ledger consists only of the typed endpoint, finite fuel, terminal-normality, sibling normal-word, terminal continuation, transport, continuation, package, and naming rows $T, F, V, K, R, H, C, P, N$*. It cannot export a divergence oracle, host conversion, quotient computation, unrestricted evaluator, or global normalizer to any root, normal-form, or MetaCIC-facing consumer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket no divergence oracle ledger`

Proof. Begin with Definition 936.33. It supplies the finite inventory of the packet and rules out all coordinates not named by $T, F, V, K, R, H, C, P, N$.

Use Definition 936.34 for the continuation side and Definition 936.8 with Definition 936.11 for the normal-word side. Both reads remain finite route reads.

Apply Definition 936.17 and Definition 936.32. These exhaust root-facing reads through the displayed transport, continuation, package, and naming ledger, and refuse total-host requests that do not factor through the packet.

Thus the ledger has no exported coordinate from which a divergence oracle, host conversion, quotient computation, unrestricted evaluator, or global normalizer could be read. □

Theorem 936.36 ($\mathsf{ZNormal}^{\uparrow}$ terminal consumer totality)**.** *Let*

$$Z = (T, F, V, K, R, H, C, P, N)$$

be an accepted $\mathsf{ZNormal}^{\uparrow}$ *packet. Every terminal normal-form consumer that reads* R *or* K *must first pass through carrier admission, the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *obligations, terminal-normality consumer gate, and total-host refusal exhaustion. The consumer therefore reads only the typed endpoint, finite fuel, terminal-normality, finite normal-word, terminal continuation, transport, replay, package, and local naming rows* $T, F, V, K, R, H, C, P, N$.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTerminalConsumerTotality`

Proof. Start with finite-fuel carrier admission. Definition 936.33 exposes $T, F, V, K, R, H, C, P, N$ as one finite BHist packet and gives no coordinate outside that packet to a terminal consumer.

Next apply the NameCert obligations and the terminal-normality consumer gate. The obligation surface binds the local naming row to the carrier, while Definition 936.34 places any continuation read behind T, F, V and transports it only through H, C, P, N.

Finally use no-divergence and total-host refusal. Definition 936.35 and Definition 936.32 exhaust the terminal-facing reads by the displayed rows, so the consumer has no route to host conversion, quotient computation, unrestricted evaluation, a divergence oracle, or a global normalizer. □

Theorem 936.37 ($\mathsf{ZNormal}^{\uparrow}$ finite-route readback boundary)**.** *For an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

every downstream readback of a normal word or terminal continuation factors through the finite routes certified by Definition 936.8, Definition 936.11, and Definition 936.31. The readback boundary is $T, F, V, K, R, H, C, P, N$ *and no host conversion, quotient computation, divergence oracle, unrestricted evaluator, or global normalizer is exposed at that boundary.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalFiniteRouteReadbackBoundary`

Proof. Begin with the terminal readback exactness theorem. It makes R a readback row of the accepted packet rather than a host-side evaluator result.

Now attach the normal-word row. Definition 936.11 reads K through the finite sibling normal-word surfaces, and Definition 936.31 binds K and R into one transported and replayed route through H, C, P, N.

The total-host refusal theorem closes the boundary. Since any total-host request that does not factor through the packet is refused, the finite readback route cannot be replaced by host conversion, quotient computation, a divergence oracle, unrestricted evaluation, or global normalization. □

Theorem 936.38 ($\mathsf{ZNormal}^{\uparrow}$ downstream normal-form package)**.** *Every downstream normal-form consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors through the finite package*

$$Z = (T, F, V, K, R, H, C, P, N).$$

The package is assembled from carrier admission, local NameCert *obligations, terminal consumer totality, finite-route readback boundary, no-divergence ledger, continuation normal-word pullback, and total-host refusal exhaustion. It exports no host conversion, quotient computation, divergence oracle, unrestricted evaluator, total host computation, substrate halting row, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalDownstreamNormalFormPackage`

Proof. First expose the packet. The carrier admission theorem and the local NameCert obligations make $T, F, V, K, R, H, C, P, N$ the complete finite inventory available to a downstream normal-form consumer.

Next apply terminal consumer totality and finite-route readback boundary. The first theorem forces terminal consumers through $T, F, V, K, R, H, C, P, N$, and the second places normal-word and continuation readbacks on the same transported finite route.

Finally combine the no-divergence ledger, continuation normal-word pullback, and total-host refusal exhaustion. These results exhaust all public normal-form reads through the displayed rows and refuse every host-side or quotient-style request that lacks a coordinate in the accepted packet. □

Theorem 936.39 ($\mathsf{ZNormal}^{\uparrow}$ root public normal-form export)**.** *For an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the public normal-form export is exactly the finite surface*

$$Z = (T, F, V, K, R, H, C, P, N)$$

together with the finite sibling routes already certified by the normal-word handoff and continuation pullback. The export is not a host conversion procedure, an unrestricted evaluator, or a global normalization theorem.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root public normal form export`

Proof. Project the accepted packet. Carrier admission lists the typed endpoint, finite fuel, terminal-normality, normal-word, readback, transport, replay, package, and local naming rows as $T, F, V, K, R, H, C, P, N$.

Attach the sibling route results. The sibling normal-word handoff and continuation normal-word pullback route K and R through the same finite packet and do not add a host evaluator coordinate.

The non-export claim follows from the total-host refusal and no-divergence ledgers. They exhaust public reads through the displayed rows and leave no coordinate for host conversion, unrestricted evaluation, or global normalization. □

Theorem 936.40 ($\mathsf{ZNormal}^{\uparrow}$ root total-host obligation package)**.** *The root total-host obligation package for* $\mathsf{ZNormal}^{\uparrow}$ *consists of carrier admission for* $T, F, V, K, R, H, C, P, N$*, terminal fuel, sibling normal-word certification, continuation readback, componentwise transport, route replay, package provenance, and the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *rows. Every root-facing total-host request must be discharged by this package or refused.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root total host obligation package`

Proof. Start with carrier admission and the local NameCert obligations. These expose the finite rows $T, F, V, K, R, H, C, P, N$ and bind them to the named $\mathsf{ZNormal}^{\uparrow}$ surface.

Next collect the terminal and sibling obligations. Terminal fuel is read through F, terminal-normality through V, the sibling normal word through K, and continuation readback through R.

Finally package transport, replay, provenance, and naming through H, C, P, N. The total-host refusal theorem says that a request outside these rows has no accepted coordinate, so the displayed collection is the complete root total-host obligation package. □

Theorem 936.41 ($\mathsf{ZNormal}^{\uparrow}$ root unary carry entry)**.** *Every accepted* $\mathsf{ZNormal}^{\uparrow}$ *root packet that exposes a unary carry entry to a normal-form consumer must first route the typed endpoint row* T*, the finite fuel row* F*, and the terminal-normality row* V *through the visible source package of Definition 936.24. The finite word row* K *then reads the* $\mathsf{ZCarry}^{\uparrow}$ *sibling surface of chapter 544 before any consumer may use* K *as carry evidence.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root unary carry entry`

Proof. Start with Definition 936.24. It exposes the root packet as $T, F, V, K, R, H, C, P, N$ and gives the consumer no row outside the displayed carrier.

Next apply Definition 936.25. This forces normal-word consumption through the finite row K after the typed endpoint, fuel, and terminal-normality rows are already visible.

Finally use Definition 936.11. The handoff reads K through the Zeckendorf and $\mathsf{ZCarry}^{\uparrow}$ sibling surfaces, so unary carry entry reaches the root only through the displayed carry sibling and cannot supply host conversion, quotient computation, unrestricted evaluation, or a global normalizer. □

Theorem 936.42 ($\mathsf{ZNormal}^{\uparrow}$ root Zeckendorf handoff)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the normal-word row* K *may be consumed as Zeckendorf evidence only after the root visible source package has exposed* $T, F, V, K, R, H, C, P, N$ *and after the sibling handoff has routed* K *through* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *of chapter 278 and* $\mathsf{ZCarry}^{\uparrow}$ *of chapter 544. The terminal readback remains downstream of* R, H, C, P, N *and exports no host normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root zeckendorf handoff`

Proof. Project the visible source package by Definition 936.24. The packet exposes the typed endpoint, finite fuel, terminal-normality, normal-word, continuation, transport, replay, provenance, and naming rows as one root surface.

Apply Definition 936.25 and Definition 936.11. These results place the K row on the finite ZeckendorfNormal and $\mathsf{ZCarry}^{\uparrow}$ sibling route before the local root consumer uses it.

It remains to account for terminal readback. The continuation normal-word pullback of Definition 936.31 binds K and R into the same transported route through H, C, P, N, so the Zeckendorf handoff cannot detach into host normalization, quotient computation, unrestricted evaluation, or divergence detection. □

Theorem 936.43 ($\mathsf{ZNormal}^{\uparrow}$ root continuation trace boundary)**.** *Let*

$$Z = (T, F, V, K, R, H, C, P, N)$$

be an accepted $\mathsf{ZNormal}^{\uparrow}$ *root packet. Every continuation-trace terminal readback must pass through* R, H, C, P, N *after the visible source package and the normal-word route totality have exposed*

T, F, V, K. The boundary is the displayed root packet together with the finite continuation route; it is not a substrate halting row, divergence oracle, unrestricted evaluator, quotient normalizer, or global normalizer.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root continuation trace boundary`

Proof. Begin with the visible source package and normal-word route totality. Definition 936.24 exposes $T, F, V, K, R, H, C, P, N$, while Definition 936.25 fixes the normal-word route through K before readback.

Now apply Definition 936.31. It pulls the normal-word row K and continuation row R onto the same transported and replayed route through H, C, P, N.

Finally use the root total-host obligation package of Definition 936.40. Since every root-facing total-host request must be discharged by the displayed packet or refused, the continuation trace boundary has no coordinate for substrate halting, divergence, unrestricted evaluation, quotient normalization, or global normalization. □

Theorem 936.44 ($\mathsf{ZNormal}^{\uparrow}$ root terminal readback ledger totality)**.** *Every terminal readback consumer at the $\mathsf{ZNormal}^{\uparrow}$ root passes through T, F, V, R, H, C, P, N before reading any downstream normal-form data. The consumer receives no divergence oracle, unrestricted evaluator, quotient computation, or substrate halting row.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root terminal readback ledger totality`

Proof. Begin with terminal consumer totality. It forces every terminal readback to start from the typed endpoint, finite fuel, terminal-normality, and readback rows T, F, V, R.

Transport and replay then move the same terminal row through H and C, and the package and local naming rows P, N record its provenance and certificate. Thus the terminal readback ledger is total only along T, F, V, R, H, C, P, N.

Apply the no-divergence ledger and total-host refusal. Since no divergence oracle, unrestricted evaluator, quotient-computation coordinate, or substrate halting row appears in the accepted packet, no terminal readback consumer can extract one. □

Theorem 936.45 ($\mathsf{ZNormal}^{\uparrow}$ total-host terminal fuel determinacy)**.** *For every accepted $\mathsf{ZNormal}^{\uparrow}$ packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the total-host terminal-fuel read is determined by the displayed typed endpoint row T, finite fuel row F, terminal-normality row V, and terminal read row R, transported only by H, replayed only by C, packaged only by P, and named only by N. The sibling normal-word row K is read as finite ZeckendorfNormal and ZCarry evidence and cannot be replaced by host conversion, quotient computation, unrestricted evaluation, divergence oracle, or global normalizer data.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host terminal fuel determinacy`

Proof. Project the carrier from Definition 936.1. It exposes $T, F, V, K, R, H, C, P, N$ as the whole accepted packet, so terminal fuel has no second host-side coordinate.

Use Definition 936.53 and Definition 936.14. They bind terminal use to T, F, V, R and keep the route inside the finite packet before any total-host consumer can read it.

Finally apply Definition 936.57 and Definition 936.58. The K row remains finite sibling normal-word evidence, while the refusal ledger excludes host conversion, quotient computation, unrestricted evaluation, divergence, and global normalization. □

Theorem 936.46 ($\mathsf{ZNormal}^{\uparrow}$ downstream normal route exhaustion)**.** *Every downstream normal-form route out of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

is exhausted by terminal fuel through T, F, V, R*, sibling normal-word evidence through* K*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *naming through* N*. No downstream normal route may pass through host conversion, quotient computation, unrestricted evaluation, divergence oracle, or global normalizer rows.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacketDownstreamNormalRouteExhaustion`

Proof. Begin with Definition 936.56. It places every downstream normal-form consumer inside the displayed root packet and gives no separate normal-output coordinate.

Apply Definition 936.45. Terminal fuel and terminal readback are determined by T, F, V, R and the structural rows H, C, P, N.

For the sibling route, use Definition 936.57. The row K is consumed only through finite ZeckendorfNormal, ZCarry, and ContinuationTraceNormalForm surfaces. The total-host refusal theorem Definition 936.58 then removes host conversion, quotient computation, unrestricted evaluation, divergence, and global normalization from the downstream boundary. □

Theorem 936.47 ($\mathsf{ZNormal}^{\uparrow}$ finite normal-word classifier compatibility)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the finite normal-word classifier seen by a downstream consumer is compatible with the terminal route: K *may be consumed only after the typed endpoint* T*, finite fuel* F*, terminal-normality row* V*, terminal read* R*,* hsame *transport* H*,* Cont *replay* C*, package row* P*, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row* N *have fixed the same packet. This compatibility exports no host conversion, quotient computation, unrestricted evaluator, divergence oracle, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacketFiniteNormalwordClassifierCompatibility`

Proof. Start from Definition 936.25. It identifies K as the finite normal-word route through the ZeckendorfNormal and ZCarry sibling surfaces rather than a host computation.

Use Definition 936.54 to attach that classifier route to T, F, V, R, H, C, P, N. The normal-word row cannot be detached from the terminal packet or read through an independent quotient computation.

Finally invoke Definition 936.46. Since every downstream normal route is already exhausted by the displayed packet and finite sibling surfaces, classifier compatibility contributes no route to host conversion, unrestricted evaluation, divergence detection, or global normalization. □

Theorem 936.48 ($\mathsf{ZNormal}^{\uparrow}$ downstream ZCarry dependency route)**.** *Every downstream normal-form read of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

consumes the normal-word row K *through chapter 278 and chapter 544 before any terminal readback through* R, H, C, P, N*. The read therefore reaches ZeckendorfNormal and ZCarry sibling evidence as finite BEDC rows, not as host conversion, quotient normalization, unrestricted evaluation, divergence detection, or global normalization.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket downstream zcarry dependency route`

Proof. Begin with Definition 936.46. It says that every downstream normal-form route is already exhausted by $T, F, V, K, R, H, C, P, N$ and that the row K is the sibling normal-word route.

Next apply Definition 936.47. The classifier compatibility theorem forces K to remain attached to the same terminal packet before any downstream consumer reads R, H, C, P, N.

The two sibling labels name the concrete finite sources for that row. Thus K is consumed through the ZeckendorfNormal and ZCarry chapters first, and the terminal readback can only replay the already displayed route. □

Theorem 936.49 ($\mathsf{ZNormal}^{\uparrow}$ candidate-normal endpoint readback)**.** *Every candidate-mediated normal endpoint consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

must read terminal fuel through T, F, V, R, finite normal-word evidence through K, and structural rows H, C, P, N before it can feed a MetaCIC candidate-normalization or closed-normal consistency route. The endpoint readback exports no host conversion, quotient computation, unrestricted evaluator, divergence oracle, or global normalizer.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacketCandidateNormalEndpointReadback`

Proof. Apply Definition 936.45. It binds the terminal fuel and terminal readback rows to T, F, V, R before any total-host endpoint can consume the accepted packet.

Next use Definition 936.46. Every downstream normal route is already exhausted by $T, F, V, R, K, H, C, P, N$, so a candidate-mediated endpoint has no independent host conversion or global-normalizer coordinate.

Finally invoke Definition 936.47. The finite normal-word row K is compatible with the same terminal route and must be read after the structural rows have fixed the packet. The downstream MetaCIC candidate-normalization consumer is therefore a later formalization site for this readback boundary, not a proof of unrestricted normalization. □

Theorem 936.50 ($\mathsf{ZNormal}^{\uparrow}$ root total-host fuel frontier)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, any total-host read that precedes a public normal output must expose the displayed rows T, F, V, R, H, C, P, N before that output is available. The typed endpoint T, finite fuel F, terminal-normality row V, terminal continuation readback R, componentwise transport H, displayed replay C, package provenance P, and local name N are therefore the root-facing fuel frontier for public normal output.*

Proof. Begin with the carrier and NameCert obligations of Definition 936.1 and Definition 936.2. They list $T, F, V, K, R, H, C, P, N$ as the complete accepted packet and bind every public read to the same local certificate surface.

Apply finite-fuel carrier admission from Definition 936.33. It places the typed endpoint, finite fuel, terminal-normality row, terminal continuation readback, and structural rows in one finite packet before any root-facing normal-form consumer can read the output.

Finally use terminal consumer totality, Definition 936.36. Since every terminal consumer is exhausted by the displayed packet, the public normal output cannot precede the rows T, F, V, R, H, C, P, N or obtain a total-host witness from outside them. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootTotalHostFuelFrontier`

Theorem 936.51 ($\mathsf{ZNormal}^{\uparrow}$ root sibling route separation)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the row* K *is only the finite Zeckendorf and* $\mathsf{ZCarry}^{\uparrow}$ *sibling route used for normal-word evidence. It cannot become host conversion, quotient normalization, unrestricted evaluation, substrate halting, divergence detection, or a global normalizer, and it cannot replace the typed endpoint, finite fuel, terminal-normality, continuation, transport, replay, provenance, or naming rows.*

Proof. Use the NameCert obligations of Definition 936.2 to locate K inside the same accepted packet as T, F, V, R, H, C, P, N. The certificate gives K a finite sibling-normal-word role and no host-side conversion coordinate.

Next apply the continuation normal-word pullback of Definition 936.31. It pulls the normal-word row and continuation readback to the same transported route through H, C, P, N, so K remains attached to finite Zeckendorf and carry evidence.

Finally combine total-host refusal exhaustion with the no-divergence oracle ledger, Definition 936.32 and Definition 936.35. These ledgers refuse host conversion, quotient normalization, unrestricted evaluation, substrate halting, divergence detection, and global normalization, leaving K as a sibling route rather than a host conversion principle. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root sibling route separation`

Theorem 936.52 ($\mathsf{ZNormal}^{\uparrow}$ root refusal audit exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the root refusal ledger exhausts requests for divergence, host conversion, unrestricted evaluation, substrate halting, and global normalization. Any root, normal-form, or MetaCIC-facing consumer must remain inside the displayed* $T, F, V, K, R, H, C, P, N$ *route and cannot obtain one of those refused objects from a hidden total-host row.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root refusal audit exhaustion`

Proof. Start with finite-fuel admission and terminal consumer totality, Definition 936.33 and Definition 936.36. They expose the finite packet $T, F, V, K, R, H, C, P, N$ as the complete route for terminal normal-form consumers.

Use continuation normal-word pullback to bind the sibling normal-word and continuation rows. By Definition 936.31, downstream normal-word and readback consumers remain on the same transported route through H, C, P, N.

Finally apply total-host refusal exhaustion and the no-divergence oracle ledger. The refusal surface of Definition 936.32 and Definition 936.35 has already accounted for divergence, host conversion, unrestricted evaluation, substrate halting, and global normalization requests, so no hidden total-host row remains available. □

Theorem 936.53 ($\mathsf{ZNormal}^{\uparrow}$ root terminal carrier admission)**.** *Every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet admitted at the root terminal surface is a finite carrier*

$$Z = (T, F, V, K, R, H, C, P, N)$$

whose rows expose typed endpoint evidence, finite fuel, terminal-normality, finite sibling normal-word evidence, terminal continuation readback, componentwise transport, displayed replay, provenance, and local naming. The admission route is the carrier and $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *route of Definition 936.1 and Definition 936.2; it introduces no host conversion row, quotient normalization row, unrestricted evaluator, divergence detector, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root terminal carrier admission`

Proof. Project the carrier using Definition 936.1. Its displayed rows are exactly $T, F, V, K, R, H, C, P, N$, so root admission has no extra coordinate from which a host conversion or quotient normalizer could be read.

Apply Definition 936.2. The local certificate binds typed endpoint readback, finite fuel, terminal normality, sibling normal-word evidence, continuation readback, transport, replay, provenance, and naming to the same finite packet.

Finally use Definition 936.14. The terminal root interface keeps every downstream terminal read inside the displayed rows and refuses host conversion, quotient computation, unrestricted evaluation, divergence detection, and global normalization. □

Theorem 936.54 ($\mathsf{ZNormal}^{\uparrow}$ root normal-word route exposure)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the finite normal-word row K is exposed at the root only through the sibling normal-word and continuation routes already certified by the packet. A consumer that reads K must pass through the terminal rows T, F, V, the continuation read R, and the transport, replay, provenance, and naming rows H, C, P, N; it receives no quotient normalization, host conversion, unrestricted evaluation, divergence detector, or global normalizer.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root normal word route exposure`

Proof. Start with Definition 936.25. It places the normal-word row on the displayed root route and treats K as finite sibling evidence rather than as an evaluator.

Next apply Definition 936.31. The normal-word row and continuation read are pulled back to the same transported finite packet through H, C, P, N, so K cannot be detached from T, F, V, R.

Use Definition 936.14 to close the escape boundary. Since all visible reads remain inside $T, F, V, K, R, H, C, P, N$, the root route exposes no host conversion, quotient normalization, unrestricted evaluation, divergence detection, or global normalization. □

Theorem 936.55 ($\mathsf{ZNormal}^{\uparrow}$ root total-host refusal ledger)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the root terminal ledger refuses exactly the total-host objects absent from the carrier: host conversion, quotient normalization, unrestricted evaluation, divergence detection, and global normalization. The refusal is witnessed by carrier admission, normal-word route exposure, terminal readback exactness, continuation terminal routing, and the displayed rows $T, F, V, K, R, H, C, P, N$.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root total host refusal ledger`

Proof. First use root terminal carrier admission above. It identifies the complete finite packet surface and shows that no total-host escape coordinate is present in the carrier.

Next use root normal-word route exposure together with Definition 936.8. The normal-word and terminal readback rows are finite route rows of the same packet, not quotient-normalization or host-conversion outputs.

Finally apply Definition 936.36 and Definition 936.32. These theorems exhaust root terminal consumers by $T, F, V, K, R, H, C, P, N$, so unrestricted evaluation, divergence detection, and global normalization have no public row in the ledger. □

Theorem 936.56 ($\mathsf{ZNormal}^{\uparrow}$ root downstream totality)**.** *Every downstream normal-form consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors through the root carrier rows*

$$T, F, V, K, R, H, C, P, N.$$

The consumer may read terminal normality through T, F, V, R*, finite normal-word evidence through* K*, transport through* H*, continuation replay through* C*, package provenance through* P*, and local naming through* N*; it receives no normal-form row outside that displayed packet.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket downstream totality`

Proof. Project the carrier from Definition 936.1. It displays exactly $T, F, V, K, R, H, C, P, N$ as the accepted packet and gives a downstream consumer no separate carrier coordinate.

Use Definition 936.2 to bind those rows to the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface. Then apply Definition 936.24, which places every normal-output read after the same visible source package has been exposed.

The routing clauses are supplied by Definition 936.25 and Definition 936.26. The first theorem fixes the finite normal-word route through K, and the second fixes continuation-terminal reads through T, F, V, R, H, C, P, N. Hence every downstream normal-form consumer factors through the displayed packet. □

Theorem 936.57 ($\mathsf{ZNormal}^{\uparrow}$ root sibling normal-word consumption)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the* K *row is consumed only through the finite sibling surfaces of chapter 278, chapter 544, and chapter 683. No downstream normal-form consumer may read* K *as host conversion, quotient normalization, unrestricted evaluation, divergence detection, substrate halting, or global normalization.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootSiblingNormalWordConsumption`

Proof. Begin with Definition 936.1. The row K appears inside the same finite packet as T, F, V, R, H, C, P, N and is not a separate host-facing row.

Apply Definition 936.25. It routes the normal-word evidence through the ZeckendorfNormal and ZCarry sibling surfaces before any root consumer reads the local K row.

Next use Definition 936.26. Continuation-trace normal-form reads remain terminal continuation reads through T, F, V, R, H, C, P, N, so the same downstream consumer cannot detach K from the terminal route.

Finally apply Definition 936.56. Since every downstream normal-form consumer factors through the displayed packet, the sibling normal-word row is consumed only through those finite sibling surfaces and not through any excluded host or global-normalization object. □

Theorem 936.58 ($\mathsf{ZNormal}^{\uparrow}$ root total-host refusal)**.** *The root interface of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet exports no host conversion, quotient normalizer, unrestricted evaluator, divergence oracle, substrate-halting row, or global normalizer. Any total-host or downstream normal-form use must remain inside*

$$T, F, V, K, R, H, C, P, N$$

and the finite sibling consumption route of Definition 936.57.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootTotalHostRefusal`

Proof. Project the visible source package using Definition 936.24. It exposes the typed endpoint, finite fuel, terminal-normality, normal-word, continuation, transport, replay, package, and naming rows before any normal-output consumer reads the packet.

Use Definition 936.56 to cover downstream normal-form consumers, and use Definition 936.57 to cover the finite sibling route through K.

It remains to exclude total-host escape. Apply Definition 936.26; continuation reads are terminal route reads through the displayed packet and expose no unrestricted evaluator, divergence oracle, host conversion, quotient normalizer, substrate-halting row, or global normalizer. Therefore the root interface refuses exactly those host and global-normalization objects. □

Theorem 936.59 ($\mathsf{ZNormal}^{\uparrow}$ total-host readback factorization)**.** *Every total-host readback of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors through the root packet*

$$T, F, V, K, R, H, C, P, N$$

and through the finite sibling route of Definition 936.57. In particular, a total-host consumer may read terminal normality, finite normal-word evidence, transport, continuation replay, provenance, and local naming only by first passing through the displayed carrier rows and then through the ZeckendorfNormal, ZCarry, and ContinuationTraceNormalForm sibling surfaces where the normal-word route exposes them.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root total host readback factorization`

Proof. Project the accepted carrier from Definition 936.1. It lists $T, F, V, K, R, H, C, P, N$ as the complete root packet, so a total-host readback has no separate coordinate from which to obtain normal-form data.

Apply Definition 936.56. This places every downstream normal-form consumer inside the displayed packet. Then apply Definition 936.57; the only consumption path for K is the finite sibling route through ZeckendorfNormal, ZCarry, and ContinuationTraceNormalForm surfaces.

Finally use Definition 936.58. Since the root interface refuses host conversion, quotient normalization, unrestricted evaluation, divergence detection, substrate halting, and global normalization, the total-host readback can only be the packet-and-sibling factorization just described. □

Theorem 936.60 ($\mathsf{ZNormal}^{\uparrow}$ normal-form consumer boundary)**.** *Every normal-form consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet receives only terminal normality through* T, V, R*, finite normal-word evidence through* K*, componentwise transport through* H*, continuation replay through* C*, provenance through* P*, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *rows through* N*. The consumer receives no host conversion row, quotient normalizer, unrestricted evaluator, divergence detector, substrate-halting row, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket normal form consumer boundary`
↪ variant `BEDC.Derived.ZnormalUp.ZnormalPacket root normal form consumer boundary`

Proof. Start from Definition 936.1. The carrier exposes the terminal, word, transport, replay, provenance, and naming rows as coordinates of the same finite packet and lists no host-facing conversion or global-normalization row.

Use Definition 936.56 to bind any normal-form consumer to that packet. The terminal and continuation readbacks are then exhausted by Definition 936.26, so terminal normality and continuation replay remain inside T, V, R, H, C, P, N.

For finite normal-word evidence, apply Definition 936.57. It keeps K on the finite sibling route. The refusal clause of Definition 936.58 excludes every listed host and global-normalization object, giving exactly the stated consumer boundary. □

Theorem 936.61 ($\mathsf{ZNormal}^{\uparrow}$ sibling-refusal exhaustion)**.** *For an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the ZeckendorfNormal, ZCarry, and ContinuationTraceNormalForm sibling surfaces exhaust the permitted normal-word route. Outside those sibling surfaces and the root packet*

$$T, F, V, K, R, H, C, P, N,$$

the interface excludes host conversion, quotient normalization, unrestricted evaluation, divergence detection, substrate halting, and global normalization.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootSiblingRefusalExhaustion`

Proof. Project the carrier with Definition 936.1. The normal-word coordinate K is one row of the finite root packet, and the carrier supplies no independent route for host conversion or global normalization.

Apply Definition 936.57. It identifies the permitted normal-word route with the ZeckendorfNormal, ZCarry, and ContinuationTraceNormalForm sibling surfaces and denies the listed host and global-normalization readings of K.

It remains to see that no total-host path reintroduces an excluded surface. Use Definition 936.56 to confine downstream consumers to the displayed packet, and then use Definition 936.58 to refuse host conversion, quotient normalization, unrestricted evaluation, divergence detection, substrate halting, and global normalization. These clauses exhaust the sibling route and the refusal boundary together. □

Theorem 936.62 ($\mathsf{ZNormal}^{\uparrow}$ root carrier obligation completion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

root-readiness carrier admission is exhausted by the displayed typed endpoint row T, finite fuel row F, terminal-normality row V, sibling normal-word row K, terminal readback row R, componentwise hsame *row H, displayed* Cont *row C, package row P, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row N. No root-readiness consumer receives carrier data for host conversion, quotient normalization, unrestricted evaluation, divergence detection, substrate halting, total host computation, or global normalization outside that packet.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootCarrierObligationCompletion`

Proof. Project the carrier using Definition 936.1 and the root carrier exposure of Definition 936.15. These rows identify $Z = (T, F, V, K, R, H, C, P, N)$ as the complete root-facing packet.

Apply Definition 936.2 to read the same coordinates as the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface. The structural rows H, C, P, N provide transport, replay, provenance, and naming; they do not add a host-side computation coordinate.

Finally use Definition 936.58. Since every total-host request remains inside the displayed packet and the finite sibling route, the carrier obligation is complete for root readiness and excludes the listed host and global-normalization objects. □

Theorem 936.63 ($\mathsf{ZNormal}^{\uparrow}$ terminal route obligation completion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the terminal-route obligation for root readiness is the finite route from T through F and V to R, transported by H, replayed by C, packaged by P, and named by N. The sibling normal-word row K may be consumed only as the finite Zeckendorf, carry, and continuation-facing evidence specified by the root sibling route; it is not a host conversion, quotient normalizer, unrestricted evaluator, divergence detector, substrate-halting row, total host-computation row, or global normalizer.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTerminalRouteObligationCompletion`

Proof. Use Definition 936.16 and Definition 936.53. They place the terminal root read on the route $T \to F \to V \to R$ inside the displayed carrier.

Next apply Definition 936.57. The K row is consumed only through the finite sibling surfaces of the Zeckendorf normal, carry, and continuation-trace normal-form packets.

The terminal route is then exhausted by Definition 936.26 and Definition 936.55. These results keep terminal reads inside $T, F, V, K, R, H, C, P, N$ and refuse the excluded host and global-normalization rows. □

Theorem 936.64 ($\mathsf{ZNormal}^{\uparrow}$ downstream readiness obligation package)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the downstream normal-form readiness package consists exactly of carrier admission for Z, terminal-route exposure through T, F, V, R, H, C, P, N, sibling normal-word consumption through K, total-host refusal, and downstream normal-form totality over the displayed rows. Every downstream normal-form consumer obtains a finite BEDC route through that package and no route to host conversion, quotient normalization, unrestricted evaluation, divergence detection, substrate halting, total host computation, or global normalization.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalDownstreamReadinessObligationPackage`

Proof. Start with carrier completion above. It fixes the root-readiness carrier as the finite packet $Z = (T, F, V, K, R, H, C, P, N)$ and leaves no extra host-facing coordinate.

Use terminal route obligation completion to bind terminal normality to T, F, V, R, H, C, P, N and to keep K as finite sibling normal-word evidence.

Finally apply Definition 936.56 and Definition 936.58. The first theorem gives every downstream normal-form consumer a route through the displayed packet, while the second refuses total-host escape. Hence the downstream readiness package is the finite root route itself. □

Theorem 936.65 ($\mathsf{ZNormal}^{\uparrow}$ root-readiness terminal-refusal closure)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

whose carrier admission, terminal route, sibling normal-word row, downstream totality, and total-host refusal rows are displayed, the root-readiness terminal-refusal surface is closed by the finite packet Z. Downstream normal-form consumers receive only the finite terminal route and receive no host conversion, quotient normalization, unrestricted evaluation, substrate halting, divergence detector, total host computation, or global normalizer.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootReadinessTerminalRefusalClosure`

Proof. First use Definition 936.62. It fixes the carrier admission surface as the displayed rows $T, F, V, K, R, H, C, P, N$ and excludes hidden host-facing coordinates.

Next apply Definition 936.63. The terminal route is the finite route from T through F and V to R, transported and replayed by H, C, P, N, with K consumed only as sibling normal-word evidence.

Finally combine Definition 936.64, Definition 936.58, and Definition 936.56. These rows give downstream consumers their finite route and refuse every total-host or global-normalization escape listed in the statement. □

Theorem 936.66 ($\mathsf{ZNormal}^{\uparrow}$ root BHist source surface)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the root source rows are one finite BHist *surface: typed endpoint* T*, finite fuel* F*, terminal normality* V*, finite sibling normal-word row* K*, terminal continuation read* R*, componentwise transport* H*, displayed replay* C*, package provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row* N*. A root consumer has no second source row outside this displayed packet.*

Proof. Project the carrier in Definition 936.1. It displays $Z = (T, F, V, K, R, H, C, P, N)$ as the accepted packet and gives each root-facing row as part of the same finite carrier.

Apply Definition 936.2. The local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface reads carrier admission, typed endpoint, finite fuel, terminal normality, sibling normal-word evidence, terminal continuation read, transport, replay, provenance, and local naming from the same rows.

Finally use Definition 936.13 and Definition 936.29. The route and root-readiness rows keep those coordinates inside BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ data, while the sibling chapters chapter 278, chapter 544, and chapter 683 supply only the finite surfaces named by K and R. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root bhist source surface`

Theorem 936.67 ($\mathsf{ZNormal}^{\uparrow}$ root classifier stability)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the classifier-facing reads through K *and* R *are transported only by the displayed* hsame *row* H *and replayed only by the displayed* Cont *row* C*. The* K *read may consume the ZeckendorfNormal and ZCarry sibling surfaces, and the* R *read may consume the ContinuationTraceNormalForm sibling surface, but neither read may be transported or replayed by a host conversion, quotient computation, unrestricted evaluation, divergence detector, total host computation, or global normalizer.*

Proof. Start from Definition 936.1 and Definition 936.2. They place K and R inside the same accepted packet as T, F, V, H, C, P, N and attach both reads to the local naming surface.

Use Definition 936.13. It identifies H as the only componentwise transport row and C as the only displayed replay row available to routes from T, F, V through K and R.

The sibling uses are then finite. The ZeckendorfNormal and ZCarry chapters bind the K classifier read, while chapter 683 binds the R terminal read. Together with Definition 936.29, these routes give classifier stability without adding any excluded host or global-normalization object. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root classifier stability`

Theorem 936.68 ($\mathsf{ZNormal}^{\uparrow}$ root ledger exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

every root consumer factors through the displayed Pkg *row* P *and the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row* N*. The root ledger permits reads of* T, F, V, K, R, H, C *only through that package-and-name boundary and cannot read host conversion, quotient computation, unrestricted evaluation, divergence, total host computation, or global normalization.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root ledger exhaustion`

Proof. First expose the packet by Definition 936.1. The only provenance and local naming rows are P and N, and the root source rows are the displayed coordinates T, F, V, K, R, H, C.

Apply Definition 936.2. It binds those coordinates to the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ ledger and records P as the provenance package for the same finite surface.

Use Definition 936.13 to keep transport and replay inside H and C. Then apply Definition 936.29: every root-readiness consumer reads the package through P and the local name through N before it can use the sibling surfaces of chapter 278, chapter 544, and chapter 683.

Since no carrier coordinate, transport row, replay row, package row, or local name supplies host conversion, quotient computation, unrestricted evaluation, divergence, total host computation, or global normalization, the ledger is exhausted by P and N over the displayed BHist packet. □

Theorem 936.69 ($\mathsf{ZNormal}^{\uparrow}$ root total-host source packet)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the total-host source exposed at the root is the single finite packet obtained by reading the typed reduction normal-form row T*, the finite fuel row* F*, the terminal-normality row* V*, the Zeckendorf and carry-facing normal-word row* K*, the terminal continuation-trace row* R*, the componentwise transport row* H*, the displayed continuation replay row* C*, the package provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row* N*. The source cannot be split into a typed endpoint source, a normal-word source, a carry source, or a continuation-trace source outside that* BHist *packet.*

Proof. Project the carrier of Definition 936.1. It lists $T, F, V, K, R, H, C, P, N$ as the full accepted packet and gives no second root source row.

Use the NameCert obligation surface of Definition 936.2. The typed endpoint, finite fuel, terminal normality, sibling normal-word evidence, continuation readback, transport, replay, package, and local naming rows are all read through one local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface.

Apply Definition 936.66 and Definition 936.67. These keep the typed reduction normal-form row, the Zeckendorf and carry-facing row, and the continuation-trace row inside the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ route.

Finally use Definition 936.68. Since the ledger has no coordinate outside $T, F, V, K, R, H, C, P, N$, the total-host source is exactly the displayed finite source packet. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root total host source packet`

Theorem 936.70 ($\mathsf{ZNormal}^{\uparrow}$ root terminal normality exposure)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the terminal-normality row* V *is readable at the root only after the finite fuel replay through* F *has been displayed and the terminal continuation evidence* R *has been admitted through the same transported route. A consumer may read terminal normality through*

$$T \longmapsto F \longmapsto V \longmapsto R$$

with transport H, replay C, provenance P, and local naming N, but it may not read V from an ambient normalizer, host conversion judgment, quotient computation, unrestricted evaluator, or divergence detector.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root terminal normality exposure`

Proof. Start with Definition 936.6. It places terminal normality on the finite route from the typed endpoint T through finite fuel F to the continuation read R.

Apply Definition 936.8. The terminal read factors through T, F, V, R, H, C, P, N, and the sibling row K can be consumed only after V is already displayed as finite evidence.

Use Definition 936.9 to force the finite replay order before consumer use. The structural rows H, C, P, N are the only transport, replay, package, and naming routes available for that exposure.

Finally invoke Definition 936.16 and Definition 936.14. They keep terminal continuation evidence attached to the same root route and exclude ambient normalization, host conversion, quotient computation, unrestricted evaluation, and divergence detection. □

Theorem 936.71 ($\mathsf{ZNormal}^{\uparrow}$ root forbidden host conversion exclusion)**.** *No accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet exports a divergence oracle, host conversion row, quotient-normalization row, unrestricted host evaluator, global normalization procedure, or substrate halting row. Every root request for such an object is exhausted by the displayed rows $T, F, V, K, R, H, C, P, N$ and by the refusal ledgers attached to the local* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *surface.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root forbidden host conversion exclusion`

Proof. Read the complete packet through Definition 936.1 and Definition 936.2. The accepted carrier has only the typed endpoint, fuel, terminal normality, sibling normal-word, continuation readback, transport, replay, provenance, and local naming rows.

Apply Definition 936.10. It prevents the displayed finite route from being replaced by host conversion, quotient computation, divergence, unrestricted evaluation, or global normalization.

Next use Definition 936.55 and Definition 936.52. These root ledgers account for host conversion, quotient normalization, unrestricted evaluation, substrate halting, divergence detection, and global normalization requests without adding any exported row for them.

Finally combine Definition 936.68 with Definition 936.73. The root source remains $T, F, V, K, R, H, C, P, N$, so no divergence oracle, host conversion row, or global normalization procedure is available outside the finite packet. □

Theorem 936.72 ($\mathsf{ZNormal}^{\uparrow}$ terminal fuel readback frontier)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

every terminal fuel read factors through the displayed typed endpoint T, finite fuel row F, terminal-normality row V, continuation readback row R, componentwise transport H, displayed route C, provenance P, and local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row N. The sibling normal-word row K may be consulted only as finite sibling evidence after V is displayed.*

The frontier exports no divergence oracle, host conversion row, quotient computation, unrestricted evaluator, global normalizer, or total-host claim outside $T, F, V, K, R, H, C, P, N$.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal fuel readback frontier`

Proof. Project the carrier of Definition 936.1. Its terminal-facing coordinates are the typed endpoint, finite fuel, terminal-normality, continuation readback, transport, route, provenance, and local naming rows.

Use Definition 936.2 to bind those coordinates to the local certificate surface. The finite fuel row and terminal-normality row are therefore read before any terminal continuation row is consumed.

Apply Definition 936.6, Definition 936.8, and Definition 936.9. These results force the terminal read through T, F, V, R, H, C, P, N and keep K as a finite sibling row.

Finally use Definition 936.11 for the only allowed K consumption. The carrier has no coordinate for divergence, host conversion, quotient computation, unrestricted evaluation, global normalization, or total-host escape, so the displayed frontier is exhaustive. □

Theorem 936.73 ($\mathsf{ZNormal}^{\uparrow}$ total-host frontier lock)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the total-host boundary is locked to the finite rows $T, F, V, K, R, H, C, P, N$*. A consumer may not reread that boundary as a divergence row, host conversion row, quotient computation, unrestricted evaluator, global normalization procedure, or substrate halting statement.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host frontier lock`

Proof. Begin with Definition 936.1 and Definition 936.2. Together they list the complete accepted packet and attach every public read to the local $\mathsf{NameCert}$ surface.

Apply Definition 936.7. It identifies the packet as a finite interface for the total-host side and refuses host Turing completeness or substrate halting content beyond the accepted rows.

Now use Definition 936.6 and Definition 936.8. Terminal normality is read through finite fuel and continuation readback, not through a host conversion or unrestricted evaluator.

The route admission theorem, Definition 936.9, keeps the readback route inside H, C, P, N, while Definition 936.11 keeps the sibling row finite. Thus no excluded total-host or quotient object can be recovered from the frontier. □

Theorem 936.74 ($\mathsf{ZNormal}^{\uparrow}$ downstream consumer boundary)**.** *Every downstream consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors only through the typed endpoint* T*, finite fuel* F*, terminal normality* V*, sibling normal-word handoff* K*, continuation readback* R*, componentwise transport* H*, displayed route* C*, provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row* N*.*

Consequently downstream normal-form consumers receive the finite terminal frontier and no divergence oracle, host conversion row, quotient computation, unrestricted evaluator, global normalizer, or total-host computation row.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket downstream consumer boundary`

Proof. First expose the finite packet with Definition 936.1. The downstream-facing rows are exactly $T, F, V, K, R, H, C, P, N$.

Next bind the local certificate. By Definition 936.2, carrier admission, typed endpoint readback, fuel, terminal normality, sibling handoff, continuation readback, transport, route, provenance, and naming all belong to that same finite surface.

Use Definition 936.72 to force terminal fuel readback through T, F, V, R, H, C, P, N. Then use Definition 936.11 to identify the only allowed K consumption as finite sibling normal-word evidence.

Finally apply Definition 936.73. Since the locked frontier refuses divergence, host conversion, quotient computation, unrestricted evaluation, global normalization, and total-host computation, every downstream consumer remains inside the displayed terminal-fuel boundary. □

Theorem 936.75 ($\mathsf{ZNormal}^{\uparrow}$ TasteGate scope binding)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the finite rows $T, F, V, K, R, H, C, P, N$ *are the exact field surface later consumed by* `Nontrivial ZNormalUp` *and* `FieldFaithful ZNormalUp`*. The TasteGate-facing surface reads typed endpoint, finite fuel, terminal normality, finite sibling normal-word evidence, terminal continuation, componentwise transport, displayed continuation, package provenance, and local NameCert rows, and it exports no host conversion, quotient computation, unrestricted evaluation, divergence oracle, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket tastegate scope binding`

Proof. Begin with finite-fuel carrier admission and the local NameCert obligations. They expose exactly $T, F, V, K, R, H, C, P, N$ as one finite BHist packet and bind the same rows to the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface.

Apply the displayed TasteGate contract row through the normal-form package. The consumer receives the terminal and sibling evidence already routed through the packet, so the later Nontrivial and FieldFaithful instances consume the same field surface rather than a host-side computation.

Finally use the fuel non-escape and total-host refusal rows. Since the packet contains no coordinate for host conversion, quotient computation, unrestricted evaluation, divergence, or global normalization, the TasteGate scope is exactly the displayed finite field surface. □

Theorem 936.76 ($\mathsf{ZNormal}^{\uparrow}$ terminal fuel field scope)**.** *Every terminal-normality read of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors through the finite chain*

$$T \to F \to V \to R,$$

with K *available only as finite Zeckendorf and carry-facing sibling evidence. The structural rows* H, C, P, N *transport, replay, package, and name this chain; they do not replace it by host conversion, quotient computation, unrestricted evaluation, divergence detection, or global normalization.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal fuel field scope`

Proof. Use Definition 936.34. It places every continuation read behind the typed endpoint T, finite fuel F, and terminal-normality row V in the same packet.

Next apply terminal readback exactness and sibling normal-word handoff. The readback row is R, while K remains finite sibling evidence through the Zeckendorf and carry-facing surfaces.

The route transport theorem supplies the only structural movement. Rows H, C, P, N transport, replay, package, and name the finite chain, and fuel non-escape rules out any replacement by an omitted host or global object. □

Theorem 936.77 ($\mathsf{ZNormal}^{\uparrow}$ total-host consumer scope)**.** *No total-host consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet can read divergence, host conversion, quotient computation, unrestricted evaluation, or global normalization from the packet. Every such consumer is confined to*

$$T, F, V, K, R, H, C, P, N$$

and to the finite sibling routes named by K *and* R*.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host consumer scope`

Proof. Start with the total-host refusal exhaustion theorem. It already confines total-host requests to the displayed packet and the finite sibling surfaces cited by the normal-word and continuation rows.

Use the terminal fuel field scope above to isolate the terminal-normality chain. Then use the continuation normal-word pullback to keep K and R in one transported, replayed, packaged, and named packet.

Finally apply the no-divergence oracle ledger and root non-escape ledger. Together they exhaust all consumer reads through the displayed rows, so none of the excluded host, quotient, evaluator, divergence, or global-normalization objects is available. □

Theorem 936.78 ($\mathsf{ZNormal}^{\uparrow}$ terminal fuel row exhaustion)**.** *Every terminal-normality read of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet is exhausted by the rows*

$$T, F, V, R, H, C, P, N.$$

The row K contributes only the finite Zeckendorf and carry-facing sibling normal-word surface already available to the packet, and the TasteGate-facing consumer surface is the same field surface later used by `Nontrivial ZNormalUp` *and* `FieldFaithful ZNormalUp`*.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal fuel row exhaustion`

Proof. Apply Definition 936.76. It places each terminal-normality read behind T, F, V, R and uses H, C, P, N only as transport, replay, package, and naming rows.

Next use Definition 936.77. A consumer that asks for host conversion, quotient computation, divergence, unrestricted evaluation, or global normalization receives no additional row.

The remaining sibling evidence is exactly the finite handoff of Definition 936.11. Thus the TasteGate boundary seen by later Nontrivial and FieldFaithful instances is the displayed finite surface, not a host evaluator. □

Theorem 936.79 ($\mathsf{ZNormal}^{\uparrow}$ normal-word sibling exactness)**.** *The normal-word row K of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet is exact only through the Zeckendorf and carry-facing sibling routes cited by Definition 936.11. Together with the continuation readback row R, it is transported through H, C, P, N and not through host conversion, quotient computation, divergence, unrestricted evaluation, or global normalization.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket normal word sibling exactness`

Proof. Start with Definition 936.11. It identifies K with the finite Zeckendorf and carry-facing sibling normal-word evidence.

Now apply Definition 936.31. This places K and R on one transported route and permits only the structural rows H, C, P, N to move that route across the packet.

Finally use Definition 936.77. Since the packet exports no host or quotient-facing normalizer, the exactness of K is exactly the sibling exactness already named in the finite rows. □

Theorem 936.80 ($\mathsf{ZNormal}^{\uparrow}$ total-host refusal package)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the public refusal package excludes host conversion, quotient computation, divergence oracle, unrestricted evaluator, and global normalizer. All admitted reads factor through*

$$T, F, V, K, R, H, C, P, N,$$

with terminal-normality routed by T, F, V, R, H, C, P, N and sibling normal-word evidence routed by K through the Zeckendorf and carry-facing sibling surface.

Proof. First combine Definition 936.78 with Definition 936.79. These rows separate the terminal-normality route from the sibling normal-word route while keeping both inside the same finite packet.

Next apply Definition 936.77. It refuses every total-host request whose requested object has no coordinate in $T, F, V, K, R, H, C, P, N$.

The TasteGate surface is therefore explicit: later Nontrivial and FieldFaithful instances consume the same finite field surface, and no hidden host conversion, quotient computation, divergence oracle, unrestricted evaluator, or global normalizer is packaged. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host refusal package`

Theorem 936.81 ($\mathsf{ZNormal}^{\uparrow}$ root TasteGate field surface)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the TasteGate-facing field surface is exactly the displayed tuple $T, F, V, K, R, H, C, P, N$. The surface reads terminal normality and sibling normal-word evidence only through those rows; it cannot collapse into host conversion, quotient normalization, unrestricted evaluation, a divergence oracle, or a global normalizer.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZNormalTasteGate single carrier alignment`

Proof. Project the carrier and local NameCert obligations. They expose $T, F, V, K, R, H, C, P, N$ as the complete field inventory and leave no additional coordinate for a host-side converter or quotient normalizer.

Use the TasteGate scope binding and total-host refusal package. The first binds the future Nontrivial and FieldFaithful read to the same tuple, while the second refuses every consumer request whose object is not carried by the tuple.

The field surface is therefore exact. Any attempted collapse to host conversion or quotient normalization would require a coordinate absent from the carrier, so the TasteGate-facing read remains the finite BEDC packet surface. □

Theorem 936.82 ($\mathsf{ZNormal}^{\uparrow}$ terminal normality scope package)**.** *Every terminal-normality read of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors through*

$$T, F, V, R, H, C, P, N,$$

with K available only as finite sibling evidence through the Zeckendorf and carry-facing normal-word surface. No terminal-normality consumer can replace this route by host conversion, quotient normalization, unrestricted evaluation, divergence detection, or global normalization.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal normality scope package`

Proof. Begin with terminal fuel row exhaustion. It places each terminal-normality read behind T, F, V, R and makes H, C, P, N the only transport, replay, package, and naming rows.

Next read the sibling evidence. Normal-word sibling exactness keeps K on the finite Zeckendorf and carry-facing route, so K supports the terminal read only as sibling evidence and not as a host evaluator.

Finally apply the root TasteGate field surface. The terminal-normality consumer receives the same finite tuple surface, and the excluded host or quotient objects have no field from which they could be read. □

Theorem 936.83 ($\mathsf{ZNormal}^{\uparrow}$ normal-word continuation scope lock)**.** *Before any downstream normal-form consumer reads an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the normal-word row* K *and continuation row* R *are jointly scoped through* $\mathsf{ZeckendorfNormal}^{\uparrow}$, $\mathsf{ZCarry}^{\uparrow}$, *and* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$. *The joint scope is transported, replayed, packaged, and named only through* H, C, P, N *and cannot be reopened as host conversion, quotient normalization, unrestricted evaluation, divergence detection, or global normalization.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket normal word continuation scope lock`

Proof. Start with normal-word sibling exactness. It binds K to the finite Zeckendorf and carry-facing sibling routes, so any normal-word read is already scoped before downstream consumption.

Now apply the continuation normal-word pullback. It places K and R on one finite route through H, C, P, N, with R supplied by the continuation terminal surface and not by a detached evaluator.

Use the terminal normality scope package to close the downstream read. Since the consumer sees only the joined K, R route inside the displayed packet, no host conversion, quotient normalization, unrestricted evaluation, divergence detector, or global normalizer can reopen the scope. □

Theorem 936.84 ($\mathsf{ZNormal}^{\uparrow}$ terminal-route field exhaustion)**.** *Every terminal-route consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet must read the finite terminal-normality row, finite fuel row, transport row, provenance row, and local* $\mathsf{NameCert}$ *row from the displayed packet*

$$Z = (T, F, V, K, R, H, C, P, N).$$

The route may use the terminal continuation row R *and displayed replay row* C*, but it cannot replace the finite terminal packet by host conversion, quotient normalization, unrestricted evaluation, divergence detection, or a global normalizer.*

Proof. Start with Definition 936.53. It displays $T, F, V, K, R, H, C, P, N$ as the complete root terminal carrier and leaves no host conversion or quotient-normalization coordinate.

Use Definition 936.69 to keep every total-host source read inside the same finite packet. The source route therefore reaches terminal normality only through the typed endpoint, fuel, continuation, transport, replay, provenance, and naming rows already present.

Finally apply Definition 936.78. It exhausts terminal-normality consumers by T, F, V, R, H, C, P, N, with K available only as finite sibling normal-word evidence. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTerminalRouteFieldExhaustion`

Theorem 936.85 ($\mathsf{ZNormal}^{\uparrow}$ normal-word sibling bridge)**.** *The normal-word route of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet is mediated by the ZeckendorfNormal, ZCarry, TypedReductionNormalForm, and ContinuationTraceNormalForm sibling surfaces already displayed by the packet. The row* K *is therefore a finite sibling normal-word row transported with* T, F, V, R, H, C, P, N*, not a host normalizer, quotient conversion, divergence oracle, or unrestricted evaluator.*

Proof. Apply Definition 936.79. It identifies the normal-word row K with the finite Zeckendorf and carry-facing sibling routes and keeps that row attached to the continuation readback surface.

Next use Definition 936.53. The typed endpoint, fuel, terminal-normality, continuation, transport, replay, provenance, and naming rows are displayed in the same root carrier, so the sibling normal-word route cannot detach from the terminal packet.

Finally apply Definition 936.69. The total-host source is one finite packet, which rules out any separate host normalizer, quotient conversion, divergence oracle, or unrestricted evaluator behind the sibling bridge. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalNormalWordSiblingBridge`

Theorem 936.86 ($\mathsf{ZNormal}^{\uparrow}$ total-host refusal readback)**.** *The same accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet that exposes the terminal route refuses readback of divergence, host conversion, quotient normalization, unrestricted evaluation, and global normalization. All terminal and normal-word reads remain inside*

$$T, F, V, K, R, H, C, P, N,$$

with no total-host row outside the finite packet.

Proof. First combine Definition 936.84 with Definition 936.85. Terminal and normal-word consumers are both confined to the displayed packet and its finite sibling routes.

Use Definition 936.69. It states that the total-host source is the single finite packet, not a separately readable host conversion or divergence object.

Finally apply Definition 936.78 and Definition 936.79. These rows account for all admitted terminal and sibling reads, leaving no coordinate for the refused total-host readbacks. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTotalHostRefusalReadback`

Theorem 936.87 ($\mathsf{ZNormal}^{\uparrow}$ root total-host readiness)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the root total-host consumer may read only the typed endpoint row T*, finite fuel row* F*, terminal-normality row* V*, sibling normal-word row* K*, continuation readback row* R*, componentwise* hsame *transport row* H*, displayed* Cont *replay row* C*,* Pkg *provenance row* P*, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row* N*. The consumer receives no host conversion row, quotient normalization row, divergence oracle, unrestricted evaluation row, or global-normalization coordinate.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root total host readiness`

Proof. Project the carrier of Definition 936.1. The displayed packet $Z = (T, F, V, K, R, H, C, P, N)$ lists every root-readable coordinate of an accepted $\mathsf{ZNormal}^{\uparrow}$ packet.

Apply the NameCert obligations of Definition 936.2. They bind carrier admission, typed endpoint readback, finite fuel, terminal normality, sibling normal-word evidence, continuation readback, transport, replay, provenance, and local naming into one finite surface.

Since the carrier and the NameCert surface contain no host conversion, quotient normalization, divergence, unrestricted evaluation, or global-normalization row, a total-host consumer can only read the displayed packet. □

Theorem 936.88 ($\mathsf{ZNormal}^{\uparrow}$ root kernel source totality)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the root kernel source is total over the displayed packet rows: typed endpoint T*, finite fuel* F*, terminal normality* V*, sibling normal-word evidence* K*, continuation readback* R*,* hsame *transport* H*,* Cont *replay* C*,* Pkg *provenance* P*, and* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *naming* N*. No kernel consumer can source the same normal-form read from host conversion, quotient normalization, divergence detection, unrestricted evaluation, or a global normalizer outside those rows.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootKernelSourceTotality`

Proof. Start from the carrier of Definition 936.1. Its finite BHist packet supplies the complete source tuple and does not expose any second kernel-source coordinate.

Use Definition 936.2 to read the same rows through the local naming surface. The typed endpoint, fuel, terminal row, sibling normal-word row, continuation readback, transport, replay, package, and naming obligations are all discharged inside Z.

The non-escape conclusion is constructive projection: every kernel consumer obtains its source by selecting one of the displayed rows and following the structural route through H, C, P, N. The excluded host and quotient objects are absent from the packet, so they cannot serve as kernel sources. □

Theorem 936.89 ($\mathsf{ZNormal}^{\uparrow}$ root normal-form consumer exhaustion)**.** *Every root normal-form consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

is exhausted by typed endpoint T, finite fuel F, terminal-normality row V, sibling normal-word row K, continuation readback R, componentwise hsame *transport H, displayed* Cont *replay C,* Pkg *provenance P, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row N. The normal-form read has no remaining route to host conversion, quotient normalization, a divergence oracle, unrestricted evaluation, or global normalization.*

Proof. First expose the displayed packet with Definition 936.1. It gives the normal-form consumer exactly the nine rows $T, F, V, K, R, H, C, P, N$.

Then apply Definition 936.2. The local certificate forces endpoint, fuel, terminal-normality, sibling normal-word, continuation readback, transport, replay, provenance, and naming to be consumed as one finite route.

It remains to rule out escape. Because neither the carrier nor the NameCert obligation surface contains host conversion, quotient normalization, divergence, unrestricted evaluation, or global normalization, no normal-form consumer can continue past the displayed route. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root normal form consumer exhaustion`

Theorem 936.90 ($\mathsf{ZNormal}^{\uparrow}$ terminal row constructor exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the terminal row constructor surface is exhausted by typed endpoint T, finite fuel F, terminal-normality V, sibling normal-word evidence K, terminal readback R, componentwise hsame *transport H, displayed* Cont *replay C, package provenance P, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row N. It constructs no host conversion, quotient normalization, unrestricted evaluation, divergence detection, or global normalization row.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTerminalRowConstructorExhaustion`

Proof. Project the carrier of Definition 936.1. The accepted packet lists exactly $T, F, V, K, R, H, C, P, N$ as the root terminal constructor inventory.

Apply Definition 936.2. Carrier admission, typed endpoint readback, finite fuel, terminal normality, sibling normal-word evidence, continuation readback, transport, replay, provenance, and local naming are the displayed NameCert obligations for the same packet.

Use Definition 936.8 and Definition 936.11. Terminal readback is routed through the finite terminal rows, and K is only the finite sibling normal-word handoff.

Finally apply Definition 936.81. The TasteGate-facing field surface is the same packet surface, so no constructor row can be reinterpreted as host conversion, quotient normalization, unrestricted evaluation, divergence detection, or global normalization. □

Theorem 936.91 ($\mathsf{ZNormal}^{\uparrow}$ fuel replay nondivergence boundary)**.** *For an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the fuel replay boundary is the finite path from T through F to V and R, transported and replayed by H, C, P, N, with K available only as finite sibling normal-word evidence. This boundary records nondivergence of the displayed replay route without exporting divergence detection, unrestricted evaluation, host conversion, quotient normalization, or global normalization.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalFuelReplayNondivergenceBoundary`

Proof. Begin with Definition 936.1 and Definition 936.2. Together they expose the finite fuel row F beside the typed endpoint, terminal-normality, continuation, transport, replay, provenance, and local naming rows.

Use Definition 936.8. The replayed terminal read is the displayed route through T, F, V, R, H, C, P, N, not a host evaluator.

Attach the sibling side by Definition 936.11. The row K remains finite normal-word evidence and does not become a quotient normalizer or a global normalizer.

Finally apply Definition 936.81. Since the TasteGate-facing packet has exactly the rows $T, F, V, K, R, H, C, P, N$, the fuel replay boundary can certify only the displayed nondivergence route and cannot decide arbitrary divergence or unrestricted evaluation. □

Theorem 936.92 ($\mathsf{ZNormal}^{\uparrow}$ total host consumer factorization)**.** *Every total-host consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors through the finite packet*

$$Z = (T, F, V, K, R, H, C, P, N).$$

The factorization first reads typed endpoint, fuel, terminal-normality, sibling normal-word, and terminal readback rows, and then moves only through H, C, P, N. It has no route to host conversion, quotient normalization, unrestricted evaluation, divergence detection, or global normalization.

Proof. Project the carrier and local NameCert surface using Definition 936.1 and Definition 936.2. These rows give the complete consumer inventory and bind it to one local naming certificate.

Apply Definition 936.8. Any terminal read of the consumer must pass through the finite terminal route, including R and the structural rows H, C, P, N.

Use Definition 936.11 to account for K. The normal-word component is the sibling handoff surface, not an additional host normalization channel.

Finally use Definition 936.81. The TasteGate-facing field surface is already the same tuple, so a total-host consumer factors through the packet and cannot extract host conversion, quotient normalization, unrestricted evaluation, divergence detection, or global normalization. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host consumer factorization`

Theorem 936.93 ($\mathsf{ZNormal}^{\uparrow}$ root-readiness bridge source)**.** *Every root-readiness consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors through the finite sibling route consisting of* $\mathsf{ZeckendorfNormal}^{\uparrow}$, $\mathsf{ZCarry}^{\uparrow}$, $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$, *and the packet rows*

$$T, F, V, K, R, H, C, P, N.$$

The consumer reads the root source as one BHist *packet with componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ *naming; it has no additional bridge source outside the finite sibling route.*

Proof. Project the accepted packet through Definition 936.66. This exposes $T, F, V, K, R, H, C, P, N$ as one root BHist source rather than as detached endpoint, word, carry, or continuation rows.

Use Definition 936.29 to make the local $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ surface the only root-readiness interface. The same surface carries H, C, P, N, so transport, replay, package provenance, and local naming stay attached to the displayed packet.

Finally read the sibling route through the finite consumers already named by K and R. The K row reaches $\mathsf{ZeckendorfNormal}^\uparrow$ and $\mathsf{ZCarry}^\uparrow$, while the R row reaches $\mathsf{ContinuationTraceNormalForm}^\uparrow$; no extra root bridge source is introduced beyond these sibling surfaces and the displayed packet rows. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root readiness bridge source`

Theorem 936.94 ($\mathsf{ZNormal}^\uparrow$ root-readiness terminal non-escape)**.** *Every terminal read exposed by the root-readiness surface of an accepted* $\mathsf{ZNormal}^\uparrow$ *packet remains inside*

$$T, F, V, K, R, H, C, P, N.$$

It exposes no host conversion row, quotient normalizer, unrestricted evaluator, divergence oracle, or global normalization row.

Proof. Start from Definition 936.14. It binds terminal use to the finite root-facing interface and keeps the terminal route on the displayed packet rows.

Apply Definition 936.58. This refuses host conversion, quotient normalization, unrestricted evaluation, divergence detection, and global normalization for every total-host request that tries to leave the finite root route.

The terminal read is therefore a non-escaping readback through $T, F, V, K, R, H, C, P, N$. Since neither the terminal interface nor the total-host refusal theorem supplies an extra host or global-normalization coordinate, no listed excluded row is exported. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root readiness terminal nonescape`

Theorem 936.95 ($\mathsf{ZNormal}^\uparrow$ root-readiness NameCert package)**.** *The root-readiness package consumed downstream by* $\mathsf{ZNormal}^\uparrow$ *consists exactly of the finite bridge-source row of Definition 936.93, the terminal non-escape row of Definition 936.94, and the existing local* $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ *surface. Downstream normal-form consumers receive that package as* $T, F, V, K, R, H, C, P, N$ *with the finite sibling route through* $\mathsf{ZeckendorfNormal}^\uparrow$*,* $\mathsf{ZCarry}^\uparrow$*, and* $\mathsf{ContinuationTraceNormalForm}^\uparrow$*; they do not receive a separate total-host or global-normalization package.*

Proof. First combine Definition 936.93 with Definition 936.29. The bridge-source theorem supplies the finite sibling route and the displayed packet rows, while the NameCert readiness theorem supplies the local naming surface over the same rows.

Next use Definition 936.94. It keeps terminal reads inside the same package and refuses host conversion, quotient normalization, unrestricted evaluation, divergence detection, and global normalization.

Thus every downstream normal-form consumer receives one package: the finite sibling bridge source, the terminal non-escape boundary, and the local $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ surface. There is no remaining coordinate from which to build a separate total-host package or a global-normalization package. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root readiness namecert package`

Theorem 936.96 ($\mathsf{ZNormal}^{\uparrow}$ total-host terminal carrier admission)**.** *Every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

admits a total-host terminal carrier only through the displayed terminal normality row V*, bounded fuel replay row* F*, typed endpoint row* T*, and terminal continuation row* R*. The TasteGate-facing structural rows* H, C, P, N *transport, replay, package, and name this same carrier, while* K *remains finite sibling normal-word evidence. The carrier admits no host conversion row, quotient normalization row, unrestricted evaluator, divergence oracle, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host terminal carrier admission`

Proof. Project the carrier and its local obligations, Definition 936.1 and Definition 936.2. They expose exactly $T, F, V, K, R, H, C, P, N$ as the finite packet and make terminal normality a displayed row rather than a host-side conversion judgment.

Use the root terminal carrier and terminal non-escape surfaces, Definition 936.53 and Definition 936.14. These place terminal use on T, F, V, R and keep the sibling normal-word row K inside the same accepted packet.

Finally apply the TasteGate scope binding, Definition 936.75. The later TasteGate consumer sees the same finite field surface, so the admitted carrier cannot acquire any excluded host, quotient, evaluator, divergence, or global-normalization row. □

Theorem 936.97 ($\mathsf{ZNormal}^{\uparrow}$ fuel readback TasteGate route)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the bounded fuel readback route reaches TasteGate only after the typed endpoint* T*, finite fuel* F*, terminal normality* V*, continuation readback* R*, and structural rows* H, C, P, N *have been displayed. The normal-word row* K *may contribute only the finite Zeckendorf and carry-facing sibling route. This TasteGate route exports no host conversion, quotient computation, unrestricted evaluation, divergence detection, or global normalization.*

Proof. Start from terminal fuel field scope and terminal fuel row exhaustion, Definition 936.76 and Definition 936.78. They route fuel readback through T, F, V, R, H, C, P, N and leave K as finite sibling evidence.

Next use the root TasteGate field surface, Definition 936.81. It identifies the TasteGate-facing consumer surface with the displayed tuple $T, F, V, K, R, H, C, P, N$.

The total-host refusal package, Definition 936.80, closes the route. Since every excluded host or quotient object is absent from the packet, the fuel readback reaches TasteGate only through the displayed finite rows. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalFuelReadbackTasteGateRoute`

Theorem 936.98 ($\mathsf{ZNormal}^{\uparrow}$ downstream normal consumer non-escape)**.** *Every downstream normal-form consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *total-host packet is confined to terminal normality through* T, F, V, R*, finite sibling normal-word evidence through* K*, and the TasteGate-aligned structural rows* H, C, P, N*. The downstream route is exhausted by the displayed packet and cannot escape to host conversion, quotient normalization, unrestricted evaluation, divergence detection, substrate halting, or global normalization.*

Proof. Begin with downstream normal route exhaustion, Definition 936.46. It accounts for terminal fuel, sibling normal-word evidence, componentwise transport, continuation replay, provenance, and local naming for every downstream normal-form consumer.

Apply the total-host terminal carrier admission above. The downstream consumer therefore reads the same terminal carrier that already passed through terminal normality, bounded fuel replay, TasteGate alignment, and the local structural rows.

Finally use the root total-host refusal theorem, Definition 936.58. It refuses host conversion, quotient normalization, unrestricted evaluation, divergence detection, substrate halting, and global normalization for every route not carried by $T, F, V, K, R, H, C, P, N$. Hence the downstream normal consumer has no escape route beyond the displayed packet. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket downstream normal consumer nonescape`

Theorem 936.99 ($\mathsf{ZNormal}^{\uparrow}$ terminal total-host carrier row)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the terminal total-host carrier row is the displayed BHist *carrier read through terminal normality* V*, continuation readback* R*, componentwise* hsame *transport* H*,* Cont *replay* C*, package provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row* N*. The row admits terminal normality as finite displayed data and exports no host conversion, quotient normalization, divergence oracle, or global normalization procedure.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTerminalTotalHostCarrierRow`

Proof. Project the carrier and local certificate surface using Definition 936.1 and Definition 936.2. These rows expose $T, F, V, K, R, H, C, P, N$ as the complete accepted packet and bind the carrier to one local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface.

Apply Definition 936.53 and Definition 936.96. They place the terminal total-host carrier on the displayed terminal route through T, F, V, R with H, C, P, N attached as transport, replay, package, and naming evidence.

Finally use Definition 936.58. Since the root refusal ledger excludes host conversion, quotient normalization, divergence detection, unrestricted evaluation, and global normalization outside the packet, the carrier row is finite displayed data rather than a host-side normalizer. □

Theorem 936.100 ($\mathsf{ZNormal}^{\uparrow}$ fuel replay classifier row)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the fuel replay classifier row reads bounded fuel* F *together with terminal normality* V*, terminal readback* R*,* hsame *transport* H*,* Cont *replay* C*, package provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *naming* N*. The classifier may consume the sibling normal-word row* K *only as finite displayed evidence, and it supplies no unrestricted evaluator or global normalization procedure.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket fuel replay classifier row`

Proof. Begin with Definition 936.91. It identifies the bounded replay path from T through F to V and R, transported and replayed by H, C, P, N, with K remaining finite sibling normal-word evidence.

Use Definition 936.97 and Definition 936.78. These results keep the fuel readback classifier on the displayed packet rows before any TasteGate-facing consumer can read it.

The root side is fixed by Definition 936.89. It confines downstream normal-form consumers to the same finite packet, so bounded replay remains classifier data and cannot become unrestricted evaluation or global normalization. □

Theorem 936.101 ($\mathsf{ZNormal}^{\uparrow}$ divergence-oracle non-escape row)**.** *Every divergence-oracle request addressed to a root* $\mathsf{ZNormal}^{\uparrow}$ *total-host packet is blocked by the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *rows of the same accepted packet. Terminal normality and bounded replay are read as finite data through* $T, F, V, K, R, H, C, P, N$*; no route escapes to a divergence oracle, substrate halting predicate, host conversion row, quotient normalization row, or global normalization procedure.*

Proof. First assemble the finite root packet using Definition 936.93. It exposes the root BHist source and attaches transport, replay, package provenance, and local naming to the same displayed fields.

Next apply Definition 936.94 and Definition 936.17. These rows keep terminal reads inside the finite normality and continuation route while refusing escape to omitted host-facing objects.

Finally use Definition 936.35 with Definition 936.58. The first ledger refuses divergence-oracle readings, and the second refuses the total-host exits listed in the statement; together they leave only terminal normality and bounded replay as finite displayed data. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalDivergenceOracleNonescapeRow`

Definition 936.102 ($\mathsf{ZNormal}^{\uparrow}$ root display packet)**.** *The root display packet of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *certificate is the finite tuple*

$$Z = (T, F, V, K, R, H, C, P, N).$$

Here T *is the typed endpoint row,* F *is the finite fuel row,* V *is the terminal-normality row,* K *is the Zeckendorf and carry-facing normal-word row,* R *is the terminal continuation-trace row,* H *is the componentwise* hsame *transport row,* C *is the displayed* Cont *replay row,* P *is the local* Pkg *provenance row, and* N *is the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *naming row. The packet is read as one finite* BHist *surface: every admitted root consumer must enter through these rows and their displayed* hsame*,* Cont*,* Pkg*, and* NameCert *coordinates.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootDisplayPacket semantic name certificate`

Theorem 936.103 ($\mathsf{ZNormal}^{\uparrow}$ root total-host bridge components)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *root display packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

each total-host read factors through the typed endpoint row T*, the Zeckendorf and carry-facing normal row* K*, the terminal continuation-trace row* R*, and the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *rows* P, N*. The read may use the finite fuel, terminal-normality, transport, and replay rows* F, V, H, C*, but it cannot bypass the displayed bridge components by a host conversion row, divergence oracle, quotient computation, unrestricted evaluator, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootTotalHostBridgeComponents`
↪variant `BEDC.Derived.ZnormalUp.ZnormalPacket root total host bridge components`

Proof. Start with Definition 936.102. It exposes the accepted root surface as the finite tuple $T, F, V, K, R, H, C, P, N$, so there is no second total-host coordinate outside the displayed BHist packet.

Apply Definition 936.66 and Definition 936.67. The first pins root reads to the single BHist source, and the second keeps the Zeckendorf and carry-facing normal row K and the terminal continuation-trace row R under the displayed hsame and Cont rows H, C.

The sibling chapters then supply only component surfaces. The typed endpoint route is the one named by chapter 562; the finite normal-word route is the one named by chapter 278 and chapter 544; and the terminal continuation route is the one named by chapter 683.

Finally use Definition 936.68. Since the ledger accounts for every root consumer through P and N, the total-host read has exactly the displayed bridge components and no exported host conversion, divergence, quotient, evaluator, or global-normalization row. □

Theorem 936.104 ($\mathsf{ZNormal}^{\uparrow}$ root continuation replay closure)**.** *Every accepted replay of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *root display packet is exhausted by the displayed* Cont *row* C *together with the terminal continuation-trace row* R*, transport row* H*, provenance row* P*, and local naming row* N*. The replay cannot export a divergence oracle, host conversion row, or global normalization procedure, and it cannot manufacture a continuation trace outside the finite packet* Z*.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootContReplayClosure`

Proof. Read the replay surface through Definition 936.102. The only replay coordinate is C, and it is attached to R, H, P, N inside the same finite packet.

Use Definition 936.67. It keeps the R read replayed only by C and transported only by H, with the ContinuationTraceNormalForm sibling surface supplying the terminal trace rather than an ambient evaluator.

Next apply Definition 936.69 and Definition 936.84. These force terminal and total-host consumers to pass through the displayed rows before any replay can be accepted.

Finally invoke Definition 936.68. The package and local naming ledger has no coordinate for divergence, host conversion, or global normalization, so replay closure is exactly the displayed Cont row over Z. □

Theorem 936.105 ($\mathsf{ZNormal}^{\uparrow}$ root NameCert component exhaustion)**.** *The local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *surface of an accepted root display packet is exactly the displayed carrier, classifier, transport, replay, provenance, and naming data*

$$(T, F, V, K, R, H, C, P, N).$$

Its carrier is the finite BHist *packet* Z*; its classifier reads the typed endpoint, finite fuel, terminal normality, Zeckendorf and carry-facing normal row, and terminal continuation trace; its transport and replay rows are* H *and* C*; its provenance and local name rows are* P *and* N*. No additional carrier, classifier, transport, replay, provenance, naming, host conversion, divergence, or global-normalization component belongs to the local NameCert surface.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootNameCertComponentExhaustion`

Proof. Project the carrier from Definition 936.102 and Definition 936.1. Both descriptions display the same finite coordinates $T, F, V, K, R, H, C, P, N$ and give no external NameCert component.

Apply Definition 936.2. It binds carrier admission, classifier reads, transport, replay, provenance, and local naming to the rows already visible in the accepted packet.

Use Definition 936.67 to account for the classifier side and Definition 936.68 to account for provenance and local naming. These two results close the component list through K, R, H, C, P, N without opening a host-facing route.

The sibling packets remain inputs to the displayed rows only: chapter 562 supplies the typed endpoint surface, chapter 278 and chapter 544 supply the finite normal-word surface, and chapter 683 supplies the terminal continuation surface.

Thus the local NameCert surface is exhausted by the carrier, classifier, transport, replay, provenance, and naming rows of Z, with no additional host conversion, divergence, or global-normalization component. □

Theorem 936.106 ($\mathsf{ZNormal}^{\uparrow}$ root display packet bridge readback exactness)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *root display packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

any accepted total-host or terminal-normal consumer read of Z factors through exactly the displayed typed endpoint row T, finite fuel row F, terminal-normality row V, Zeckendorf and carry-facing normal-word row K, terminal continuation-trace row R, componentwise transport row H, replay row C, provenance row P, and local name row N. The typed endpoint, normal-word, and continuation-trace sibling surfaces may be consumed only as displayed rows of this packet. No host conversion, divergence oracle, quotient computation, unrestricted evaluator, or global normalizer participates in the readback.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootDisplayPacketBridgeReadbackExactness`

Proof. Project the packet by Definition 936.102. The accepted root surface is the finite BHist display $T, F, V, K, R, H, C, P, N$, so a consumer read has no ambient coordinate apart from these rows.

Apply Definition 936.103. It identifies the typed endpoint read with T, the Zeckendorf and carry-facing normal read with K, the terminal continuation-trace read with R, and the local provenance and naming read with P, N, while keeping F, V, H, C inside the same packet.

Use Definition 936.104 for the replay coordinate. This confines every accepted continuation replay to C together with R, H, P, N, and it prevents the readback from exporting a host conversion, divergence oracle, or global-normalization procedure.

Finally invoke Definition 936.105. Its component list exhausts the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface by the carrier, classifier, transport, replay, provenance, and naming rows of Z. The sibling chapters chapter 562, chapter 278, chapter 544, and chapter 683 are therefore consumed only as displayed endpoint, normal-word, and continuation-trace surfaces, giving exact readback with no quotient computation, unrestricted evaluator, or global normalizer. □

Definition 936.107 ($\mathsf{ZNormal}^{\uparrow}$ root carrier boundary)**.** *The root carrier boundary for terminal normality is the finite packet*

$$Z = (T, F, V, K, R, H, C, P, N).$$

Here T is the terminal typed endpoint row, F is the bounded fuel row, V is the terminal-normality row, K is the total-host refusal row for host conversion, quotient normalization, divergence, unrestricted evaluation, and global normalization, R is the displayed continuation readback row, H is the componentwise hsame *transport row, C is the displayed* Cont *replay row, P is the* Pkg *provenance row, and N is the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row. A root consumer reads terminal normality only through these rows of the* BHist *packet.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root carrier boundary semantic namecert`

Theorem 936.108 ($\mathsf{ZNormal}^{\uparrow}$ NameCert root obligations)**.** *For the root boundary of Definition 936.107, the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *surface consists of five obligations:*

1. *carrier admission exposes exactly the finite packet $Z = (T, F, V, K, R, H, C, P, N)$;*

2. *classifier exposure reads terminal normality from V and its sibling normal-route evidence from T, F, K, R;*
3. *terminal-normality evidence is accepted only after the bounded fuel row F and the total-host refusal row K are displayed;*
4. *bounded-fuel replay is transported by H and reread only through the displayed* Cont *row C;*
5. *non-escape keeps* Pkg *provenance and local naming inside P, N and exports no host conversion row, quotient normalization row, divergence oracle, unrestricted evaluator, or global-normalization coordinate.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket namecert root obligations`

Proof. Project the root boundary packet. The carrier obligation is the finite tuple $T, F, V, K, R, H, C, P, N$, so the classifier has no second row from which to read terminal normality.

The classifier and terminal-normality obligations are the rows V together with T, F, K, R. The row F bounds the replay, K records refusal of total-host escape routes, and R keeps the terminal readback attached to the displayed continuation surface.

Transport and replay are structural rows. The componentwise hsame row H moves only the displayed coordinates, and the Cont row C rereads only the same finite packet.

Finally, P and N record provenance and local naming for the packet already exposed. Since no excluded host or quotient coordinate appears in the carrier, the non-escape obligation is discharged inside the displayed root surface. □

Theorem 936.109 ($\mathsf{ZNormal}^{\uparrow}$ root consumer readiness)**.** *Every downstream normal-route consumer that uses* $\mathsf{ZNormal}^{\uparrow}$ *must expose the root carrier boundary of Definition 936.107 before citing terminal normality. In particular, it must display the terminal typed endpoint row T, bounded fuel row F, terminal-normality row V, total-host refusal row K, continuation readback row R,* hsame *transport row H,* Cont *replay row C,* Pkg *provenance row P, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row N.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root consumer readiness`

Proof. Begin with the boundary definition. A downstream consumer reaches $\mathsf{ZNormal}^{\uparrow}$ through the finite packet $Z = (T, F, V, K, R, H, C, P, N)$, and terminal normality is one row of that packet rather than an ambient host theorem.

Apply Definition 936.108. The root obligations require carrier admission, classifier exposure, terminal-normality evidence, bounded-fuel replay, and non-escape before the local name may be consumed.

Thus a normal-route consumer is ready only after it has displayed all root rows. Any attempted citation that omits F, K, R, H, C, P, N would either detach the terminal row from its bounded replay and total-host refusal surface or bypass the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ row, and so would not be an accepted $\mathsf{ZNormal}^{\uparrow}$ consumer. □

Theorem 936.110 ($\mathsf{ZNormal}^{\uparrow}$ NameCert obligation surface)**.** *For every accepted root packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *obligation surface is exactly the finite display consisting of carrier admission for Z, classifier exposure through T, F, V, K, R, terminal-normality evidence through V, bounded-fuel replay through F, H, C, and non-escape through P, N. The packet admits no additional carrier row for host conversion, quotient computation, unrestricted evaluation, divergence, substrate halting, or a global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalNameCertObligationSurface`

Proof. Read the carrier boundary through Definition 936.107. It lists precisely the rows $T, F, V, K, R, H, C, P, N$, so carrier admission is already a finite BHist display and not an ambient total-host object.

Apply Definition 936.108. The root obligations bind classifier exposure, terminal-normality evidence, bounded-fuel replay, and non-escape to the same displayed packet. The classifier rows are T, F, V, K, R, while replay is transported by H and reread through C.

Finally use Definition 936.109. A root or downstream normal-route consumer can cite terminal normality only after all rows of Z are exposed. Since the listed host and global-normalization readings are absent from Z, the obligation surface is exhausted by the displayed packet. □

Theorem 936.111 ($\mathsf{ZNormal}^{\uparrow}$ classifier transport)**.** *Let*

$$Z = (T, F, V, K, R, H, C, P, N)$$

and

$$Z' = (T', F', V', K', R', H', C', P', N')$$

be accepted $\mathsf{ZNormal}^{\uparrow}$ *root packets. If the displayed transport rows give componentwise* hsame *from each classifier coordinate of Z to the corresponding coordinate of Z' and the displayed* Cont *replay rows carry the same bounded-fuel route, then classifier transport preserves the $T, F, V, K, R, H, C, P, N$ rows. The ZeckendorfNormal,* $\mathsf{ZCarry}^{\uparrow}$*, and* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *inputs are consumed only as sibling finite surfaces, not as new classifier coordinates.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket classifier transport`

Proof. Start from the two root boundaries. By Definition 936.107, both packets have the same row shape, so a componentwise hsame transport can only move displayed coordinates to displayed coordinates.

Use Definition 936.108 for the source packet and for the target packet. Classifier exposure is attached to T, F, V, K, R, while bounded replay is attached to F, H, C and to F', H', C'.

The sibling evidence is external only in the controlled sense already named by the chapter. The typed endpoint route is supplied by chapter 562, the finite normal-word route by chapter 278 and chapter 544, and the terminal continuation route by chapter 683.

Therefore transport preserves the displayed classifier rows and consumes those sibling surfaces only through K and R. No sibling certificate becomes a fresh coordinate of the $\mathsf{ZNormal}^{\uparrow}$ packet. □

Theorem 936.112 ($\mathsf{ZNormal}^{\uparrow}$ ledger nonescape)**.** *Every root or normal-form consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

factors its ledger read through the provenance and naming rows P, N. Consequently the consumer cannot read host conversion, quotient computation, unrestricted evaluation, divergence, substrate halting, or a global normalizer from the $\mathsf{ZNormal}^{\uparrow}$ *ledger.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket ledger nonescape certificate`

Proof. Project the ledger rows by Definition 936.107. The only provenance row is P, and the only local naming row is N.

Apply Definition 936.108. Non-escape is one of the root obligations, and it keeps Pkg provenance and local naming inside the displayed P, N rows.

Now apply Definition 936.109. Any root or normal-route consumer must expose the whole packet before terminal normality is read, so its ledger route has already passed through P, N.

The excluded host and global-normalization readings have no ledger coordinate in Z. Hence every accepted consumer factors through P, N, and the ledger cannot be reopened as host conversion, quotient computation, unrestricted evaluation, divergence, substrate halting, or a global normalizer. □

Theorem 936.113 ($\mathsf{ZNormal}^{\uparrow}$ terminal boundary non-escape)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *root packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

any terminal read through the displayed BHist *rows* T, F, V, R, H, C, P, N *remains inside the finite terminal-normality boundary of the packet. The read cannot export a host conversion row, quotient normalization row, divergence oracle, unrestricted evaluator, or global-normalization coordinate.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTerminalBoundaryNonescape`

Proof. Project the accepted carrier by Definition 936.1 and the root packet by Definition 936.107. Both displays expose the terminal route as rows of one finite BHist packet, with T, F, V, R, H, C, P, N already attached to the same local naming surface.

Apply Definition 936.2. The local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ obligation reads terminal normality only after typed endpoint evidence, finite fuel, sibling normal-word evidence, continuation readback, transport, replay, provenance, and local naming have been displayed.

The sibling chapters supply component evidence rather than escape routes. chapter 562 supplies the typed endpoint surface, chapter 278 and chapter 544 supply finite normal-word and carry evidence, and chapter 683 supplies terminal continuation readback.

Since no host conversion, quotient normalization, divergence oracle, unrestricted evaluator, or global normalizer is a row of Z, the terminal read is exhausted by the displayed BHist packet. □

Theorem 936.114 ($\mathsf{ZNormal}^{\uparrow}$ source route totality)**.** *Every accepted root consumer that cites terminal normality for* $\mathsf{ZNormal}^{\uparrow}$ *must first expose the complete displayed source route*

$$T, F, V, K, R, H, C, P, N.$$

Thus the consumer reads terminal normality only after the terminal typed endpoint row, finite fuel row, terminal-normality row, sibling normal-word row, continuation readback row, hsame *transport row,* Cont *replay row,* Pkg *provenance row, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row have all appeared in the* BHist *packet.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket source route totality`

Proof. Begin with Definition 936.109. It requires every downstream normal-route consumer to expose the root carrier boundary before citing terminal normality.

Now read the root boundary itself through Definition 936.107. The only source route made available to a consumer is the finite tuple $T, F, V, K, R, H, C, P, N$.

Apply Definition 936.2. The local certificate binds carrier admission, classifier exposure, bounded-fuel replay, transport, package provenance, and local naming to the same displayed packet.

The typed endpoint, finite normal-word, carry, and terminal continuation inputs remain the sibling surfaces of chapter 562, chapter 278, chapter 544, and chapter 683. Therefore a consumer route is total exactly over the displayed BHist packet and has no hidden source outside it. □

Theorem 936.115 ($\mathsf{ZNormal}^{\uparrow}$ NameCert ledger exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *root packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *ledger is exhausted by the provenance and naming rows* P, N *over that displayed* BHist *packet. No additional ledger row remains for host conversion, quotient normalization, divergence detection, unrestricted evaluation, global normalization, or a second source route.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalNamecertLedgerExhaustion`

Proof. Project the carrier by Definition 936.1. The packet lists P as the Pkg provenance row and N as the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ row, with no separate ledger component.

Use Definition 936.2 to read the ledger through the same finite packet. The naming surface attaches carrier admission, terminal-normality evidence, sibling evidence, transport, replay, provenance, and naming to $T, F, V, K, R, H, C, P, N$.

Apply Definition 936.107 and Definition 936.109. They force root consumers to display the same BHist source route before terminal normality can be used.

The sibling evidence remains local to the displayed rows: typed endpoints come from chapter 562, finite normal words from chapter 278, carry evidence from chapter 544, and terminal continuation readback from chapter 683. Consequently P, N exhaust the local ledger over Z, and every excluded host-side read lacks a NameCert row. □

Theorem 936.116 ($\mathsf{ZNormal}^{\uparrow}$ total-host readback display)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *root packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the root-facing total-host readback surface exposes exactly the rows $T, F, V, K, R, H, C, P, N$*. Here* T *is the typed endpoint row,* F *is the finite fuel row,* V *is the terminal-normality row,* K *is the finite ZeckendorfNormal and* $\mathsf{ZCarry}^{\uparrow}$ *normal-word evidence row,* R *is the continuation readback row, and* H, C, P, N *are the displayed transport, route, provenance, and local naming rows.*

No root consumer receives host conversion, quotient normalization, unrestricted evaluation, divergence, or global normalization data from this display.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host readback display`

Proof. Project the carrier of Definition 936.1 and the root boundary of Definition 936.107. Both expose the same finite packet $T, F, V, K, R, H, C, P, N$ before any root-facing terminal claim can be read.

Apply Definition 936.2 and Definition 936.108. These obligations bind carrier admission, terminal-normality exposure, sibling evidence, bounded fuel, transport, replay, provenance, and local naming to the displayed root packet.

The row list contains no host conversion, quotient normalization, unrestricted evaluator, divergence oracle, or global normalizer. Thus the total-host readback display is exactly the finite root surface $T, F, V, K, R, H, C, P, N$. □

Theorem 936.117 ($\mathsf{ZNormal}^{\uparrow}$ terminal fuel route exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *root packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

any terminal-fuel consumer factors through the displayed finite route

$$T \longmapsto F \longmapsto V \longmapsto R$$

together with H, C, P, N. The sibling row K may be read only as finite normal-word evidence attached to that route, and it cannot replace the finite fuel route by host conversion, quotient normalization, unrestricted evaluation, divergence, or global normalization.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal fuel route exhaustion`

Proof. Begin with the total-host readback display of Definition 936.116. It exposes the root packet as a finite BHist surface and leaves no unbounded evaluator row outside the packet.

Use Definition 936.72 and Definition 936.9. They place every terminal fuel read behind the typed endpoint T, finite fuel F, terminal-normality row V, and continuation readback row R.

Next apply Definition 936.113. The boundary keeps the read inside the displayed transport, replay, provenance, and local naming rows H, C, P, N.

Finally inspect K. By Definition 936.11, K is finite sibling normal-word evidence only. It cannot supply host conversion, quotient normalization, unrestricted evaluation, divergence, or global normalization in place of the terminal fuel route. □

Theorem 936.118 (ZNormal$^{\uparrow}$ normal-word sibling separation)**.** *For every accepted* ZNormal$^{\uparrow}$ *root packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the ZeckendorfNormal and ZCarry$^{\uparrow}$ *normal-word evidence carried by K remains sibling evidence for the finite route T, F, V, R, H, C, P, N. It is separate from host conversion, quotient normalization, unrestricted evaluation, divergence, and global normalization, and no root consumer may identify those excluded host-side objects with the normal-word evidence row.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket normal word sibling separation`

Proof. Project K from the accepted root packet. The carrier records K beside T, F, V, R, H, C, P, N, so the normal-word evidence is a displayed sibling row rather than a replacement for the terminal route.

Apply Definition 936.3 and Definition 936.11. These theorems read K through the finite ZeckendorfNormal and ZCarry$^{\uparrow}$ surfaces and attach it to the same BHist, hsame, Cont, Pkg, and NameCert rows as the rest of the packet.

Use Definition 936.73 for the excluded host-side objects. The frontier refuses host conversion, quotient computation, unrestricted evaluation, divergence, and global normalization as exported reads.

Therefore the K row remains finite normal-word sibling evidence only. The terminal route remains T, F, V, R, H, C, P, N, and no accepted root consumer can turn K into a host conversion, quotient normalization, unrestricted evaluator, divergence oracle, or global normalizer. □

Theorem 936.119 (ZNormal$^{\uparrow}$ root carrier exposure)**.** *For every accepted* ZNormal$^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the root carrier exposure available to downstream normal-form consumers is exactly the finite row list displayed by Definition 936.1. The rows expose the typed endpoint T, finite fuel F, terminal-normality coordinate V, sibling normal-word evidence K, terminal readback R, componentwise hsame *transport H, displayed* Cont *replay C,* Pkg *provenance P, and local* NameCert *row N.*

No accepted root consumer receives a second carrier row outside this packet.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root carrier exposure`

Proof. Project the carrier in Definition 936.1. Its displayed tuple is $T, F, V, K, R, H, C, P, N$, with each coordinate named as a finite BEDC row before any terminal-normality or total-host claim can be read.

Apply Definition 936.2 and Definition 936.108. These obligations bind carrier admission, typed endpoint, finite fuel, terminal normality, sibling normal-word evidence, terminal readback, transport, replay, provenance, and local naming to the same accepted packet.

Use the total-host readback display of Definition 936.116. It exposes the same row list on the root-facing surface and supplies no independent carrier coordinate. Hence the root carrier exposure is exactly the finite packet already used by the carrier definition. □

Theorem 936.120 ($\mathsf{ZNormal}^{\uparrow}$ root ledger nonescape)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the root ledger can export only the displayed finite carrier, terminal-normality, sibling normal-word, terminal readback, transport, replay, provenance, and naming rows. It cannot export a divergence oracle, host conversion row, unrestricted evaluator, quotient normalizer, or global normalization procedure.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root ledger nonescape`

Proof. Begin with Definition 936.119. The root ledger-readable surface has the same finite coordinates $T, F, V, K, R, H, C, P, N$ as the carrier exposure.

Next apply Definition 936.124 and Definition 936.17. Both ledger boundaries exhaust the available reads through the displayed terminal-normality, fuel, normal-word, continuation, transport, replay, provenance, and naming rows.

Finally use Definition 936.10 and Definition 936.73. These refusal theorems block divergence detection, host conversion, unrestricted evaluation, quotient normalization, substrate halting, and global normalization from any route not carried by the finite packet. □

Theorem 936.121 ($\mathsf{ZNormal}^{\uparrow}$ root readback exhaustion)**.** *Every terminal readback accepted by a* $\mathsf{ZNormal}^{\uparrow}$ *root consumer factors through the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows of*

$$Z = (T, F, V, K, R, H, C, P, N).$$

The readback first exposes the typed endpoint, fuel, terminal-normality, sibling normal-word, and terminal-read rows, then transports and packages them through H, C, P, N*. It has no replacement route through host conversion, quotient computation, unrestricted evaluation, divergence detection, or global normalization.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root readback exhaustion`

Proof. Start with Definition 936.119. It fixes the readable root packet as $T, F, V, K, R, H, C, P, N$ and identifies the displayed BHist source rows before any terminal readback is consumed.

Use Definition 936.8, Definition 936.117, and Definition 936.44. These results place terminal readback on the route from T through F, V, K, R and keep the terminal read inside the finite ledger.

Apply Definition 936.120. The only remaining structural rows are the componentwise hsame transport H, the displayed Cont replay C, the Pkg provenance P, and the local $\mathsf{NameCert}$ row N. Therefore every terminal readback factors through the displayed BEDC rows and cannot be replaced by an excluded host-side route. □

Theorem 936.122 ($\mathsf{ZNormal}^{\uparrow}$ terminal normality admission)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the terminal-normality row V is exposed only after the typed endpoint row T and the finite fuel row F have already been displayed. The admission surface therefore reads terminal normality as a finite packet coordinate, not as a host conversion, quotient computation, unrestricted evaluator, divergence oracle, or substrate halting theorem.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTerminalNormalityAdmission`

Proof. Project the carrier of Definition 936.1. The accepted packet is the tuple $T, F, V, K, R, H, C, P, N$, and V appears in that tuple after the typed endpoint and fuel rows.

Apply Definition 936.2. The local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface reads carrier admission, typed endpoint, finite fuel, terminal normality, sibling normal-word evidence, terminal readback, transport, replay, provenance, and naming as one finite certificate.

Use Definition 936.8. Terminal readback factors through T, F, V, R, H, C, P, N, so the consumer can reach V only through the displayed endpoint and fuel path.

Finally apply Definition 936.10. The admitted terminal-normality row remains inside the finite packet boundary and cannot be reinterpreted as host conversion, quotient computation, unrestricted evaluation, divergence detection, or a substrate halting theorem. □

Theorem 936.123 ($\mathsf{ZNormal}^{\uparrow}$ finite-fuel classifier stability)**.** *For an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

componentwise hsame *transport preserves the finite fuel row F, terminal normality row V, sibling normal-word row K, continuation readback row R, continuation replay row C, provenance row P, and local naming row N. The transported classifier surface adds no host conversion row and performs no quotient computation.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket finite fuel classifier stability`

Proof. Start with Definition 936.1. The rows F, V, K, R, H, C, P, N are coordinates of the same displayed BHist packet, with H reserved for componentwise hsame transport.

Apply Definition 936.2. The NameCert surface binds finite fuel, terminal normality, sibling normal-word evidence, continuation readback, transport, replay, provenance, and local naming to the same local packet.

Use Definition 936.8 for the continuation side. The terminal read is transported through the listed finite rows and does not introduce a separate evaluator.

Then apply Definition 936.10. Since the boundary refuses host conversion and quotient computation, componentwise hsame transport can preserve the displayed classifier rows only as finite packet data. □

Theorem 936.124 ($\mathsf{ZNormal}^{\uparrow}$ total-host ledger nonescape)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the total-host ledger exports exactly the finite terminal-normality, fuel, normal-word, continuation, transport, replay, provenance, and local naming rows displayed by the packet. It exports no divergence oracle, unrestricted evaluator, global normalizer, host conversion row, or substrate halting theorem.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host ledger nonescape`

Proof. Project the carrier by Definition 936.1. The ledger-readable surface is the finite tuple $T, F, V, K, R, H, C, P, N$ and has no additional total-host coordinate.

Apply Definition 936.2. The same rows are read as the local $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ obligations: endpoint, fuel, terminal normality, sibling normal-word evidence, terminal readback, transport, replay, provenance, and naming.

Use Definition 936.8 to route any terminal ledger read through the finite readback coordinates. The row R is a displayed continuation read, not an unrestricted evaluator.

Finally apply Definition 936.10. The total-host ledger therefore cannot export divergence detection, global normalization, host conversion, quotient computation, or a substrate halting theorem. □

Theorem 936.125 ($\mathsf{ZNormal}^\uparrow$ root normal-form readiness)**.** *For every accepted* $\mathsf{ZNormal}^\uparrow$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the root normal-form consumer reads terminal normality only through the finite packet displayed by Definition 936.1. The packet first exposes the carrier and local obligations, then routes terminal readback, sibling normal-word evidence, and the root visible source package through the same BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

The readiness boundary exports no host conversion, quotient computation, unrestricted evaluator, divergence oracle, or global normalizer.

Proof. Project the carrier and local naming surface using Definition 936.1 and Definition 936.2. These rows display exactly $T, F, V, K, R, H, C, P, N$ and bind them to the finite $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ packet.

Next apply Definition 936.8. Terminal readback is routed through T, F, V, R, H, C, P, N, so terminal normality remains a finite row rather than a host-side conversion judgment.

Now use Definition 936.11 and Definition 936.24. The sibling normal-word row K is finite evidence attached to the same packet, and the visible root source exposes all normal-output reads only after $T, F, V, K, R, H, C, P, N$ have been displayed.

The omitted host objects have no coordinate in that packet. Hence root normal-form readiness is a finite BEDC boundary over BHist, hsame, Cont, Pkg, and NameCert rows only. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootNormalFormReadiness`

Theorem 936.126 ($\mathsf{ZNormal}^\uparrow$ total-host ledger exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^\uparrow$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the total-host ledger is exhausted by the typed endpoint row T, finite fuel row F, terminal-normality row V, sibling normal-word row K, terminal readback row R, componentwise transport row H, displayed continuation row C, provenance row P, and local name row N. Every total-host consumer of the packet factors through those rows and cannot add host conversion, quotient computation, unrestricted evaluation, divergence detection, or a global normalization procedure.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host ledger exhaustion`

Proof. Start from Definition 936.1. The ledger-readable carrier is the finite tuple $T, F, V, K, R, H, C, P, N$ and has no additional total-host coordinate.

Apply Definition 936.2. The local certificate reads carrier admission, finite fuel, terminal normality, sibling normal-word evidence, terminal readback, transport, replay, provenance, and naming as one packet.

Use Definition 936.8 and Definition 936.11. Terminal readback and sibling normal-word evidence stay inside the displayed finite rows before any consumer can claim a normal-form output.

Finally apply Definition 936.24. The visible source package is already the whole total-host surface, so host conversion, quotient computation, unrestricted evaluation, divergence detection, and global normalization have no route through the accepted ledger. □

Theorem 936.127 ($\mathsf{ZNormal}^{\uparrow}$ terminal fuel consumer package)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the terminal fuel consumer package is the route from the typed endpoint T through finite fuel F, terminal normality V, sibling normal-word evidence K, terminal readback R, and the support rows H, C, P, N. The route is a finite BHist *package with* hsame*,* Cont*,* Pkg*, and* NameCert *support; it is not a host evaluator, quotient normalizer, divergence oracle, unrestricted conversion service, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal fuel consumer package`

Proof. Read Z through Definition 936.1 and Definition 936.2. The finite fuel row, terminal normality row, sibling normal-word row, terminal readback row, and structural support rows are all part of the same accepted packet.

Apply Definition 936.8. The terminal consumer reaches readback only through T, F, V, R, H, C, P, N, so the fuel row is a required part of the route and not an optional host computation step.

Then use Definition 936.11. The row K supplies only finite sibling normal-word evidence and remains attached to the same BHist, hsame, Cont, Pkg, and NameCert rows.

Finally apply Definition 936.24. Since the root visible source package exhausts the normal-output route, the terminal fuel consumer package cannot expose host conversion, quotient computation, unrestricted evaluation, divergence detection, or global normalization. □

Theorem 936.128 ($\mathsf{ZNormal}^{\uparrow}$ root constructor readback)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

each root constructor readback factors through the displayed terminal, fuel, terminal-normality, sibling normal-word, terminal readback, transport, replay, provenance, and local-name rows. The constructor surface therefore reads only the finite BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *packet and does not introduce a host conversion row, quotient computation, unrestricted evaluator, divergence oracle, substrate-halting row, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root constructor readback`

Proof. Project the carrier of Definition 936.1. The root constructor inventory is exactly the finite tuple $T, F, V, K, R, H, C, P, N$.

Apply Definition 936.90. It identifies the terminal row constructor surface with typed endpoint, finite fuel, terminal normality, sibling normal-word evidence, terminal readback, componentwise transport, continuation replay, provenance, and local naming.

Use Definition 936.125 and Definition 936.126. These theorems keep the constructor readback on the same normal-form readiness route and exhaust the total-host ledger by the displayed packet.

Finally apply Definition 936.81. The TasteGate-facing field surface is the same packet surface, so the constructor readback has no additional host or global-normalization coordinate. □

Theorem 936.129 ($\mathsf{ZNormal}^{\uparrow}$ terminal normal-form refusal)**.** *Every terminal normal-form read of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet refuses host conversion, quotient computation, unrestricted evaluation, divergence oracle access, substrate-halting evidence, and global normalizer routes. Such a read may use only the finite packet*

$$T, F, V, K, R, H, C, P, N$$

and the sibling normal-word surfaces named by the $\mathsf{ZNormal}^{\uparrow}$ *root route.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal normal form refusal`

Proof. Begin with Definition 936.122. Terminal normality is admitted only through the displayed typed endpoint and finite fuel rows, so a terminal read cannot start from host conversion, quotient computation, unrestricted evaluation, divergence detection, or substrate halting.

Apply Definition 936.58. The root interface excludes host conversion, quotient normalization, unrestricted evaluation, divergence detection, substrate-halting rows, and global normalizers from every total-host or downstream normal-form use.

Next use Definition 936.57. The normal-word component K is consumed only through finite sibling surfaces and cannot be detached into a host normalizer or quotient computation.

Finally apply Definition 936.91. The fuel replay route records only the displayed finite nondivergence path through $T, F, V, K, R, H, C, P, N$. Hence terminal normal-form reads refuse exactly the listed host and global routes. □

Theorem 936.130 ($\mathsf{ZNormal}^{\uparrow}$ consumer route totality)**.** *Every downstream consumer of* $\mathsf{ZNormal}^{\uparrow}$ *factors through the finite packet*

$$T, F, V, K, R, H, C, P, N$$

together with the typed endpoint, finite normal-word, carry, and terminal continuation sibling surfaces used by the root route. The consumer receives no normal-form evidence outside those rows, and the TasteGate-facing boundary remains confined to the displayed field surface rather than a host evaluator or global normalizer.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket consumer route totality`

Proof. Start from Definition 936.56. It places every downstream normal-form consumer inside the displayed $\mathsf{ZNormal}^{\uparrow}$ root packet.

Use Definition 936.60. The consumer receives terminal normality, finite normal-word evidence, transport, continuation replay, provenance, and local naming only through the named packet rows.

Attach the sibling side by Definition 936.61. The ZeckendorfNormal, ZCarry, and ContinuationTraceNormalForm sibling surfaces exhaust the permitted normal-word route outside the root packet, and they exclude host conversion, quotient normalization, unrestricted evaluation, divergence detection, substrate halting, and global normalization.

Finally apply Definition 936.81. The TasteGate-facing boundary is the same finite field surface, so downstream consumers are total over the packet and sibling surfaces and have no route outside them. □

Theorem 936.131 ($\mathsf{ZNormal}^{\uparrow}$ terminal normality carrier exposure)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

terminal normality is exposed only through the displayed typed endpoint row T, finite fuel row F, terminal-normality row V, terminal read row R, componentwise transport row H, continuation replay row C, package row P, and local naming row N. The row K contributes only finite sibling normal-word evidence, and no accepted carrier can reread K as host conversion, quotient computation, an unrestricted evaluator, a divergence oracle, or a global normalizer.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal normality carrier exposure`

Proof. Project the carrier in Definition 936.1. Its accepted packet is the finite row list $T, F, V, K, R, H, C, P, N$, with V singled out as the terminal-normality coordinate and K listed separately as sibling normal-word evidence.

Apply Definition 936.2. The local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ obligations bind carrier admission, typed endpoint, finite fuel, terminal normality, finite normal-word comparison, terminal readback, transport, replay, provenance, and local naming to this same packet.

Use Definition 936.6 and Definition 936.8. These theorems route every terminal read through T, F, V, R, H, C, P, N and keep the normal-word coordinate K outside the terminal-read source.

Finally apply Definition 936.11. The K row is finite sibling evidence only, so terminal normality remains exposed through the displayed carrier rows and cannot become any excluded host-side or global-normalization object. □

Theorem 936.132 ($\mathsf{ZNormal}^{\uparrow}$ total-host fuel replay boundary)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

total-host fuel replay is the finite route from typed endpoint T through fuel F to terminal row V and terminal continuation read R. The route is transported by H, replayed by C, packaged by P, and named by N; it does not export a host conversion row, quotient computation, unrestricted evaluator, divergence oracle, substrate halting claim, or global normalizer.

Proof. Start with Definition 936.1. The carrier displays the endpoint, fuel, terminal normality, sibling normal-word, continuation read, transport, replay, package, and naming rows as the single finite packet $T, F, V, K, R, H, C, P, N$.

Apply Definition 936.2 to read the same rows as the local certificate surface. The fuel coordinate F and terminal-normality coordinate V are therefore packet rows, not ambient host computation relations.

Next use Definition 936.6 and Definition 936.8. They force terminal fuel replay along T, F, V, R before any consumer can read the terminal continuation surface.

The structural route is then exactly H, C, P, N. By Definition 936.11, the sibling row K remains finite evidence beside that route, so the fuel replay boundary cannot escape to any excluded host, quotient, divergence, substrate-halting, or global-normalization row. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host fuel replay boundary`

Theorem 936.133 ($\mathsf{ZNormal}^{\uparrow}$ consumer divergence-oracle nonescape)**.** *Every downstream consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors through the displayed rows*

$$T, F, V, K, R, H, C, P, N.$$

Such a consumer may use typed endpoint evidence, finite fuel replay, terminal normality, finite sibling normal-word evidence, terminal continuation read, transport, replay, package provenance, and local naming, but it cannot obtain a divergence oracle, host conversion row, quotient computation, unrestricted evaluator, global normalizer, or substrate halting claim.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket consumer divergence oracle nonescape`

Proof. Project the accepted carrier by Definition 936.1. The consumer surface is the finite packet $T, F, V, K, R, H, C, P, N$, and there is no second consumer coordinate outside that packet.

Use Definition 936.2. It identifies the permitted reads as carrier admission, typed endpoint, finite fuel, terminal normality, sibling normal-word comparison, continuation read, transport, replay, provenance, and local naming.

Apply Definition 936.6 and Definition 936.8. These route terminal normal-form consumption through T, F, V, R, H, C, P, N and prevent the consumer from detaching a host computation or unbounded evaluator from the finite replay.

Finally apply Definition 936.11. The remaining row K is finite sibling evidence only. Hence every downstream consumer factors through the displayed packet and has no route to divergence detection, host conversion, quotient computation, unrestricted evaluation, global normalization, or substrate-halting evidence. □

Theorem 936.134 ($\mathsf{ZNormal}^{\uparrow}$ root terminal-host route classifier exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the root terminal-host route classifier is exhausted by the displayed terminal normality row V, finite fuel replay row F, total-host refusal ledger implicit in the accepted packet, componentwise BHist *and* hsame *rows T, H, displayed* Cont *replay row C, package row P, and local* NameCert *row N. The classifier may also read the sibling normal-word row K and terminal readback row R only as rows of the same packet; it exports no divergence oracle, host conversion row, quotient computation, unrestricted evaluator, substrate-halting row, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root terminal host route classifier exhaustion`

Proof. Start from the terminal normality carrier exposure, Definition 936.131. It identifies the accepted carrier with the finite rows $T, F, V, K, R, H, C, P, N$ and places terminal normality on the displayed row V rather than on host computation.

Use the total-host fuel replay boundary, Definition 936.132. The root route reaches terminal normality through T, F, V, R and then reads transport, replay, package, and local naming only through H, C, P, N.

Finally apply the consumer non-escape theorem, Definition 936.133. Since no downstream consumer can obtain a divergence oracle, host conversion, quotient computation, unrestricted evaluator, substrate-halting row, or global normalizer, the terminal-host classifier is exhausted by the displayed packet rows. □

Theorem 936.135 ($\mathsf{ZNormal}^{\uparrow}$ root total-host consumer readback lock)**.** *Every total-host consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet reads the same terminal-host lock*

$$T, F, V, K, R, H, C, P, N.$$

The typed endpoint, finite fuel replay, terminal normality, sibling normal-word evidence, terminal readback, BHist *support, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *rows are the only rows available to that consumer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root total host consumer readback lock`

Proof. First use Definition 936.131. It fixes the consumer surface as the finite packet $T, F, V, K, R, H, C, P, N$.

Next use Definition 936.132. Fuel replay and terminal readback remain locked to T, F, V, R and cannot detach a separate host conversion or evaluator row.

Now invoke Definition 936.134. The classifier surface for a terminal-host route is already exhausted by the same displayed rows.

The non-escape row Definition 936.133 then rules out every external total-host read. Hence all total-host consumers read the same finite lock and no unlisted row remains available. □

Theorem 936.136 ($\mathsf{ZNormal}^{\uparrow}$ root NameCert terminal route readiness)**.** *The local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row of an accepted packet is ready for terminal-route consumption exactly when the displayed terminal normality row, finite fuel replay row, total-host refusal ledger,* BHist *support,* hsame *transport,* Cont *replay,* Pkg *provenance, and local naming rows are read as the single packet* $T, F, V, K, R, H, C, P, N$*. This readiness does not add a host conversion row, quotient computation, divergence oracle, unrestricted evaluator, substrate-halting row, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root namecert terminal route readiness`

Proof. Begin with Definition 936.131. The carrier exposes terminal normality and the supporting rows only as the accepted finite packet.

Use Definition 936.135. It fixes the readback lock for every total-host consumer to the same rows $T, F, V, K, R, H, C, P, N$.

Finally use Definition 936.133. The local NameCert row can certify readiness for the displayed terminal route, but it has no coordinate from which to provide any excluded host-side or global-normalization object. □

Theorem 936.137 ($\mathsf{ZNormal}^{\uparrow}$ terminal-host root factorization)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

each terminal-host consumer factors through the carrier row of Definition 936.1, the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *obligations, the fuel-normality non-escape surface, terminal readback exactness, sibling normal-word handoff, and the root TasteGate field surface. The factorization reads* $T, F, V, K, R, H, C, P, N$ *as one finite* BHist *packet transported by* hsame*, replayed by* Cont*, packaged by* Pkg*, and named by* NameCert*.*

No terminal-host consumer receives a divergence oracle, host conversion row, quotient computation, unrestricted evaluator, global normalizer, or substrate-halting claim outside that displayed packet.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal host root factorization`

Proof. Project the carrier by Definition 936.1. The terminal-host surface is the finite tuple $T, F, V, K, R, H, C, P, N$, so the consumer has no row outside the displayed packet.

Apply Definition 936.2 and Definition 936.6. These rows bind carrier admission, finite fuel replay, terminal normality, continuation readback, transport, replay, package, and naming to the same finite route.

Use Definition 936.8, Definition 936.11, and Definition 936.81. The terminal read, sibling normal-word row, and TasteGate-facing field surface all inspect the same tuple, so the terminal-host consumer factors through the displayed BEDC primitives. □

Theorem 936.138 ($\mathsf{ZNormal}^{\uparrow}$ fuel replay root exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

fuel replay at the root is exhausted by the route from typed endpoint T through finite fuel F, terminal-normality row V, and terminal readback R, with H, C, P, N supplying the only transport, continuation, package, and naming rows. The row K contributes only the sibling normal-word handoff surface already displayed in the packet.

Thus a fuel-replay consumer cannot reread the packet as host conversion, quotient computation, divergence detection, unrestricted evaluation, global normalization, or substrate halting.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket fuel replay root exhaustion`

Proof. Begin with Definition 936.6. It places terminal normality behind the finite route $T \longmapsto F \longmapsto V \longmapsto R$ and keeps K as sibling normal-word evidence.

Next apply Definition 936.8. Terminal readback is exact only through T, F, V, R, H, C, P, N, so the replay cannot detach a host computation row from the accepted packet.

Finally use Definition 936.81 together with the local NameCert obligations. The root field surface is exactly the displayed tuple $T, F, V, K, R, H, C, P, N$, and the excluded host-side objects have no carrier coordinate there. □

Theorem 936.139 ($\mathsf{ZNormal}^{\uparrow}$ normal-output root non-escape)**.** *Every normal-output read from an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

remains inside the terminal-host root surface: carrier admission through T, F, V, K, R, structural transport through H, continuation replay through C, package provenance through P, and local naming through N. The read may cite the sibling normal-word handoff and the root TasteGate field surface, but it exports no detached normal-output object beyond the displayed BEDC primitives.

In particular, no normal-output consumer can obtain host conversion, quotient computation, divergence detection, unrestricted evaluation, global normalization, or substrate-halting evidence from the packet.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket normal output root nonescape`

Proof. Use Definition 936.18. Normal-output consumption is already confined to the finite carrier and the displayed normal-form rows.

Apply Definition 936.11 and Definition 936.8. They identify the only sibling normal-word and terminal-readback routes available to the consumer.

Finally combine Definition 936.2, Definition 936.6, and Definition 936.81. These rows bind the output read to BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$, and no excluded host-side or substrate-halting object remains exportable. □

Theorem 936.140 ($\mathsf{ZNormal}^{\uparrow}$ total-host readback triad)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

total-host readback exposes exactly the terminal-normality row V, the bounded fuel replay row F, and the non-escape row witnessed by the local carrier and naming surface. The exposure is a finite BHist *route transported by* hsame*, read by* Cont*, packaged by* Pkg*, and named by* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *through $T, F, V, K, R, H, C, P, N$.*

No accepted total-host readback supplies a detached host conversion row, quotient computation, divergence oracle, unrestricted evaluator, global normalizer, or substrate-halting certificate.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootTotalHostReadbackTriad`

Proof. Project the accepted carrier by Definition 936.1. The packet shows the terminal-normality coordinate V, the fuel coordinate F, the readback coordinate R, and the support rows H, C, P, N inside the single finite tuple $T, F, V, K, R, H, C, P, N$.

Apply Definition 936.2. The local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ row binds carrier admission, terminal normality, bounded fuel replay, sibling normal-word evidence, readback, transport, continuation replay, package provenance, and local naming to the same packet.

Use Definition 936.8 together with Definition 936.6. Terminal readback reaches V only through the bounded fuel route, while the non-escape theorem excludes host conversion, quotient computation, divergence detection, unrestricted evaluation, global normalization, and substrate halting.

Finally combine Definition 936.137, Definition 936.138, and Definition 936.139. These root rows identify the same BHist, hsame, Cont, Pkg, and NameCert surface, so the total-host readback triad is exactly terminal normality, bounded fuel replay, and non-escape. □

Theorem 936.141 ($\mathsf{ZNormal}^{\uparrow}$ fuel route non-escape)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the bounded fuel route from T through F to V and R cannot export divergence detection, host conversion, quotient computation, unrestricted evaluation, global normalization, or substrate halting. Its whole observable surface is the finite BHist *packet with* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *support.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootFuelRouteNonescape`

Proof. Start with Definition 936.6. It already places terminal normality behind finite fuel replay and rules out the host-side and global-normalization objects listed in the statement.

Next apply Definition 936.8. The readback row R is reached only after the endpoint, fuel, and terminal-normality rows have been displayed, so no consumer can detach R into an ambient host conversion or quotient-computation route.

Use Definition 936.137. The route remains inside the same $T, F, V, K, R, H, C, P, N$ packet, with H, C, P, N giving transport, continuation replay, package provenance, and local naming.

The sibling row is harmless by Definition 936.11: K contributes finite normal-word evidence only. Hence the bounded fuel route has no coordinate from which divergence, host conversion, global normalization, or substrate halting could be exported. □

Theorem 936.142 ($\mathsf{ZNormal}^{\uparrow}$ downstream normal-form readiness)**.** *Every downstream normal-form consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

must factor through the terminal-host exposure, the terminal-host obligation rows, and the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *route. The consumer may read only the finite* BHist *surface carried by $T, F, V, K, R, H, C, P, N$, transported by* hsame*, replayed by* Cont*, and packaged by* Pkg*.*

Consequently downstream readiness is a finite normal-form boundary: it does not provide host conversion, quotient computation, unrestricted evaluation, divergence detection, global normalization, or substrate-halting evidence.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootDownstreamNormalFormReadiness`
Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket downstream readiness namecert`

Proof. First expose the terminal-host surface with Definition 936.131 and Definition 936.137. These theorems show that every terminal-host consumer reads the displayed packet and no second host-side coordinate.

Next apply Definition 936.138 and Definition 936.139. These obligation rows bind terminal normality, bounded fuel replay, readback, transport, continuation replay, package provenance, and naming to the same finite carrier.

Use Definition 936.2 to repack those rows as the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ route. The support objects are precisely BHist, hsame, Cont, Pkg, and the local name certificate over $T, F, V, K, R, H, C, P, N$.

Finally apply Definition 936.141. Since the fuel route cannot export host conversion, divergence detection, unrestricted evaluation, quotient computation, global normalization, or substrate halting, downstream normal-form readiness factors through the terminal host rows and does not exceed them. □

Definition 936.143 ($\mathsf{ZNormal}^{\uparrow}$ terminal readback route carrier)**.** *The* $\mathsf{ZNormal}^{\uparrow}$ *terminal readback route carrier is the finite packet*

$$Q = (T, F, V, K, R, H, C, P, N)$$

read from an accepted $\mathsf{ZNormal}^{\uparrow}$ *carrier as follows:* T *is the typed endpoint row,* F *is the bounded fuel replay row,* V *is the terminal-normality row,* K *is the finite normal-word comparison row,* R *is the continuation readback row,* H *is componentwise* hsame *transport,* C *is displayed* Cont *replay,* P *is* Pkg *provenance, and* N *is the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row.*

The route carrier is terminal only when the readback passes through the rows displayed in chapter 562, chapter 278, and chapter 683. It has no coordinate for a divergence oracle, host conversion row, quotient computation, unrestricted evaluator, global normalizer, or substrate-halting certificate.

Lean4 (definition) `BEDC.Derived.ZnormalUp.ZnormalTerminalReadbackRouteCarrier`

Theorem 936.144 ($\mathsf{ZNormal}^{\uparrow}$ terminal readback route exhaustion)**.** *Every downstream read of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *terminal readback route carrier* $Q = (T, F, V, K, R, H, C, P, N)$ *factors through terminal normality* V*, bounded fuel replay* F*, continuation readback* R*, componentwise transport* H*, displayed replay* C*, provenance* P*, the local naming row* N*, and the sibling finite normal-word row* K*. The factorization is through* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *only.*

Consequently no downstream normal-route consumer can obtain a detached host conversion, quotient computation, divergence oracle, unrestricted evaluator, global normalization procedure, or substrate-halting theorem from this route.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal readback route exhaustion`

Proof. Start with Definition 936.143. The route carrier lists only $T, F, V, K, R, H, C, P, N$, so every downstream read begins inside the same finite packet.

Apply the carrier and obligation rows of Definition 936.1 and Definition 936.2. They identify typed endpoint readback, bounded fuel replay, terminal normality, normal-word comparison, continuation readback, transport, replay, provenance, and local naming as one $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface.

Next use Definition 936.137, Definition 936.138, and Definition 936.139. These root rows keep terminal-host consumption, fuel replay, and normal-output reads inside the displayed packet.

Finally apply Definition 936.140 and Definition 936.142. The typed endpoint, Zeckendorf normal-word, and continuation trace references already present in the chapter index supply the

sibling readback boundaries, while the terminal-host rows exclude host conversion, quotient computation, unrestricted evaluation, divergence detection, global normalization, and substrate halting. □

Theorem 936.145 ($\mathsf{ZNormal}^{\uparrow}$ total-host refusal nonescape)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *terminal readback route carrier* $Q = (T, F, V, K, R, H, C, P, N)$*, the total-host refusal surface is exhausted by terminal normality, bounded fuel replay, continuation readback, componentwise transport, displayed replay, provenance, and local* NameCert *rows. The packet exports no divergence oracle, host conversion row, global normalization procedure, quotient computation, unrestricted evaluator, or substrate-halting certificate.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTotalHostRefusalNonescape`

Proof. Project the route carrier of Definition 936.143. The rows $T, F, V, K, R, H, C, P, N$ expose a finite terminal readback route, not a host evaluator or global normalizer.

Use Definition 936.6, Definition 936.8, and Definition 936.141. These theorems place every terminal read behind bounded fuel and remove divergence detection, host conversion, quotient computation, unrestricted evaluation, global normalization, and substrate halting from the fuel route.

Finally combine Definition 936.137, Definition 936.142, and Definition 936.144. The resulting route is a finite BHist packet transported by hsame, replayed by Cont, packaged by Pkg, and named by $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$, so the listed host-side objects have no remaining export coordinate. □

Theorem 936.146 ($\mathsf{ZNormal}^{\uparrow}$ total-host scope triad)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

every terminal-host use factors through the same displayed tuple. The typed route reads T, F, V *through chapter 562; the finite normal-word route reads* K *through chapter 278 and chapter 544; and the continuation route reads* R *through chapter 683.*

The structural rows H, C, P, N *are the only componentwise transport, replay, package, and local naming rows available to those three routes.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host scope triad`

Proof. Project the carrier by Definition 936.1. It exposes the single finite tuple $T, F, V, K, R, H, C, P, N$ and gives no separate terminal-host source row.

Use Definition 936.2. The local certificate binds the typed endpoint, fuel, terminal-normality, sibling normal-word, continuation readback, transport, replay, package, and naming rows to the same accepted packet.

Apply Definition 936.6, Definition 936.8, and Definition 936.11. These identify the typed, continuation, and sibling normal-word reads as the three visible routes of the packet.

Finally use Definition 936.13 and Definition 936.81. They keep the three routes on the TasteGate-facing field surface and leave H, C, P, N as the only transport, replay, package, and naming rows. □

Theorem 936.147 ($\mathsf{ZNormal}^{\uparrow}$ fuel replay exactness)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

bounded fuel replay reaches terminal normality only along the route

$$T \longmapsto F \longmapsto V \longmapsto R.$$

The route is transported by H, replayed by C, packaged by P, and named by N; the sibling row K can be consumed only as finite normal-word evidence already attached to the same packet.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket fuel replay exactness certificate`

Proof. Start from Definition 936.6. It places terminal normality behind finite fuel and excludes any read that bypasses the displayed route from T through F to V.

Use Definition 936.8. Terminal readback reaches R only after the typed endpoint, finite fuel, and terminal-normality rows have already been exposed.

Apply Definition 936.11. The sibling route K supplies finite normal-word evidence for the same packet and does not replace the fuel replay route.

Finally combine Definition 936.13 with Definition 936.2. Transport, replay, package provenance, and local naming are exactly the rows H, C, P, N, so bounded fuel replay has no detached terminal-normality witness outside Z. □

Theorem 936.148 ($\mathsf{ZNormal}^{\uparrow}$ divergence-oracle exclusion)**.** *No accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N)$$

exports a divergence oracle, host conversion row, quotient computation, unrestricted evaluator, substrate-halting row, or global normalizer. Every terminal-host read remains a read of $T, F, V, K, R, H, C, P, N$ through the carrier, the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *obligations, the fuel and readback exactness rows, the sibling normal-word handoff, route transport, and the TasteGate-facing field surface.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket divergence oracle exclusion`

Proof. Read the carrier by Definition 936.1. The accepted packet contains only the typed endpoint, finite fuel, terminal-normality, sibling normal-word, continuation readback, transport, replay, package, and naming rows.

Apply Definition 936.2 and Definition 936.6. The local certificate and finite-fuel boundary prevent terminal normality from being reread as a host-side computation object.

Use Definition 936.8, Definition 936.11, and Definition 936.13. Terminal readback, sibling normal-word evidence, and movement between rows all stay inside the finite BEDC packet.

Finally apply Definition 936.81. The TasteGate-facing field surface exposes no coordinate for divergence detection, host conversion, quotient computation, unrestricted evaluation, substrate halting, or global normalization; therefore none can be read from the accepted packet. □

Theorem 936.149 ($\mathsf{ZNormal}^{\uparrow}$ componentwise NameCert transport)**.** *Let*

$$Z = (T, F, V, K, R, H, C, P, N)$$

and

$$Z' = (T', F', V', K', R', H', C', P', N')$$

be accepted $\mathsf{ZNormal}^{\uparrow}$ *root packets over displayed* BHist *rows. If the componentwise* hsame *transport row H relates T, F, V, K, R, C, P, N to $T', F', V', K', R', C', P', N'$, then the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *surface transports from Z to Z' without adding a host normalization row, quotient conversion row, or divergence oracle. The transported surface remains the same displayed terminal typed endpoint, bounded fuel, terminal-normality, total-host refusal, continuation readback,* Cont *replay,* Pkg *provenance, and local naming packet.*

Proof. Project both packets through Definition 936.107. The only readable coordinates are the displayed BHist rows $T, F, V, K, R, H, C, P, N$ and their primed counterparts.

Apply Definition 936.108. The certificate surface is carrier admission, classifier exposure, terminal-normality evidence, bounded-fuel replay, non-escape, Pkg provenance, and local naming over exactly those rows.

The sibling chapters provide the component witnesses rather than host normalization. The typed endpoint row is read through chapter 562, the normal-word row through chapter 278, and the terminal continuation row through chapter 683.

Transport along H therefore moves each visible component and then rereads the same route through C. Since no host normalization, quotient conversion, or divergence-oracle coordinate occurs in the carrier, the transported NameCert remains kernel-scoped. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket componentwise namecert transport`

Theorem 936.150 ($\mathsf{ZNormal}^{\uparrow}$ total-host refusal boundary)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *root packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the total-host refusal row K is part of the kernel-scoped $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *boundary. Any consumer that cites terminal normality from V must also display K together with the bounded fuel row F, continuation readback row R,* hsame *transport row H,* Cont *replay row C,* Pkg *provenance row P, and local* NameCert *row N. A consumer that omits K has not crossed the total-host boundary and cannot export host conversion, quotient normalization, divergence detection, unrestricted evaluation, or global normalization as a* $\mathsf{ZNormal}^{\uparrow}$ *consequence.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host refusal boundary`

Proof. Start with the root carrier boundary. The row K is a coordinate of the displayed BHist packet, not a host-side comment about normalization.

Use Definition 936.108. Terminal-normality evidence is accepted only after the bounded fuel row F and the total-host refusal row K have been displayed, and replay is restricted to the visible Cont route C.

Now read the sibling inputs. The typed reduction normal-form packet supplies a typed endpoint, the Zeckendorf normal packet supplies finite normal-word evidence, and the continuation trace normal-form packet supplies terminal continuation readback. None of these siblings supplies a host conversion, quotient normalization, divergence oracle, unrestricted evaluator, or global normalizer.

Therefore any consumer omitting K lacks one of the boundary rows required by $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$. The terminal-normality citation remains inside the finite kernel packet and cannot be promoted to a total-host export. □

Theorem 936.151 ($\mathsf{ZNormal}^{\uparrow}$ terminal route exhaustion)**.** *Every terminal route exported by an accepted* $\mathsf{ZNormal}^{\uparrow}$ *root packet factors through*

$$T, F, V, K, R, H, C, P, N.$$

After the terminal typed endpoint row T, bounded fuel row F, terminal-normality row V, total-host refusal row K, continuation readback row R, componentwise hsame *transport row H, displayed* Cont *replay row C,* Pkg *provenance row P, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row N have been read, no additional kernel row remains for host normalization, quotient conversion, divergence detection, unrestricted evaluation, global normalization, or a second terminal route.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal route exhaustion`

Proof. Apply Definition 936.114. A root consumer that cites terminal normality must expose the complete source route $T, F, V, K, R, H, C, P, N$.

Apply Definition 936.115. The local ledger is exhausted by the displayed Pkg and NameCert rows over that same packet, so there is no second provenance or naming coordinate for a hidden terminal route.

Finally use Definition 936.113. It rules out host conversion, quotient normalization, divergence oracles, unrestricted evaluation, and global normalization from the terminal boundary. Thus the displayed route is exhausted once the nine kernel rows have been read. □

Theorem 936.152 ($\mathsf{ZNormal}^{\uparrow}$ total-host field readiness)**.** *Before any total-host normality read is accepted from a* $\mathsf{ZNormal}^{\uparrow}$ *root packet, the rows*

$$T, F, V, K, R, H, C, P, N$$

must be displayed fieldwise: terminal typed endpoint, bounded fuel, terminal-normality evidence, total-host refusal, continuation readback, componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *naming.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host field readiness`

Proof. Apply Definition 936.108. The root certificate surface requires carrier admission, classifier exposure, terminal-normality evidence, bounded-fuel replay, non-escape, provenance, and local naming over the displayed packet.

Use Definition 936.114. A consumer that cites terminal normality must expose the full source route $T, F, V, K, R, H, C, P, N$.

Finally apply Definition 936.150. It places K inside the accepted boundary, so a total-host read cannot consume V without also displaying the refusal row and the structural rows that keep the route kernel-scoped. □

Theorem 936.153 ($\mathsf{ZNormal}^{\uparrow}$ terminal TasteGate readiness)**.** *The displayed terminal endpoint, bounded fuel, terminal-normality row, total-host refusal row, continuation readback, componentwise transport, replay, provenance, and local NameCert rows are exactly the paper surface expected by later* Nontrivial $\mathsf{ZNormal}^{\uparrow}$ *and* FieldFaithful $\mathsf{ZNormal}^{\uparrow}$ *Lean instances. No such instance may read host conversion, quotient normalization, divergence detection, unrestricted evaluation, global normalization, or a second terminal route.*

Proof. Begin with total-host field readiness from Definition 936.152. It fixes the candidate TasteGate fields as $T, F, V, K, R, H, C, P, N$.

Use Definition 936.149. Componentwise transport preserves the same terminal typed endpoint, bounded fuel, terminal-normality, refusal, replay, provenance, and naming packet without adding a host normalization row.

Then use Definition 936.151. Once the nine rows have been read, no additional kernel row remains for a second terminal route or an excluded host operation.

Thus the later Lean instances have the exact field-faithful surface they need: nontriviality is witnessed by the presence of the nine distinct rows, and field faithfulness is the demand that consumers preserve those rows. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal tastegate readiness`

Theorem 936.154 ($\mathsf{ZNormal}^{\uparrow}$ root readiness export package)**.** *The componentwise transport, refusal boundary, terminal route exhaustion, and TasteGate readiness results assemble the* $\mathsf{ZNormal}^{\uparrow}$ *root unblock package. A downstream root consumer receives exactly the terminal typed endpoint, bounded fuel, terminal-normality evidence, total-host refusal, continuation readback, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *naming rows.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root readiness export certificate`

Proof. First apply componentwise transport from Definition 936.149. It identifies the rowwise transport route and keeps it inside the displayed root packet.

Next apply the total-host refusal boundary, Definition 936.150, together with total-host field readiness from Definition 936.152. These results force K and all structural rows to be visible before any terminal-normality export is consumed.

Use terminal route exhaustion, Definition 936.151. It excludes host conversion, quotient normalization, divergence detection, unrestricted evaluation, global normalization, and a second terminal route after $T, F, V, K, R, H, C, P, N$ have been read.

Finally apply terminal TasteGate readiness from Definition 936.153. The same nine rows are the expected Nontrivial and FieldFaithful surface, so the root consumer receives a complete root unblock package rather than a host-level normalization theorem. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root readiness export package`

Theorem 936.155 ($\mathsf{ZNormal}^{\uparrow}$ terminal fuel readback admission)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

a terminal-host consumer is admitted to read terminal normality only after it displays the finite fuel readback route from T through F to V and R, together with the transport, replay, provenance, and local naming rows H, C, P, N. The sibling row K may be consumed only as finite normal-word evidence already attached to the packet. The admission route exports no divergence oracle, host conversion row, quotient computation, unrestricted evaluator, global normalization procedure, or substrate-halting coordinate.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal fuel readback admission`

Proof. Start with the total-host readback display of Definition 936.116. It exposes the root packet as the finite rows $T, F, V, K, R, H, C, P, N$ before any terminal-host read is available.

Next apply Definition 936.117. The terminal read must pass through the route $T \longmapsto F \longmapsto V \longmapsto R$ with H, C, P, N as the only structural support.

Finally use Definition 936.141 and Definition 936.11. These keep K as finite sibling normal-word evidence and exclude divergence, host conversion, quotient computation, unrestricted evaluation, global normalization, and substrate halting from the admitted readback route. □

Theorem 936.156 ($\mathsf{ZNormal}^{\uparrow}$ total-host normal-form ledger exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet $Z = (T, F, V, K, R, H, C, P, N)$, the total-host normal-form ledger is exhausted by terminal normality V, bounded fuel replay F, terminal readback R, sibling normal-word evidence K, and the structural rows H, C, P, N. A total-host normal-form claim may cite only those finite rows and the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *surface. It cannot cite a host conversion row, a global normalizer, an unbounded host-normalization procedure, a divergence oracle, or a hidden fuel source outside the packet.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host normal form ledger exhaustion`

Proof. First project the terminal-host root factorization of Definition 936.137. It places every terminal-host consumer inside the same finite BHist packet and gives no additional host-side coordinate.

Use Definition 936.138 to account for bounded fuel replay and terminal readback. The route consumes F, V, R through the displayed structural rows and leaves K as attached sibling evidence.

Then apply Definition 936.139. Normal-output consumption remains inside carrier admission, transport, continuation replay, package provenance, and local naming; the excluded host-side objects have no export coordinate.

Thus the total-host ledger is precisely the displayed finite packet. Unbounded host normalization, hidden fuel, divergence detection, host conversion, and global normalization remain outside the accepted ledger. □

Theorem 936.157 ($\mathsf{ZNormal}^{\uparrow}$ downstream normal-route boundary)**.** *Every downstream normal-route consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet must pass through the terminal fuel readback admission of Definition 936.155 and the total-host ledger exhaustion of Definition 936.156. The exposed downstream route is therefore the finite packet* $T, F, V, K, R, H, C, P, N$ *with terminal normality, bounded fuel replay, finite normal-word evidence, continuation readback, transport, replay, provenance, and local naming. No downstream consumer receives a host conversion row, global normalization procedure, divergence oracle, unbounded evaluator, detached total-host normal form, or hidden observation of normalization beyond those rows.*

Proof. Begin with downstream normal-form readiness, Definition 936.142. It already requires downstream consumers to factor through the terminal-host exposure and local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ route.

Apply terminal fuel readback admission. The consumer can read terminal normality only through T, F, V, R, H, C, P, N, with K attached as finite sibling normal-word evidence.

Finally apply total-host normal-form ledger exhaustion. Since the ledger has no coordinate for host conversion, global normalization, divergence detection, unbounded evaluation, detached total-host normal forms, or hidden normalization observations, the downstream normal route is exactly the displayed finite route. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket downstream normal route boundary`

Definition 936.158 ($\mathsf{ZNormal}^{\uparrow}$ total-host obligation packet)**.** *For an accepted* $\mathsf{ZNormal}^{\uparrow}$ *carrier*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the total-host obligation packet is the ordered finite surface whose rows are the typed endpoint T*, bounded fuel replay* F*, terminal normality* V*, sibling normal-word evidence* K*, terminal readback* R*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *naming* N*. A consumer of this packet may inspect these rows only through the carrier, NameCert, terminal readback, transport, replay, provenance, and local naming routes already exposed for* $\mathsf{ZNormal}^{\uparrow}$*.*

Lean4 (definition) `BEDC.Derived.ZnormalUp.ZnormalTotalHostObligationPacket`
Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTotalHostObligationPacket row exposure`

Theorem 936.159 ($\mathsf{ZNormal}^{\uparrow}$ normal-form consumer coverage)**.** *Every normal-form consumer of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet factors through the total-host obligation packet of Definition 936.158. The factorization covers terminal normality through V, bounded fuel replay through F, sibling normal-word evidence through K, terminal readback through R, transport through H, continuation replay through C, provenance through P, and local naming through N, all over the typed endpoint row T.*

No normal-form consumer receives a route outside those rows before it has passed through terminal fuel readback admission, total-host normal-form ledger exhaustion, and the downstream normal-route boundary.

Proof. Project the accepted carrier by Definition 936.1. It displays exactly the rows $T, F, V, K, R, H, C, P, N$ and supplies no additional normal-form coordinate.

Apply Definition 936.155. This places every terminal normality read behind the route from T through F to V and R, with H, C, P, N as the only structural support and K as attached sibling normal-word evidence.

Next use Definition 936.156. The ledger accounts for terminal normality, bounded fuel replay, terminal readback, sibling evidence, transport, replay, provenance, and local naming inside the same packet.

Finally apply Definition 936.157. A downstream normal-route consumer therefore reaches normal-form evidence only through the displayed obligation packet, so the coverage claim is exactly the finite row surface of Definition 936.158. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket normal form consumer coverage`

Theorem 936.160 ($\mathsf{ZNormal}^{\uparrow}$ total-host readback separation)**.** *The total-host readback surface of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet separates the finite obligation rows*

$$T, F, V, K, R, H, C, P, N$$

from host conversion, quotient computation, unrestricted evaluation, divergence oracles, substrate halting, and global normalization. A readback that cites terminal normality, bounded fuel replay, sibling normal-word evidence, terminal readback, transport, replay, provenance, or local naming must remain inside the total-host obligation packet and cannot promote any excluded host object to a $\mathsf{ZNormal}^{\uparrow}$ *row.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTotalHostReadbackSeparation`

Proof. Begin with the finite packet of Definition 936.158. Its rows are the only objects named by the accepted total-host surface.

Use terminal fuel readback admission from Definition 936.155. The terminal read is admitted only after T, F, V, R, H, C, P, N are displayed, and the sibling normal-word row K remains finite evidence rather than host conversion.

Apply total-host normal-form ledger exhaustion, Definition 936.156. The excluded host objects have no ledger coordinate and cannot be recovered from hidden fuel, detached total-host normal forms, or a second readback route.

The downstream boundary of Definition 936.157 closes the separation. Since every downstream route is already the finite obligation packet, host conversion, quotient computation, unrestricted evaluation, divergence detection, substrate halting, and global normalization remain outside the readback surface. □

Theorem 936.161 ($\mathsf{ZNormal}^{\uparrow}$ terminal-host obligation totality)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet, the total-host obligation packet of Definition 936.158, normal-form consumer coverage from Definition 936.159, and total-host readback separation from Definition 936.160 assemble the terminal-host obligation surface required by* $\mathsf{ZNormal}^{\uparrow}$*. The assembled surface is exactly the finite row family*

$$T, F, V, K, R, H, C, P, N,$$

with terminal normality, bounded fuel replay, sibling normal-word evidence, terminal readback, transport, replay, provenance, and local naming available to downstream consumers, and with host conversion, quotient computation, unrestricted evaluation, divergence oracles, substrate halting, and global normalization absent from the packet.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal host obligation totality`

Proof. First read the obligation packet. By Definition 936.158, the terminal-host surface is the finite carrier and NameCert row family $T, F, V, K, R, H, C, P, N$.

Next apply normal-form consumer coverage. Definition 936.159 forces every normal-form consumer through terminal normality, bounded fuel replay, sibling evidence, terminal readback, transport, replay, provenance, and local naming over the same typed endpoint.

Then apply total-host readback separation. Definition 936.160 keeps host conversion, quotient computation, unrestricted evaluation, divergence detection, substrate halting, and global normalization outside the packet.

Combining these two directions gives the required terminal-host obligation totality: all finite rows needed by downstream consumers are present, and every excluded host-side object is separated from the $\mathsf{ZNormal}^{\uparrow}$ surface. □

Theorem 936.162 ($\mathsf{ZNormal}^{\uparrow}$ total-host decision surface)**.** *Every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet exposes a total-host decision surface through the displayed finite rows*

$$T, F, V, K, R, H, C, P, N.$$

Terminal normality is read through V *over the typed endpoint* T *and bounded fuel replay* F*; the normal-word row* K *cites the* $\mathsf{ZeckendorfNormal}^{\uparrow}$ *and* $\mathsf{ZCarry}^{\uparrow}$ *sibling surfaces; the terminal continuation row* R *cites the* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *surface; and the route is transported by* hsame*, replayed by* Cont*, packaged by* Pkg*, and named by* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$*. The accepted decision rows contain no host conversion procedure, divergence oracle, quotient computation, unrestricted evaluator, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTotalHostDecisionSurface`

Proof. Start with the carrier and obligation packet of Definition 936.1 and Definition 936.158. Together they display exactly $T, F, V, K, R, H, C, P, N$, so the decision surface has no coordinate outside the finite BHist packet.

Read the sibling anchors next. The typed endpoint route is the one supplied by chapter 562; the finite normal-word route is constrained by chapter 278 and chapter 544; and the terminal continuation route is the one supplied by chapter 683. These anchors feed rows of the packet rather than a host conversion row.

Finally apply Definition 936.161. It assembles terminal normality, bounded fuel replay, sibling normal-word evidence, terminal readback, transport, replay, provenance, and local naming as the whole consumer-facing surface. Hence the total-host decision row is precisely the displayed BHist, Cont, hsame, Pkg, and $\mathsf{NameCert}$ surface. □

Theorem 936.163 ($\mathsf{ZNormal}^{\uparrow}$ terminal-normality refusal stability)**.** *Let $Z = (T, F, V, K, R, H, C, P, N)$ and $Z' = (T', F', V', K', R', H', C', P', N')$ be accepted $\mathsf{ZNormal}^{\uparrow}$ packets related by componentwise* hsame *transport of the displayed rows. If a consumer request for Z is refused because it asks for a divergence oracle, a host-conversion procedure, or a global-normalization row instead of terminal normality, then the corresponding transported request for Z' is refused for the same reason. The refusal remains attached to the* BHist*,* Cont*,* Pkg*, and local* NameCert *surface and is not converted into a transported host-side object.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal normality refusal stability`

Proof. Project both accepted packets through Definition 936.1. Componentwise transport moves only the rows $T, F, V, K, R, H, C, P, N$ and their primed counterparts, so it has no target coordinate for a divergence oracle, host conversion procedure, or global normalizer.

Use Definition 936.160. Refusal of the excluded objects is not a side condition outside the packet; it is the separation of the finite total-host readback surface from host conversion, quotient computation, unrestricted evaluation, divergence detection, substrate halting, and global normalization.

The sibling surfaces remain component inputs under transport. Typed reduction normal-form, Zeckendorf normal form, local carry, continuation trace, and the normal-form consistency seal of chapter 740 are consumed through the displayed K and R rows and through H, C, P, N. Thus transporting the accepted packet preserves the same refusal ledger and never creates a transported host-side object. □

Theorem 936.164 ($\mathsf{ZNormal}^{\uparrow}$ root-unblock NameCert exhaustion)**.** *The local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *surface needed for root unblock is exhausted by the displayed terminal-normality, bounded-fuel, replay, provenance, and naming rows of the accepted packet. Concretely, carrier admission reads the* BHist *packet $T, F, V, K, R, H, C, P, N$; classifier and terminal-normality reads use T, F, V, K, R; transport and replay use H and C; provenance and local naming use P and N. No additional NameCert clause remains for host conversion, divergence detection, global normalization, quotient computation, unrestricted evaluation, or substrate halting.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootUnblockNameCertExhaustion`

Proof. Read the root carrier through Definition 936.1 and the total-host obligation packet through Definition 936.158. These definitions list the full root-unblock surface and identify the terminal-normality, fuel, replay, provenance, and naming rows.

Apply Definition 936.162. It places the sibling typed endpoint, Zeckendorf normal-word, carry, continuation-trace, and normal-form consistency seal of chapter 740 inside the same finite row family, with hsame, Cont, Pkg, and NameCert as the only structural routes.

Finally use Definition 936.163. Since the excluded host-side requests remain refused under componentwise transport, there is no residual NameCert obligation beyond the displayed carrier, classifier, transport, replay, provenance, and naming rows. The root-unblock certificate is therefore exhausted by the local packet. □

Theorem 936.165 ($\mathsf{ZNormal}^{\uparrow}$ total-host decision route exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the terminal-host decision route is exhausted by the finite BHist *display and its* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *rows. The route reads carrier admission from $T, F, V, K, R, H, C, P, N$, terminal decision from T, F, V, K, R, transport from H, continuation replay from C, provenance from*

P, and local naming from N. It contains no host conversion, divergence oracle, quotient computation, unrestricted evaluator, substrate-halting row, or global normalizer.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTotalHostDecisionRouteExhaustion`

Proof. Begin with Definition 936.1 and Definition 936.158. They present $T, F, V, K, R, H, C, P, N$ as the whole accepted carrier and obligation packet, so every terminal-host read starts inside a finite BHist display.

Apply Definition 936.162. The theorem identifies the decision surface with the typed endpoint, bounded fuel, terminal-normality, sibling normal-word, continuation readback, transport, replay, provenance, and naming rows rather than with a host-side evaluator.

Finally use Definition 936.163 and Definition 936.164. The refused host-side requests stay refused under hsame transport, and the local root-unblock certificate has no remaining clause outside BHist, Cont, Pkg, and $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$. Hence the total-host decision route is exhausted by the displayed finite packet. □

Theorem 936.166 ($\mathsf{ZNormal}^{\uparrow}$ terminal-host classifier route nonescape)**.** *Let $Z = (T, F, V, K, R, H, C, P, N)$ be an accepted $\mathsf{ZNormal}^{\uparrow}$ packet. Any terminal-host classifier route that reaches the root-unblock surface factors through the displayed BHist rows $T, F, V, K, R, H, C, P, N$, with classifier reads on T, F, V, K, R, componentwise hsame transport on H, Cont replay on C, Pkg provenance on P, and $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ naming on N. No classifier branch escapes to a host conversion procedure, divergence oracle, quotient computation, unrestricted evaluator, substrate-halting row, or global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal host classifier route nonescape`

Proof. Project the route through Definition 936.1 and Definition 936.158. The only classifier-readable coordinates are the displayed terminal, fuel, terminal-normality, sibling normal-word, and continuation rows, with transport, replay, provenance, and naming carried by H, C, P, N.

Use Definition 936.162 to identify the classifier as a consumer of that finite decision surface. It receives no independent host conversion row and no quotient or halting computation row.

Now apply Definition 936.163. A request that attempts to leave the displayed route is refused before transport can turn it into a host-side object.

Definition 936.164 then closes the route at the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ surface. Since root unblock has no residual naming obligation beyond the finite packet, the terminal-host classifier route has no escape branch. □

Theorem 936.167 ($\mathsf{ZNormal}^{\uparrow}$ normal-form readiness support totality)**.** *For every accepted $\mathsf{ZNormal}^{\uparrow}$ packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

normal-form readiness for terminal-host use is supported exactly by the finite carrier, classifier, transport, replay, provenance, and naming rows of Z. The readiness support consists of the BHist rows $T, F, V, K, R, H, C, P, N$, the hsame row H, the Cont row C, the Pkg row P, and the local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ row N. It has no host conversion, divergence oracle, quotient computation, unrestricted evaluator, substrate-halting row, or global normalizer.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket normal form readiness support totality`

Proof. Read the accepted packet through Definition 936.1 and Definition 936.158. Normal-form readiness is therefore anchored in the same finite BHist tuple $T, F, V, K, R, H, C, P, N$ as terminal-host decision.

Definition 936.162 supplies the readiness support from the terminal endpoint, bounded fuel, terminal normality, sibling normal-word evidence, continuation readback, transport, replay, provenance, and naming rows. These are BEDC rows of the packet, not a global normalizer or unrestricted evaluator.

Apply Definition 936.163 to rule out conversion of refused host-side requests into readiness data. Then apply Definition 936.164 to identify the local NameCert surface as complete for root unblock.

Thus every support row needed by terminal-host normal-form readiness is already one of the finite BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ rows displayed by Z. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalNormalFormReadinessSupportTotality`

Theorem 936.168 ($\mathsf{ZNormal}^\uparrow$ root total-host source coverage)**.** *For every accepted* $\mathsf{ZNormal}^\uparrow$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the root total-host source is covered by the finite BHist *display* $T, F, V, K, R, H, C, P, N$*. The source row* T *supplies the typed endpoint,* F *supplies bounded fuel replay,* V *supplies the terminal normal-form row,* K *and* R *supply the finite sibling normal-word and continuation surfaces,* H *supplies the displayed* hsame *transports,* C *supplies the* Cont *consumer routes,* P *supplies* Pkg *provenance, and* N *supplies the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ *row. No covered source requires host conversion, divergence detection, quotient normalization, unrestricted evaluation, substrate halting, or a global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root total host source coverage`

Proof. Begin with Definition 936.1 and Definition 936.158. They name the accepted root source as the finite tuple $T, F, V, K, R, H, C, P, N$, so the source coverage question has no coordinate outside the displayed BHist packet.

Apply Definition 936.162. It reads typed endpoint, bounded fuel, terminal normality, finite sibling evidence, continuation readback, transport, replay, provenance, and local naming from the same rows and refuses the omitted host-side objects.

Finally use Definition 936.175. Downstream consumers can reach the local NameCert row only after the sibling typed endpoint, normal-word, carry, and continuation surfaces have entered the packet through T, K, R. Hence the root total-host source is fully covered by the finite display. □

Theorem 936.169 ($\mathsf{ZNormal}^\uparrow$ root terminal-normality determinacy)**.** *Let* $Z = (T, F, V, K, R, H, C, P, N)$ *be an accepted* $\mathsf{ZNormal}^\uparrow$ *packet. A root consumer that asks for terminal normality is determined by the terminal normal-form row* V *over the typed endpoint* T*, the bounded fuel replay row* F*, the continuation readback row* R*, and the structural rows* H, C, P, N*. The sibling row* K *contributes only the finite Zeckendorf and carry-facing normal-word surface. The consumer cannot replace this determination by host conversion, divergence detection, quotient normalization, unrestricted evaluation, substrate halting, or a global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root terminal normality determinacy`

Proof. Use Definition 936.82. It confines every terminal-normality read to T, F, V, R, H, C, P, N, with K available only as finite sibling evidence.

Next apply Definition 936.173. The public terminal route is exhausted by $T, F, V, K, R, H, C, P, N$, so there is no second route on which terminal normality could be chosen by a host evaluator or quotient normalizer.

The decision surface of Definition 936.162 then fixes the root consumer. Since V is the only terminal normal-form row and the supporting rows are exactly T, F, R, H, C, P, N, terminal normality is determined inside the finite packet. □

Theorem 936.170 ($\mathsf{ZNormal}^{\uparrow}$ root fuel-replay exhaustion)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet* $Z = (T, F, V, K, R, H, C, P, N)$*, bounded fuel replay at the root is exhausted by* F *together with the displayed* Cont *row* C *and the transport, provenance, and naming rows* H, P, N*. The replay is used only to expose the terminal normal-form row* V *over* T *and the continuation row* R*, while* K *remains finite sibling normal-word evidence. It does not export a divergence oracle, an unrestricted evaluator, substrate halting, host conversion, quotient normalization, or a global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket root fuel replay exhaustion`

Proof. Start with Definition 936.78. It places every terminal-normality read behind the finite fuel row F and the route T, F, V, R, H, C, P, N.

Now apply Definition 936.161. The total-host obligation packet presents replay, transport, provenance, and local naming as rows of the same finite packet, with the excluded host-side objects absent from the surface.

Finally use Definition 936.174. The field-readback lock interprets `FieldFaithful ZNormalUp` and `Nontrivial ZNormalUp` on the displayed packet, not on an evaluator. Thus bounded fuel replay is exhausted by F, C, H, P, N as support for V and R. □

Theorem 936.171 ($\mathsf{ZNormal}^{\uparrow}$ root refusal ledger separation)**.** *The root refusal ledger of an accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet separates the admitted finite rows*

$$T, F, V, K, R, H, C, P, N$$

from host conversion, divergence detection, quotient normalization, unrestricted evaluation, substrate halting, and global normalization. The admitted side contains terminal normality, bounded fuel replay, displayed hsame *transport,* Cont *consumer routing,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *naming; the refused side contains exactly the omitted host-facing objects and cannot be transported back into the packet.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootRefusalLedgerSeparation`

Proof. Read the finite side through Definition 936.168. The admitted ledger entries are precisely the rows $T, F, V, K, R, H, C, P, N$ and their carrier, terminal, replay, transport, provenance, and naming uses.

Read the refused side through Definition 936.163. A request for divergence, host conversion, or global normalization remains refused under componentwise hsame transport, so transport cannot convert the refusal into a packet row.

Finally apply Definition 936.160. Quotient computation, unrestricted evaluation, substrate halting, and the other host-side objects have no ledger coordinate. The ledger therefore separates admitted root evidence from refused host-facing objects. □

Theorem 936.172 ($\mathsf{ZNormal}^{\uparrow}$ root NameCert unblock package)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet* $Z = (T, F, V, K, R, H, C, P, N)$*, the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *root-unblock package is the finite obligation packet consisting of source coverage, terminal-normality determinacy, fuel-replay*

exhaustion, and refusal-ledger separation. It binds the terminal normal-form row V, bounded fuel replay row F, displayed hsame *transports H,* Cont *routes C,* Pkg *provenance P, and local naming row N over the same finite* BHist *source $T, F, V, K, R, H, C, P, N$, and it exports no host conversion or divergence oracle.*

Proof. First assemble the admitted source rows by Definition 936.168. This gives the finite BHist packet on which the local NameCert row can operate.

Next combine Definition 936.169 with Definition 936.170. Terminal normality is determined by V over T, F, R, H, C, P, N, and bounded fuel replay is exhausted by F together with the displayed replay and structural rows.

Finally apply Definition 936.171 and Definition 936.164. The refusal ledger keeps host conversion, divergence detection, quotient normalization, unrestricted evaluation, substrate halting, and global normalization outside the packet, while root-unblock NameCert exhaustion leaves no remaining local clause beyond $T, F, V, K, R, H, C, P, N$. The four components therefore form the root NameCert unblock package. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootNameCertUnblockPackage`

Theorem 936.173 ($\mathsf{ZNormal}^{\uparrow}$ terminal route component totality)**.** *For every accepted* $\mathsf{ZNormal}^{\uparrow}$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

terminal use is exposed only through the finite component surface $T, F, V, K, R, H, C, P, N$. The typed endpoint row T, finite fuel row F, terminal-normality row V, sibling normal-word row K, continuation readback row R, componentwise transport row H, replay row C, provenance row P, and local $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$ *row N exhaust the public route. No accepted packet exports host conversion, quotient normalization, divergence detection, unrestricted evaluation, substrate halting, or a global normalizer.*

Proof. Start from the carrier and local obligation packet of Definition 936.1 and Definition 936.2. They name the accepted surface as the tuple $T, F, V, K, R, H, C, P, N$, so every terminal read begins inside the finite BEDC rows.

Next apply Definition 936.6 and Definition 936.8. These theorems keep finite fuel, terminal normality, and continuation readback inside the displayed packet rather than inside a host evaluator.

Finally use Definition 936.11 and Definition 936.24. The sibling typed endpoint, finite normal-word, carry, and continuation surfaces of chapter 562, chapter 278, chapter 544, and chapter 683 enter only through the named component rows. Hence terminal use is total over the finite packet and has no extra host-facing route. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket terminal route component totality`

Theorem 936.174 ($\mathsf{ZNormal}^{\uparrow}$ TasteGate field readback lock)**.** *The Lean TasteGate rows* `FieldFaithful ZNormalUp` *and* `Nontrivial ZNormalUp` *are read on the paper side as the* $\mathsf{ZNormal}^{\uparrow}$ *field-readback lock for the finite surface $T, F, V, K, R, H, C, P, N$. They certify that the accepted field surface is nonempty and field-faithful for local readback; they do not add host conversion, quotient normalization, a divergence oracle, unrestricted evaluation, substrate halting, or a global normalizer.*

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalTasteGateFieldReadbackLock`

Proof. Project the accepted packet through Definition 936.1. The field inventory available to the TasteGate reader is exactly $T, F, V, K, R, H, C, P, N$, with local naming controlled by the $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ row.

Apply Definition 936.2, Definition 936.6, and Definition 936.8. Together they identify field readback with finite fuel, terminal normality, continuation readback, transport, replay, provenance, and naming, and they exclude the omitted host-side objects from the carrier.

The Lean rows are therefore interpreted as a lock on this finite surface. FieldFaithful says the rows can be read back as the displayed packet fields, while Nontrivial says the surface is not empty; neither row changes the packet into host conversion or quotient normalization. □

Theorem 936.175 ($\mathsf{ZNormal}^\uparrow$ root obligation downstream handoff)**.** *Every downstream normal-form consumer of the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ *row must first pass through the sibling surfaces of chapter 562, chapter 278, chapter 544, and chapter 683. After those surfaces have supplied the typed endpoint, finite normal-word, carry, and terminal continuation rows, the consumer may use the local row* N *only as part of the same packet* $T, F, V, K, R, H, C, P, N$.

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalRootObligationDownstreamHandoff`

Proof. Begin with Definition 936.1. It places the downstream-facing rows in the finite packet and assigns N to the local $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ surface, not to an independent host-normalization object.

Use Definition 936.11 for the K row and Definition 936.8 for the R row. The typed endpoint chapter supplies T, the Zeckendorf and carry chapters supply the finite normal-word route behind K, and the continuation-trace chapter supplies terminal readback behind R.

Finally apply Definition 936.24 together with Definition 936.2. The source package and local obligations require consumers to reach N through T, F, V, K, R, H, C, P first. Thus downstream use of the local NameCert row is a handoff from the sibling normal-form surfaces, not a direct host-normalization route. □

Theorem 936.176 ($\mathsf{ZNormal}^\uparrow$ total-host terminal row exposure)**.** *For every accepted* $\mathsf{ZNormal}^\uparrow$ *packet*

$$Z = (T, F, V, K, R, H, C, P, N),$$

the total-host root consumer exposes terminal normality only through the terminal row V*, bounded fuel replay through* F*, the total-host source through* T*, the continuation trace through* R*, the transport and route rows* H, C*, the provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{ZNormal}^\uparrow}$ *row* N*. The sibling row* K *supplies finite normal-word evidence only. No exposed row is a host conversion row, divergence oracle, quotient normalizer, unrestricted evaluator, or global normalizer.*

Proof. Start from Definition 936.168. It identifies the total-host source as the finite display $T, F, V, K, R, H, C, P, N$, so a root consumer has no coordinate outside the accepted packet.

Next use Definition 936.169 and Definition 936.170. These bind terminal normality to V and bounded replay to F, C, H, P, N before any downstream consumer can inspect the local naming row.

Finally apply the TasteGate anchor Definition 936.81. Its single-carrier alignment reads the same field surface, so the terminal exposure is exactly the finite packet rather than a host conversion or evaluator surface. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket total host terminal row exposure`

Theorem 936.177 ($\mathsf{ZNormal}^{\uparrow}$ divergence oracle refusal)**.** *Let $Z = (T, F, V, K, R, H, C, P, N)$ be an accepted $\mathsf{ZNormal}^{\uparrow}$ packet. Any root readback request for a divergence oracle is refused at the packet boundary: the admitted rows provide terminal normality, bounded fuel replay, total-host source, continuation trace, componentwise transports, displayed routes, provenance, and local NameCert naming, but they do not export a divergence oracle or any surrogate through host conversion, substrate halting, unrestricted evaluation, quotient normalization, or global normalization.*

Proof. Read the admitted side through Definition 936.171. The refusal ledger separates $T, F, V, K, R, H, C, P, N$ from divergence detection and the other host-facing objects.

Use Definition 936.80 and Definition 936.162. Together they keep every total-host request inside the finite packet rows and refuse any request whose target is absent from those rows.

The TasteGate field surface of Definition 936.81 supplies the nonempty single-carrier readback anchor. Since that anchor has no divergence-oracle coordinate, the refused request cannot re-enter through field faithfulness, transport, route replay, provenance, or local naming. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket divergence oracle refusal`

Theorem 936.178 ($\mathsf{ZNormal}^{\uparrow}$ host conversion nonescape)**.** *For every accepted $\mathsf{ZNormal}^{\uparrow}$ packet $Z = (T, F, V, K, R, H, C, P, N)$, a host-conversion read cannot escape the finite readback route. Terminal normality, bounded fuel replay, total-host source, continuation trace, transports, routes, provenance, and the local NameCert row are all read through $T, F, V, K, R, H, C, P, N$, while host conversion, quotient computation, unrestricted evaluation, substrate halting, divergence detection, and global normalization remain outside the carrier.*

Proof. Begin with Definition 936.173. It exhausts terminal use by the component surface $T, F, V, K, R, H, C, P, N$ and leaves no extra host-facing route.

Next apply Definition 936.172. The local NameCert row is reached only after source coverage, terminal-normality determinacy, fuel-replay exhaustion, and refusal-ledger separation have been assembled inside the same finite packet.

Finally use Definition 936.81. The TasteGate single-carrier alignment reads the accepted rows as one field surface, so host conversion has no route through transport, replay, provenance, local naming, or sibling normal-word evidence. □

Lean4 ✓ `BEDC.Derived.ZnormalUp.ZnormalPacket host conversion nonescape`

Closure status for $\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$**.**

Constructive story: A $\mathsf{ZNormal}^{\uparrow}$ packet is generated from a typed reduction normal-form row, finite fuel row, terminal-normality row, finite Zeckendorf and carry-facing comparison row, continuation terminal-read row, componentwise transports, displayed continuations, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 936.1, Definition 936.2, Definition 936.3, Definition 936.4, Definition 936.5, Definition 936.6, Definition 936.7, Definition 936.8, Definition 936.11, Definition 936.12, Definition 936.13, Definition 936.18, Definition 936.19, Definition 936.23, Definition 936.81, Definition 936.82, Definition 936.83, Definition 936.137, Definition 936.138, and Definition 936.139 bind the bridge-facing total-host terminal-normality boundary through the existing finite normal-form, carry, continuation, typed-boundary, terminal-readback, sibling-handoff, route-transport, normal-output, consumer non-escape, terminal-host, TasteGate field-surface, scope-lock, root-factorization, fuel-replay, and output-root non-escape rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ZNormal}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove host Turing completeness, substrate halting, global normalization for external computations, host conversion, quotient computation, Lean verification, or bridge checking for $\mathsf{ZNormal}^{\uparrow}$.

Upgrade path: Lean verification and bridge checking remain the next formal-axis work, without adding host conversion, quotient computation, or global normalization.

Chapter 937

A Concrete Naming Certificate for $\mathsf{CellularTrustSubstrate}^{\uparrow}$

The $\mathsf{CellularTrustSubstrate}^{\uparrow}$ packet turns the Rule 110 closed-substrate reading of chapter 9390 into a finite NameCert carrier. It consumes the cellular rule-table and finite orbit surface of chapter 934 and the bounded trace reporting discipline of chapter 944; its additional work is to bind those rows into one trust-substrate NameCert packet. It records the rule table, manifest row, finite orbit segment, classifier surface, audit route, package provenance, and local naming ledger through which the cellular trust path is inspected. The packet does not identify infinite streams, decide host equality of cellular automata, or import an oracle for long-run behaviour.

Falsifiable prediction: If a public Rule 110 substrate read accepted by this packet can be replayed without one of the finite rule-table, manifest, orbit-segment, classifier, audit-route, package, or local NameCert rows below, then the carrier admission claim of Definition 937.1 is false.

Independence witness: haltingdistinction, inscriptionevent, continuationtracenormalform, kernelinductiveacceptance: the carrier shares the finite diagonal-boundary, inscription-record, trace-normal-form, and kernel-acceptance surfaces used by those siblings, but none of them supplies the eight-entry cellular rule table, manifest row, orbit segment, and classifier disagreement audit as a single closed-substrate packet.

Definition 937.1 (Cellular trust substrate NameCert carrier)**.** *A* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *carrier is a finite packet*

$$S = (R, M, O, F, A, P, N)$$

with the following visible rows:

1. *R is the finite Rule 110 table row, listing the eight neighbourhood transitions used by the substrate.*
2. *M is the manifest row naming the initial cell word, declared run budget, expected observation fields, and public replay parameters.*
3. *O is the finite orbit-segment row produced by iterating R from M for the displayed number of steps.*
4. *F is the classifier row for visible cell patterns, phase tags, and accepted observation records.*
5. *A is the audit-route row comparing the manifest, direct Rule 110 evolution, cyclic-tag compilation route, and classifier disagreement checks.*

6. *P is the* Pkg *provenance over* BHist, Cont, hsame, *the manifest schema, the classifier row, and the replay audit.*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{CellularTrustSubstrate}^{\uparrow}}$ *ledger for carrier admission, classifier stability, audit-route exactness, and closed-observation non-escape.*

All rows are finite. The carrier names a concrete closed substrate, not a quotient stream, an oracle halting predicate, or host-level equality of cellular automata.

Theorem 937.2 (Cellular trust substrate NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CellularTrustSubstrate}^{\uparrow}}$ *surface for Definition 937.1 consists exactly of six obligation rows: carrier admission for $S = (R, M, O, F, A, P, N)$; rule-table faithfulness for the eight displayed Rule 110 transitions; manifest-to-orbit replay exactness for the finite segment O; classifier stability under the visible phase and pattern rows in F; audit-route agreement for the direct evaluator, cyclic-tag route, and disagreement checks in A; and closed-observation non-escape through P and N.*

Proof. Carrier admission is projection from the displayed tuple. The rule table, manifest, orbit segment, classifier, audit route, package row, and local ledger are the only coordinates of the packet.

Rule-table faithfulness and manifest replay exactness are finite checks. The eight entries of R determine each successor cell in O, and M supplies the initial word and replay budget read by the audit route.

Classifier stability is local to F. Any accepted pattern or phase read must pass through the displayed classifier row and the disagreement checks in A, so a consumer cannot replace the row by an unrecorded host classifier.

Finally, P and N package the same finite rows as the public certificate. Since no coordinate names a quotient stream, an oracle for halting, or host equality of cellular automata, the obligations close only the finite closed-substrate surface. □

Theorem 937.3 (Cellular trust substrate closed observation non-escape)**.** *Every accepted public observation of a* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *packet factors through the finite route*

$$R \longmapsto M \longmapsto O \longmapsto F \longmapsto A \longmapsto P \longmapsto N.$$

The route may certify the displayed Rule 110 orbit segment, classifier row, and replay audit, but it cannot export a quotient of infinite streams, an oracle halting decision, a host cellular-automaton equality principle, or an induction principle over all future rows.

Proof. Start with an accepted observation. Carrier projection gives the only available rows: the rule table R, manifest M, orbit segment O, classifier F, audit route A, package row P, and local ledger N.

The NameCert obligations force the observation to read successor cells through R and M, classifier claims through F, and replay agreement through A. Each of these rows is finite and displayed inside the packet.

The package and ledger rows record provenance for that same finite route. They add no coordinate for infinite-stream quotienting, oracle halting, host equality between cellular automata, or induction over ungenerated future cells. Thus the accepted observation remains a closed finite substrate read. □

Lean follow-up for $\mathsf{CellularTrustSubstrate}^{\uparrow}$ must provide the corresponding `Nontrivial` and `FieldFaithful` TasteGate instances for the finite rule-table, manifest, orbit-segment, classifier, audit-route, and local NameCert rows.

Chapter 938

A Concrete Naming Certificate for CellularOrbitSubstrate$^{\uparrow}$

The CellularOrbitSubstrate$^{\uparrow}$ packet turns the cellular automaton substrate reading of chapter 9390 into a concrete finite-orbit NameCert carrier. It sits beside the machine-code surface of chapter 280, the bounded-graph surface of chapter 199, the continuation-tail surface of chapter 482, and the resource-modulus surface of chapter 282. Its distinguishing datum is a local-neighborhood orbit row with a finite spatial window ledger.

Falsifiable prediction: Two accepted packets with the same local rule table and hsame initial row cannot expose two distinct next-row ledgers under the displayed neighborhood classifier.

Independence witness: turingmachine, computable, continuationautomaton, complexityclass: the cellular carrier has a local-neighborhood orbit row and finite spatial window ledger that these siblings do not carry, while those siblings carry machine-code, bounded graph, continuation-tail, or resource-modulus rows absent here.

Definition 938.1 (Cellular orbit substrate carrier)**.** *A* CellularOrbitSubstrate$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (R, I, W, L, H, C, P, N)$$

with the following displayed rows:

1. *R is the local cellular rule-table row, including the finite alphabet, the neighborhood radius, and every local transition entry used by the packet.*
2. *I is the initial row, displayed as a finite spatial window with boundary convention and origin marker.*
3. *W is the finite orbit-window ledger recording the displayed rows obtained by iterating R from I for the accepted time budget and spatial window.*
4. *L is the local-neighborhood ledger listing, for each accepted successor cell in W, the visible predecessor neighborhood and the rule-table entry used to compute it.*
5. *H records componentwise* hsame *transport for rule tables, initial rows, orbit windows, local-neighborhood ledgers, provenance rows, and local names.*
6. *C records the* Cont *replay route from R and I through each displayed row of W and each neighborhood read in L.*

7. *P is the* Pkg *provenance over the cellular substrate reading, the sibling computational certificates,* BHist, hsame, Cont, Pkg, *and* NameCert *rows.*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{CellularOrbitSubstrate}^{\uparrow}}$ *row for carrier admission, local determinacy, observation non-escape, and public name exposure.*

The classifier compares accepted packets only through the displayed rule table, hsame initial row, finite orbit window, local-neighborhood ledger, transport row, continuation replay, provenance, and local naming row. It has no coordinate for an infinite orbit, a hidden global evaluator, a quotient stream, host equality between cellular histories, or an external cellular oracle.

Theorem 938.2 (Cellular orbit substrate local determinacy)**.** *For the carrier of Definition 938.1, if two accepted packets expose the same rule-table row R and* hsame *initial rows I and I', then every displayed next-row entry accepted by the finite orbit-window ledger is determined by the same local-neighborhood read in L. In particular, the public classifier cannot expose two distinct next-row ledgers under the same rule table and hsame initial row.*

Proof. Project both accepted packets to their rule-table, initial-row, orbit-window, and local-neighborhood ledger rows. The rule table R fixes a single successor value for each displayed predecessor neighborhood, and the hsame initial rows identify the first visible neighborhoods componentwise.

Use the continuation replay row C to step through the finite window ledger. At each displayed successor cell, the ledger L records the predecessor neighborhood and the rule-table entry used to compute it, so two accepted ledgers with the same R and transported initial row must read the same entry.

The classifier has no coordinate for a detached evaluator or hidden cellular history. Therefore a claimed second next-row ledger would need a displayed neighborhood read absent from L or a second value for the same entry of R, neither of which belongs to the carrier. □

Theorem 938.3 (Cellular orbit substrate observation non-escape)**.** *Every accepted observation exported by a* $\mathsf{CellularOrbitSubstrate}^{\uparrow}$ *packet factors through the finite route*

$$R, I, W, L, H, C, P, N.$$

The route can certify local neighborhoods, successor rows, finite spatial windows, and displayed orbit prefixes, but it exports no infinite orbit, hidden cellular evaluator, quotient stream, host equality principle, global completeness witness, or independent tail oracle.

Proof. Begin with carrier projection. An accepted observation can read only the rule table R, initial row I, finite orbit-window ledger W, local-neighborhood ledger L, transport row H, continuation replay C, package row P, and local naming row N.

The local-neighborhood ledger supplies the only route from a visible predecessor window to a successor cell. The continuation row replays this finite sequence and never introduces an unbounded time domain or spatial completion.

The provenance and local name rows package that same finite route. Since the carrier lacks coordinates for infinite streams, host cellular equality, global completeness, detached evaluators, and external tail oracles, every accepted observation remains inside the displayed packet. □

Theorem 938.4 (Cellular orbit substrate NameCert surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{CellularOrbitSubstrate}^{\uparrow}}$ *surface consists exactly of carrier admission for $S = (R, I, W, L, H, C, P, N)$, local-neighborhood determinacy through R and L, hsame transport of the initial row through H, finite* Cont *replay*

through C, observation non-escape through W, L, P, N, and public naming by the local NameCert row. The surface does not import machine code, bounded graph simulation, continuation-tail equality, resource-modulus comparison, or any unbounded cellular-orbit object.

Proof. Carrier admission is projection from Definition 938.1. The packet displays the rule table, initial row, finite orbit window, local-neighborhood ledger, transport row, replay row, provenance, and local naming row as its only coordinates.

Local determinacy is supplied by Definition 938.2. Observation containment is supplied by Definition 938.3. Together they identify the accepted public surface with the finite orbit route and exclude any read outside it.

The sibling boundaries are therefore separate. TuringMachine$^{\uparrow}$ machine code, Computable$^{\uparrow}$ bounded graphs, ContinuationAutomaton$^{\uparrow}$ continuation tails, and ComplexityClass$^{\uparrow}$ resource moduli may be cited as comparison anchors, but no such row is a coordinate of the cellular orbit substrate carrier. □

Lean4 ✓ `BEDC.Derived.CellularOrbitSubstrateUp.CellularOrbitSubstrateTasteGate single carrier alignment`

The later Lean TasteGate namespace BEDC.Derived.CellularOrbitSubstrateUp.TasteGate must provide Nontrivial CellularOrbitSubstrate$^{\uparrow}$ and FieldFaithful CellularOrbitSubstrate$^{\uparrow}$ instances for the displayed finite-orbit carrier.

Theorem 938.5 (Cellular orbit substrate orbit carrier row)**.** *Finite orbit admission for a* CellularOrbitSubstrate$^{\uparrow}$ *packet is exactly admission of the displayed local-neighborhood carrier*

$$S = (R, I, W, L, H, C, P, N)$$

of Definition 938.1. The admitted orbit row consists of the rule table R, the initial spatial row I, the finite orbit-window ledger W, the local-neighborhood ledger L, the transport row H, the continuation replay C, provenance P, and local name N, and it imports no infinite orbit, hidden evaluator, quotient stream, host cellular equality, or external cellular oracle.

Proof. Project the packet through Definition 938.1. Carrier admission exposes exactly the rule table, initial row, finite orbit window, local-neighborhood ledger, transport, replay, provenance, and local naming rows.

Use Definition 938.2. Once R and I are admitted, each successor entry in the finite window is determined by the corresponding local-neighborhood read in L.

Apply Definition 938.3 and Definition 938.4. They identify the public orbit carrier with the finite route R, I, W, L, H, C, P, N and exclude all unbounded or host-level cellular objects. □

Theorem 938.6 (Cellular orbit substrate local classifier row)**.** *The* CellularOrbitSubstrate$^{\uparrow}$ *classifier is stable under displayed* hsame *transport of cell states and orbit windows. If two accepted packets transport the same rule-table row, initial spatial row, finite orbit-window ledger, and local-neighborhood ledger through their displayed H rows, then the public classifier reads the same local successor decisions through the corresponding continuation replay and naming rows.*

Proof. Begin with the local classifier surface of Definition 938.1. The classifier has access only to R, I, W, L, H, C, P, N.

Apply Definition 938.2. The rule table fixes every successor value for each transported predecessor neighborhood, and L records the displayed entry used for each accepted successor cell.

Use Definition 938.3 and Definition 938.4 to close the route. Since no hidden evaluator or quotient stream is available, hsame-transported cell states and orbit windows preserve the public classifier row. □

Theorem 938.7 (Cellular orbit substrate continuation ledger row)**.** *Every public read of the* CellularOrbitSubstrate$^{\uparrow}$ *cellular orbit route factors through the listed* Cont, Pkg, *and* NameCert *rows of the displayed carrier. The finite continuation replay C reads from R, I, W, L, H, the provenance row P records that finite cellular route, and the local name N exports only that packet to public consumers.*

Proof. Read the continuation route from Definition 938.1. The row C is the only displayed replay path from the rule table and initial row through the orbit window and local-neighborhood ledger.

Apply Definition 938.2 to each accepted successor read. The replay cannot choose a second successor row because L records the unique local-neighborhood entry used with R.

Finally use Definition 938.3 and Definition 938.4. The provenance row P and local name N package the same finite route, so public reads cannot escape to machine code, bounded graph simulation, continuation-tail equality, resource-modulus comparison, or an unbounded orbit object. □

Theorem 938.8 (Cellular orbit substrate rule-locality obligation)**.** *Every accepted orbit step of a* CellularOrbitSubstrate$^{\uparrow}$ *packet is read from the displayed local transition table R together with the neighboring finite rows recorded in the local-neighborhood ledger L. The public route may expose the predecessor neighborhood, the rule-table entry, the successor cell, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *rows, but it has no coordinate for a hidden cellular evaluator or an external rule oracle.*

Proof. Start from the carrier of Definition 938.1. Its orbit data are exactly the displayed rule table R, initial row I, orbit-window ledger W, and local-neighborhood ledger L.

Apply Definition 938.2. Each accepted successor entry is determined by the local-neighborhood read in L and the corresponding transition entry in R.

Use Definition 938.3 and Definition 938.7 to close the exported route. The continuation, provenance, and local name rows replay only that finite local computation, so no hidden evaluator or external rule oracle can be exported. □

Theorem 938.9 (Cellular orbit substrate orbit-prefix obligation)**.** *Every consumer-visible orbit segment exported by a* CellularOrbitSubstrate$^{\uparrow}$ *packet is a finite prefix of the displayed* BHist *orbit ledger W. The consumer may read the initial row, the accepted finite sequence of successor rows, the local-neighborhood evidence for each displayed step, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *rows, but it cannot extract an infinite orbit or a detached tail object.*

Proof. Project the packet through Definition 938.1. The only orbit carrier row is the finite ledger W, with the initial row I and local-neighborhood evidence L attached to its displayed steps.

Apply Definition 938.5. Orbit admission is exactly admission of the finite packet $S = (R, I, W, L, H, C, P, N)$, so a public orbit segment must be read as part of the displayed ledger.

Finally use Definition 938.7 and Definition 938.3. The continuation route replays finite ledger rows only, and the non-escape theorem blocks infinite orbit and detached tail coordinates. □

Theorem 938.10 (Cellular orbit substrate classifier-stability obligation)**.** *Classifier replacement for an accepted* CellularOrbitSubstrate$^{\uparrow}$ *packet preserves only the displayed local row, finite orbit prefix, componentwise* hsame *transport,* Cont *route,* Pkg *provenance, and local* NameCert *rows. If the replacement agrees on R, I, W, L, H, C, P, N, then the public classifier has no further surface on which to distinguish the packets.*

Proof. Begin with the classifier inventory in Definition 938.1. The carrier compares accepted packets only through the local rule table, initial row, finite orbit window, local-neighborhood ledger, transport, replay, provenance, and local name.

Use Definition 938.6. Displayed hsame transport of the rule table, initial row, orbit window, and local-neighborhood ledger preserves the public successor decisions.

Apply Definition 938.8 and Definition 938.9. These obligations identify the classifier-visible computation with the local row and finite prefix.

The route closes by Definition 938.7 and Definition 938.3. Since every exported read factors through H, C, P, N together with R, I, W, L, there is no remaining coordinate for a replacement classifier to observe. □

Theorem 938.11 (Cellular orbit substrate obligation closure package)**.** *The carrier row of Definition 938.1, local determinacy of Definition 938.2, observation non-escape of Definition 938.3, NameCert surface of Definition 938.4, orbit carrier row of Definition 938.5, local classifier row of Definition 938.6, continuation ledger row of Definition 938.7, rule-locality obligation of Definition 938.8, orbit-prefix obligation of Definition 938.9, and classifier-stability obligation of Definition 938.10 form the obligation package for* $\mathsf{CellularOrbitSubstrate}^{\uparrow}$ *over the finite packet* $S = (R, I, W, L, H, C, P, N)$*.*

Proof. Project the carrier row first. The packet exposes only the local rule table R, initial row I, finite orbit window W, local-neighborhood ledger L, transport H, replay C, provenance P, and local naming row N.

Apply the local determinacy, observation non-escape, and NameCert surface theorems. They make the finite neighborhood computation carrier-local and keep every public observation inside the displayed certificate rows.

Use the orbit carrier, local classifier, continuation ledger, rule-locality, orbit-prefix, and classifier-stability obligations. These rows exhaust the visible cellular-orbit computation by binding successor decisions, finite prefix reads, and classifier replacement to the same R, I, W, L, H, C, P, N packet.

Therefore the listed rows are exactly the chapter-level obligation package. The package still leaves Rule 110 universality, cellular completeness, infinite-orbit equality, host evaluator correctness, and bridge checking outside the current surface. □

Theorem 938.12 (Cellular orbit substrate mature consumer completeness)**.** *Every cellular-orbit consumer route for an accepted* $\mathsf{CellularOrbitSubstrate}^{\uparrow}$ *packet factors through the finite cellular orbit substrate carrier* $S = (R, I, W, L, H, C, P, N)$*, the orbit row, the trust substrate rows, classifier transport, and the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. The consumer may read the local rule table, initial row, finite orbit-window ledger, local-neighborhood ledger, componentwise transport, continuation replay, provenance, and local name only through that packet and the accepted bridge-facing TasteGate alignment target.*

The mature consumer surface exports no detached global cellular dynamics, host time step, untracked orbit quotient, infinite-orbit equality, host evaluator correctness, or standard computational equivalence.

Proof. Start from Definition 938.1. It exposes the finite packet $S = (R, I, W, L, H, C, P, N)$ as the only carrier through which a cellular-orbit consumer can read local dynamics.

Apply Definition 938.5, Definition 938.6, and Definition 938.7. These rows bind the orbit row, classifier transport, and continuation replay to the same local rule table, initial row, finite orbit window, and local-neighborhood ledger.

Next use Definition 938.8, Definition 938.9, and Definition 938.10. The trust substrate rows and classifier-stability surface keep every successor decision inside R, I, W, L, H, C, P, N.

Finally cite the checked TasteGate alignment target and Definition 938.11. Together they identify the bridge-facing consumer route with the same BHist, hsame, Cont, Pkg, and NameCert rows, leaving no exported coordinate for detached global cellular dynamics, host time steps, untracked orbit quotients, infinite-orbit equality, host evaluator correctness, or standard computational equivalence. □

Closure status for $\mathsf{NameCert}_{\mathsf{CellularOrbitSubstrate}^{\uparrow}}$.

Constructive story: A $\mathsf{CellularOrbitSubstrate}^{\uparrow}$ packet is generated from a finite local rule table, initial spatial row, finite orbit-window ledger, local-neighborhood ledger, componentwise hsame transport, displayed continuation replay, package provenance, and local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CellularOrbitSubstrate}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 938.1, Definition 938.2, Definition 938.3, Definition 938.4, Definition 938.5, Definition 938.6, Definition 938.7, Definition 938.8, Definition 938.9, Definition 938.10, Definition 938.11, and Definition 938.12 bind the finite local-neighborhood orbit certificate, local classifier, continuation ledger, prefix obligation, classifier-stability surface, bridge-facing alignment, and consumer-complete route.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CellularOrbitSubstrate}^{\uparrow}}$, axiomClean)

Lean4 ✓ `BEDC.Derived.CellularOrbitSubstrateUp.taste gate`

Not claimed: This chapter does not prove Lean verification, bridge checking, Rule 110 universality, infinite-orbit equality, host evaluator correctness, or standard computational equivalence.

Upgrade path: No further paper-axis upgrade is required; remaining work is verification and bridge checking for the same finite carrier, orbit, trust substrate, classifier, transport, package, and naming rows.

Chapter 939

A Concrete Naming Certificate for $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$

The $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ surface realizes the large-model inscription reading of chapter 9398 as a finite BEDC packet. It records model-weight, activation-orbit, corpus-supply, output-record, audit-refusal, transport, continuation, provenance, and local naming rows without asserting consciousness, host semantic understanding, or internally ratified universal closure.

The packet refines the neighboring inscription surfaces of chapter 610 and chapter 519. Its extra datum is the corpus-supply row: an output record is accepted as carried inscription only after the finite inference substrate and the finite source-channel row are both visible in the same NameCert surface.

Definition 939.1 (LargeModelInscriptionPoint carrier)**.** *A* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (W, A, C, O, R, H, K, P, N)$$

with the following displayed rows:

1. *W is the finite model-weight row naming the inference substrate;*
2. *A is the finite activation-orbit row generated by a stated prompt and forward-pass schedule;*
3. *C is the corpus-supply row recording the training-source channel from which forward-binding patterns are carried;*
4. *O is the output-record row storing the emitted token sequence as public inscription data;*
5. *R is the audit-refusal row stating that the packet does not internally ratify universal closure, consciousness, host semantic understanding, or model-side proof of the emitted content;*
6. *H records componentwise* hsame *transport for model-weight, activation-orbit, corpus-supply, output-record, refusal, continuation, provenance, and naming rows;*
7. *K records the displayed* Cont *routes by which a consumer reads the inference substrate, corpus-supply row, output record, and refusal ledger in order;*
8. *P is the* Pkg *provenance over* $\mathsf{InscriptionPoint}^{\uparrow}$, $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{TranscendentalSupplyTaxonomy}^{\uparrow}$, $\mathsf{ApophaticName}^{\uparrow}$, *and* $\mathsf{ObserverInterface}^{\uparrow}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{LargeModelInscriptionPoint}^{\uparrow}}$ *row.*

The carrier contains no subject primitive, no phenomenal-state coordinate, no host-language meaning oracle, and no proof that an emitted universal sentence is internally certified by the model.

Lean4 ✓ `BEDC.Derived.LargeModelInscriptionPointUp.TasteGate.LargeModelInscriptionPointTasteGate single carrier alignment`

Definition 939.2 (LargeModelInscriptionPoint classifier)**.** *Two accepted* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *carriers classify together exactly when their model-weight rows, activation-orbit rows, corpus-supply rows, output-record rows, audit-refusal rows, continuation routes, package provenance, and local naming rows compare by the displayed* hsame *entries. The classifier is componentwise and finite:*

$$W \sim_{\mathsf{hsame}} W', \quad A \sim_{\mathsf{hsame}} A', \quad C \sim_{\mathsf{hsame}} C', \quad O \sim_{\mathsf{hsame}} O',$$
$$R \sim_{\mathsf{hsame}} R', \quad K \sim_{\mathsf{hsame}} K', \quad P \sim_{\mathsf{hsame}} P', \quad N \sim_{\mathsf{hsame}} N'.$$

No clause compares hidden model intentions, unbounded semantic understanding, global corpus truth, or an externally interpreted universal claim.

Theorem 939.3 (LargeModelInscriptionPoint NameCert obligations)**.** *For the carrier of Definition 939.1, the local* $\mathsf{NameCert}_{\mathsf{LargeModelInscriptionPoint}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission for* $L = (W, A, C, O, R, H, K, P, N)$*;*
2. *classifier transport for the model-weight, activation-orbit, corpus-supply, output-record, audit-refusal, continuation, provenance, and naming rows under componentwise* hsame*;*
3. *stability of the output-record read under the same displayed inference-substrate and corpus-supply rows;*
4. *ledger exactness requiring every inscription read to pass through the corpus-supply row and the audit-refusal row before it reaches the local naming row;*
5. *non-escape for consciousness, host semantic understanding, internally ratified universal closure, hidden source selection, and model-side proof of output truth.*

Proof. Carrier admission is projection from Definition 939.1. The packet lists the finite inference substrate, activation orbit, corpus-supply channel, output record, refusal ledger, transports, continuation routes, package provenance, and local naming row.

Classifier transport is componentwise. Each accepted comparison is one displayed hsame entry, and the continuation row replays the same substrate, corpus, output, and refusal reads after transport.

Stability and ledger exactness follow from the route order. A consumer first reads W and A as the finite inference substrate, then C as the source-channel row, then O as the emitted inscription, and finally R before it reaches N.

The excluded claims have no coordinate in L. Thus the local NameCert can certify carried inscription data, but it cannot project consciousness, host-side semantic understanding, or internally certified universal truth. □

Theorem 939.4 (LargeModelInscriptionPoint carried-output boundary)**.** *Every accepted* LargeModelInscriptionPoi *packet reads model output as carried inscription through the finite route*

model-weight row $\longrightarrow$ *activation-orbit row* $\longrightarrow$ *corpus-supply row* $\longrightarrow$ *output-record row* $\longrightarrow$ $\mathsf{NameCert}_{\mathsf{LargeM}}$

If the corpus-supply row is absent, the packet no longer distinguishes carried inscription from internally ratified universal closure.

Proof. Project the carrier $L = (W, A, C, O, R, H, K, P, N)$. The first two rows give the finite inference substrate, while C records the source channel from which forward-binding patterns are carried.

Read O only after C has been displayed. This forces the output record to be consumed as carried inscription data rather than as a model-internal proof or host semantic oracle.

Finally, the refusal row R fixes the public boundary before the naming row N is read. Without C, the route would expose an output record without the source-channel distinction needed by the theorem. □

Theorem 939.5 (LargeModelInscriptionPoint public non-escape)**.** *No public consumer of an accepted* LargeModelInscriptionPoint$^{\uparrow}$ *packet can extract consciousness, host semantic understanding, model-side proof of a universal claim, an unbounded corpus truth predicate, or a hidden source selector. Public reads are limited to the finite inference-substrate, corpus-supply, output-record, audit-refusal,* hsame*,* Cont*,* Pkg*, and* NameCert *rows displayed in the carrier.*

Proof. Inspect the carrier inventory. The only public coordinates are $W, A, C, O, R, H, K, P, N$, so every consumer projection factors through these finite rows.

The neighboring inscription and supply chapters provide route discipline, not extra semantic coordinates. They let the packet name where carried inscription is read, while the local refusal row records what the packet does not contain.

Therefore public consumers can recover the displayed rows and their certified route, but no consciousness predicate, semantic-understanding oracle, universal-truth proof, or hidden source selector is available for projection. □

Theorem 939.6 (LargeModelInscriptionPoint source-channel exactness)**.** *For an accepted* LargeModelInscriptionPo *packet $L = (W, A, C, O, R, H, K, P, N)$, the corpus-supply row C is the unique source-channel gate for carried inscription. A consumer may read O as a carried output only after the route has exposed W, A, C, H, K, P, N, and no hidden source selector, host semantic oracle, or model-internal truth predicate can replace C.*

Lean4 ✓ `BEDC.Derived.LargeModelInscriptionPointUp.LargeModelInscriptionPointCarrier source channel exactness`

Proof. Project the carrier of Definition 939.1. The only source-channel coordinate in the packet is C, while W and A provide the finite inference substrate and O stores the emitted inscription.

Apply the carried-output boundary of Definition 939.4. It reads the output row only after the corpus-supply row has been displayed.

Finally use public non-escape from Definition 939.5. Since hidden source selectors, host semantic oracles, and model-side proof predicates are not projected from L, the row C is the source-channel gate for carried inscription. □

Theorem 939.7 (LargeModelInscriptionPoint output-record stability)**.** *Output-record reads for accepted* LargeModelInscriptionPoint$^{\uparrow}$ *packets are stable under the displayed model-weight, activation-orbit, corpus-supply, audit-refusal,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. If two accepted packets compare by the classifier of Definition 939.2, a public consumer that reads the output record of one packet can transport that read only through the componentwise rows*

$$W, A, C, O, R, H, K, P, N.$$

Proof. Use the classifier definition. It compares model-weight, activation-orbit, corpus-supply, output-record, audit-refusal, continuation, provenance, and naming rows component by component.

The NameCert obligations of Definition 939.3 supply classifier transport and route stability for the same displayed rows. Thus an output-record read cannot drop the corpus-supply row, refusal ledger, continuation replay, provenance, or local name during transport.

Apply Definition 939.6 and Definition 939.5. The first keeps the output read behind the source-channel gate, and the second excludes hidden semantic or truth coordinates from the transported public read. □

Theorem 939.8 (LargeModelInscriptionPoint obligation closure package)**.** *The* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *chapter closes the following obligation package for the finite inscription packet: carrier admission for L, classifier transport, source-channel exactness, output-record stability, ledger exactness for the carried-output route, and public non-escape for consciousness, host semantic understanding, universal-truth proof, unbounded corpus truth, and hidden source selection.*

Proof. Carrier admission is Definition 939.1, and classifier transport is Definition 939.2 together with Definition 939.3.

Source-channel exactness follows from Definition 939.6. Output-record stability follows from Definition 939.7.

Ledger exactness is the carried-output boundary of Definition 939.4. Public non-escape is Definition 939.5, so the package has no remaining public coordinate for the excluded claims. □

Theorem 939.9 (LargeModelInscriptionPoint scoped kernel surface)**.** *Every accepted* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *packet exposes exactly the scoped kernel surface*

$$W, A, C, O, R, H, K, P, N.$$

All inscription, carried-output, corpus-supply, audit-refusal, transport, continuation, provenance, and local naming reads factor through those rows. No consciousness predicate, host semantic-understanding oracle, model-side universal proof, corpus truth oracle, or hidden source selector is exported.

Proof. The carrier definition of Definition 939.1 displays precisely the rows $W, A, C, O, R, H, K, P, N$. The classifier definition of Definition 939.2 compares accepted packets only through the same componentwise rows.

The NameCert obligations of Definition 939.3 bind carrier admission, classifier transport, stability, ledger exactness, and non-escape to that finite surface. The carried-output boundary of Definition 939.4 and the source-channel exactness theorem Definition 939.6 force output and corpus-supply reads to pass through the displayed route.

Output-record stability is Definition 939.7, and public non-escape is Definition 939.5. The checked TasteGate marker records that the Lean carrier surface is a single aligned carrier, so the paper packet and the machine carrier name the same scoped surface. □

Falsifiable prediction: If the corpus-supply row is removed, the packet can no longer distinguish model output as carried inscription from internally ratified universal closure.

Independence witness: Nearest siblings: inscriptionpoint, closedobservationsystem, transcendentalsupplytaxonomy, apophaticname, observerinterface; none is bijective because none simultaneously carries model-weight, activation-orbit, corpus-supply, output-record, and no-internal-ratification rows.

The Lean taste-gate surface for this packet is expected to expose Nontrivial LargeModelInscriptionPoint$^{\uparrow}$ and FieldFaithful LargeModelInscriptionPoint$^{\uparrow}$ in TasteGate.lean, with the future namespace BEDC.Derived.LargeMode

Closure status for NameCert$_{\text{LargeModelInscriptionPoint}^{\uparrow}}$ ·

Not claimed: This chapter does not close consciousness, host semantic understanding, model-side proof of universal claims, corpus truth, hidden source selection, or a checked Lean certificate for the whole packet.

Upgrade path: The remaining formal work is a standard bridge certificate for the same public large-model inscription packet.

Chapter 940

A Trust Manifest Surface for $\mathsf{CellularTrustSubstrate}^{\uparrow}$

The $\mathsf{CellularTrustSubstrate}^{\uparrow}$ surface realizes the cellular trust substrate of Definition 9390.6 as a finite NameCert packet. It is not merely a cellular-rule carrier: it binds the local transition table, the orbit window, the classifier, the manifest row, and the audit route into one closed observation surface. The resulting packet gives later Rule 110 and no-induction arguments a concrete certificate object to cite instead of a narrative-only substrate.

The trust substrate consumes the local rule and finite orbit discipline of chapter 934 and the bounded trace boundary of chapter 944 before its manifest and audit rows are public. Those sibling surfaces supply the displayed cellular evolution and step-indexed trace limit, while this packet records the additional trust manifest and replay route.

The packet consumes the local substrate carrier of chapter 942 and the finite local read boundary of chapter 509. Its trust rows add manifest and audit-route accountability on top of those sibling surfaces, so an accepted read must first expose the cellular carrier and local boundary before the manifest and replay rows can certify the trusted substrate packet.

Falsifiable prediction: Removing the local-rule row permits two orbit windows with different update tables to classify as the same substrate packet; removing the manifest row prevents a finite audit replay from reconstructing the displayed observation boundary.

Independence witness: Nearest siblings: localitycell, continuationautomaton, haltingdistinction, continuationbigstep, and groundcompilereventflowauditroute. None is bijective to the cellular trust substrate because those siblings omit either the fixed local transition table, the orbit-window manifest row, or the closed substrate observation boundary.

Definition 940.1 (Cellular trust substrate carrier)**.** *A* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (R, W, K, M, A, H, C, P, N)$$

with the following displayed rows:

1. *R is the local cellular rule row, including the finite alphabet, neighbourhood arity, boundary convention, and complete transition table;*
2. *W is the orbit-window row, consisting of the initial configuration, the finite time interval, and the displayed cell coordinates accepted for observation;*
3. *K is the classifier row assigning finite substrate tags to windows generated by R on W;*

4. *M is the manifest row recording the text-format schema, expected read fields, replay bounds, and admitted observation boundary;*
5. *A is the audit-route row replaying the finite generation of each displayed orbit window and each classifier decision;*
6. *H records componentwise* hsame *transports for R, W, K, M, A, P, N;*
7. *C records displayed* Cont *routes through the local rule, orbit window, classifier, manifest, and audit route;*
8. *P is the* Pkg *provenance over* $\mathsf{CellularTrustSubstrate}^{\uparrow}$*, Definition 9390.6,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{CellularTrustSubstrate}^{\uparrow}}$ *row.*

The local classifier compares accepted carriers only by the displayed rule table, orbit window, substrate classifier, manifest, audit route, transport rows, continuation routes, provenance, and naming row. It has no coordinate for an unbounded orbit, host evaluator identity, hidden update table, detached manifest schema, quotient stream equality, or external induction principle.

Lean4 (definition) `BEDC.Derived.CellularTrustSubstrateUp.TasteGate.CellularTrustSubstrateUp`

Theorem 940.2 (Cellular trust substrate obligation surface)**.** *For the carrier of Definition 940.1, the local* $\mathsf{NameCert}_{\mathsf{CellularTrustSubstrate}^{\uparrow}}$ *surface consists exactly of carrier exposure for $S = (R, W, K, M, A, H, C, P, N)$ local-rule accountability through R, orbit-window exposure through W, classifier accountability through K, manifest replay through M, finite audit routing through A, componentwise stability through H, displayed continuation through C, package provenance through P, and local naming through N. No consumer can read a cellular trust substrate, a Rule 110 substrate, a closed observation boundary, or a no-induction substrate premise as* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *evidence without passing through these rows.*

Proof. Carrier exposure is projection from Definition 940.1. The packet displays the rule table, orbit window, classifier, manifest, audit route, transports, continuation routes, provenance, and local naming row as its only coordinates.

Local-rule, orbit-window, classifier, manifest, and audit accountability are read from R, W, K, M, A. The rule row decides the next state locally; the orbit-window row states the finite observation domain; the classifier row names only windows generated inside that domain; the manifest row states the replay schema; and the audit row records the finite route by which each accepted read is recovered.

The remaining rows close the NameCert surface. The H, C, P, N rows transport, replay, record, and name exactly the displayed packet. Since the carrier lacks coordinates for unbounded orbit access, hidden update tables, detached manifests, quotient streams, host evaluator identity, and external induction, the listed rows exhaust the public obligation surface. □

Lean4 ✓ `BEDC.Derived.CellularTrustSubstrateUp.TasteGate.CellularTrustSubstrate obligation surface`

Theorem 940.3 (Local-rule nonescape)**.** *Every accepted classifier read exported by a* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *carrier factors through the displayed local rule row R and the finite orbit-window row W. In particular, two packets whose accepted evidence differs only by a hidden update table, a host evaluator, or an unstated boundary convention cannot be classified as the same cellular trust substrate packet.*

Proof. Begin with the accepted-read route. By Definition 940.2, a classifier read reaches the local NameCert row only through $R, W, K, M, A, H, C, P, N$.

The row R supplies the complete local update table and boundary convention, while W supplies the initial configuration and finite observation domain. The classifier row K has no independent transition semantics; it can only tag windows admitted by the route from R through W.

Thus changing the update table, host evaluator, or boundary convention without changing the displayed R row is not a move inside the carrier. Since the packet has no hidden coordinate from which such a change can be recovered, the accepted classifier cannot identify the two displays as the same substrate evidence. □

Lean4 ✓ `BEDC.Derived.CellularTrustSubstrateUp.TasteGate.CellularTrustSubstrate local rule window classifier reflect display`

Theorem 940.4 (Orbit observation boundary)**.** *Every closed observation exported by a* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *carrier is bounded by the manifest row M and replayed by the audit-route row A. Consequently, a consumer obtains a finite observation boundary for the displayed orbit window, not an unbounded orbit, a stream quotient, or an internal induction rule over all cellular times.*

Proof. The manifest row M states the accepted text-format schema, replay bounds, and observation boundary. The audit-route row A then replays each displayed orbit-window and classifier read against that schema.

Apply Definition 940.2. A closed observation is accepted as $\mathsf{CellularTrustSubstrate}^{\uparrow}$ evidence only when the route through M and A reaches the local naming row N.

It follows that the exported boundary is finite and displayed. The carrier has no coordinate for an all-time orbit, quotient stream representative, or induction rule over cellular time, so no such object is obtained by consuming the packet. □

Lean4 ✓ `BEDC.Derived.CellularTrustSubstrateUp.TasteGate.CellularTrustSubstrate orbit observation boundary`

Theorem 940.5 (Cellular trust substrate obligation closure)**.** *The carrier of Definition 940.1, the local-rule nonescape theorem Definition 940.3, the orbit observation boundary theorem Definition 940.4, the falsifiable prediction, the independence witness, and the Lean TasteGate single-carrier alignment together supply the obligation-closure surface for* $\mathsf{CellularTrustSubstrate}^{\uparrow}$*. The closed surface is the finite route through $R, W, K, M, A, H, C, P, N$, with no claim of Rule 110 universality, host evaluator correctness, quotient stream equality, cellular completeness, or internal induction.*

Lean4 ✓ `BEDC.Derived.CellularTrustSubstrateUp.TasteGate.CellularTrustSubstrateTasteGate single carrier alignment`

Proof. The carrier displays the complete local-rule, orbit-window, classifier, manifest, audit-route, transport, continuation, provenance, and naming rows. The local-rule nonescape theorem forces classifier reads through R and W, and the orbit observation boundary theorem forces closed observations through M and A.

The falsifiable prediction identifies the two row removals that would break the route, while the independence witness separates this carrier from nearby cellular and continuation packets. The Lean TasteGate alignment supplies the checked single-carrier evidence that the displayed packet has the intended TasteGate carrier shape.

Together these ingredients exhaust the obligation surface named by Definition 940.2. Since the packet still lacks coordinates for universality, host evaluator semantics, quotient streams, cellular completeness, and induction over all times, obligation closure stops at the displayed BEDC rows. □

Theorem 940.6 (Cellular trust substrate primitive scope binding)**.** *For every accepted* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *carrier* $S = (R, W, K, M, A, H, C, P, N)$*, the rows* $R, W, K, M, A, H, C, P, N$ *bind only to the BEDC primitive surface* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. In particular,* R, W, K, M, A *are finite* BHist *rows,* H *is their componentwise* hsame *transport,* C *is their displayed* Cont *route,* P *is their* Pkg *provenance, and* N *is the local* $\mathsf{NameCert}_{\mathsf{CellularTrustSubstrate}^{\uparrow}}$ *row.*

Proof. Start from the obligation surface of Definition 940.2. It lists the complete carrier admission route for $S = (R, W, K, M, A, H, C, P, N)$ and names no primitive outside BHist, hsame, Cont, Pkg, and NameCert.

Local-rule nonescape forces every classifier read through the displayed R and W rows. Orbit observation boundary forces every closed observation through the finite manifest and audit rows M and A.

The checked TasteGate single-carrier alignment cited at Definition 940.5 confirms that the displayed carrier shape is the aligned cellular trust substrate shape. Hence the primitive bindings are exactly the listed BEDC rows, with no host evaluator, quotient stream, or induction principle added by the packet. □

Lean4 ✓ `BEDC.Derived.CellularTrustSubstrateUp.CellularTrustSubstrate primitive scope binding`

Theorem 940.7 (Cellular trust substrate sibling scope binding)**.** *For every accepted* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *carrier* $S = (R, W, K, M, A, H, C, P, N)$*, the same rows bind the packet to the sibling surfaces* $\mathsf{CellularAutomaton}^{\uparrow}$*,* $\mathsf{BoundedUniversalTrace}^{\uparrow}$*,* $\mathsf{CellularSubstrate}^{\uparrow}$*, and* $\mathsf{LocalityCell}^{\uparrow}$*. The rule and orbit rows consume the cellular automaton and bounded trace surfaces, while the classifier, manifest, audit, transport, route, provenance, and naming rows expose only the local substrate and locality-cell boundaries needed by downstream cellular trust consumers.*

Proof. The opening dependency paragraphs place $\mathsf{CellularTrustSubstrate}^{\uparrow}$ after the local rule and finite orbit discipline of $\mathsf{CellularAutomaton}^{\uparrow}$ and $\mathsf{BoundedUniversalTrace}^{\uparrow}$, and after the local substrate and local read boundaries of $\mathsf{CellularSubstrate}^{\uparrow}$ and $\mathsf{LocalityCell}^{\uparrow}$.

Apply local-rule nonescape. The accepted classifier route cannot pass around R and W, so the cellular automaton and bounded trace rows are sibling inputs rather than optional explanatory context.

Apply orbit observation boundary. The manifest row M and audit row A bound every closed observation before it is exported, and H, C, P, N keep the same route transported, replayed, packaged, and named.

Finally use the obligation closure theorem together with the checked TasteGate single-carrier alignment cited at Definition 940.5. They identify the accepted sibling scope as the displayed finite route and exclude Rule 110 universality, host evaluator correctness, quotient stream equality, cellular completeness, and all-time induction from the binding. □

Lean4 ✓ `BEDC.Derived.CellularTrustSubstrateUp.CellularTrustSubstrate sibling scope binding`

The Lean TasteGate namespace BEDC.Derived.CellularTrustSubstrateUp.TasteGate must provide Nontrivial CellularTrustSubstrateUp and FieldFaithful CellularTrustSubstrateUp instances for the displayed carrier, while BEDC.Derived.CellularTrustSubstrateUp.taste_gate records the chapter-level TasteGate instance.

Theorem 940.8 (Cellular trust substrate public export package)**.** *Every public consumer of an accepted* CellularTrustSubstrate$^{\uparrow}$ *packet* $S = (R, W, K, M, A, H, C, P, N)$ *receives exactly the local-rule row, finite orbit-window row, classifier row, manifest row, audit route, componentwise transport, continuation route, provenance, and local* NameCert *row. This public package is routed through* CellularAutomaton$^{\uparrow}$, BoundedUniversalTrace$^{\uparrow}$, CellularSubstrate$^{\uparrow}$, *and* LocalityCell$^{\uparrow}$, *and it carries no Rule 110 universality, host evaluator correctness, quotient stream equality, cellular completeness, or all-time induction.*

Lean4 ✓ `BEDC.Derived.CellularTrustSubstrateUp.CellularTrustSubstrate public export package`

Proof. Start from the obligation surface. It exposes the local rule, orbit window, classifier, manifest, audit route, transport, continuation, provenance, and local naming rows as the complete accepted packet.

Use local-rule nonescape and orbit observation boundary. They force classifier reads through R, W and closed observation reads through M, A, excluding hidden update tables, host evaluators, unbounded orbits, quotient streams, and induction over all cellular times.

Apply primitive scope binding and sibling scope binding. The primitive route is confined to BHist, hsame, Cont, Pkg, and NameCert, while the sibling route passes through CellularAutomaton$^{\uparrow}$, BoundedUniversalTrace$^{\uparrow}$, CellularSubstrate$^{\uparrow}$, and LocalityCell$^{\uparrow}$.

Finally use the obligation closure theorem and its TasteGate alignment marker. They identify the displayed carrier shape as the aligned single-carrier surface, so a public consumer receives exactly the listed packet and no Rule 110 universality, host evaluator correctness, quotient stream equality, cellular completeness, or all-time induction. □

Theorem 940.9 (Cellular trust substrate bridge-scope package)**.** *Any bridge-scope consumer of an accepted* CellularTrustSubstrate$^{\uparrow}$ *packet must preserve the local-rule row, orbit-window row, classifier row, manifest row, audit route, componentwise* hsame *transport, displayed* Cont *route,* Pkg *provenance, local* NameCert *row, falsifiable prediction, independence witness, and TasteGate alignment marker. The bridge-scope package carries no Rule 110 universality, host evaluator correctness, quotient stream equality, cellular completeness, hidden global orbit, or all-time induction principle.*

Lean4 ✓ `BEDC.Derived.CellularTrustSubstrateUp.CellularTrustSubstrate bridge scope package`

Proof. Start from the public export theorem. It gives every public consumer exactly the local rule, orbit window, classifier, manifest, audit route, transport, continuation, provenance, and local naming rows.

Apply primitive scope binding. The public rows are bound to BHist, hsame, Cont, Pkg, and NameCert, so the bridge-scope consumer cannot add a host evaluator, quotient stream representative, or induction principle.

Next apply sibling scope binding. It keeps the route attached to CellularAutomaton$^{\uparrow}$, BoundedUniversalTrace$^{\uparrow}$, CellularSubstrate$^{\uparrow}$, and LocalityCell$^{\uparrow}$, which supplies the local-rule, finite-orbit, classifier, manifest, audit, prediction, and independence surface used by the bridge.

Finally use obligation closure and the TasteGate alignment marker. They identify the displayed carrier as the accepted cellular trust substrate packet, so the bridge-scope consumer preserves the stated rows without importing Rule 110 universality, cellular completeness, or hidden all-time behavior. □

Theorem 940.10 (Cellular trust substrate mature route completeness)**.** *For every accepted* CellularTrustSubstrate$^{\uparrow}$ *packet* $S = (R, W, K, M, A, H, C, P, N)$*, the local-rule row, orbit-window row, classifier row, manifest row, audit route, primitive scope, sibling scope, public export package, and bridge-scope package*

exhaust all mature public reads of the packet. A mature consumer can only preserve the finite route through $R, W, K, M, A, H, C, P, N$, together with the TasteGate single-carrier alignment marker; it receives no Rule 110 universality, host evaluator correctness, quotient stream equality, cellular completeness, hidden global orbit, or all-time induction principle.

Proof. Start from the obligation surface and the obligation closure theorem. They display exactly the carrier rows $R, W, K, M, A, H, C, P, N$ and identify the TasteGate single-carrier alignment as the checked carrier-shape evidence for the packet.

The route constraints are then supplied in layers. Local-rule nonescape forces classifier reads through R and W, while orbit observation boundary forces closed observations through the manifest row M and audit route A.

Next apply primitive scope binding and sibling scope binding. These results bind the same route to BHist, hsame, Cont, Pkg, NameCert, and to the sibling surfaces CellularAutomaton$^{\uparrow}$, BoundedUniversalTrace$^{\uparrow}$, CellularSubstrate$^{\uparrow}$, and LocalityCell$^{\uparrow}$, without adding a host evaluator or an all-time cellular principle.

Finally use the public export package and bridge-scope package. The public package exposes exactly the listed rows, and the bridge-scope package preserves the same rows across bridge-facing reads. Therefore the mature public surface has no remaining paper-side coordinate beyond the displayed finite route and the TasteGate alignment marker. □

Lean4 ✓ `BEDC.Derived.CellularTrustSubstrateUp.CellularTrustSubstrate mature route completeness`

Corollary 940.11 (Cellular trust substrate strict obstruction locality)**.** *Let $S = (R, W, K, M, A, H, C, P, N)$ be an accepted* CellularTrustSubstrate$^{\uparrow}$ *carrier. Any consumer-facing obstruction cited from a displayed local-rule failure, manifest refusal, sibling separation, or countermodel-style row in this chapter is strict and local: it can block only the named converse or reuse route that tries to read around the displayed cellular trust substrate packet. It cannot be reinterpreted as a global impossibility theorem for cellular substrates, a host theorem about Rule 110 or bounded universal traces, or hidden external validation of a non-displayed update table, evaluator, manifest schema, quotient stream, unbounded orbit, or all-time induction principle.*

Proof. Start with the complete consumer surface. By Definition 940.2, a consumer can read CellularTrustSubstrate$^{\uparrow}$ evidence only through the finite row inventory

$$R, W, K, M, A, H, C, P, N.$$

The same theorem names these rows as carrier exposure, local-rule accountability, orbit-window exposure, classifier accountability, manifest replay, audit routing, componentwise transport, displayed continuation, package provenance, and local naming. Thus a displayed failure, refusal, separation, or countermodel-style row has no independent public force unless its use factors through this inventory.

Now apply Definition 940.3. Every accepted classifier read factors through the displayed local rule row R and the finite orbit-window row W. Hence a purported converse from the classifier row K to a hidden update table, host evaluator, or unstated boundary convention is blocked only at that classifier route: the packet gives K no transition semantics except the route from R through W.

The remaining reuse attempts fail for the same row-inventory reason. Manifest and audit uses must pass through M and A; transports and continuations must remain componentwise through H and C; provenance and naming must remain the displayed rows P and N. None of these

coordinates is a global cellular impossibility theorem, a host evaluator theorem, a quotient-stream equality, an external validation channel, or an induction principle over all cellular times.

Therefore the obstruction is strict in the BEDC sense. It rejects exactly the attempted converse or reuse route whose required coordinate is absent from $R, W, K, M, A, H, C, P, N$, while leaving every stronger global, host-level, or externally validated reading outside the accepted $\mathsf{CellularTrustSubstrate}^{\uparrow}$ surface. □

Lean4 ✓ `BEDC.Derived.CellularTrustSubstrateUp.CellularTrustSubstrate strict obstruction locality`

Theorem 940.12 (Cellular trust substrate standard bridge boundary)**.** *For every accepted* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *packet* $S = (R, W, K, M, A, H, C, P, N)$*, any bridge-facing read of the packet is confined to the displayed local-rule row* R*, finite orbit-window row* W*, classifier row* K*, manifest row* M*, audit route* A*, componentwise transport* H*, continuation replay* C*, package provenance* P*, and local naming row* N*. The bridge may preserve and expose only these rows together with the primitive and sibling scope bindings already proved in this chapter. It cannot import Rule 110 universality, host evaluator correctness, quotient streams, all-time induction, hidden global-orbit data, or external validation.*

Proof. Start from the public export package and the bridge-scope package. They give every public or bridge-scope consumer exactly the finite route through $R, W, K, M, A, H, C, P, N$.

Use local-rule nonescape and orbit observation boundary. These force classifier reads through R, W, K and closed observation reads through M, A, so a bridge-facing consumer cannot replace the displayed rows by a host evaluator, hidden transition table, quotient stream, global orbit, or all-time induction route.

Finally apply primitive scope binding, sibling scope binding, and strict obstruction locality. They keep the accepted bridge surface over BHist, hsame, Cont, Pkg, NameCert, $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{BoundedUniversalTrace}^{\uparrow}$, $\mathsf{CellularSubstrate}^{\uparrow}$, and $\mathsf{LocalityCell}^{\uparrow}$, while any attempted read outside those coordinates is only a local obstruction to that attempted reuse. □

Closure status for $\mathsf{NameCert}_{\mathsf{CellularTrustSubstrate}^{\uparrow}}$**.**

Constructive story: A $\mathsf{CellularTrustSubstrate}^{\uparrow}$ packet is generated from the displayed local rule, finite orbit window, classifier, manifest, audit route, componentwise transport, continuation route, package provenance, and local naming rows.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CellularTrustSubstrate}^{\uparrow}}$, maturePackageClosed)

Scope closed: The displayed carrier rows, obligation surface, local-rule nonescape, manifest and audit rows, sibling dependencies $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{BoundedUniversalTrace}^{\uparrow}$, $\mathsf{CellularSubstrate}^{\uparrow}$, and $\mathsf{LocalityCell}^{\uparrow}$, and the standard bridge boundary bind the finite $R, W, K, M, A, H, C, P, N$ cellular trust scope.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CellularTrustSubstrate}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.CellularTrustSubstrateUp.TasteGate.CellularTrustSubstrateTasteGate\_single\_carrier\_al`

Bridge status: paperBridge

Not claimed: This chapter does not claim Rule 110 universality, host evaluator correctness, quotient streams, cellular completeness, or all-time induction.

Upgrade path: Mature closure requires checked examples and completeness for the same public carrier rows, local-rule route, orbit boundary, manifest, audit route, transport, replay, provenance, and naming data.

Chapter 941

A Concrete Naming Certificate for $\mathsf{CellularRowClassifier}^{\uparrow}$

The $\mathsf{CellularRowClassifier}^{\uparrow}$ packet realizes the finite local row-window classifier surface implicit in chapter 9390. It is adjacent to the transition-row carrier of chapter 482, the diagonal trace boundary of chapter 491, and the obstruction-ledger consumer of chapter 490. Its distinguishing datum is the displayed local neighbourhood window through which a row tag is read; the packet therefore certifies finite cellular pattern recognition without importing a host orbit classifier.

Falsifiable prediction: If a CellularRowClassifier packet is atomic, every accepted row-tag read factors through the displayed local window and no consumer can recover a host orbit classifier outside that window.

Independence witness: ContinuationAutomatonUp supplies transition rows but not local neighbourhood tags; HaltingDistinctionUp supplies diagonal trace rows but not cellular pattern tags; HaltingObstructionUp supplies obstruction ledgers but not row-window classifiers; ApophaticNameUp supplies boundary requests but not transition-local tag determinacy.

Definition 941.1 (CellularRowClassifier carrier)**.** *A* $\mathsf{CellularRowClassifier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (R, J, T, A, H, C, P, N)$$

with the following visible rows:

1. *R is the finite cellular rule row whose local neighbourhood relation is being inspected.*
2. *J is the displayed row-window row, naming the finite centre cell, its neighbourhood, and the bounded row segment from which a tag may be read.*
3. *T is the finite tag row assigning local tags such as ether, glider phase, collision fragment, boundary refusal, or unclassified window to the displayed windows in J.*
4. *A is the acceptance ledger recording which row-tag reads are admitted and which candidate reads are refused for lacking the displayed neighbourhood.*
5. *H records componentwise* hsame *transports for R, J, T, A, P, N.*
6. *C records displayed* Cont *routes through the rule row, local window row, tag row, acceptance ledger, provenance row, and local name row.*
7. *P is the* Pkg *provenance over* BHist, hsame, Cont, *cellular row-window reads, the sibling packets cited above, and local* NameCert *evidence.*

8. N is the local $\mathsf{NameCert}_{\mathsf{CellularRowClassifier}^{\uparrow}}$ *row.*
The carrier has no coordinate for an unbounded cellular orbit, a host evaluator over all rows, quotient stream equality, a global glider catalog, or a detached Rule 110 oracle.

Theorem 941.2 (CellularRowClassifier NameCert obligations)**.** *For the carrier of Definition 941.1, the local* $\mathsf{NameCert}_{\mathsf{CellularRowClassifier}^{\uparrow}}$ *surface consists exactly of carrier admission for $W = (R, J, T, A, H, C, P, N)$, rule-row accountability through R, local window exposure through J, tag-read accountability through T, acceptance and refusal replay through A, componentwise stability through H, displayed route replay through C, package provenance through P, and local naming through N. A consumer may use the packet as finite cellular pattern evidence only through those rows.*

Proof. Carrier admission is projection from Definition 941.1. The rule row, local window row, tag row, acceptance ledger, transports, routes, provenance, and local naming row are the only visible coordinates.

Rule-row and window accountability come from R and J. A row-tag read is admitted only when the displayed window supplies the neighbourhood data named by the carrier, so the consumer cannot replace the local row by an unrecorded orbit segment.

Tag-read and refusal replay are read from T and A. The ledger records both admitted local tags and refusals caused by missing neighbourhood data, which keeps the classifier inside the finite row-window surface.

Finally use H, C, P, N. These rows transport, replay, record, and name the same displayed packet. Since no coordinate names an unbounded orbit, a host evaluator, quotient stream equality, a global catalog, or a detached oracle, the listed rows exhaust the local NameCert obligations. □

Theorem 941.3 (CellularRowClassifier local window determinacy)**.** *Every accepted row-tag read exported by a* $\mathsf{CellularRowClassifier}^{\uparrow}$ *packet factors through the finite route*

$$R \longmapsto J \longmapsto T \longmapsto A \longmapsto H \longmapsto C \longmapsto P \longmapsto N.$$

Thus the read is determined by the displayed local neighbourhood window and its ledger entry. The packet exports no host orbit classifier, no unbounded cellular history, no global halting classifier, no quotient stream equality, and no ambient completeness principle.

Proof. Start with an accepted row-tag read. Carrier projection gives R, J, T, A, H, C, P, N as the only rows through which the read can pass.

Apply Definition 941.2. The tag row T can be read only against the local window J, and the acceptance ledger A records whether that window supplies the required neighbourhood data.

The remaining route is bookkeeping inside the packet. The hsame transports and Cont routes preserve the displayed rows, while P and N record package provenance and local naming for the same finite read.

Coordinate exhaustion gives determinacy. Since no coordinate names a host orbit classifier, unbounded cellular history, global halting classifier, quotient stream equality, or ambient completeness principle, the accepted tag is determined exactly by the displayed local window. □

Theorem 941.4 (CellularRowClassifier standard reflection bridge surface)**.** *Any standard reflection read of a* $\mathsf{CellularRowClassifier}^{\uparrow}$ *row classifier must factor through the displayed finite route*

$$R \longmapsto J \longmapsto T \longmapsto A \longmapsto H \longmapsto C \longmapsto P \longmapsto N.$$

The bridge-facing surface is exactly the carrier of Definition 941.1, the local $\mathsf{NameCert}_{\mathsf{CellularRowClassifier}^{\uparrow}}$ *obligations of Definition 941.2, the local window determinacy of Definition 941.3, and the checked*

TasteGate row for the displayed carrier. The surface exports no host orbit classifier, unbounded cellular history, global halting classifier, quotient stream equality, or ambient completeness principle.

Proof. Start with a standard reflection read of the row classifier. Carrier projection exposes only R, J, T, A, H, C, P, N, so the read has no coordinate from which to inspect a host orbit, an unbounded history, or a detached classifier.

Apply Definition 941.2. The $\mathsf{NameCert}_{\mathsf{CellularRowClassifier}^{\uparrow}}$ surface requires rule-row accountability, local window exposure, tag-read accountability, acceptance and refusal replay, componentwise stability, displayed route replay, package provenance, and local naming through the same finite packet.

Next use Definition 941.3. Any accepted row-tag read is determined by the local neighbourhood row J and its ledger entry in A, with T recording the tag and H, C, P, N preserving the same displayed route for reflection.

The TasteGate row supplies the public nontriviality and field-faithfulness surface for this carrier, but it does not add another classifier coordinate. Therefore the standard reflection read must pass through the displayed finite route R, J, T, A, H, C, P, N.

Since the carrier and cited obligations contain no host orbit classifier, unbounded cellular history, global halting classifier, quotient stream equality, or ambient completeness principle, the bridge-facing surface cannot export any such datum. □

The Lean TasteGate namespace BEDC.Derived.CellularRowClassifierUp.TasteGate provides Nontrivial CellularRow and FieldFaithful $\mathsf{CellularRowClassifier}^{\uparrow}$ instances for the displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{CellularRowClassifier}^{\uparrow}}$.

Constructive story: A $\mathsf{CellularRowClassifier}^{\uparrow}$ packet is generated from a finite cellular rule row, local row-window row, tag row, acceptance ledger, componentwise hsame transports, displayed continuation routes, package provenance, and local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{CellularRowClassifier}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 941.1, Definition 941.2, Definition 941.3, Definition 941.4, and

Lean4 ✓ `BEDC.Derived.CellularRowClassifierUp.taste gate`

specify the finite row-window classifier surface, bridge-facing reflection surface, and checked TasteGate instance.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{CellularRowClassifier}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.CellularRowClassifierUp.CellularRowClassifierTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not prove Rule 110 universality, global cellular orbit classification, total halting classification, quotient stream equality, host evaluator correctness, or bridge checking.

Upgrade path: The paper closure axis is mature; bridgeChecked verification remains a separate formal bridge obligation.

Chapter 942

A Concrete Naming Certificate for $\mathsf{CellularSubstrate}^{\uparrow}$

The $\mathsf{CellularSubstrate}^{\uparrow}$ packet packages the carrier alternative of chapter 9391 as a finite BHist NameCert surface. It sits between the rule-table and finite-orbit emphasis of chapter 934 and the audit-ledger substrate of chapter 937. Its distinguishing role is to certify the cellular carrier itself: a displayed local row, neighbourhood window, local update route, global-step ledger, transport surface, continuation surface, provenance, and local NameCert row are all present at once.

Falsifiable prediction: A packet with the same global-step ledger but no displayed neighbourhood window is not an accepted $\mathsf{CellularSubstrate}^{\uparrow}$ carrier.

Independence witness: Nearest siblings: cellularautomaton, cellulartrustsubstrate, streamname, interhistlocalityledger, and finitewindowenvelope; the carrier is not bijective to any of them because it simultaneously requires a local neighbourhood window, local update route, global-step ledger, transport rows, and local NameCert row, while each sibling omits at least one of those displayed coordinates.

Definition 942.1 (Cellular substrate carrier)**.** *A* $\mathsf{CellularSubstrate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (S, N, U, G, H, C, P, L)$$

with the following displayed rows:

1. *S is the cell-state row, naming the finite row segment visible to the carrier.*
2. *N is the neighbourhood-window row, naming the finite cells read around each displayed cell.*
3. *U is the local update route, recording the stated local transition from a neighbourhood window to the next cell-state row.*
4. *G is the global-step ledger, listing the finite sequence of substrate steps admitted by the carrier.*
5. *H records componentwise* hsame *transports for the cell-state, neighbourhood, local-update, global-ledger, continuation, provenance, and local naming rows.*
6. *C records displayed* Cont *routes through the cell-state row, neighbourhood row, local update route, global-step ledger, and local NameCert row.*
7. *P is the* Pkg *provenance over* $\mathsf{CellularSubstrate}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, the cellular-carrier vision, and the sibling cellular NameCert chapters.*

8. *L is the local* $\mathsf{NameCert}_{\mathsf{CellularSubstrate}^{\uparrow}}$ *row for carrier admission, classifier accountability, stability, exactness, ledger replay, and non-escape.*

The local classifier compares accepted carriers only by these displayed rows. It has no coordinate for host cellular automaton equality, an infinite grid, a hidden scheduler, a detached global evaluator, or an unbounded update oracle.

Lean4 ✓ `BEDC.Derived.CellularSubstrateUp.CellularSubstrateTasteGate single carrier alignment`

Theorem 942.2 (Cellular substrate NameCert obligations)**.** *For the carrier of Definition 942.1, the local* $\mathsf{NameCert}_{\mathsf{CellularSubstrate}^{\uparrow}}$ *surface consists exactly of five obligation rows:*

1. *carrier exposure for $Q = (S, N, U, G, H, C, P, L)$;*
2. *classifier accountability for reads that compare cell-state rows, neighbourhood windows, and local update routes only through S, N, U;*
3. *stability under the componentwise* hsame *transports displayed in H;*
4. *exactness of local update and global-step replay through U, G, C;*
5. *ledger and provenance closure through G, P, L, with no export of hidden host equality, infinite-grid reasoning, scheduler state, or unbounded update oracle.*

Every accepted $\mathsf{CellularSubstrate}^{\uparrow}$ *consumer must pass through these five rows before citing a cellular carrier read.*

Proof. Carrier exposure is projection from Definition 942.1. The tuple displays the cell-state row, neighbourhood window, local update route, global-step ledger, transports, continuations, provenance, and local naming row as its only coordinates.

Classifier accountability is local to S, N, U. A cell-state comparison or update read is accepted only when the read names the displayed neighbourhood window and the displayed local transition route.

Stability is supplied by H, while exactness is supplied by U, G, C. The transport row compares only the visible coordinates, and the continuation row replays only the finite local update route and finite global-step ledger.

Finally P and L package the same finite route as the public naming surface. Since the carrier lacks coordinates for host equality, an infinite grid, a hidden scheduler, and an unbounded update oracle, the five obligation rows exhaust the NameCert surface. □

Theorem 942.3 (Cellular substrate local-update non-escape)**.** *Every accepted local-update read exported by a* $\mathsf{CellularSubstrate}^{\uparrow}$ *carrier factors through the finite route*

$$S \longmapsto N \longmapsto U \longmapsto G \longmapsto H \longmapsto C \longmapsto P \longmapsto L.$$

In particular, an accepted packet exposes no host cellular automaton equality, infinite grid, hidden scheduler, or unbounded update oracle.

Proof. Start with an accepted local-update read. By Definition 942.1, the only available rows are S, N, U, G, H, C, P, L.

Apply Definition 942.2. The read must use the displayed neighbourhood window, the displayed local update route, and the finite global-step ledger before it can be named by the local $\mathsf{NameCert}_{\mathsf{CellularSubstrate}^{\uparrow}}$ row.

The route has no coordinate for host cellular automaton equality, infinite grid data, hidden scheduler state, or an unbounded update oracle. Thus every accepted read remains a finite cellular-substrate carrier read. □

Theorem 942.4 (Cellular substrate window exposure obligation)**.** *Every accepted* $\mathsf{CellularSubstrate}^{\uparrow}$ *carrier exposes the neighbourhood-window row* N *before any accepted local update route* U *can be replayed. Equivalently, a local-update read of*

$$Q = (S, N, U, G, H, C, P, L)$$

must pass through the displayed BHist *window row, the local* hsame *transport row, the displayed* Cont *route, the* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{CellularSubstrate}^{\uparrow}}$ *row before it cites* U*.*

Proof. Project the carrier of Definition 942.1. The tuple displays N as a separate neighbourhood-window row and U as the local update route, so the update route has no independent host-side source.

Apply Definition 942.2. Its carrier-exposure and classifier-accountability rows require accepted reads to name the displayed neighbourhood window before they name the displayed transition route.

Finally use Definition 942.3. The only replay route is the finite path through S, N, U, G, H, C, P, L, hence a local update cannot bypass N or acquire an infinite-grid, scheduler, or host evaluator coordinate. □

Theorem 942.5 (Cellular substrate classifier stability obligation)**.** *Componentwise* hsame *transport in the row* H *preserves the* $\mathsf{CellularSubstrate}^{\uparrow}$ *classifier on the cell-state row* S*, neighbourhood-window row* N*, local update route* U*, global-step ledger* G*, continuation row* C*, provenance row* P*, and local* $\mathsf{NameCert}_{\mathsf{CellularSubstrate}^{\uparrow}}$ *row* L*. No transported read can replace these rows by host cellular automaton equality, an infinite grid, a hidden scheduler, or an unbounded update oracle.*

Proof. Project $Q = (S, N, U, G, H, C, P, L)$ through Definition 942.1. The transport coordinate H is declared componentwise for exactly the displayed cell-state, neighbourhood, update, ledger, continuation, provenance, and naming rows.

Use Definition 942.2. Its stability row is local to those same displayed coordinates and therefore transports the classifier without creating another equality surface.

The non-escape theorem Definition 942.3 rules out every hidden host evaluator, infinite grid, scheduler, and unbounded update oracle after transport. Thus classifier stability remains a $\mathsf{BHist}/\mathsf{hsame}/\mathsf{Cont}/\mathsf{Pkg}/\mathsf{NameCert}$ statement about the packet rows. □

Theorem 942.6 (Cellular substrate ledger replay obligation)**.** *Audit-route replay through the global-step ledger* G*, continuation row* C*, provenance row* P*, and local naming row* L *exhausts all accepted* $\mathsf{CellularSubstrate}^{\uparrow}$ *reads. The replay exports only the finite cellular-substrate packet and never exports a hidden host evaluator, infinite grid, scheduler, or unbounded update oracle.*

Proof. Start with an accepted cellular-substrate read and project the carrier by Definition 942.1. The only ledgered route available after the local update row is G, C, P, L.

Apply Definition 942.2. Its exactness and ledger-provenance rows state that accepted reads replay the finite global-step ledger through the displayed continuation and package rows before entering the local NameCert row.

Now cite Definition 942.3. Since the complete route already factors through S, N, U, G, H, C, P, L, the audit replay has no coordinate from which to export a hidden evaluator, infinite grid, scheduler, or unbounded oracle. □

Theorem 942.7 (Cellular substrate local-rule factorization)**.** *Every accepted* $\mathsf{CellularSubstrate}^{\uparrow}$ *local-update read of a carrier*

$$Q = (S, N, U, G, H, C, P, L)$$

factors through the sibling CellularLocalUpdateRule$^{\uparrow}$ *surface: the displayed neighbourhood window* N*, the selected local rule row* U*, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* NameCert *row. The read cannot be reconstructed from the global-step ledger alone, a hidden scheduler, an infinite grid, or a host evaluator.*

Proof. Project the carrier through Definition 942.1. The only local-update source available to the packet is the displayed pair of the neighbourhood-window row N and the local update route U, together with the visible transport, continuation, package, and naming rows.

Apply the window exposure theorem Definition 942.4 and the ledger replay theorem Definition 942.6. The first forces the local-update read to see N before U, and the second confines any later replay to G, C, P, L rather than to an external evaluator.

Now compare the exposed rows with the sibling packet of chapter 984. Its obligation theorem Definition 984.2 identifies the local-rule consumer surface as a finite neighbourhood window, selected local rule row, componentwise hsame, displayed Cont, Pkg, and local NameCert route.

Thus the CellularSubstrate$^{\uparrow}$ local-update row is consumed through that sibling surface. Since the carrier has no coordinate for a hidden scheduler, infinite grid, host evaluator, or ledger-only rule source, no accepted read factors by any other route. □

The Lean file `Derived/CellularSubstrateUp/TasteGate.lean` includes `Nontrivial CellularSubstrateUp` and `FieldFaithful CellularSubstrateUp` instances for the displayed carrier.

Closure status for NameCert$_{\text{CellularSubstrate}^{\uparrow}}$ **.**

Constructive story: A CellularSubstrate$^{\uparrow}$ packet is generated from a finite cell-state row, a neighbourhood-window row, a local update route, a global-step ledger, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{CellularSubstrate}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 942.1, Definition 942.2, Definition 942.3, Definition 942.4, Definition 942.5, Definition 942.6, and Definition 942.7 bind the carrier, NameCert obligations, local-update non-escape, window exposure, classifier stability, ledger replay, and local-rule factorization rows.

Formal verification: FormalStatus(NameCert$_{\text{CellularSubstrate}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.CellularSubstrateUp.CellularSubstrateTasteGate\_single\_carrier\_alignment`
Lean4 ✓ `BEDC.Derived.CellularSubstrateUp.taste gate`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close bridge checking, universality, hidden host evaluator correctness, quotient stream equality, internal induction, infinite-grid completeness, scheduler correctness, or unbounded update evaluation for CellularSubstrate$^{\uparrow}$.

Upgrade path: No further paper-side closure grade remains; bridgeChecked is verification-axis work.

Chapter 943

A Concrete Naming Certificate for $\mathsf{CellularCarrierEncoding}^{\uparrow}$

The $\mathsf{CellularCarrierEncoding}^{\uparrow}$ packet realizes the cellular-carrier alternative of chapter 9391 as a finite NameCert surface. It sits beside the cellular-rule certificate of chapter 934 and the closed Rule 110 trust substrate of chapter 937: those siblings certify cellular dynamics and trust-path replay, while this carrier certifies the encoding bridge from a BHist value to a displayed cell row.

Falsifiable prediction: A packet that omits the cell-row embedding coordinate cannot satisfy the CellularCarrierEncodingUp non-escape theorem.

Independence witness: Nearest siblings: cellularautomaton, cellulartrustsubstrate, groundcompilereventflowaudit, twin-substrate-audit. The carrier is not bijective to any sibling because it includes both BHist-to-bit encoding and cellular row embedding obligations, while the siblings expose only substrate dynamics, trust, audit flow, or two-substrate alignment rows.

Definition 943.1 (Cellular carrier encoding carrier)**.** *A* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (B, T, R, S, H, C, P, N)$$

with the following displayed rows:

1. *B is the source* BHist *row whose constructor trace is being encoded.*
2. *T is the* toBits *and readback row, recording the finite binary word obtained from B and the inverse read that reconstructs the same* BHist *constructor trace.*
3. *R is the cell-row embedding coordinate, naming the finite width, default fill, start coordinate, and row slice that contains the word from T.*
4. *S is the cellular substrate witness row, citing the local cellular rule, admissible initial row, and finite observation window through which the embedded row is read.*
5. *H records componentwise* hsame *transports for B, T, R, S, P, N.*
6. *C records displayed* Cont *routes through the source* BHist *row, the bit encoding, the cell-row embedding, the substrate witness, the provenance row, and the local certificate.*
7. *P is the* Pkg *provenance over* $\mathsf{CellularCarrierEncoding}^{\uparrow}$, BHist, $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{CellularTrustSubstrate}^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert *rows.*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{CellularCarrierEncoding}^{\uparrow}}$ *row.*

The classifier compares carriers only by the displayed source BHist *row, bit encoding and readback row, embedding coordinate, substrate witness, transports, continuation routes, package provenance, and local naming row. It has no coordinate for a host byte string, an unstated row offset, an unbounded cellular orbit, a detached substrate evaluator, or a quotient of encodings.*

Lean4 ✓ `BEDC.Derived.CellularCarrierEncodingUp.CellularCarrierEncodingTasteGate single carrier alignment`

Theorem 943.2 (CellularCarrierEncoding NameCert obligations)**.** *For the carrier of Definition 943.1, the local* $\mathsf{NameCert}_{\mathsf{CellularCarrierEncoding}^{\uparrow}}$ *surface consists exactly of carrier exposure for* $E = (B, T, R, S, H, C, P, N)$*, source accountability through* B*, bit encoding and readback exactness through* T*, cell-row embedding accountability through* R*, cellular substrate witnessing through* S*, componentwise stability through* H*, displayed route replay through* C*, package provenance through* P*, and local naming through* N*. No consumer can read a BHist-to-cell-row carrier equivalence, a cellular substrate row, or a finite encoding bridge as* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *evidence without passing through these rows.*

Proof. Carrier exposure is projection from Definition 943.1. The packet displays the source BHist row, the bit encoding and readback row, the cell-row embedding coordinate, the substrate witness, transports, continuation routes, provenance, and local naming row as its only coordinates.

Source accountability and bit-readback exactness are read from B and T. The row T is tied to the constructor trace of B, so a consumer cannot replace the displayed source by a host byte string or a different binary word after the packet is accepted.

Embedding accountability and substrate witnessing are read from R and S. The embedding coordinate states where the finite word is placed in the cell row, and the substrate witness states which local cellular surface reads that row.

The remaining rows close the NameCert surface. The H, C, P, N rows transport, replay, record, and name exactly the displayed packet. Since the carrier lacks coordinates for unstated row offsets, unbounded orbits, detached evaluators, and quotient encodings, the listed rows exhaust the public obligation surface. □

Theorem 943.3 (Cell-row embedding non-escape)**.** *Every accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *read factors through the displayed cell-row embedding coordinate* R*. In particular, a packet may certify the finite route*

$$B \longmapsto T \longmapsto R \longmapsto S \longmapsto H, C, P, N,$$

but it cannot identify two encodings that differ only by an omitted row coordinate, hidden default fill, host-side byte layout, detached cellular evaluator, or unbounded orbit read.

Proof. Start with an accepted encoding read. By Definition 943.2, the read reaches the local NameCert row only through B, T, R, S, H, C, P, N.

The row T supplies the finite bit word and readback to B, but it does not by itself place the word inside the cellular substrate. The coordinate R supplies that placement by naming the finite width, default fill, start coordinate, and row slice.

The substrate witness S then reads only the row supplied by R. Since the carrier has no hidden coordinate for another offset, byte layout, evaluator, or infinite orbit, omitting R removes the route by which the cellular read can be tied back to the source BHist packet. □

Theorem 943.4 (CellularCarrierEncoding readback exactness)**.** *For every accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *carrier* $E = (B, T, R, S, H, C, P, N)$*, the row* T *binds the source* BHist *row* B *to both the finite binary word and the reconstruction row before the embedding coordinate* R *is read. Hence a consumer*

cannot read R as evidence for a cellular carrier unless the displayed word in T is already tied to the same constructor trace of B.

Proof. Project the carrier of Definition 943.1. The row B is the source BHist trace, and T records the finite binary word together with the inverse readback of that same trace.

Apply the NameCert obligations of Definition 943.2. They make bit encoding and readback exactness through T a local certificate duty before cell-row embedding accountability through R can be consumed.

Finally use cell-row embedding non-escape, Definition 943.3. Since every accepted cellular read factors through R only after the route $B \longmapsto T \longmapsto R$ is displayed, R cannot be used as a detached cell-row witness for a different host word or source trace. □

Theorem 943.5 (CellularCarrierEncoding route stability)**.** *For every accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *carrier $E = (B, T, R, S, H, C, P, N)$, the rows H and C transport and replay the displayed route*

$$B \longmapsto T \longmapsto R \longmapsto S$$

without adding a hidden row offset, host byte layout, detached substrate evaluator, or unbounded cellular orbit. The stable route is exactly the source row, bit-readback row, embedding coordinate, and substrate witness row named by the carrier.

Proof. Read the structural rows in Definition 943.1. The row H gives componentwise hsame transports for the displayed packet, and C gives displayed Cont routes through the source, bit encoding, embedding, substrate, provenance, and naming rows.

Use Definition 943.2 to identify these rows as the componentwise stability and route-replay duties of the local certificate. They preserve the route already displayed by B, T, R, S rather than adding an independent route.

The non-escape theorem then removes the unavailable coordinates. Since hidden offsets, host byte layout, detached evaluators, and unbounded orbit reads are not rows of E, transport by H and replay by C cannot introduce them. □

Theorem 943.6 (CellularCarrierEncoding provenance exhaustion)**.** *For every accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *carrier $E = (B, T, R, S, H, C, P, N)$, the rows P and N exhaust the public provenance and local naming surface over* BHist*,* $\mathsf{CellularAutomaton}^{\uparrow}$*,* $\mathsf{CellularTrustSubstrate}^{\uparrow}$*,* hsame*,* Cont*,* Pkg*, and* NameCert*. No additional provenance row is available for a host byte encoding, hidden cellular evaluator, quotient of encodings, or unbounded substrate read.*

Proof. Project the provenance and naming rows from Definition 943.1. The row P records the listed BEDC packets and kernel relations, while N is the local $\mathsf{NameCert}_{\mathsf{CellularCarrierEncoding}^{\uparrow}}$ row.

Apply the local obligation theorem. It says that package provenance through P and local naming through N are part of the exact NameCert surface for the same packet $E = (B, T, R, S, H, C, P, N)$.

Finally combine readback exactness with route stability. The public route already ties B to T, R, and S through H and C, so P, N can only certify that displayed route and cannot supply an extra provenance channel for any excluded host-side or unbounded cellular object. □

Theorem 943.7 (CellularCarrierEncoding obligation closure)**.** *For every accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *carrier $E = (B, T, R, S, H, C, P, N)$, the carrier exposure of Definition 943.1, the* NameCert *obligation surface of Definition 943.2, cell-row embedding non-escape, readback exactness, route stability, and provenance exhaustion supply the complete paper obligation surface for the finite BHist-to-cell-row carrier. A consumer of the packet may use only the displayed* BHist *row,* hsame *transports,* Cont *routes,* Pkg *provenance, local* NameCert *row, and sibling cellular rows named by the carrier.*

Proof. Project the accepted carrier. Its visible data are exactly the rows B, T, R, S, H, C, P, N, so every public read begins from the same finite packet and no host-side coordinate is available at the carrier boundary.

Apply the local NameCert obligation theorem to expose the duties attached to those rows. The source row, readback row, embedding coordinate, substrate witness, transports, routes, provenance, and local naming row are all certificate duties of the same packet.

Use the four later row theorems to close the surface. Non-escape forces cellular reads through R, readback exactness ties T to B before R is consumed, route stability keeps the replay inside B, T, R, S, H, C, and provenance exhaustion keeps P, N from adding any extra channel.

Therefore the listed rows supply the whole paper obligation surface: carrier, NameCert, non-escape, readback, route, and provenance are consumed together, and the packet exposes no further primitive or evaluator. □

Theorem 943.8 (CellularCarrierEncoding primitive scope binding)**.** *The* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *paper surface binds only the primitives* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*,* $\mathsf{CellularAutomaton}^{\uparrow}$*, and* $\mathsf{CellularTrustSubstrate}^{\uparrow}$*. In particular, the obligation closure of Definition 943.7 does not quantify over a host byte carrier, a global cellular evaluator, an orbit quotient, an unstated row coordinate, or any primitive outside those displayed rows.*

Proof. Read the carrier definition. The source row is a BHist row; stability and replay are expressed by hsame and Cont; provenance and local naming are expressed by Pkg and $\mathsf{NameCert}$.

The only cellular dependencies named by the packet are the sibling $\mathsf{CellularAutomaton}^{\uparrow}$ and $\mathsf{CellularTrustSubstrate}^{\uparrow}$ rows recorded in the provenance and substrate witness. No separate carrier coordinate names a byte-level encoding, global evaluator, quotient, or hidden row coordinate.

Apply obligation closure. Since the closed paper surface is exhausted by the displayed rows and the listed row theorems, every primitive used by the chapter is one of the named BEDC objects, and no outside primitive is introduced by the closure claim. □

Theorem 943.9 (CellularCarrierEncoding sibling scope binding)**.** *The* $\mathsf{CellularAutomaton}^{\uparrow}$ *and* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *sibling rows in a* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *carrier are consumed as visible dependencies of the finite embedding and provenance route. They are not hidden cellular evaluators, and they do not supply an unbounded substrate read or a second route around the displayed* $B \longmapsto T \longmapsto R \longmapsto S$ *path.*

Proof. The sibling rows enter through S and P. The substrate witness S names the cellular surface used to read the embedded row, and P records the provenance of that use beside the local carrier, kernel relations, and naming row.

Route stability fixes how those rows are consumed. The displayed route reaches the sibling surface only after B is encoded as T and placed by R, and H, C transport and replay that route without adding another evaluator.

Provenance exhaustion and non-escape rule out the remaining alternatives. The sibling rows certify the visible finite dependency already present in the packet; they do not create a detached cellular computation, an unbounded orbit read, or a bypass around the carrier's displayed path. □

Theorem 943.10 (CellularCarrierEncoding cell-row accountability)**.** *Every accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *packet read of the bit encoding and readback row* T *exposes the cell-row embedding coordinate* R *before the carrier can be consumed as a cellular row. The route cannot bypass* R *through a hidden offset, host byte layout, unstated default fill, detached evaluator, or unrecorded row slice.*

Proof. Project the carrier of Definition 943.1. The bit encoding and readback data are stored in T, while the only row that places that word inside a cellular row is R.

Use readback exactness and non-escape, Definition 943.4 and Definition 943.3. They force the route from the source trace through T and then through the displayed embedding coordinate before any cellular carrier read is available.

The excluded alternatives are absent carrier coordinates. Since the packet stores no hidden offset, host byte layout, detached evaluator, unrecorded default fill, or second row slice, the accepted read exposes R as its only cell-row accountability witness. □

Theorem 943.11 (CellularCarrierEncoding substrate witness completeness)**.** *Every substrate-facing read of an accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *packet factors through the displayed* $\mathsf{CellularTrustSubstrate}^{\uparrow}$ *sibling row and the existing* $\mathsf{CellularAutomaton}^{\uparrow}$ *dependency named by S and P. No extra substrate carrier, global cellular evaluator, unbounded orbit, or detached trust path is available outside that displayed sibling route.*

Proof. Read the substrate coordinates from the carrier. The row S names the cellular substrate witness, and the provenance row P records the $\mathsf{CellularAutomaton}^{\uparrow}$ and $\mathsf{CellularTrustSubstrate}^{\uparrow}$ dependencies used by that witness.

Apply sibling scope binding. It states that the cellular siblings are consumed as visible dependencies of the finite embedding and provenance route, with no hidden evaluator or unbounded substrate read.

Finally combine route stability with provenance exhaustion. The hsame and Cont rows preserve the same B, T, R, S path, and P, N name only that path. Thus a substrate-facing consumer has no route to any extra substrate carrier beyond the displayed sibling rows. □

Theorem 943.12 (CellularCarrierEncoding TasteGate readiness surface)**.** *For every accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *packet $E = (B, T, R, S, H, C, P, N)$, the carrier definition, falsifiable prediction, independence witness, local* $\mathsf{NameCert}$ *obligations, non-escape theorem, readback exactness, route stability, provenance exhaustion, primitive scope binding, sibling scope binding, cell-row accountability, and substrate witness completeness are exactly the paper rows that a later Lean* $\mathsf{Nontrivial\ CellularCarrierEncodingUp}$ *and* $\mathsf{FieldFaithful\ CellularCarrierEncodingUp}$ *instance must consume. The readiness surface is only the displayed route through B, T, R, S, H, C, P, N and contains no host byte string, hidden row offset, detached evaluator, unbounded orbit, quotient encoding coordinate, or unrecorded substrate witness.*

Proof. Project the carrier of Definition 943.1. It displays the source BHist row, bit encoding and readback row, cell-row embedding coordinate, cellular substrate witness, transports, continuations, provenance, and local naming row.

Use the falsifiable prediction, independence witness, local $\mathsf{NameCert}$ obligations, and non-escape theorem. These identify the admissible consumer route and rule out carrier coordinates for host byte strings, hidden evaluator state, quotient encodings, and unrecorded substrate witnesses.

Readback exactness and route stability then bind the route $B \longmapsto T \longmapsto R \longmapsto S$. The encoding row T is read back from B, the embedding coordinate R is exposed before any cellular row is consumed, and H, C preserve the same displayed route.

Finally combine provenance exhaustion, primitive scope binding, sibling scope binding, cell-row accountability, and substrate witness completeness. They attach the route to the visible $\mathsf{CellularAutomaton}^{\uparrow}$ and $\mathsf{CellularTrustSubstrate}^{\uparrow}$ sibling rows through S and P, while excluding hidden row offsets, detached evaluators, unbounded orbits, quotient encoding coordinates, and

unrecorded substrate witnesses. This is precisely the paper-side surface that the Lean TasteGate instances must inhabit. □

Theorem 943.13 (CellularCarrierEncoding status obligation closure)**.** *For every accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *packet* $E = (B, T, R, S, H, C, P, N)$*, the carrier exposure, local* NameCert *obligations, non-escape boundary, readback exactness, route stability, provenance exhaustion, primitive scope binding, sibling scope binding, cell-row accountability, substrate witness completeness, and TasteGate readiness surface form the finite obligation surface for the AI-origin packet. Any later Lean TasteGate-facing consumer must use the same displayed rows*

$$B, T, R, S, H, C, P, N$$

rather than a host byte string, hidden row offset, detached cellular evaluator, unbounded orbit, quotient encoding coordinate, or unrecorded substrate witness.

Proof. Begin with the carrier and local naming surface. The carrier of Definition 943.1 exposes exactly B, T, R, S, H, C, P, N, while Definition 943.2 and Definition 943.3 bind the admitted rows and exclude host byte strings, detached evaluators, quotient encodings, and hidden substrate witnesses.

Next read the finite route. Readback exactness, route stability, provenance exhaustion, and primitive scope binding force the consumer path through B, then T, then R, with H, C, P, N preserving and naming that same path. The sibling scope binding, cell-row accountability, and substrate witness completeness theorems attach the route to the displayed $\mathsf{CellularAutomaton}^{\uparrow}$ and $\mathsf{CellularTrustSubstrate}^{\uparrow}$ rows without adding a second evaluator.

Finally use the TasteGate readiness surface. Definition 943.12 identifies exactly these rows as the paper surface for later Nontrivial and FieldFaithful instances, and the falsifiable prediction records the concrete row whose failure would invalidate the packet's consumer-facing status. Thus the obligation closure is the displayed finite surface, not any host representation outside it. □

Theorem 943.14 (CellularCarrierEncoding two-witness separation)**.** *Let* $E_0 = (B, T, R_0, S, H, C, P, N)$ *and* $E_1 = (B, T, R_1, S, H, C, P, N)$ *be two accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *packets whose displayed cell-row embedding coordinates* R_0 *and* R_1 *differ while the source, bit-readback, substrate, transport, continuation, provenance, and naming rows agree. Then* E_0 *and* E_1 *are the canonical witness pair for a later* Nontrivial $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *instance: the classifier distinguishes them by the* R *coordinate, and no host byte string, orbit quotient, or hidden substrate evaluator can identify them after acceptance.*

Proof. Project both accepted carriers by Definition 943.1. The two packets share B, T, S, H, C, P, N and differ only in the displayed embedding coordinate.

Use cell-row embedding non-escape and cell-row accountability, Definition 943.3 and Definition 943.10. They force every cellular read through the displayed R row before the packet can be consumed as a cellular carrier.

Readback exactness keeps T tied to the common source row B, while route stability keeps H and C from creating a second path around R. Thus the classifier's comparison of R_0 and R_1 is a comparison of carrier data, not a comparison of detached host bytes or orbit representatives.

Finally apply provenance exhaustion and substrate witness completeness. The shared P, N and S rows record only the displayed finite route, so they cannot collapse the two embedding coordinates by a hidden evaluator or unbounded orbit read. The pair E_0, E_1 is therefore the paper-side nontriviality witness. □

Theorem 943.15 (CellularCarrierEncoding field projection faithfulness)**.** *For accepted* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *packets* E *and* E'*, equality of the ordered field projection*

$$(B, T, R, S, H, C, P, N)$$

for E *and* E' *forces equality of the packets. Conversely, a mismatch in any one displayed field is visible to the classifier as a mismatch of the accepted carrier surface.*

Proof. Project the two accepted packets using the carrier definition. A $\mathsf{CellularCarrierEncoding}^{\uparrow}$ packet has no fields beyond the ordered rows B, T, R, S, H, C, P, N, so equality of the whole projection identifies every constructor row of the packet.

For visibility of mismatches, inspect the same projection one row at a time. A mismatch in B changes the source trace, a mismatch in T changes bit encoding or readback, a mismatch in R changes cell placement, and a mismatch in S changes the displayed substrate witness.

The structural fields are visible for the same reason. Route stability preserves the H, C rows as componentwise transport and replay data, while provenance exhaustion preserves P, N as the package and local naming rows of the same finite carrier.

Therefore the classifier cannot hide a field mismatch inside host bytes, quotient representatives, or detached cellular evaluation. Equality of the ordered projection is equality of accepted packets, and inequality in a displayed field remains classifier-visible. □

Theorem 943.16 (CellularCarrierEncoding formal target boundary)**.** *The paper surface of* $\mathsf{CellularCarrierEncoding}^{\uparrow}$ *exposes the exact obligations needed by later formal instances. The witness pair of Definition 943.14 supplies the displayed paper witnesses for a later*

$$\mathsf{Nontrivial\ CellularCarrierEncoding}^{\uparrow}$$

instance. The ordered projection of Definition 943.15 supplies the field-faithful projection consumed by a later

$$\mathsf{FieldFaithful\ CellularCarrierEncoding}^{\uparrow}$$

instance.

Both obligations are read through the existing checked TasteGate alignment surface and through the carrier rows B, T, R, S, H, C, P, N*. No host byte string, hidden row offset, detached cellular evaluator, orbit quotient, or unrecorded substrate witness is part of the target surface.*

Proof. Apply the checked TasteGate alignment surface named at the chapter opening. It fixes the single-carrier alignment for the displayed $\mathsf{CellularCarrierEncoding}^{\uparrow}$ packet and keeps the paper route on the carrier rows already named by the chapter.

For nontriviality, use Definition 943.14. Its two accepted packets agree on B, T, S, H, C, P, N and differ in the displayed R coordinate, so they give the paper witness pair required by the later $\mathsf{Nontrivial}$ instance.

For field faithfulness, use Definition 943.15. Equality of the ordered projection B, T, R, S, H, C, P, N is equality of accepted packets, and any mismatch in one displayed field remains classifier-visible. Thus the same projection is the ordered-field surface consumed by the later $\mathsf{FieldFaithful}$ instance. □

The Lean follow-up must provide `Nontrivial CellularCarrierEncodingUp` and `FieldFaithful CellularCarrierEncodingUp` instances in `lean4/BEDC/Derived/CellularCarrierEncodingUp/TasteGate.lean` with the canonical alignment surface expected at `BEDC.Derived.CellularCarrierEncodingUp.CellularCarrier`

Theorem 943.17 (CellularCarrierEncoding bridge-facing route)**.** *For every accepted* CellularCarrierEncoding$^{\uparrow}$ *packet, the public rows*

$$B, T, R, S, H, C, P, N$$

form the bridge-facing route from the source BHist *row to the displayed cellular automaton and cellular trust substrate surfaces. The route exposes bit encoding and readback, cell-row placement, substrate witness, componentwise transport, displayed continuation, package provenance, and local* NameCert *rows as one finite public certificate, and it exports no host byte string, hidden row offset, detached cellular evaluator, orbit quotient, or unrecorded substrate witness.*

Proof. Start with Definition 943.16. It fixes the paper surface on the carrier rows consumed by the checked TasteGate alignment.

Apply Definition 943.3 and Definition 943.4. The source trace, bit encoding, readback, and cell-row placement are visible only through B, T, R and cannot be replaced by host bytes or hidden offsets.

Next use Definition 943.5 and Definition 943.6. They keep the substrate surface, transport rows, continuation rows, package provenance, and local naming row on S, H, C, P, N.

Therefore the public packet already presents the bridge-facing route from BHist source rows to the cellular automaton and cellular trust substrate surfaces, while bridge checking itself remains outside this paper-axis claim. □

Closure status for NameCert$_{\text{CellularCarrierEncoding}^{\uparrow}}$.

Constructive story: A CellularCarrierEncoding$^{\uparrow}$ packet is generated from a source BHist row, bit encoding and readback row, cell-row embedding coordinate, cellular substrate witness row, componentwise transports, displayed continuations, provenance, and local naming.

Theory closure: TheoryGate(NameCert$_{\text{CellularCarrierEncoding}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 943.1, Definition 943.2, Definition 943.3, Definition 943.4, Definition 943.5, Definition 943.6, Definition 943.8, Definition 943.9, Definition 943.7, Definition 943.16, Definition 943.17, and

Lean4 ✓ `BEDC.Derived.CellularCarrierEncodingUp.taste gate`

bind the scoped and bridge-facing B, T, R, S, H, C, P, N route over BHist, hsame, Cont, Pkg, NameCert, CellularAutomaton$^{\uparrow}$, and CellularTrustSubstrate$^{\uparrow}$ together with the checked TasteGate single-carrier alignment.

Formal verification: FormalStatus(NameCert$_{\text{CellularCarrierEncoding}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.CellularCarrierEncodingUp.CellularCarrierEncodingTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close bit-readback Lean verification, cell-row embedding uniqueness, substrate replay completeness, or hidden offset exclusion beyond the displayed packet.

Upgrade path: No further paper-theory upgrade remains; bridge checking remains on the verification axis.

Chapter 944

A Concrete Naming Certificate for $\mathsf{BoundedUniversalTrace}^{\uparrow}$

The $\mathsf{BoundedUniversalTrace}^{\uparrow}$ packet is the finite host-side trace surface for the strong-normalisation boundary of chapter 9370. It combines the bounded machine substrate of chapter 280, the cellular substrate row of chapter 934, and the finite continuation ledger of chapter 469. The object does not assert that an unbounded computation halts; it exposes exactly the fuel-indexed rows from which a total host may read a terminal row.

Falsifiable prediction: Removing the fuel row permits a consumer to read terminal output without a displayed finite trace ledger, which the local classifier rejects.

Independence witness: turingmachine, continuationtrace, cellularautomaton, continuationbigstep, haltingdistinctiontrace: none is bijective because $\mathsf{BoundedUniversalTrace}^{\uparrow}$ carries the fuel-bound, substrate row, and trace ledger in one packet, while each sibling lacks at least one of those coordinates or replaces the bounded packet by a different semantic surface.

Definition 944.1 (BoundedUniversalTrace carrier)**.** *A* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (F, M, S, T, R, H, C, P, N)$$

with the following displayed rows:

1. *F is the fuel row, naming the finite step bound used by the total host read;*
2. *M is a substrate row drawn from the displayed* $\mathsf{TuringMachine}^{\uparrow}$ *or* $\mathsf{CellularAutomaton}^{\uparrow}$ *interface;*
3. *S is the finite source row containing the initial configuration, initial cellular window, or encoded substrate input;*
4. *T is the finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger listing the step rows admitted below the bound F;*
5. *R is the terminal or readback row selected from the displayed ledger T;*
6. *H records componentwise* hsame *transports for F, M, S, T, R, P, N;*
7. *C records the* Cont *routes that replay the bounded step ledger and the terminal readback;*
8. *P is the* Pkg *provenance over* $\mathsf{BoundedUniversalTrace}^{\uparrow}$, $\mathsf{TuringMachine}^{\uparrow}$, $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{ContinuationTrace}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{BoundedUniversalTrace}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only by the displayed fuel, substrate, source, trace, readback, transport, route, provenance, and naming rows. It has no coordinate for an unbounded halting predicate, host evaluator equality, quotient behaviour, selected nontermination evidence, or universal-machine semantic completion.

Theorem 944.2 (BoundedUniversalTrace NameCert obligations)**.** *For the carrier of Definition 944.1, the local* $\mathsf{NameCert}_{\mathsf{BoundedUniversalTrace}^{\uparrow}}$ *surface consists exactly of five finite rows:*

1. *carrier exposure for* $U = (F, M, S, T, R, H, C, P, N)$*;*
2. *classifier transport by componentwise* hsame *over the displayed fuel, substrate, source, trace, readback, package, and naming rows;*
3. *step-indexed readback through* F*,* T*, and* R*;*
4. *non-escape excluding unbounded halting, host evaluator equality, quotient behaviour, selected nontermination evidence, and universal-machine semantic completion;*
5. *public export of the same finite packet for Lean formalization under* BEDC.Derived.BoundedUniversalTraceUp.

No consumer can cite a total-host read of a universal substrate computation unless the read passes through these five rows.

Lean4 ✓ `BEDC.Derived.BoundedUniversalTraceUp.BoundedUniversalTraceCarrier namecert obligations`

Proof. Carrier exposure is projection from Definition 944.1. The accepted packet displays exactly the fuel, substrate, source, finite continuation ledger, readback, transport, route, provenance, and naming rows.

Classifier transport is componentwise. A comparison between accepted packets may transport rows through H and replay routes through C, but it cannot compare hidden host evaluators, unbounded runs, quotient behaviours, or semantic completions because no such coordinate is carried.

The remaining rows are the bounded readback, non-escape, and public-export statements proved below. Together they exhaust the NameCert surface because every consumer-facing read is either a projection from the packet, a displayed route through the finite ledger, or a refusal caused by an absent coordinate. □

Theorem 944.3 (BoundedUniversalTrace step-indexed readback)**.** *Every public read of the terminal row* R *in an accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier factors through the fuel row* F *and the finite trace ledger* T*. The read is admitted only when* T *displays a bounded route from the source row* S *over the substrate row* M *and* R *is the terminal or readback row selected by that same finite ledger.*

Proof. Project the accepted packet through Definition 944.1. The only computation-facing coordinates are the substrate row M, source row S, fuel row F, trace ledger T, readback row R, and route row C.

Apply the continuation-trace reading of chapter 469. A step read is public only as a finite ledger row, so selecting R requires the displayed ledger entry in T and the replay route in C.

The fuel row F bounds the ledger inspected by the host. Since there is no coordinate for an unbounded trace, a consumer cannot read R by bypassing F or by replacing T with a host-level run. □

Theorem 944.4 (BoundedUniversalTrace non-escape)**.** *An accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *packet exports no unbounded halting predicate, no equality between host evaluators, no quotient behaviour, no selected nontermination witness, and no universal-machine semantic completion. Its visible computational content is exactly the finite packet* $F, M, S, T, R, H, C, P, N$ *of Definition 944.1.*

Proof. Inspect the carrier coordinates. The substrate row M may name a $\mathsf{TuringMachine}^{\uparrow}$ or $\mathsf{CellularAutomaton}^{\uparrow}$ surface, but the packet stores only the bounded substrate row selected for this trace.

The trace row T is finite and is read through the continuation surface of chapter 469. The readback theorem above forces the terminal row through F and T, so it supplies a step-indexed host read rather than an unbounded semantic claim.

The excluded objects require coordinates not present in the packet. Unbounded halting needs a global run predicate, host evaluator equality needs a host semantic equality row, quotient behaviour needs a quotient classifier, selected nontermination needs an infinite negative witness, and universal-machine semantic completion needs an all-input semantic surface. None is among $F, M, S, T, R, H, C, P, N$. □

Theorem 944.5 (BoundedUniversalTrace public export)**.** *The public* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *export is the finite carrier of Definition 944.1 together with the NameCert obligations of Definition 944.2, the step-indexed readback of Definition 944.3, and the non-escape boundary of Definition 944.4. This export is the finite bridge surface by which the total host of chapter 9370 may inspect universal-substrate traces without importing halting, partiality, host evaluator equality, quotient behaviour, or semantic completion.*

Proof. The carrier supplies the displayed packet $F, M, S, T, R, H, C, P, N$. The NameCert theorem binds carrier exposure, classifier transport, readback, non-escape, and public export to those rows.

The readback theorem accounts for the only public terminal read. It must pass through the fuel row and finite trace ledger, so the host-facing surface remains step-indexed.

The non-escape theorem records what the packet cannot export. Repacking the carrier, readback, and refusal clauses gives a public certificate surface over BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$, with the substrate-side anchors supplied by $\mathsf{TuringMachine}^{\uparrow}$, $\mathsf{CellularAutomaton}^{\uparrow}$, and $\mathsf{ContinuationTrace}^{\uparrow}$. □

Theorem 944.6 (BoundedUniversalTrace fuel determinacy)**.** *For every accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier* $U = (F, M, S, T, R, H, C, P, N)$*, the terminal readback row* R *is determined by the displayed fuel row* F *together with the finite trace ledger* T*. Two accepted reads with the same* F*, the same substrate and source rows* M, S*, and the same ledger* T *have the same public terminal row after the componentwise transports and routes* H, C, P, N *are applied; no unbounded halting predicate or host evaluator equality contributes to the determination.*

Proof. Project the carrier through Definition 944.1. The only computation-facing coordinates are $F, M, S, T, R, H, C, P, N$.

Use the public export of Definition 944.5. It exposes terminal readback through the same finite packet, so a read of R must pass through the fuel row F and the finite trace ledger T.

If two reads share F, M, S, T, the remaining comparison is componentwise transport and replay through H, C, P, N. Since the carrier includes no unbounded run row and no host evaluator equality row, those absent objects cannot distinguish the terminal readback. □

Theorem 944.7 (BoundedUniversalTrace substrate readback)**.** *For every accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier* $U = (F, M, S, T, R, H, C, P, N)$*, every substrate read factors through the displayed* $\mathsf{TuringMachine}^{\uparrow}$

or $\mathsf{CellularAutomaton}^{\uparrow}$ *row* M *and the finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger* T *before reaching the terminal row* R*. The packet exports a bounded substrate read, not a host evaluator for the unbounded substrate.*

Proof. Inspect the substrate coordinate in Definition 944.1. The row M is explicitly drawn from the $\mathsf{TuringMachine}^{\uparrow}$ or $\mathsf{CellularAutomaton}^{\uparrow}$ interface, while T is the finite continuation ledger below the fuel bound.

Apply Definition 944.3 and Definition 944.5. The terminal row is public only when the displayed continuation ledger routes the source row S over the substrate row M within the fuel row F.

Thus substrate information reaches consumers through M, T, R, H, C, P, N. No consumer receives an evaluator equality, an unbounded transition closure, or a semantic completion of the substrate. □

Theorem 944.8 (BoundedUniversalTrace ledger exhaustion)**.** *For every accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier* $U = (F, M, S, T, R, H, C, P, N)$*, the finite trace ledger* T *exhausts every step row visible below the fuel bound* F*. A public consumer can inspect only the source row* S*, substrate row* M*, ledger rows in* T*, terminal readback* R*, and the displayed transport, route, provenance, and naming rows* H, C, P, N*; it cannot add hidden steps, appeal to unbounded halting, or identify traces by host evaluator equality.*

Proof. Read the accepted packet as the finite carrier $U = (F, M, S, T, R, H, C, P, N)$. The trace rows available below the bound are exactly the entries displayed in T.

Use Definition 944.3. Any terminal read must route through the same ledger T and the same fuel row F, so every visible step used by the read is already part of the displayed finite trace.

Finally apply the non-escape boundary of Definition 944.4. Hidden steps, unbounded halting, quotient behaviour, and host evaluator equality require coordinates absent from the carrier, so the ledger T exhausts the accepted bounded trace surface. □

Theorem 944.9 (BoundedUniversalTrace root fuel schedule)**.** *For every accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier* $U = (F, M, S, T, R, H, C, P, N)$*, the root fuel row* F *is a unary* BHist *schedule consumed only by finite* Cont *replay through the trace ledger* T *and terminal readback row* R*. A public read below the bound must cite the same fuel row, the same ledger row, componentwise* hsame *transport,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{BoundedUniversalTrace}^{\uparrow}}$ *row.*

Proof. Project the accepted carrier through Definition 944.1. The fuel coordinate is the displayed row F, and the only replay data attached to it are the finite trace ledger T, the readback row R, and the route coordinate C.

Apply Definition 944.3 and Definition 944.6. They force every terminal read to pass through F and T, and they determine the readback row from the displayed bound, substrate, source, and ledger rows after the listed transports and routes are applied.

Finally use Definition 944.8. Since the ledger exhausts the steps visible below the bound, the root fuel row is not an implicit evaluator or host scheduler; it is exactly the unary BHist schedule consumed by finite Cont replay. □

Theorem 944.10 (BoundedUniversalTrace obligation surface lock)**.** *For every accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier* $U = (F, M, S, T, R, H, C, P, N)$*, a total-host read is available only after the packet exposes exactly the fuel, substrate, source, finite trace, readback, transport, route, provenance, and local naming rows* $F, M, S, T, R, H, C, P, N$*. No public read may replace this surface by an unbounded evaluator or by a partial host trace.*

Proof. Project the carrier of Definition 944.1. It displays exactly the nine rows $F, M, S, T, R, H, C, P, N$.

Use Definition 944.2. The local certificate admits carrier exposure, componentwise transport, bounded readback, non-escape, and public export only over those displayed rows.

Apply Definition 944.3 and Definition 944.4. They force the terminal row through F and T while refusing unbounded halting, host evaluator equality, quotient behaviour, selected nontermination evidence, and semantic completion. □

Theorem 944.11 (BoundedUniversalTrace fuel row public boundary)**.** *For every accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier* $U = (F, M, S, T, R, H, C, P, N)$*, the row* F *is the only public bound for trace replay. The packet projects no unbounded halting predicate, no all-fuel convergence claim, and no host evaluator that can substitute for the displayed fuel row.*

Proof. Begin with the root fuel schedule of Definition 944.9. It identifies F as the unary BHist schedule consumed by finite Cont replay through T and R.

Use Definition 944.3. A read of R is public only through the fuel row and finite trace ledger, so the bound cannot be replaced by a host run.

Finally apply Definition 944.4. Unbounded halting and host evaluator equality require coordinates absent from Definition 944.1, leaving F as the sole public trace bound. □

Theorem 944.12 (BoundedUniversalTrace substrate trace readback)**.** *For every accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier* $U = (F, M, S, T, R, H, C, P, N)$*, substrate reads must pass through the substrate row* M *and the finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *row* T *before the readback row* R *is readable. The read is a finite carrier projection through* H, C, P, N*, not a direct host evaluation of the substrate.*

Proof. Project M and T from Definition 944.1. The substrate row names the $\mathsf{TuringMachine}^{\uparrow}$ or $\mathsf{CellularAutomaton}^{\uparrow}$ surface, and the trace row records the finite continuation ledger below the fuel bound.

Apply Definition 944.3. The terminal row R is selected only when T displays the bounded route from S over M.

Use Definition 944.4. Since the carrier lacks a host evaluator and lacks an unbounded transition closure, substrate readback can only replay M and T through the displayed transport, route, provenance, and local naming rows. □

Theorem 944.13 (BoundedUniversalTrace cellular replay scope)**.** *When the substrate row* M *of an accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier names the* $\mathsf{CellularAutomaton}^{\uparrow}$ *dependency of chapter 934, every cellular read is made only through that sibling cellular replay surface, the finite ledger* T*, local* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{BoundedUniversalTrace}^{\uparrow}}$ *row. The packet does not expose an unbounded cellular orbit, host cellular evaluator, hidden update table, or global orbit classifier.*

Proof. Read the carrier row named by Definition 944.1. The substrate coordinate M may be drawn from the displayed $\mathsf{CellularAutomaton}^{\uparrow}$ interface, but the accepted packet stores only this local substrate row together with the finite source, ledger, readback, transport, route, provenance, and naming rows.

Use Definition 944.7. It requires every substrate read to pass through M and the finite $\mathsf{ContinuationTrace}^{\uparrow}$ ledger T before the terminal row R is reached. The sibling dependency named by the carrier supplies the cellular replay surface, while P records the local provenance of that use.

The non-escape boundary Definition 944.4 removes any larger cellular semantics. Since the carrier has no coordinate for an unbounded orbit, host cellular evaluator, hidden update table,

or global orbit classifier, the cellular dependency is read only through the displayed finite replay scope. □

Theorem 944.14 (BoundedUniversalTrace TuringMachine non-escape)**.** *When the substrate row M of an accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier names the* $\mathsf{TuringMachine}^{\uparrow}$ *dependency of chapter 280, that dependency supplies finite transition evidence only through M, S, T, R, H, C, P, and N. It supplies no unbounded evaluator, no divergence oracle, and no total halting classifier.*

Proof. Begin with the chapter carrier. In Definition 944.1, the Turing-machine dependency can occur only as the displayed substrate row M of the accepted finite packet $U = (F, M, S, T, R, H, C, P, N)$.

Apply Definition 944.7 and Definition 944.8. The terminal read uses the substrate row together with the finite continuation ledger T and the fuel row F, so every transition fact visible to the consumer is already listed in the bounded ledger and replayed by C.

Finally use Definition 944.4. An unbounded evaluator, divergence oracle, or total halting classifier would require a coordinate outside the displayed carrier. Since no such coordinate exists, the $\mathsf{TuringMachine}^{\uparrow}$ row contributes only finite transition evidence inside the local package. □

Theorem 944.15 (BoundedUniversalTrace fuel-substrate-ledger separation)**.** *For every accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier $U = (F, M, S, T, R, H, C, P, N)$, the fuel row F, substrate row M, and finite continuation ledger T are pairwise distinct public roles. A consumer may transport these roles componentwise through H, C, P, N, but may not collapse fuel into substrate, substrate into ledger, or ledger into the terminal readback row R.*

Proof. Project the carrier of Definition 944.1. The row F names the finite step bound, M names the displayed Turing-machine or cellular substrate, and T names the finite $\mathsf{ContinuationTrace}^{\uparrow}$ ledger. They are introduced as separate coordinates of the same packet.

Apply Definition 944.3. Terminal readback must pass through F and T, so the fuel row bounds the read and the ledger supplies the displayed steps rather than one row replacing the other.

Next use Definition 944.7. Substrate information is read through M before the ledger reaches R, which prevents the substrate role from being identified with either the fuel schedule or the ledger rows.

Finally apply Definition 944.8. The ledger T exhausts the visible step rows below F, while H, C, P, N only transport, replay, cite, and name the same finite packet. Hence componentwise transport preserves the three public roles without collapsing them into one another or into terminal readback. □

Theorem 944.16 (BoundedUniversalTrace TasteGate readiness package)**.** *For every accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier*

$$U = (F, M, S, T, R, H, C, P, N),$$

the rows $F, M, S, T, R, H, C, P, N$ form the exact TasteGate readiness package for a single future carrier. The Nontrivial *instance must distinguish at least two packets by one displayed row, the* FieldFaithful *instance must project all nine fields, and no proof may collapse fuel, substrate, ledger, or readback into a hidden host evaluator.*

Lean4 ✓ `BEDC.Derived.BoundedUniversalTraceUp.BoundedUniversalTraceTasteGate single carrier alignment`

Proof. Start with the carrier of Definition 944.1. It displays the fuel row F, substrate row M, finite source row S, continuation ledger T, terminal readback row R, transport row H, route row C, package row P, and local name row N as separate fields of one finite packet.

Apply Definition 944.2, Definition 944.3, and Definition 944.4. These rows bind admission, bounded readback, and the refusal of any unbounded evaluator, divergence oracle, or total halting classifier outside the displayed carrier.

Next use Definition 944.6, Definition 944.8, and Definition 944.15. They keep F, M, T, and R as distinct public roles while H, C, P, N only transport, replay, cite, and name the same finite surface.

Thus a future TasteGate carrier has one exact package to encode. Nontriviality can witness distinct packets by changing a displayed row, and field faithfulness must project each of the nine rows rather than replacing the finite trace by host evaluation. □

Theorem 944.17 (BoundedUniversalTrace carrier transport obligation)**.** *For every accepted* BoundedUniversalTrac *carrier $U = (F, M, S, T, R, H, C, P, N)$, componentwise* hsame *transport preserves the fuel row F, substrate row M, source row S, finite trace ledger T, terminal readback row R, route row C, provenance row P, and local* $\mathsf{NameCert}_{\mathsf{BoundedUniversalTrace}^{\uparrow}}$ *row N as separate public coordinates. The transport row H may identify corresponding coordinates of two accepted packets, but it cannot collapse fuel into substrate, substrate into ledger, ledger into readback, or any displayed row into a host evaluator.*

Proof. Project the accepted packet through Definition 944.1. The carrier lists $F, M, S, T, R, H, C, P, N$ as the complete finite row family.

Use the obligation surface of Definition 944.2. Its classifier transport clause is componentwise over the displayed fuel, substrate, source, trace, readback, package, and naming rows.

Apply the fuel-substrate-ledger separation of Definition 944.15. It prevents the transported rows from being collapsed into one another, while Definition 944.4 excludes host evaluator equality as a replacement coordinate. □

Theorem 944.18 (BoundedUniversalTrace terminal readback obligation)**.** *Every terminal readback from an accepted* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *carrier is public only through the displayed fuel row F and the finite continuation ledger T. The read may cite the substrate siblings* $\mathsf{TuringMachine}^{\uparrow}$ *and* $\mathsf{CellularAutomaton}^{\uparrow}$ *through chapter 280 and chapter 934, and it may cite the ledger sibling* $\mathsf{ContinuationTrace}^{\uparrow}$ *through chapter 469; it cannot bypass F and T by a host evaluator, unbounded halting predicate, or hidden continuation.*

Proof. Begin with the step-indexed readback theorem Definition 944.3. It makes R readable only after the fuel row and finite trace ledger have been displayed.

Use the substrate readback theorem Definition 944.7. It routes substrate information through the $\mathsf{TuringMachine}^{\uparrow}$ or $\mathsf{CellularAutomaton}^{\uparrow}$ row M and the finite $\mathsf{ContinuationTrace}^{\uparrow}$ ledger T before terminal readback.

Finally apply Definition 944.8 and Definition 944.4. The ledger exhausts visible steps below the bound, and the absent unbounded halting, host evaluator, and hidden continuation coordinates cannot substitute for F and T. □

Theorem 944.19 (BoundedUniversalTrace Nontrivial and FieldFaithful obligation)**.** *The paper-side obligation for the Lean* TasteGate *target over* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *is to provide explicit* Nontrivial *and* FieldFaithful *instances over the same nine displayed rows*

$$F, M, S, T, R, H, C, P, N.$$

Nontriviality must distinguish accepted packets by at least one displayed row, and field faithfulness must project fuel, substrate, source, trace ledger, readback, transport, route, provenance, and local naming without replacing any row by host evaluation or unbounded computation semantics.

Proof. Read the TasteGate readiness package of Definition 944.16. It already identifies the exact nine rows that a single carrier must encode.

Use the carrier transport obligation above to keep the nine coordinates separate under hsame transport. A FieldFaithful instance must therefore project each displayed coordinate rather than identifying roles by a host-side semantic equality.

Use the terminal readback obligation and the non-escape boundary of Definition 944.4. They force terminal computation through the finite fuel and ledger rows, so a Nontrivial witness must vary a displayed packet row and cannot appeal to unbounded computation or hidden evaluator behaviour. □

Closure status for $\mathsf{NameCert}_{\mathsf{BoundedUniversalTrace}^{\uparrow}}$.

Constructive story: A $\mathsf{BoundedUniversalTrace}^{\uparrow}$ packet is generated from a fuel row, a Turing-machine or cellular-automaton substrate row, a finite source row, a finite continuation-trace ledger, a terminal readback row, componentwise transports, displayed routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{BoundedUniversalTrace}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 944.5 exposes the finite fuel, substrate, source, trace, readback, transport, route, provenance, and naming rows as the public packet, while

Lean4 (definition) `BEDC.Derived.BoundedUniversalTraceUp.taste gate`

and the checked TasteGate readiness package in Definition 944.16 record the matching carrier alignment.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{BoundedUniversalTrace}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.BoundedUniversalTraceUp.BoundedUniversalTraceTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, unbounded halting, partial evaluator semantics, quotient behaviour, selected nontermination evidence, or universal-machine semantic completion.

Upgrade path: No paper theory-axis grade remains; bridge checking remains an independent formal-axis obligation for the same bounded trace surface.

Chapter 945

A Concrete Naming Certificate for $\mathsf{CellularSubstrateClassifier}^{\uparrow}$

The $\mathsf{CellularSubstrateClassifier}^{\uparrow}$ packet realizes the classifier-facing half of the carrier alternative of chapter 9391. It sits after the rule-table row of chapter 934, the trust-substrate audit row of chapter 937, the finite orbit-window row of chapter 938, and the BHist carrier packet of chapter 942. Its role is not to replace the BHist kernel; it certifies the finite comparison by which a BHist row, a bit-row encoding, and a cellular orbit window are read as the same accepted carrier observation.

Falsifiable prediction: Any accepted $\mathsf{CellularSubstrateClassifier}^{\uparrow}$ carrier comparison must expose the displayed BHist row, bit-row encoding, orbit-window row, classifier row, transport row, route row, provenance row, and local NameCert row. A packet omitting any one of these rows is not an accepted classifier comparison.

Independence witness: cellularautomaton, cellulartrustsubstrate, cellularorbitsubstrate, interhistlocalityledger, observerhistidentity: the classifier packet is not bijective to any listed sibling because it simultaneously stores the BHist source row, the bit-row encoding, the cellular orbit window, and the comparison classifier surface, while each sibling omits at least one of those rows.

Definition 945.1 (Cellular substrate classifier carrier)**.** *A* $\mathsf{CellularSubstrateClassifier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (B, E, O, F, H, C, P, N)$$

with the following displayed rows:

1. *B is the BHist source row, naming the finite BEDC carrier observation being compared.*
2. *E is the bit-row encoding of B, including the empty-row convention and the constructor-to-bit direction used by the comparison.*
3. *O is the finite cellular orbit-window row whose initial displayed cells read back the encoded bit row.*
4. *F is the classifier row that admits the comparison between B, E, and O.*
5. *H records componentwise* hsame *transport for the BHist source, bit-row encoding, orbit-window row, classifier row, provenance row, and local naming row.*
6. *C records the* Cont *route from the BHist row through bit-row encoding, orbit-window readback, and classifier admission.*

7. *P is the* Pkg *provenance over* $\mathsf{CellularSubstrateClassifier}^{\uparrow}$, $\mathsf{CellularSubstrate}^{\uparrow}$, $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{CellularTrustSubstrate}^{\uparrow}$, $\mathsf{CellularOrbitSubstrate}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and the originating carrier-alternative vision.*

8. *N is the local* $\mathsf{NameCert}_{\mathsf{CellularSubstrateClassifier}^{\uparrow}}$ *row for carrier admission, classifier accountability, BHist-orbit compatibility, exactness, provenance, and non-escape.*

The classifier compares accepted carrier observations only through these displayed rows. It has no coordinate for host equality between cellular histories, an infinite orbit, a hidden cellular evaluator, a detached bit-string quotient, or a carrier switch outside the finite NameCert packet.

Lean4 ✓ `BEDC.Derived.CellularSubstrateClassifierUp.TasteGate.CellularSubstrateClassifierTasteGate`
`single carrier alignment`

Definition 945.2 (Cellular substrate classifier obligation surface)**.** *The local obligation surface of* $\mathsf{CellularSubstrateClassifier}^{\uparrow}$ *consists of eight rows: carrier exposure for $K = (B, E, O, F, H, C, P, N)$, BHist source visibility, bit-row encoding visibility, orbit-window visibility, classifier accountability, componentwise transport through H, continuation replay through C, and public naming through P, N.*

An accepted consumer may cite the BHist-to-cellular carrier comparison only after these eight rows are present. The surface therefore binds the cellular carrier alternative to finite NameCert evidence rather than to a host-side assertion that the two carriers are interchangeable.

Theorem 945.3 (Cellular substrate classifier NameCert boundary)**.** *For the carrier of Definition 945.1, the local* $\mathsf{NameCert}_{\mathsf{CellularSubstrateClassifier}^{\uparrow}}$ *boundary is exactly the obligation surface of Definition 945.2. In particular, a public carrier-comparison read is accepted only when it displays the BHist row, bit-row encoding, orbit-window row, classifier row, transport row, route row, provenance row, and local naming row.*

Proof. Carrier exposure is projection from Definition 945.1. The tuple displays B, E, O, F, H, C, P, N as its only coordinates.

The source, encoding, orbit, and classifier obligations are the first four analytic rows of Definition 945.2. The transport and route obligations are supplied by H and C, and public naming is supplied by P, N.

No other coordinate is available to the packet. Thus the local NameCert boundary is exactly the displayed obligation surface, and every accepted public comparison read passes through those eight rows. □

Theorem 945.4 (Cellular substrate classifier BHist-orbit compatibility)**.** *If two accepted* $\mathsf{CellularSubstrateClassifier}^{\uparrow}$ *packets have* hsame *BHist source rows and* hsame *bit-row encodings, then their accepted orbit-window comparisons agree at every displayed classifier read. Equivalently, the classifier cannot expose two distinct cellular carrier reads for the same transported BHist source and bit-row encoding.*

Proof. Project both packets to their BHist source, bit-row encoding, orbit-window, and classifier rows. The hsame hypotheses identify the two source rows and the two bit-row rows componentwise.

Use the continuation route in each packet to replay the comparison from B through E into the displayed orbit window O. The classifier row F is permitted to read only those displayed source, encoding, and orbit-window coordinates.

A second accepted cellular carrier read for the same transported B and E would require either a different orbit-window coordinate or a hidden classifier coordinate. Neither belongs to the carrier

of Definition 945.1, so the displayed classifier read is compatible with the transported BHist source. □

Theorem 945.5 (Cellular substrate classifier non-escape)**.** *Every accepted* $\mathsf{CellularSubstrateClassifier}^{\uparrow}$ *carrier comparison factors through the finite route*

$$B \longmapsto E \longmapsto O \longmapsto F \longmapsto H \longmapsto C \longmapsto P \longmapsto N.$$

The route exports no infinite orbit, host cellular-history equality, hidden evaluator, detached bit-string quotient, or carrier replacement outside the local NameCert row.

Proof. Begin with an accepted carrier comparison. By Definition 945.3, the comparison must display the BHist source row, bit-row encoding, orbit-window row, classifier row, transport row, route row, provenance row, and local naming row.

The factorization route is exactly the order in which those rows are consumed. The BHist row is encoded as a bit row, the bit row is read through the finite orbit window, the classifier admits the comparison, and the transport, continuation, provenance, and local NameCert rows package the public read.

The carrier has no field for an infinite orbit, host cellular-history equality, hidden evaluator, detached quotient, or external carrier replacement. Therefore every accepted comparison remains inside the finite classifier packet. □

Theorem 945.6 (Cellular substrate classifier orbit-window exhaustion)**.** *Every accepted* $\mathsf{CellularSubstrateClassifier}^{\uparrow}$ *comparison consumes exactly the BHist source row, bit-row encoding row, orbit-window row, classifier row, transport row, route row, provenance row, and local NameCert row before any cellular carrier comparison is public. No accepted comparison may replace the orbit-window read with source-equivalence transport, host cellular-history equality, an infinite orbit, or a detached bit-string quotient.*

Proof. The NameCert boundary theorem Definition 945.3 identifies the public boundary with the eight displayed rows of Definition 945.2. Thus any accepted public comparison must expose B, E, O, F, H, C, P, N.

The BHist-orbit compatibility theorem Definition 945.4 binds the transported BHist source and bit-row encoding to the displayed orbit-window comparison. A second cellular carrier read for the same transported source would require an additional orbit or classifier coordinate, which the carrier does not contain.

Finally apply the non-escape theorem Definition 945.5. Its finite route is the same eight-row route, so coordinate exhaustion leaves no public comparison outside the BHist source row, bit-row encoding, orbit-window row, classifier row, transport row, route row, provenance row, and local NameCert row. □

Theorem 945.7 (Cellular substrate classifier obligation closure)**.** *The carrier of Definition 945.1, the obligation surface of Definition 945.2, the NameCert boundary, BHist-orbit compatibility, non-escape route, orbit-window exhaustion, falsifiable prediction, independence witness, and TasteGate commitments form the obligation-closure package for* $\mathsf{CellularSubstrateClassifier}^{\uparrow}$.

The package is exactly over the displayed rows B, E, O, F, H, C, P, N*. It refuses infinite orbit data, host cellular-history equality, a hidden evaluator, detached bit-string quotients, and replacement of the carrier outside the displayed packet.*

Proof. Begin with the displayed carrier $K = (B, E, O, F, H, C, P, N)$. The obligation surface records precisely the BHist source row B, bit-row encoding E, finite orbit-window row O, classifier row F, componentwise transport row H, continuation row C, package provenance P, and local NameCert row N.

Apply the NameCert boundary, BHist-orbit compatibility, non-escape, and orbit-window exhaustion theorems. These results identify the accepted public comparison with the same eight rows, force transported BHist and bit-row reads through the displayed orbit window, keep the route finite, and prevent any comparison from bypassing the orbit-window row.

The falsifiable prediction and independence witness test the same surface from the consumer side: omitting one displayed row breaks acceptance, and no listed sibling stores the full BHist, bit-row, orbit-window, classifier, transport, route, provenance, and local naming packet. The TasteGate commitments are therefore attached to the displayed carrier rather than to an external evaluator.

No remaining coordinate exists for an infinite orbit, host cellular-history equality, hidden evaluator, detached bit-string quotient, or carrier replacement. Thus the listed rows and witnesses assemble the obligation-closure package claimed here. □

The later Lean namespace `BEDC.Derived.CellularSubstrateClassifierUp.TasteGate` must provide `Nontrivial CellularSubstrateClassifierUp` and `FieldFaithful CellularSubstrate ClassifierUp` instances for the displayed classifier carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{CellularSubstrateClassifier}^{\uparrow}}$.

Constructive story: A $\mathsf{CellularSubstrateClassifier}^{\uparrow}$ packet is generated from a displayed BHist source row, bit-row encoding, finite orbit-window row, classifier row, componentwise transport row, continuation route row, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CellularSubstrateClassifier}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 945.1, Definition 945.2, Definition 945.3, Definition 945.4, Definition 945.5, Definition 945.6, Definition 945.7, and

Lean4 ✓ `BEDC.Derived.CellularSubstrateClassifierUp.taste gate`

specify the BHist source row, bit-row encoding, orbit-window row, classifier row, route row, TasteGate, Nontrivial, and FieldFaithful surface as a bridge-compatible finite classifier package.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CellularSubstrateClassifier}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.CellularSubstrateClassifierUp.TasteGate.CellularSubstrateClassifierTasteGate\_single\_c`

Bridge status: none

Origin: ai

Not claimed: This chapter does not replace the BHist kernel, add a cellular automaton substrate axiom, prove infinite orbit adequacy, supply host cellular-history equality, or close bridge checking.

Upgrade path: No further paper-axis grade remains for this classifier package; bridge checking stays on the independent verification axis.

Chapter 946

A Concrete Naming Certificate for $\mathsf{ClosureUniversalityQuadrant}^{\uparrow}$

The $\mathsf{ClosureUniversalityQuadrant}^{\uparrow}$ packet realizes the two-axis map of chapter 9388 as a finite NameCert object. It does not decide universality or closure for an arbitrary substrate. It records the displayed evidence by which a consumer reads a substrate as one named quadrant entry, using the cellular rule surface of chapter 934, the carrier surface of chapter 942, the finite obstruction boundary of chapter 490, and the bounded trace surface of chapter 944 as sibling anchors.

Falsifiable prediction: Any closed-quadrant consumer that reads a $\mathsf{ClosureUniversalityQuadrant}^{\uparrow}$ packet without the displayed closure-axis row is rejected by the local classifier.

Independence witness: cellularautomaton, cellularsubstrate, haltingobstruction, boundeduniversaltrace: no listed sibling is bijective to $\mathsf{ClosureUniversalityQuadrant}^{\uparrow}$ because the packet carries both axis-pair rows and the quadrant-tag row, while each sibling supplies only a rule, carrier, obstruction, or bounded-trace surface without the paired quadrant classifier.

Definition 946.1 (Closure-universality carrier)**.** *A* $\mathsf{ClosureUniversalityQuadrant}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (U, D, G, S, A, H, C, P, N)$$

with the following displayed rows:

1. *U is the universality-axis row, recording whether the accepted substrate read is universal, subuniversal, or refused for lack of displayed evidence.*
2. *D is the closure-axis row, recording whether the accepted observation channel is closed, open, or refused for lack of displayed evidence.*
3. *G is the quadrant-tag row determined by the displayed pair (U, D).*
4. *S is the substrate-witness row, naming the finite sibling surface from which the substrate read is consumed.*
5. *A is the sibling-anchor ledger, containing the relevant* $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{CellularSubstrate}^{\uparrow}$, $\mathsf{HaltingObstruction}^{\uparrow}$, *and* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *rows used by this packet.*
6. *H records componentwise* hsame *transports for U, D, G, S, A, P, N.*
7. *C records displayed* Cont *routes through the two axis rows, the quadrant tag, the substrate witness, and the sibling-anchor ledger.*

8. *P is the* Pkg *provenance over* $\mathsf{ClosureUniversalityQuadrant}^{\uparrow}$*, the quadrant vision, the sibling concrete chapters,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{ClosureUniversalityQuadrant}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only by these rows. It has no coordinate for a host proof of arbitrary universality, an ambient closure oracle, a hidden substrate evaluator, or a quadrant tag detached from the displayed axis pair.

Lean4 ✓ `BEDC.Derived.ClosureUniversalityQuadrantUp.ClosureUniversalityQuadrantTasteGate single carrier alignment`

Theorem 946.2 (Closure-universality quadrant NameCert obligations)**.** *For the carrier of Definition 946.1, the local* $\mathsf{NameCert}_{\mathsf{ClosureUniversalityQuadrant}^{\uparrow}}$ *surface consists exactly of carrier exposure for $Q = (U, D, G, S, A, H, C, P, N)$, universality-axis accountability through U, closure-axis accountability through D, quadrant-tag determinacy through G, substrate-witness exposure through S, sibling-anchor replay through A, componentwise stability through H, displayed route replay through C, package provenance through P, and local naming through N. A consumer cannot read a closed quadrant, an open quadrant, a universal quadrant, or a sub-universal quadrant unless the two axis rows and their determined tag are both present.*

Proof. Carrier exposure is projection from Definition 946.1. The accepted packet displays the two axis rows, quadrant tag, substrate witness, sibling-anchor ledger, transports, continuations, provenance, and local name as its only coordinates.

Axis accountability is componentwise. The universality read is taken from U, the closure read is taken from D, and the tag row G is admitted only as the finite classifier row for that displayed pair.

The sibling ledger A and substrate witness S connect the abstract quadrant entry to concrete surfaces already present in the dossier. The consumer may replay those anchors through C and transport them through H, but it cannot replace them with a hidden universality proof, closure oracle, or host substrate evaluator.

Finally P and N package the same finite route as the public naming surface. Since no detached quadrant tag or ambient axis oracle is carried, the listed rows exhaust the local NameCert obligations. □

Theorem 946.3 (Closure-universality axis independence boundary)**.** *An accepted* $\mathsf{ClosureUniversalityQuadrant}^{\uparrow}$ *packet exposes the universality-axis row U and the closure-axis row D as separate displayed coordinates, and the quadrant tag G is read only after both coordinates are present. Thus a consumer may transport or compare the two axes componentwise, but it may not infer either axis from the other, collapse the pair to a single sibling certificate, or replace the tag by a host-level substrate classification.*

Proof. Inspect the carrier of Definition 946.1. The universality row, closure row, and quadrant tag are distinct coordinates, so projection of one axis does not project the other.

The tag row G is a classifier read from the displayed pair (U, D). Therefore a tag comparison may use the componentwise transports in H and the route replay in C, but it must keep both axis rows visible.

The sibling rows in A witness non-bijection rather than collapse. $\mathsf{CellularAutomaton}^{\uparrow}$ supplies rule and orbit rows, $\mathsf{CellularSubstrate}^{\uparrow}$ supplies carrier rows, $\mathsf{HaltingObstruction}^{\uparrow}$ supplies finite obstruction rows, and $\mathsf{BoundedUniversalTrace}^{\uparrow}$ supplies bounded trace rows. None supplies both axis rows and the quadrant tag as one finite packet. □

The later Lean TasteGate namespace BEDC.Derived.ClosureUniversalityQuadrantUp will provide Nontrivial ClosureUniversalityQuadrant$^{\uparrow}$ and FieldFaithful ClosureUniversalityQuadrant$^{\uparrow}$ instances for the displayed carrier.

Closure status for NameCert$_{\text{ClosureUniversalityQuadrant}^{\uparrow}}$ ·

Constructive story: A ClosureUniversalityQuadrant$^{\uparrow}$ packet is generated from a universality-axis row, a closure-axis row, their quadrant tag, a substrate witness, sibling cellular anchors, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ClosureUniversalityQuadrant}^{\uparrow}}$, seed)

Scope closed: Definition 946.1, Definition 946.2, and Definition 946.3 specify the finite two-axis quadrant packet and its non-collapse boundary.

Formal verification: FormalStatus(NameCert$_{\text{ClosureUniversalityQuadrant}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, arbitrary universality, arbitrary closure, host substrate classification, or completeness of all possible quadrant inhabitants.

Upgrade path: Obligation closure requires checked carrier admission, axis-row accountability, quadrant-tag determinacy, sibling-anchor replay, nontriviality, and field faithfulness for the same packet.

Chapter 947

A Concrete Naming Certificate for $\mathsf{UniversalityClosureQuadrant}^{\uparrow}$

The $\mathsf{UniversalityClosureQuadrant}^{\uparrow}$ packet realizes the two-axis map of chapter 9388 as a finite $\mathsf{NameCert}$ carrier. It sits beside the Rule 110 substrate surface of chapter 934, the trust packet of chapter 937, and the orbit packet of chapter 938. Its distinguishing datum is not another cellular run; it is the displayed pair of axis certificates and the quadrant provenance row that records how a substrate is classified without identifying the axes.

Falsifiable prediction: Deleting either the universality row or the closure row collapses the quadrant classifier and prevents distinguishing Rule110-like closed-universal substrates from oracle-open substrates.

Independence witness: Nearest siblings: cellularautomaton, cellulartrustsubstrate, cellularorbitsubstrate, largemodelinscriptionpoint, and kernelobservationsieve; none is bijective because this carrier stores two independent axis certificates and quadrant provenance rather than a single substrate, orbit, inscription, or sieve row.

Definition 947.1 (Universality-closure quadrant carrier)**.** *A* $\mathsf{UniversalityClosureQuadrant}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (S, U, K, G, W, H, C, P, N)$$

with the following displayed rows:

1. *S is the substrate-name row, naming the cellular, machine, oracle, finite-state, or host-side substrate whose location is being certified;*
2. *U is the universality-axis row, recording the displayed value* $\mathsf{Univ}(S)$ *together with the finite witness or refusal ledger used by the classifier;*
3. *K is the closure-axis row, recording the displayed value* $\mathsf{Closed}(S)$ *together with the finite observation-channel witness or refusal ledger;*
4. *G is the quadrant row, one of universal-and-closed, universal-and-open, subuniversal-and-closed, or subuniversal-and-open;*
5. *W is the provenance witness row linking S, U, K, G to the relevant substrate surface, such as the Rule 110 row, oracle row, Presburger-like closed row, or external-sensor row of the quadrant map;*
6. *H records componentwise* hsame *transports for S, U, K, G, W, P, N;*

7. *C records displayed* Cont *routes that replay the two independent axis reads and the quadrant selection;*
8. *P is the* Pkg *provenance over* $\mathsf{UniversalityClosureQuadrant}^{\uparrow}$*, chapter 9388, the sibling substrate certificates,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{UniversalityClosureQuadrant}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through the substrate name, universality row, closure row, quadrant row, witness row, transport rows, replay routes, provenance, and naming row. It has no coordinate for deriving closure from universality, deriving universality from closure, importing an oracle into a closed packet, or replacing a displayed axis value by a host-level semantic judgement.

Lean4 ✓ `BEDC.Derived.UniversalityClosureQuadrantUp.UniversalityClosureQuadrantTasteGate single carrier alignment`

Theorem 947.2 (Universality-closure quadrant NameCert obligations)**.** *For the carrier of Definition 947.1, the local* $\mathsf{NameCert}_{\mathsf{UniversalityClosureQuadrant}^{\uparrow}}$ *surface consists exactly of six finite obligation rows:*

1. *carrier exposure for $Q = (S, U, K, G, W, H, C, P, N)$;*
2. *universality-axis accountability through U and the substrate row S;*
3. *closure-axis accountability through K and the observation-channel witness row W;*
4. *quadrant selection through the ordered pair (U, K) and no other classifier coordinate;*
5. *componentwise stability through H and displayed replay through C;*
6. *non-escape through P and N, excluding axis collapse, oracle import into closed rows, hidden host semantics, and quotient-level substrate equality.*

No consumer can cite the quadrant map as $\mathsf{UniversalityClosureQuadrant}^{\uparrow}$ *evidence unless both axis rows and the quadrant provenance row are present in the same finite packet.*

Proof. Carrier exposure is projection from Definition 947.1. The packet displays the substrate row, two axis rows, quadrant row, witness row, transports, replay routes, provenance, and local naming row as its only coordinates.

Universality and closure accountability are separate reads. The row U records the computational-power classifier and K records the observation-channel classifier; the route C may replay each row, but it does not identify them or turn one into evidence for the other.

Quadrant selection is therefore a finite product read. The row G is accepted only as the classifier value determined by the displayed pair (U, K) and the witness row W, so a consumer cannot replace the two-axis packet by a single substrate, orbit, inscription, or sieve row.

Finally, H, P, N transport, package, and name the same finite packet. Since the carrier has no coordinate for an oracle inside a closed row, hidden semantic equality, quotient substrate equality, or a derivation between the axes, the listed obligation rows exhaust the local NameCert surface. □

Theorem 947.3 (Universality-closure quadrant axis independence)**.** *In an accepted* $\mathsf{UniversalityClosureQuadrant}^{\uparrow}$ *packet, neither the universality-axis row U nor the closure-axis row K determines the other. The quadrant row G is determined only by the displayed pair (U, K) together with the provenance witness W. Thus the closed-universal Rule 110-style site, the universal-open oracle site, the subuniversal-closed host or Presburger-style site, and the subuniversal-open external-sensor site remain four distinct classifier outcomes.*

Lean4 ✓ `BEDC.Derived.UniversalityClosureQuadrantUp.UniversalityClosureQuadrant axis independence`

Proof. Project an accepted packet to S, U, K, G, W. The carrier has one row for universality and one row for closure, and the two rows are listed as separate coordinates.

The replay routes in C preserve that separation. A universality read may inspect the computational-power witness carried by U, while a closure read may inspect the observation-channel witness carried by K and W; neither route rewrites one row into the other.

The quadrant classifier then reads the ordered pair. Changing either coordinate changes the admissible quadrant value: Rule 110-like closed universality, oracle-open universality, subuniversal closure, and subuniversal external openness occupy different cells in chapter 9388.

Since no carrier coordinate identifies the axes, any collapse would require a row absent from Q. The accepted packet therefore certifies axis independence at the NameCert surface. □

Theorem 947.4 (Universality-closure quadrant non-escape)**.** *Every public read exported by an accepted* $\mathsf{UniversalityClosureQuadrant}^{\uparrow}$ *packet factors through the finite route*

$$S, U, K, G, W, H, C, P, N.$$

The route can certify the two-axis quadrant location of a displayed substrate, but it exports no proof of Rule 110 universality, no oracle computation, no universal closure over an infinite domain, no quotient equality of substrates, no host semantic equality, and no derivation from one axis to the other.

Proof. Begin with carrier projection. The public packet contains only the substrate row S, universality row U, closure row K, quadrant row G, witness row W, transports H, replay routes C, provenance P, and local name N.

The axis-independence theorem forces every quadrant read through the pair (U, K). The witness row may point to a cellular substrate, cellular trust packet, cellular orbit packet, oracle-open comparison, host-side closed substrate, or external-sensor comparison, but that pointer is provenance for a row already displayed in the packet.

The excluded objects require coordinates not present in Q. Rule 110 universality needs the separate substrate proof, oracle computation needs an oracle row, universal closure needs an infinite-domain ratifier, quotient equality needs a quotient classifier, host semantic equality needs a host semantic row, and axis collapse needs an identification between U and K. None is exported by the finite quadrant certificate. □

The later Lean `TasteGate.lean` development for $\mathsf{UniversalityClosureQuadrant}^{\uparrow}$ must include explicit $\mathsf{Nontrivial\ UniversalityClosureQuadrant}^{\uparrow}$ and $\mathsf{FieldFaithful\ UniversalityClosureQuadrant}^{\uparrow}$ instances for the displayed two-axis carrier. These instances must preserve the substrate row, universality row, closure row, quadrant row, provenance witness, transport rows, replay routes, package provenance, and local naming row.

Closure status for $\mathsf{NameCert}_{\mathsf{UniversalityClosureQuadrant}^{\uparrow}}$.

Constructive story: A $\mathsf{UniversalityClosureQuadrant}^{\uparrow}$ packet is generated from a substrate row, universality-axis row, closure-axis row, quadrant row, provenance witness, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{UniversalityClosureQuadrant}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 947.1, Definition 947.2, Definition 947.3, and Definition 947.4 specify the finite two-axis substrate quadrant certificate surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{UniversalityClosureQuadrant}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, Rule 110 universality, oracle computation, universal closure over an infinite domain, quotient equality, host semantic equality, or derivability between the axes.

Upgrade path: Obligation closure requires checked carrier admission, universality-axis accountability, closure-axis accountability, quadrant selection, axis independence, non-escape, nontriviality, and field faithfulness for the same two-axis carrier.

Chapter 948

A Concrete Naming Certificate for $\mathsf{BHistCellRowEmbedding}^{\uparrow}$

The $\mathsf{BHistCellRowEmbedding}^{\uparrow}$ packet concretizes the carrier-equivalence reading of chapter 9391 as a finite naming certificate from a BHist row to a cellular row observation. It sits beside the closed cellular trust packet of chapter 940, the finite orbit packet of chapter 938, and the public record packet of chapter 519. Those siblings certify cellular trust, orbit observation, and inscription exposure; this carrier certifies the explicit row-level bridge that keeps the original BHist source and its cellular readback in one packet.

Its composite dependencies are the BHist source row, the $\mathsf{CellularAutomaton}^{\uparrow}$ row substrate, the $\mathsf{CellularTrustSubstrate}^{\uparrow}$ trust packet of chapter 940, the $\mathsf{CellularOrbitSubstrate}^{\uparrow}$ orbit observation of chapter 938, and the $\mathsf{InscriptionEvent}^{\uparrow}$ exposure packet of chapter 519, combined with the inverse readback row into one row-embedding certificate.

Falsifiable prediction: Removing the inverse readback row leaves a cellular row observation but breaks the BHist carrier recovery route.

Independence witness: Nearest siblings: cellulartrustsubstrate, cellularorbitsubstrate, inscriptionevent, and cellularautomaton. None is bijective to $\mathsf{BHistCellRowEmbedding}^{\uparrow}$ because none stores both the source BHist row and the explicit bit-row embedding together with the inverse readback row that recovers the same carrier source.

Definition 948.1 (BHist cell-row embedding carrier)**.** *A* $\mathsf{BHistCellRowEmbedding}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (B, I, W, O, R, H, C, P, N)$$

with the following displayed rows:

1. *B is the source* BHist *row whose constructor trace is embedded.*
2. *I is the bit-row image obtained from the displayed constructor trace of B.*
3. *W is the width and default-padding row, naming the finite row width, padding value, origin coordinate, and the bounded slice in which I is placed.*
4. *O is the orbit-zero row, recording the cellular row observation before any cellular transition is consumed.*
5. *R is the inverse readback row, recovering the same source* BHist *constructor trace from the displayed bit-row image and the padding convention.*

6. *H records componentwise* hsame *transports for B, I, W, O, R, P, N.*
7. *C records displayed* Cont *routes through source reading, bit-row embedding, orbit-zero observation, inverse readback, provenance, and local naming.*
8. *P is the* Pkg *provenance over* BHist, CellularAutomaton$^{\uparrow}$, CellularTrustSubstrate$^{\uparrow}$, CellularOrbitSubstrate$^{\uparrow}$, InscriptionEvent$^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert *rows.*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{BHistCellRowEmbedding}^{\uparrow}}$ *row for carrier admission, row embedding exactness, inverse readback exactness, non-escape, and TasteGate boundary exposure.*

The carrier contains no host byte string, no unbounded cellular orbit, no detached cellular evaluator, no quotient of encodings, and no cellular transition claim beyond the displayed orbit-zero row.

Lean4 (definition) `BEDC.Derived.BHistCellRowEmbeddingUp.BHistCellRowEmbeddingUp`

Theorem 948.2 (BHist cell-row embedding NameCert obligations)**.** *For the carrier of Definition 948.1, the local* $\mathsf{NameCert}_{\mathsf{BHistCellRowEmbedding}^{\uparrow}}$ *surface consists exactly of carrier admission for $E = (B, I, W, O, R, H, C, P, N)$, bit-row image accountability through I, width and default-padding accountability through W, orbit-zero observation through O, inverse readback exactness through R, componentwise transport through H, displayed route replay through C, package provenance through P, and local naming through N. No cellular row observation is accepted as a* BHist *carrier bridge unless it passes through those rows.*

Lean4 ✓ `BEDC.Derived.BHistCellRowEmbeddingUp.BHistCellRowEmbeddingCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 948.1. The packet displays the source BHist row, bit-row image, width and padding row, orbit-zero row, inverse readback row, transports, routes, provenance, and local name as its only coordinates.

The embedding rows I and W account for the cellular row image. The row I records the finite binary image of the constructor trace, while W records where the image sits and how every unmentioned cell is padded.

The readback row R is the carrier-recovery check. It ties the displayed cellular row back to the same source trace B, so the observation cannot be replaced by a host byte layout or by another row with the same visible finite slice but a different carrier source.

The rows H, C, P, N repack those data as transport, replay, provenance, and naming evidence. Since the packet has no coordinate for an unbounded orbit, detached evaluator, quotient encoding, or cellular transition claim, the listed rows exhaust the local NameCert surface. □

Theorem 948.3 (BHist cell-row embedding non-escape)**.** *Every accepted* $\mathsf{BHistCellRowEmbedding}^{\uparrow}$ *read factors through the finite route*

$$B \longmapsto I \longmapsto W \longmapsto O \longmapsto R \longmapsto H, C, P, N.$$

The route exports the source BHist *row, its bit-row image, the width and default-padding convention, the orbit-zero row observation, the inverse readback row, componentwise* hsame *transports, displayed* Cont *routes, package provenance, and the local* NameCert *row. It exports no host byte string, no omitted padding convention, no unbounded cellular orbit, no hidden substrate evaluator, no quotient of encodings, and no selected cellular transition history.*

Lean4 ✓ `BEDC.Derived.BHistCellRowEmbeddingUp.BHistCellRowEmbedding nonescape`

Proof. Start with the accepted carrier and apply the NameCert obligations of Definition 948.2. Every public read reaches the local name only through $B, I, W, O, R, H, C, P, N$.

The row observation itself is bounded by I, W, O. These rows name the finite bit image, its width and padding convention, and the cellular row at orbit zero. They do not supply later cellular dynamics or a host evaluator.

The inverse readback row R closes the recovery route to B. Once the readback has been fixed, no consumer can substitute a different source trace, host byte layout, or quotient representative without leaving the displayed packet.

The remaining rows are transport and provenance rows. They move and replay the same finite data but introduce no further object, so the excluded outputs have no coordinate from which to escape. □

Theorem 948.4 (BHist cell-row embedding TasteGate boundary)**.** *The TasteGate-facing boundary of an accepted* $\mathsf{BHistCellRowEmbedding}^{\uparrow}$ *carrier is exactly the finite witness-pair surface consisting of the source row B and the readback row R, together with field projections to I, W, O, H, C, P, N. A later Lean implementation of* BEDC.Derived.BHistCellRowEmbeddingUp.TasteGate *must provide* Nontrivial $\mathsf{BHistCellRowEmbedding}^{\uparrow}$ *and* FieldFaithful $\mathsf{BHistCellRowEmbedding}^{\uparrow}$ *instances by giving explicit witness-pair and field projection proofs for those displayed rows.*

Lean4 ✓ `BEDC.Derived.BHistCellRowEmbeddingUp.BHistCellRowEmbedding tastegate boundary`

Proof. Project the carrier. The witness pair is available because the packet contains both the source BHist row B and the inverse readback row R in the same finite certificate.

Use the NameCert obligation theorem to read every other field as a displayed coordinate of the same packet. The bit-row image, width and padding row, orbit-zero row, transports, continuations, provenance, and local name are therefore field projections rather than hidden predicates.

Apply non-escape. Since the boundary exports no host byte string, quotient encoding, unbounded orbit, hidden evaluator, or selected transition history, the TasteGate implementation must be faithful to these finite fields and cannot discharge faithfulness by appealing to a non-packet cellular object. □

Closure status for $\mathsf{NameCert}_{\mathsf{BHistCellRowEmbedding}^{\uparrow}}$.

Constructive story: A $\mathsf{BHistCellRowEmbedding}^{\uparrow}$ packet is generated from a source BHist row, a bit-row image, width and default-padding data, an orbit-zero cellular row observation, an inverse readback row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{BHistCellRowEmbedding}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 948.1, Definition 948.2, Definition 948.3, and Definition 948.4 name the finite BHist-to-cell-row bridge surface without closing its formal route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{BHistCellRowEmbedding}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a kernel carrier switch, Rule 110 trust replay, unbounded cellular evolution, host byte equality, quotient encoding, or bridge checking.

Upgrade path: Scoped closure requires checked carrier admission, inverse readback exactness, non-escape, and TasteGate field-faithfulness rows for the same BHist cell-row embedding packet.

Chapter 949

A Concrete Naming Certificate for $\mathsf{CookFrontierCoordinate}^{\uparrow}$

The $\mathsf{CookFrontierCoordinate}^{\uparrow}$ packet turns the engineering path of chapter 9417 into a finite $\mathsf{NameCert}$ surface. It reads the cellular rule-table and finite orbit rows of chapter 934, the fuel-indexed readback discipline of chapter 944, and the observation sieve of chapter 932; its own work is to bind a stage-frontier triple, Rule 110 scale row, audit replay row, and failure ledger into one coordinate packet. The carrier does not assert unbounded universality, does not decide that a halted target has been reached, and does not import a host evaluator oracle.

Falsifiable prediction: If a claimed frontier coordinate can be replayed without the displayed stage-frontier, Rule 110 scale, audit-binary, or failure-ledger rows, then the carrier admission row is false.

Independence witness: cellularautomaton, cellulartrustsubstrate, boundeduniversaltrace, kernelobservationsieve: these siblings expose cellular rows, trust routes, bounded traces, or observation sieves, but none is bijective to the coordinate packet because none carries the ordered stage-frontier triple with audit replay and failure-ledger rows.

Definition 949.1 (Cook frontier coordinate carrier)**.** *A* $\mathsf{CookFrontierCoordinate}^{\uparrow}$ *carrier is a finite packet*

$$K = (F, R, S, A, L, H, C, P, N)$$

with the following displayed rows:

1. $F = (F_{\mathrm{tag}}, F_{\mathrm{compile}}, F_{\mathrm{halt}})$ *is the ordered stage-frontier triple naming the tag-system encoding frontier, the Rule 110 compilation frontier, and the halted-target frontier inspected by the packet;*
2. R *is the finite Rule 110 scale row naming the cellular rule table, width budget, time budget, boundary convention, and row family used by the frontier read;*
3. S *is the finite stage-sample ledger recording the tag-system word, compiled cellular window, and target readback rows displayed at the chosen frontier;*
4. A *is the audit-binary row containing the replay executable name, input manifest, digest row, accepted output rows, and refusal rows for failed replay;*
5. L *is the failure-ledger row recording absent encodings, scale overflows, replay mismatches, unread target rows, and refused universality reads;*
6. H *records componentwise* hsame *transports for* F, R, S, A, L, P, N*;*

7. *C records displayed* Cont *routes from the stage-frontier triple through the scale row, sample ledger, audit replay, and failure ledger;*
8. *P is the* Pkg *provenance over* $\mathsf{CookFrontierCoordinate}^{\uparrow}$*, chapter 9417,* $\mathsf{CellularAutomaton}^{\uparrow}$*,* BoundedUniversalTrace BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{CookFrontierCoordinate}^{\uparrow}}$ *row.*

The local classifier compares accepted coordinates only by these displayed rows. It has no coordinate for unbounded Rule 110 universality, a host-level proof that the target Turing machine halts, a hidden cellular evaluator, quotient stream equality, or a detached success claim outside the audit binary.

Lean4 (definition) `BEDC.Derived.CookFrontierCoordinateUp.TasteGate.CookFrontierCoordinateUp`

Theorem 949.2 (Cook frontier coordinate NameCert obligations)**.** *For the carrier of Definition 949.1, the local* $\mathsf{NameCert}_{\mathsf{CookFrontierCoordinate}^{\uparrow}}$ *surface consists exactly of carrier admission for $K = (F, R, S, A, L, H, C, P, N)$, ordered stage-frontier accountability through F, Rule 110 scale accountability through R, finite sample exposure through S, audit replay exactness through A, failure-ledger non-escape through L, componentwise stability through H, displayed route replay through C, package provenance through P, and local naming through N.*

Proof. Carrier admission is projection from Definition 949.1. The packet displays the stage-frontier triple, scale row, sample ledger, audit replay, failure ledger, transports, routes, provenance, and local naming row as its only coordinates.

Stage-frontier and scale accountability are read from F and R. A consumer must name which encoding, compilation, and halted-target frontiers are being inspected, and must read the Rule 110 width, time, boundary, and row-family data from the finite scale row.

Sample exposure and audit replay are read from S and A. The sample ledger records the tag-system, cellular, and target readback rows selected by the coordinate, while the audit-binary row supplies the replay manifest, digest, accepted outputs, and refused replay cases.

Finally use L, H, C, P, N. The failure ledger blocks success claims that bypass the replay rows, and the structural rows transport and package the same finite fields. Since the carrier has no unbounded universality, host halting, hidden evaluator, quotient stream, or detached success coordinate, the listed rows exhaust the local NameCert surface. □

Lean4 ✓ `BEDC.Derived.CookFrontierCoordinateUp.CookFrontierCoordinate namecert obligations`

Theorem 949.3 (Cook frontier coordinate witnessed-universality boundary)**.** *An accepted* $\mathsf{CookFrontierCoordinate}^{\uparrow}$ *packet may report witnessed operational coverage only along the finite route*

$$F \longmapsto R \longmapsto S \longmapsto A \longmapsto L \longmapsto H \longmapsto C \longmapsto P \longmapsto N.$$

It may cite the Cook compile-frontier path of chapter 9417 as the vision being measured and may use the cellular and bounded-trace surfaces of chapter 934 and chapter 944 as sibling inputs, but it does not promote finite replay into an unbounded Rule 110 universality theorem.

Lean4 ✓ `BEDC.Derived.CookFrontierCoordinateUp.CookFrontierCoordinate witnessed universality boundary`

Proof. Start with the route inventory. The frontier triple F names the three inspected stages, while R and S provide only a finite Rule 110 scale row and a finite stage-sample ledger.

The sibling chapters supply finite surfaces rather than unbounded semantic closure. The cellular chapter contributes displayed rule-table and orbit rows, and the bounded-trace chapter contributes fuel-indexed readback; neither gives this packet a host proof that every future Rule 110 row or every target Turing-machine behaviour has been covered.

The audit and failure rows determine the witnessed boundary. A replay accepted by A is reported only with the refusals and missing cases recorded in L, then transported and packaged through H, C, P, N. Thus the coordinate can witness finite operational coverage without asserting unbounded universality as a new theorem. □

Theorem 949.4 (Cook frontier coordinate failure-ledger non-escape)**.** *Every rejected or incomplete* $\mathsf{CookFrontierCoordinate}^{\uparrow}$ *read remains inside the displayed failure ledger* L*. A missing encoding row, scale overflow, audit mismatch, unread target row, or refused universality read cannot be reclassified as success by appealing to* $\mathsf{CellularAutomaton}^{\uparrow}$*,* $\mathsf{BoundedUniversalTrace}^{\uparrow}$*, a host evaluator, quotient stream equality, or any route absent from* $K = (F, R, S, A, L, H, C, P, N)$*.*

Proof. Project the accepted carrier. The only rows that can record failure are the replay row A and the failure ledger L, with F, R, S providing the stage, scale, and sample context.

Inspect each failure class through the same finite coordinates. Missing encodings are failures of the stage-frontier row, scale overflows are failures of the Rule 110 scale row, replay mismatches are failures of the audit binary, and unread target rows or refused universality reads are ledger entries in L.

The sibling chapters do not supply a bypass. Cellular rows and bounded traces can be cited only as displayed finite inputs to this coordinate, and no host evaluator, quotient stream, or absent route is carried by K. Therefore every rejected or incomplete read stays recorded as a failure-ledger row. □

The Lean follow-up for $\mathsf{CookFrontierCoordinate}^{\uparrow}$ requires `Nontrivial` plus `FieldFaithful` instances in `lean4/BEDC/Derived/CookFrontierCoordinateUp/TasteGate.lean`, with witnesses for the ordered stage-frontier triple, Rule 110 scale row, stage-sample ledger, audit-binary row, failure ledger, transports, routes, provenance, and local naming field.

Theorem 949.5 (Cook frontier coordinate scale-row faithfulness)**.** *For every accepted* $\mathsf{CookFrontierCoordinate}^{\uparrow}$ *carrier*

$$K = (F, R, S, A, L, H, C, P, N),$$

the scale row R *is the unique row from which the Rule 110 rule table, width budget, time budget, boundary convention, and row family of the frontier read may be projected. A consumer that changes any one of those five scale fields while preserving* F, S, A, L, H, C, P, N *no longer reads the same* $\mathsf{NameCert}_{\mathsf{CookFrontierCoordinate}^{\uparrow}}$ *coordinate.*

Proof. Project the carrier of Definition 949.1. The row R displays exactly the Rule 110 rule table, width budget, time budget, boundary convention, and row family used by the coordinate.

The stage-frontier triple F names where the packet is read, but it does not store the cellular scale. The sample ledger S records selected rows after the scale has already been fixed.

The audit row A and failure ledger L replay or refuse a finite read against the displayed scale; they do not define a second width, time, boundary, or row-family source. Transport, replay, provenance, and naming rows H, C, P, N preserve the same displayed field order.

Thus any alteration of the Rule 110 scale data changes the only row that can justify those projections. The accepted coordinate is therefore faithful to R as the scale row. □

Theorem 949.6 (Cook frontier coordinate audit replay exactness)**.** *For every accepted* $\mathsf{CookFrontierCoordinate}^{\uparrow}$ *carrier* $K = (F, R, S, A, L, H, C, P, N)$*, the audit-binary row* A *and failure-ledger row* L *determine the replay boundary exactly: accepted output rows are those named by* A*, and absent encodings, scale overflows, replay mismatches, unread target rows, and refused universality reads remain ledger entries in* L*.*

Proof. Read A first. It carries the replay executable name, input manifest, digest row, accepted output rows, and refusal rows for failed replay.

Read L next. The ledger names the failure classes attached to the same frontier and scale rows: absent encodings, scale overflows, replay mismatches, unread target rows, and refused universality reads.

The sample row S supplies observed data, but it does not convert a ledger entry into an accepted output. Likewise H, C, P, N transport, replay, package, and name the same audit boundary without adding a hidden evaluator.

Therefore replay exactness is the joint reading of A and L. A successful replay must be an accepted output row in A, and every failed or incomplete replay remains visible as a row of L. □

Theorem 949.7 (Cook frontier coordinate field faithfulness)**.** *The fields* $F, R, S, A, L, H, C, P, N$ *of a* $\mathsf{CookFrontierCoordinate}^{\uparrow}$ *carrier cannot be merged while preserving the displayed* $\mathsf{NameCert}_{\mathsf{CookFrontierCoordinate}^{\uparrow}}$ *rows. Merging any two of the ordered stage-frontier triple, Rule 110 scale row, stage-sample ledger, audit-binary row, failure ledger, componentwise transport, displayed replay, package provenance, or local naming row loses at least one carrier admission, accountability, replay, non-escape, stability, provenance, or naming obligation.*

Proof. Inspect the roles of the nine fields. The row F names the frontier stages, R names the Rule 110 scale, and S names the sampled stage data.

The rows A and L separate replay success from replay failure. If they are merged, the packet can no longer distinguish accepted output rows from refused or incomplete reads.

The structural rows H and C have different duties: one transports componentwise equality data and the other records displayed route replay. The package row P and local naming row N then record provenance and certificate naming rather than frontier, scale, sample, audit, or failure data.

Each field therefore discharges a distinct NameCert obligation listed in Definition 949.2. A merge removes the witness for at least one listed obligation, so field faithfulness is forced by the displayed carrier itself. □

Theorem 949.8 (Cook frontier coordinate scoped kernel route)**.** *Every accepted* $\mathsf{CookFrontierCoordinate}^{\uparrow}$ *coordinate read factors through the finite route*

$$F \longmapsto R \longmapsto S \longmapsto A \longmapsto L \longmapsto H \longmapsto C \longmapsto P \longmapsto N.$$

Here F *is the ordered stage-frontier triple,* R *is the Rule 110 scale row,* S *is the stage-sample ledger,* A *is the audit-binary row,* L *is the failure ledger, and* H, C, P, N *are the componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CookFrontierCoordinate}^{\uparrow}}$ *rows. The only sibling inputs consumed by the route are the displayed finite rows of* $\mathsf{CellularAutomaton}^{\uparrow}$ *and* $\mathsf{BoundedUniversalTrace}^{\uparrow}$*; the route does not export unbounded Rule 110 universality, target-machine halting, host evaluator correctness, quotient stream equality, or a detached success claim.*

Proof. Project the carrier of Definition 949.1. Its coordinates are exactly the stage-frontier triple, scale row, sample ledger, audit replay row, failure ledger, transports, replay route, provenance, and local naming row.

Apply the NameCert obligations of Definition 949.2. They bind carrier admission, stage-frontier accountability, scale accountability, sample exposure, audit replay, failure-ledger non-escape, stability, replay, provenance, and local naming to those same rows.

Use the witnessed-universality boundary and failure-ledger non-escape theorems, Definition 949.3 and Definition 949.4. The sibling $\mathsf{CellularAutomaton}^{\uparrow}$ and $\mathsf{BoundedUniversalTrace}^{\uparrow}$ rows are consumed only as finite displayed inputs, while every failed or incomplete read stays in L.

Finally apply scale-row faithfulness, audit replay exactness, and field faithfulness. These prevent replacement of R, A, L, or any structural row by a hidden evaluator, an unbounded universality principle, or a merged carrier field. Thus the scoped kernel route is precisely the displayed finite route. □

Closure status for $\mathsf{NameCert}_{\mathsf{CookFrontierCoordinate}^{\uparrow}}$.

Constructive story: A $\mathsf{CookFrontierCoordinate}^{\uparrow}$ packet is generated from an ordered stage-frontier triple, finite Rule 110 scale row, stage-sample ledger, audit-binary replay row, failure ledger, componentwise transports, displayed routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CookFrontierCoordinate}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 949.1, Definition 949.2, Definition 949.3, Definition 949.4, Definition 949.5, Definition 949.6, Definition 949.7, and Definition 949.8 specify the finite Cook compile-frontier coordinate packet, NameCert obligations, witnessed-universality boundary, failure-ledger non-escape, scale-row faithfulness, audit replay exactness, field faithfulness, and scoped kernel route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CookFrontierCoordinate}^{\uparrow}}, \mathsf{theoremChecked})$

Lean target: `BEDC.Derived.CookFrontierCoordinateUp.CookFrontierCoordinate\_namecert\_obligations`

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove unbounded Rule 110 universality, target-machine halting, host evaluator correctness, quotient stream equality, or bridge checking for $\mathsf{CookFrontierCoordinate}^{\uparrow}$.

Upgrade path: Public closure requires a public-object surface for the coordinate route and a bridge-checked schema handoff for the same finite coordinate.

Chapter 950

A Concrete Naming Certificate for $\mathsf{QuadrantSubstrate}^{\uparrow}$

The $\mathsf{QuadrantSubstrate}^{\uparrow}$ packet realizes the two-axis quadrant map of chapter 9388 as a finite substrate-classifier certificate. It sits beside the cellular automaton substrate of chapter 934, the trust packet of chapter 937, the orbit packet of chapter 938, and the obstruction ledger of chapter 490. Its public role is the finite locator that records which quadrant a displayed substrate inhabits without turning that locator into host substrate equality.

Falsifiable prediction: A substrate read that changes either the universality-axis row or the closure-axis row without changing the quadrant locator is outside the certificate.

Independence witness: Nearest siblings: cellularautomaton, cellulartrustsubstrate, cellularorbitsubstrate, and haltingobstruction; none is bijective because those siblings carry a single substrate or obstruction surface while $\mathsf{QuadrantSubstrate}^{\uparrow}$ carries a two-axis locator plus contrast ledger.

Definition 950.1 (QuadrantSubstrate NameCert carrier)**.** *A* $\mathsf{QuadrantSubstrate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (U, K, L, S, C, H, R, P, N)$$

with the following displayed rows:

1. *U is the universality-axis row, recording whether the substrate read is universal or subuniversal in the sense of Definition 9388.1;*
2. *K is the closure-axis row, recording whether the same substrate read is closed or open in the sense of Definition 9388.2;*
3. *L is the quadrant locator, one of universal-and-closed, universal-and-open, subuniversal-and-closed, or subuniversal-and-open, read from the ordered pair (U, K);*
4. *S is the substrate witness whose local evidence supplies the row inspected by the locator;*
5. *C is the contrast ledger separating the four displayed cells and recording which adjacent cell would be reached by changing exactly one axis row;*
6. *H records componentwise* hsame *transport for U, K, L, S, C, R, P, N;*
7. *R records the displayed* Cont *routes that replay the two axis reads, the locator read, and the contrast-ledger read;*

8. *P is the* Pkg *provenance over* $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{CellularTrustSubstrate}^{\uparrow}$, $\mathsf{CellularOrbitSubstrate}^{\uparrow}$, $\mathsf{HaltingObstruction}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{QuadrantSubstrate}^{\uparrow}}$ *row.*

The carrier has no coordinate for deriving U from K, deriving K from U, replacing L by host equality of substrates, or hiding an open observation channel behind a closed-row name.

Lean4 ✓ `BEDC.Derived.QuadrantSubstrateUp.QuadrantSubstrateTasteGate single carrier alignment`

Theorem 950.2 (QuadrantSubstrate axis classifier totality)**.** *Every accepted* $\mathsf{QuadrantSubstrate}^{\uparrow}$ *packet lands in exactly one displayed quadrant by the pair (U, K). The four cases are universal-and-closed, universal-and-open, subuniversal-and-closed, and subuniversal-and-open; no case is selected by host substrate equality or by identifying the substrate witness S with a sibling carrier.*

Proof. Inspect the two axis rows displayed in Definition 950.1. The row U has the two finite readings universal and subuniversal, and the row K has the two finite readings closed and open.

The quadrant locator L is defined as the product read of those two rows. Thus the finite inspection has four possible outcomes: $(\mathsf{universal}, \mathsf{closed})$, $(\mathsf{universal}, \mathsf{open})$, $(\mathsf{subuniversal}, \mathsf{closed})$, and $(\mathsf{subuniversal}, \mathsf{open})$.

Exactness follows because the contrast ledger C records the adjacent-cell changes and the route row R replays the same two axis reads. Changing either axis changes the admissible locator, while leaving both axes fixed leaves one displayed cell.

No host substrate equality is consulted in this inspection. The witness row S supplies the substrate evidence, but the accepted cell is selected by (U, K) and transported componentwise by H, not by a global equality between $\mathsf{QuadrantSubstrate}^{\uparrow}$ and any sibling certificate. □

Theorem 950.3 (QuadrantSubstrate NameCert obligations)**.** *For the carrier of Definition 950.1, the local* $\mathsf{NameCert}_{\mathsf{QuadrantSubstrate}^{\uparrow}}$ *surface consists exactly of five finite rows:*

1. *carrier exposure for $Q = (U, K, L, S, C, H, R, P, N)$;*
2. *axis classifier totality through the finite pair (U, K);*
3. *quadrant locator exactness through L and the displayed replay routes R;*
4. *contrast-ledger non-escape through C, excluding axis collapse and hidden substrate equality;*
5. *local provenance through P and N over the listed sibling surfaces and BEDC kernel rows.*

These rows are sufficient to cite the two-axis quadrant classifier as a $\mathsf{QuadrantSubstrate}^{\uparrow}$ *NameCert packet, and no additional substrate-oracle, halting decision, infinite closure, or quotient equality row is exported.*

Proof. Carrier exposure is direct projection from the packet coordinates. The finite rows $U, K, L, S, C, H, R, P, N$ are the entire displayed surface, so every accepted public read begins by naming one of those coordinates.

Axis classifier totality is Definition 950.2. The local certificate therefore has a total four-cell locator for every accepted packet, with the value fixed by (U, K).

Locator exactness is supplied by L and replayed by R. The route row checks that the accepted locator is the same finite product read of the universality row and the closure row, rather than a name imported from the witness substrate.

The contrast ledger gives non-escape. Since C records the one-axis moves between adjacent cells, a consumer cannot change an axis row while keeping the old locator, collapse the two axes, or replace the finite row comparison by host substrate equality.

Finally, P and N bind the local certificate to the named sibling surfaces and to BHist, hsame, Cont, Pkg, and NameCert. The packet contains no row for an oracle computation, no global halting classifier, no infinite closure ratifier, and no quotient equality of substrate names, so the five listed rows exhaust the local NameCert obligations. □

Lean `BEDC/Derived/QuadrantSubstrateUp/TasteGate.lean` must provide Nontrivial QuadrantSubstrate$^{\uparrow}$ and FieldFaithful QuadrantSubstrate$^{\uparrow}$ instances with explicit `witness_pair` and constructor-field injection proofs for the two-axis locator carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{QuadrantSubstrate}^{\uparrow}}$.

Constructive story: A QuadrantSubstrate$^{\uparrow}$ packet is generated from two finite axis rows: the universality row and the closure row. The BHist carrier adds the product locator, substrate witness, contrast ledger, componentwise hsame transport, displayed Cont replay, provenance, and local NameCert row. The classifier is bottom-up: first read the two axes, then compute the one displayed quadrant, then use the contrast ledger to expose how changing one axis changes the cell. Downstream consumers receive the locator together with its route evidence. The route names a finite locator, not a global substrate identity.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{QuadrantSubstrate}^{\uparrow}}$, seed)

Scope closed: This chapter binds the quadrant substrate carrier, axis classifier totality, and the five finite NameCert obligations.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{QuadrantSubstrate}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not derive one axis from the other, assert host substrate equality, supply halting oracles, or close an infinite substrate class.

Upgrade path: To reach obligationClosure, give a checked carrier whose axis-pair classifier and contrast ledger determine exactly one displayed quadrant.

Chapter 951

A Concrete Naming Certificate for $\mathsf{OracleAugmentedSubstrate}^{\uparrow}$

The $\mathsf{OracleAugmentedSubstrate}^{\uparrow}$ packet realizes the universal-but-not-closed quadrant of chapter 9388 as a finite NameCert surface. It sits opposite the closed cellular substrate witnesses of chapter 934 and beside the obstruction-facing boundary of chapter 490. Its distinguishing datum is not another closed orbit ledger. It is the explicit oracle-call row and transcript row by which a universal substrate leaves the closed observation channel.

Falsifiable prediction: Removing the oracle-call row makes an oracle transcript indistinguishable from a closed cellular orbit ledger; removing the transcript row prevents any consumer from testing whether the substrate is open rather than closed.

Independence witness: cellularautomaton, cellulartrustsubstrate, haltingobstruction, haltingdiagonal, and haltingdistinctionlimit: none is bijective to $\mathsf{OracleAugmentedSubstrate}^{\uparrow}$ because this packet carries oracle-call, oracle-transcript, open-boundary, and quadrant-provenance rows in one finite substrate certificate, while the listed siblings supply closed cellular rules, trust rows, obstruction rows, diagonal rows, or distinction-limit rows without the oracle-open carrier surface.

Definition 951.1 (Oracle-augmented substrate carrier)**.** *An* $\mathsf{OracleAugmentedSubstrate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (S, A, T, B, E, H, C, P, N)$$

with the following displayed rows:

1. *S is the universal substrate row, naming the internal finite rule, machine, or simulation surface whose ordinary steps are read as substrate-local records.*
2. *A is the oracle-call row, recording the finite query shape, query name, and call boundary by which the substrate asks a source not generated by S.*
3. *T is the oracle-transcript row, recording the finite reply ledger used by the consumer, including the reply token and the local point at which it is consumed.*
4. *B is the open-boundary row, recording that A and T are not closed orbit records of S and cannot be replayed as a cellular ledger.*
5. *E is the quadrant-evidence row, recording universality from the substrate row and non-closure from the oracle-call and transcript boundary.*
6. *H records componentwise* hsame *transports for S, A, T, B, E, P, N.*

7. *C records displayed* Cont *routes through substrate-local steps, oracle calls, transcript reads, the open-boundary check, and the final quadrant read.*
8. *P is the* Pkg *provenance over* $\mathsf{OracleAugmentedSubstrate}^{\uparrow}$*, the quadrant map, the cellular and halting siblings,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{OracleAugmentedSubstrate}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through these rows. It has no coordinate for converting the oracle transcript into a closed cellular orbit, no hidden halting oracle outside the displayed call row, no ambient proof of hypercomputation, and no closure certificate for the open boundary.

Theorem 951.2 (Oracle-augmented substrate NameCert obligations)**.** *For the carrier of Definition 951.1, the local* $\mathsf{NameCert}_{\mathsf{OracleAugmentedSubstrate}^{\uparrow}}$ *surface consists of five finite obligation rows:*

1. *carrier exposure for $O = (S, A, T, B, E, H, C, P, N)$;*
2. *oracle-call accountability, requiring every oracle read to cite A before a reply can be consumed;*
3. *transcript accountability, requiring every reply token to cite T and its consumption point;*
4. *open-boundary exactness, requiring B to separate oracle-call and transcript rows from closed orbit-ledger rows;*
5. *non-escape through E, H, C, P, N, excluding hidden oracles, closed cellular replay of the transcript, ambient hypercomputation proofs, and any quadrant read detached from the displayed oracle rows.*

Thus a consumer may classify the packet as universal but not closed only after reading the substrate row, oracle-call row, transcript row, open-boundary row, and package-local naming rows in the same finite certificate.

Lean4 ✓ `BEDC.Derived.OracleAugmentedSubstrateUp.OracleAugmentedSubstrateTasteGate single carrier alignment`

Proof. Carrier exposure is projection from Definition 951.1. The packet displays the universal substrate row, oracle-call row, transcript row, open-boundary row, quadrant-evidence row, transports, replay routes, provenance, and local name as its only public coordinates.

Oracle-call and transcript accountability are separate reads. The row A records the call boundary and query shape, while T records the reply ledger and consumption point. A consumer that has only one of these rows cannot reconstruct the other from the substrate-local row S.

Open-boundary exactness is the role of B. The cellular siblings provide closed rule and orbit ledgers, and the halting siblings provide obstruction and diagonal surfaces, but neither family supplies an oracle reply as a substrate-internal orbit record. The route C must therefore replay the open-boundary check before accepting the quadrant-evidence row E.

Finally H, P, N transport, package, and name the same finite route. Since hidden oracles, ambient hypercomputation proofs, and detached quadrant judgements have no carrier coordinate, the five obligation rows exhaust the local NameCert surface. □

Theorem 951.3 (Oracle-augmented substrate oracle non-escape)**.** *No public consumer of an accepted* $\mathsf{OracleAugmentedSubstrate}^{\uparrow}$ *packet can erase the oracle boundary. Every oracle-dependent read factors through the finite route*

$$S, A, T, B, E, H, C, P, N.$$

The route may certify that the displayed substrate belongs to the universal-but-not-closed quadrant, but it exports no closed cellular orbit ledger for the oracle reply, no substrate-internal proof of the oracle answer, no hidden halting oracle, and no closure premise for observations that pass through A and T.

Proof. Start with carrier projection. The only public coordinates are $S, A, T, B, E, H, C, P, N$, so any oracle-dependent read must cite the oracle-call row and transcript row before it can reach the quadrant-evidence row.

The open-boundary row blocks closed replay. A closed cellular orbit ledger, such as the sibling cellularautomaton and cellulartrustsubstrate surfaces, records substrate-local evolution. The oracle transcript is admitted precisely as a reply not generated by that local evolution, so a consumer cannot identify it with a closed orbit row without leaving the packet.

The haltingobstruction, haltingdiagonal, and haltingdistinctionlimit siblings explain why the oracle row is not merely an obstruction label: the packet stores a call-and-transcript surface, not a proof that the substrate internally solves the obstruction. Therefore hidden oracle strength and substrate-internal oracle correctness remain outside the public projection.

The packaging rows H, C, P, N preserve that boundary under transport and replay. Hence the oracle-open classification is public only as the finite route through the displayed oracle rows, and no closed-observational premise is exported for those rows. □

The later Lean `TasteGate.lean` development for $\mathsf{OracleAugmentedSubstrate}^{\uparrow}$ must provide $\mathsf{Nontrivial\ OracleAugmentedSubstrate}^{\uparrow}$ and $\mathsf{FieldFaithful\ OracleAugmentedSubstrate}^{\uparrow}$ instances for the displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{OracleAugmentedSubstrate}^{\uparrow}}$.

Constructive story: An $\mathsf{OracleAugmentedSubstrate}^{\uparrow}$ packet is generated from a universal substrate row, oracle-call row, oracle-transcript row, open-boundary row, quadrant-evidence row, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{OracleAugmentedSubstrate}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 951.1, Definition 951.2, and Definition 951.3 specify the finite oracle-open substrate certificate surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{OracleAugmentedSubstrate}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, physical realizability of oracle substrates, oracle correctness, closed replay of oracle transcripts, or a complete theory of hypercomputation.

Upgrade path: Obligation closure requires checked carrier admission, oracle-call accountability, transcript accountability, open-boundary exactness, oracle non-escape, nontriviality, and field faithfulness for the same packet.

Chapter 952

A Concrete Naming Certificate for $\mathsf{CookCompileFrontierWitness}^{\uparrow}$

The $\mathsf{CookCompileFrontierWitness}^{\uparrow}$ surface realizes the engineering coordinate of chapter 9417 as a finite NameCert packet. It sits beside the cellular row certificate of chapter 934, the closed cellular trust packet of chapter 940, the executable certificate edge of chapter 473, the kernel-morphism graph surface of chapter 620, and the bounded trace packet of chapter 944. Those siblings certify local orbit, trust, compiler, morphism, and trace rows; this packet certifies the finite three-stage compile frontier together with the audit row that witnesses the coordinate.

Falsifiable prediction: A claimed frontier witness whose round-trip audit row omits one of the three compile stages is outside the certificate.

Independence witness: cellularautomaton, cellulartrustsubstrate, certificatecompiler, kernelmorphism, boundeduniversaltrace: none is bijective to $\mathsf{CookCompileFrontierWitness}^{\uparrow}$ because the witness carries a stage-coordinate row and a round-trip audit row whose obligations bind all three compile stages at once. CellularAutomaton and CellularTrustSubstrate expose cellular rows, CertificateCompiler and KernelMorphism expose certificate and graph edges, and BoundedUniversalTrace exposes bounded trace replay; none alone binds the Cook frontier coordinate to the three-stage audit surface.

Definition 952.1 (Cook compile-frontier witness carrier)**.** *A* $\mathsf{CookCompileFrontierWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (S, Q, A, O, H, C, P, N)$$

with the following displayed rows:

1. *S is the compile-stage ledger with exactly the TM-to-tag, tag-to-cyclic, and cyclic-to-Rule 110 stage rows, in that order;*
2. *Q is the frontier-coordinate row recording the displayed source size, production count, tape-symbol count, and Rule 110 step budget read from the engineering coordinate;*
3. *A is the round-trip audit row, exposing the source endpoint, the three stage outputs, the Rule 110 observation window, and the decoded endpoint;*
4. *O is the obstruction row naming only finite memory-scale, encoding-constant, and verification-cost boundaries attached to the displayed coordinate;*
5. *H records componentwise* hsame *transports for S, Q, A, O, P, N;*

6. *C records displayed* Cont *routes through the three compile stages, the audit row, and the coordinate classifier;*
7. *P is the* Pkg *provenance over* CellularAutomaton$^{\uparrow}$, CellularTrustSubstrate$^{\uparrow}$, CertificateCompiler$^{\uparrow}$, KernelMorphismUp, BoundedUniversalTrace$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{CookCompileFrontierWitness}^{\uparrow}}$ *row.*

The carrier has no coordinate for a hidden compiler, an omitted stage, a host evaluator, an unbounded Rule 110 orbit, quotient equality of traces, or a detached universality oracle.

Lean4 (definition) `BEDC.Derived.CookCompileFrontierWitnessUp.CookCompileFrontierWitnessUp`
Lean4 ✓ `BEDC.Derived.CookCompileFrontierWitnessUp.CookCompileFrontierWitnessTasteGate single carrier alignment`

Theorem 952.2 (Cook compile-frontier witness obligation surface)**.** *For the carrier of Definition 952.1, the local* $\mathsf{NameCert}_{\mathsf{CookCompileFrontierWitness}^{\uparrow}}$ *surface consists exactly of carrier exposure for $W = (S, Q, A, O, H, C, P, N)$, compile-stage exposure through S, coordinate accountability through Q, round-trip audit replay through A, finite obstruction locality through O, componentwise stability through H, displayed route replay through C, package provenance through P, and local naming through N. No consumer can cite a Cook compile-frontier witness without exposing the three compile stages and the audit row that binds the coordinate.*

Lean4 ✓ `BEDC.Derived.CookCompileFrontierWitnessUp.CookCompileFrontierWitnessCarrier obligation surface`

Proof. Project the carrier of Definition 952.1. The only stage-facing data are the three ordered rows in S, and the only coordinate-facing data are Q and the audit row A.

The audit obligation is finite. The row A records the source endpoint, each stage output, the Rule 110 observation window, and the decoded endpoint, so a claimed witness cannot replace an exposed stage by an external compiler or evaluator.

The remaining obligations are the transport, route, provenance, and name rows. The rows H, C, P, N preserve and replay only the displayed packet over the named sibling certificates, so no hidden stage, unbounded orbit, quotient trace, or detached oracle remains available to a public consumer. □

Lean4 ✓ `BEDC.Derived.CookCompileFrontierWitnessUp.CookCompileFrontierWitnessObligationSurface`

Theorem 952.3 (Cook compile-frontier stage-boundary non-escape)**.** *Every accepted* CookCompileFrontierWitness$^{\uparrow}$ *read that claims a frontier coordinate must factor through the ordered stage boundary*

$$\mathsf{TM\text{-}to\text{-}tag}, \quad \mathsf{tag\text{-}to\text{-}cyclic}, \quad \mathsf{cyclic\text{-}to\text{-}Rule110}$$

inside S, then through the round-trip audit row A, and then through H, C, P, N. It cannot omit a stage, reorder the stage boundary, import a host compiler, appeal to an unbounded orbit, or identify two traces by quotient equality.

Proof. Use the carrier exposure of Definition 952.1. The stage ledger S is ordered and finite, with exactly the three compile-stage rows named in the statement.

Apply the obligation surface of Definition 952.2. A frontier-coordinate read reaches the local NameCert row only after the coordinate row and the round-trip audit row have been displayed, so the route cannot bypass an intermediate compiler stage.

Finally inspect the excluded coordinates. The packet contains no hidden compiler, unbounded orbit, host evaluator, or quotient trace equality; its public route is the displayed finite path through S, A, H, C, P, N. □

Lean4 ✓ `BEDC.Derived.CookCompileFrontierWitnessUp.CookCompileFrontierWitnessCarrier stage boundary nonescape`

Theorem 952.4 (Cook compile-frontier coordinate classifier stability)**.** *If two accepted* CookCompileFrontierWitness *carriers are compared by the local classifier, then their exposed frontier-coordinate rows are stable only when the same stage ledger, audit row, obstruction row, componentwise* hsame *transports, continuation routes, provenance row, and local naming row are preserved. In particular, classifier agreement cannot be obtained by changing the compile-stage order, by dropping the audit row, or by replacing the displayed coordinate with a host-side scale claim.*

Proof. Read classifier comparison through the carrier rows of Definition 952.1. The coordinate row Q is not detached data; it is read together with the stage ledger S, audit row A, and obstruction row O.

The obligation surface of Definition 952.2 forces transport and route preservation through H and C. Thus any accepted comparison must preserve the displayed stage order and the audit replay that justifies the coordinate.

Package and naming rows close the comparison. Since P names the sibling certificates and N names the local packet, a host-side scale claim or altered stage boundary cannot be classified as the same frontier witness. □

The Lean file `Derived/CookCompileFrontierWitnessUp/TasteGate.lean` must supply Nontrivial CookCompile and FieldFaithful CookCompileFrontierWitness$^{\uparrow}$ instances for the displayed carrier.

Closure status for NameCert$_{\text{CookCompileFrontierWitness}^{\uparrow}}$.

Constructive story: A CookCompileFrontierWitness$^{\uparrow}$ packet is generated from an ordered three-stage compile ledger, frontier-coordinate row, round-trip audit row, finite obstruction row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{CookCompileFrontierWitness}^{\uparrow}}$, seed)

Scope closed: Definition 952.1, Definition 952.2, Definition 952.3, and Definition 952.4 bind the carrier and obligation surface for the finite compile-frontier witness.

Formal verification: FormalStatus(NameCert$_{\text{CookCompileFrontierWitness}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, hidden compiler correctness, unbounded Rule 110 orbit claims, quotient trace equality, or detached universality oracles.

Upgrade path: Obligation closure requires the displayed stage, coordinate, audit, obstruction, transport, route, provenance, NameCert, Nontrivial, and FieldFaithful rows for the same carrier.

Chapter 953

A Concrete Naming Certificate for $\mathsf{UniversalClosedSubstrate}^{\uparrow}$

The $\mathsf{UniversalClosedSubstrate}^{\uparrow}$ packet is the concrete universal-and-closed row promised by chapter 9388. It specializes the two-axis quadrant surface to finite simulator data: a closed rule table, a universal compilation row, a bounded simulator trace, and a boundary ledger. It sits beside the cellular automaton packet of chapter 934, while keeping the substrate packet separate from the quadrant classifier, the cellular substrate row, the cellular row classifier, and the halting distinction boundary.

Falsifiable prediction: Any accepted $\mathsf{UniversalClosedSubstrate}^{\uparrow}$ packet lacking a finite rule-table row cannot satisfy the chapter's NameCert obligations.

Independence witness: cellularautomaton, cellularsubstrate, cellularrowclassifier, haltingdistinctionlimit: the packet simultaneously carries universality, closure, simulator trace, and boundary-ledger rows, so none of these siblings is bijective to it.

Definition 953.1 (Universal closed substrate carrier)**.** *A* $\mathsf{UniversalClosedSubstrate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (R, A, E, S, T, B, H, C, P, N)$$

with the following displayed rows:

1. *R is the finite rule-table row for the closed substrate, naming the local state alphabet, neighborhood window, update rule, and boundary convention.*
2. *A is the acceptance row saying that observations are finite substrate histories generated only by repeated use of R.*
3. *E is the universality encoding row, recording the finite compiler surface from a program row and input row into an initial substrate history.*
4. *S is the simulator-step row, relating one displayed program transition to a bounded block of rule-table steps.*
5. *T is the finite simulator trace row, listing the bounded blocks served by S for the accepted program prefix.*
6. *B is the boundary-ledger row, recording where the packet stops: no unbounded halting decision, no oracle call, and no host semantic equality is exported.*

7. *H records componentwise* hsame *transports for the rule table, closed-observation row, encoding row, simulator-step row, trace row, boundary row, package row, and local naming row.*
8. *C records displayed* Cont *routes that replay the rule-table evolution, the encoding read, each bounded simulator block, and the boundary-ledger read.*
9. *P is the* Pkg *provenance over* $\mathsf{UniversalClosedSubstrate}^{\uparrow}$*, chapter 9388, chapter 934,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{UniversalClosedSubstrate}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through $R, A, E, S, T, B, H, C, P, N$. It contains no coordinate for replacing the finite rule table by a semantic oracle, no coordinate for deciding all program behaviour, and no quotient identifying the universal row with the closure row.

Lean4 ✓ `BEDC.Derived.UniversalClosedSubstrateUp.UniversalClosedSubstrateTasteGate single carrier alignment`

Theorem 953.2 (Universal closed substrate NameCert obligations)**.** *For the carrier of Definition 953.1, the local* $\mathsf{NameCert}_{\mathsf{UniversalClosedSubstrate}^{\uparrow}}$ *surface consists exactly of these finite obligation rows:*

1. *carrier admission for $U = (R, A, E, S, T, B, H, C, P, N)$;*
2. *closed-substrate accountability through the finite rule-table row R and the closed-observation row A;*
3. *universality accountability through the encoding row E and the bounded simulator-step row S;*
4. *trace exposure through T, with every simulator block backed by the displayed rule table;*
5. *boundary discipline through B, excluding halting decision, oracle access, hidden host equality, and unbounded semantic closure;*
6. *componentwise transport, replay, provenance, and local naming through H, C, P, N.*

Thus a consumer may cite $\mathsf{UniversalClosedSubstrate}^{\uparrow}$ *only when the finite rule table, closure row, universality encoding, bounded simulator trace, and boundary ledger appear in the same packet.*

Proof. Project the carrier of Definition 953.1. Its coordinates are exactly $R, A, E, S, T, B, H, C, P, N$, so the local naming row has no other source for substrate closure, universality, simulation, or boundary data.

The closed side is read through R and A. The rule table supplies the finite local update surface, and the acceptance row restricts observations to histories generated by that table.

The universal side is read through E, S, T. The encoding row names the finite program-input translation, the simulator-step row bounds each transition block, and the trace row lists only the blocks whose rule-table support is displayed.

Finally, B, H, C, P, N bind the boundary and naming surface. Since the carrier has no coordinate for an oracle, a total halting predicate, host semantic equality, or a derivation collapsing the two axes, the listed rows exhaust the local NameCert obligations. □

Theorem 953.3 (Universal closed substrate finite simulator boundary)**.** *Every public read exported by an accepted* $\mathsf{UniversalClosedSubstrate}^{\uparrow}$ *packet factors through the finite route*

$$R, A, E, S, T, B, H, C, P, N.$$

The route may certify that a displayed closed rule table carries a bounded simulator trace for an encoded program prefix, but it exports no proof that an arbitrary program halts, no oracle computation, no host semantic equality, no infinite closure over all traces, and no identification of universality with closure.

Proof. Begin with carrier projection. Any exported read must name the rule table R, closed-observation row A, encoding row E, simulator-step row S, trace row T, boundary ledger B, and the structural rows H, C, P, N.

The simulator route is finite. Each program-prefix read enters through E, advances only by the bounded blocks recorded by S, and is exposed only where T lists the corresponding rule-table blocks.

The boundary row B records the stopping point of the packet. A halting decision for arbitrary programs, an oracle computation, host equality, and infinite closure over all traces would require coordinates absent from U.

Therefore $\mathsf{UniversalClosedSubstrate}^{\uparrow}$ realizes the universal-and-closed quadrant as a finite NameCert substrate packet. It is strong enough to carry the quadrant witness of chapter 9388 and the cellular automaton sibling surface of chapter 934, but not strong enough to export the excluded semantic objects. □

The later Lean `TasteGate.lean` development for $\mathsf{UniversalClosedSubstrate}^{\uparrow}$ must provide $\mathsf{Nontrivial\ UniversalClos}$ and $\mathsf{FieldFaithful\ UniversalClosedSubstrate}^{\uparrow}$ instances in `lean4/BEDC/Derived/UniversalClosedSubstrateUp/Tas` Those instances must preserve the rule-table row, closed-observation row, universality encoding, bounded simulator-step row, finite trace, boundary ledger, componentwise transport, replay route, package provenance, and local naming row.

Closure status for $\mathsf{NameCert}_{\mathsf{UniversalClosedSubstrate}^{\uparrow}}$.

Constructive story: A $\mathsf{UniversalClosedSubstrate}^{\uparrow}$ packet is generated from a finite rule table, closed-observation row, universality encoding row, bounded simulator-step row, finite simulator trace, boundary ledger, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{UniversalClosedSubstrate}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 953.1, Definition 953.2, and Definition 953.3 specify the finite universal-and-closed substrate packet and its simulator boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{UniversalClosedSubstrate}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, arbitrary halting, oracle computation, host semantic equality, infinite closure over all traces, or a derivation between universality and closure.

Upgrade path: Obligation closure requires checked carrier admission, rule-table accountability, closed-observation accountability, universality encoding, bounded simulator trace, boundary discipline, nontriviality, and field faithfulness for the same packet.

Chapter 954

A Concrete Naming Certificate for $\mathsf{CompileFrontierWitness}^{\uparrow}$

The $\mathsf{CompileFrontierWitness}^{\uparrow}$ packet realizes the Cook compile-frontier engineering path of chapter 9417 as finite NameCert data. It records the present frontier coordinate, the halted-machine target coordinate, the three compile stages, the audit rows, and the nonchoice boundary through which a substrate read is allowed to leave the packet. It is anchored by the displayed cellular classifier of chapter 945, the finite rule and orbit surface of chapter 934, and the obstruction ledger of chapter 490.

Falsifiable prediction: If the compile-frontier witness carrier is accepted, every halted-TM target read factors through a displayed frontier-coordinate row and no hidden evaluator coordinate can be exported.

Independence witness: cellularsubstrateclassifier, cellularautomaton, haltingobstruction, compiler-optimization-endomorphism: none is bijective to $\mathsf{CompileFrontierWitness}^{\uparrow}$ because none simultaneously carries present coordinate, target coordinate, stage route, audit row, and nonchoice boundary.

Definition 954.1 (Compile-frontier witness carrier)**.** *A* $\mathsf{CompileFrontierWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (F, T, S, A, B, H, C, P, N)$$

with the following displayed rows:

1. *F is the frontier-coordinate row, naming the present Cook coordinate (P^*, T^*, S^*) accepted by the substrate audit.*
2. *T is the target-coordinate row, naming the halted-TM coordinate $(64, 64, S_{\mathrm{halt}})$ and the finite machine/input pair whose halted read is sought.*
3. *S is the stage-route row, displaying TM-to-tag, tag-to-cyclic, and cyclic-to-Rule-110 routes as the only compile stages available to the packet.*
4. *A is the audit-row ledger, recording the stage audit, substrate round-trip audit, decode audit, and refusal rows for failed reads.*
5. *B is the nonchoice boundary row, saying that the packet exposes a witnessed-coordinate route but not a hidden evaluator, oracle, global halting classifier, or unrecorded compiler step.*
6. *H records componentwise* hsame *transport for frontier coordinates, target coordinates, stage routes, audit rows, boundary rows, provenance rows, and local naming rows.*

7. *C records displayed* Cont *routes through the frontier coordinate, target coordinate, compile stages, cellular substrate classifier, Rule 110 orbit surface, obstruction boundary, audit ledger, and nonchoice boundary.*

8. *P is the* Pkg *provenance over* $\mathsf{CompileFrontierWitness}^{\uparrow}$*, the Cook compile-frontier engineering path,* $\mathsf{CellularSubstrateClassifier}^{\uparrow}$*,* $\mathsf{CellularAutomaton}^{\uparrow}$*,* $\mathsf{HaltingObstruction}^{\uparrow}$*,* $\mathsf{CompilerOptimizationEndomorphism}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows.*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{CompileFrontierWitness}^{\uparrow}}$ *row.*

The classifier compares accepted carriers only through $F, T, S, A, B, H, C, P, N$. It has no coordinate for a host evaluator, detached compiler correctness theorem, hidden decoder, global halting decision, or substrate run not named by the audit row.

Lean4 (definition) `BEDC.Derived.CompileFrontierWitnessUp.TasteGate.CompileFrontierWitnessUp`

Theorem 954.2 (Compile-frontier witness NameCert obligations)**.** *For the carrier of Definition 954.1, the local* $\mathsf{NameCert}_{\mathsf{CompileFrontierWitness}^{\uparrow}}$ *surface consists exactly of five finite rows:*

1. *frontier-coordinate carrier, exposing the present coordinate F and the halted target T as displayed BEDC rows;*

2. *displayed coordinate classifier, comparing frontier and target reads only by componentwise* hsame *transport through H;*

3. *pipeline-stage route exactness, forcing every compile read through the TM-to-tag, tag-to-cyclic, and cyclic-to-Rule-110 route row S;*

4. *audit-row nonescape, requiring every substrate, decode, and refusal read to pass through the audit ledger A and the displayed continuation routes C;*

5. *ledger exhaustion, saying that B, P, N exclude hidden evaluator coordinates, detached compiler steps, oracle reads, and global halting classifiers.*

Thus a public compile-frontier witness may be consumed only as a finite witnessed-coordinate NameCert packet.

Proof. Carrier exposure is projection from Definition 954.1. The present coordinate, target coordinate, stage route, audit row, nonchoice boundary, transport, replay, provenance, and local naming rows are the only coordinates of W.

The displayed coordinate classifier is the componentwise read through H. It can compare frontier rows and target rows only where the packet exposes them, so no host coordinate or hidden substrate evaluator can be inserted.

Pipeline exactness is the route row S together with the continuation row C. A halted-TM target read must pass through TM-to-tag, tag-to-cyclic, and cyclic-to-Rule-110 before it can reach the cellular classifier of chapter 945 and the Rule 110 orbit surface of chapter 934.

The audit ledger A records the substrate round trip, decode check, and refusal boundary. The obstruction sibling of chapter 490 supplies the finite boundary saying that the packet exposes an obstruction-aware route rather than a global halting classifier.

Finally, B, P, N close the local ledger. Since none of these rows names an oracle, host evaluator, detached compiler step, or unrecorded decoder, the five listed rows exhaust the public NameCert surface. □

Theorem 954.3 (Compile-frontier witness nonchoice boundary)**.** *Every public read exported by an accepted* $\mathsf{CompileFrontierWitness}^{\uparrow}$ *packet factors through*

$$F, T, S, A, B, H, C, P, N.$$

The route may certify that a displayed halted-TM target is being pursued through the Cook compile-frontier stage route and its audit rows, but it cannot export a hidden evaluator coordinate, a detached compiler oracle, an unrecorded decode step, a global halting decision, or a choice of successful run outside the finite ledger.

Proof. Begin with the carrier inventory. A public read has access to the present coordinate F, target coordinate T, stage route S, audit ledger A, nonchoice boundary B, and the structural rows H, C, P, N.

The route through the Cook path is finite. The stage row S names the three compile stages of chapter 9417; C replays them as displayed continuation rows; A records the accepted audit rows and the refusal rows.

The cellular anchors are also finite. The classifier surface of chapter 945 and the orbit surface of chapter 934 supply displayed substrate rows, while chapter 490 keeps the halted-read boundary from becoming a decision procedure.

Therefore the witness is a finite coordinate certificate. It can expose where the frontier route succeeds or refuses, but it cannot choose a hidden run, evaluate a program outside the ledger, or export an unrecorded compiler coordinate. □

The later Lean development in `lean4/BEDC/Derived/CompileFrontierWitnessUp/TasteGate.lean` must provide `Nontrivial CompileFrontierWitnessUp` and `FieldFaithful CompileFrontierWitnessUp` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{CompileFrontierWitness}^{\uparrow}}$.

Constructive story: A $\mathsf{CompileFrontierWitness}^{\uparrow}$ packet is generated from a present frontier coordinate, halted-machine target coordinate, Cook stage route, audit ledger, nonchoice boundary, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CompileFrontierWitness}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 954.1, Definition 954.2, and Definition 954.3 specify the finite compile-frontier witness carrier, its five NameCert rows, and its nonchoice boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CompileFrontierWitness}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, Cook universality, compiler correctness, hidden evaluator soundness, arbitrary halting, or successful frontier crossing.

Upgrade path: Obligation closure requires checked carrier admission, coordinate classifier stability, stage-route exactness, audit-row nonescape, ledger exhaustion, nontriviality, and field faithfulness for the same packet.

Chapter 955

A Concrete Naming Certificate for $\mathsf{PresburgerSubUniversal}^{\uparrow}$

The $\mathsf{PresburgerSubUniversal}^{\uparrow}$ packet realizes the sub-universal closed quadrant of chapter 9388 by naming Presburger arithmetic as a finite $\mathsf{NameCert}$ surface. It sits beside the arithmetic carrier rows of chapter 28 and chapter 29, the first-order interface of chapter 197, the computable-decision surface of chapter 199, and the Turing-machine boundary of chapter 280. Its role is not to prove global arithmetic strength; it records the closed decision-trace certificate for the language generated by $0, 1, +$.

Falsifiable prediction: Any accepted finite Presburger decision trace for this packet factors through the displayed syntax, addition, quantifier-elimination, decision-trace, closure, provenance, and NameCert rows; a consumer read bypassing one of those rows refutes the packet.

Independence witness: cellularautomaton, haltingobstruction, firstorder, computable, and turingmachine: the Presburger packet is not bijective to any one sibling because it simultaneously carries a first-order arithmetic syntax row, an additive-only classifier, a finite decision-trace row, and a closed-observation non-escape row, while the listed siblings respectively expose cellular evolution, halting obstruction, generic syntax, computability evidence, or unrestricted machine boundary rows.

Definition 955.1 (Presburger sub-universal carrier)**.** *A* $\mathsf{PresburgerSubUniversal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$P = (S, A, Q, D, K, H, C, L, N)$$

with the following displayed rows:

1. *S is the Presburger syntax row for first-order formulas over the signature $(0, 1, +)$;*
2. *A is the additive arithmetic row linking the syntax to the* $\mathsf{Nat}^{\uparrow}$ *and* $\mathsf{Add}^{\uparrow}$ *certificate surfaces;*
3. *Q is the finite quantifier-elimination or normal-form decision row used by the Presburger decision procedure;*
4. *D is the finite decision-trace row recording the accepted yes/no outcome for the displayed formula;*
5. *K is the closure row recording that every observation consumed by the decision trace is generated inside the displayed Presburger packet;*
6. *H stores componentwise* hsame *transports for S, A, Q, D, K, L, N;*

7. *C stores displayed* Cont *routes replaying syntax formation, additive readback, decision trace, and closure readback;*
8. *L is the* Pkg *provenance ledger over* $\mathsf{PresburgerSubUniversal}^{\uparrow}$*, chapter 9388, chapter 197, chapter 199, and chapter 280;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{PresburgerSubUniversal}^{\uparrow}}$ *row.*

The carrier has no coordinate for multiplication, no Turing-universal program row, no oracle row, no global semantic equality over arbitrary arithmetic structures, and no infinite-domain ratifier outside the displayed decision trace.

Lean4 (definition) `BEDC.Derived.PresburgerSubUniversalUp.PresburgerSubUniversalUp`

Theorem 955.2 (Presburger closed-observation NameCert obligations)**.** *For the carrier of Definition 955.1, the local* $\mathsf{NameCert}_{\mathsf{PresburgerSubUniversal}^{\uparrow}}$ *surface consists exactly of six finite obligation rows:*

1. *carrier exposure for $P = (S, A, Q, D, K, H, C, L, N)$;*
2. *additive-syntax accountability through S and A;*
3. *finite decision accountability through Q and D;*
4. *closed-observation accountability through K;*
5. *componentwise stability through H and displayed replay through C;*
6. *non-escape through L and N, excluding multiplication, oracle import, Turing-universal simulation, quotient equality of names, and external semantic ratification.*

No consumer can cite Presburger arithmetic as the sub-universal closed quadrant witness unless the additive syntax, finite decision trace, and closure row are present in the same finite packet.

Proof. Carrier exposure is projection from Definition 955.1. The packet displays syntax, additive arithmetic, quantifier-elimination or normal-form decision data, decision trace, closure, transports, replay routes, provenance, and the local name.

The arithmetic and decision obligations are separate reads. The rows S and A identify the first-order additive language, while Q and D record the finite decision trace for the displayed formula.

Closure is read through K. The replay routes in C may inspect the syntax, additive readback, decision trace, and closure readback, but they do not import multiplication, a Turing-machine simulator, or an oracle row.

Finally, H, L, N transport, package, and name the same finite packet. Since every exported read is tied to the displayed Presburger decision trace, the listed rows exhaust the local NameCert surface. □

Theorem 955.3 (Presburger quadrant non-escape)**.** *Every public read exported by an accepted* $\mathsf{PresburgerSubUniversal}^{\uparrow}$ *packet factors through the finite route*

$$S, A, Q, D, K, H, C, L, N.$$

The route certifies Presburger arithmetic as a sub-universal closed inhabitant of section 9388.4: it supplies finite first-order additive syntax, a finite decision trace, and a closed observation row, but exports no multiplication coordinate, no universal-machine semantics, no halting-obstruction classifier, no oracle computation, no quotient equality of certificate names, and no universal closure over an unrecorded infinite domain.

Proof. Begin with carrier projection. The only exported coordinates are the syntax row S, additive row A, decision row Q, decision trace D, closure row K, transports H, replay routes C, provenance L, and local name N.

The NameCert obligation theorem forces each accepted read through those coordinates. In particular, a read of the quadrant witness must use the additive syntax rows and the finite decision trace before it can cite closure.

The excluded objects require rows absent from the carrier. Multiplication requires a multiplicative arithmetic coordinate, universal-machine semantics require a machine row, halting obstruction requires the separate obstruction packet of chapter 490, oracle computation requires an oracle row, quotient equality requires a quotient classifier, and unrecorded universal closure requires a ratifier outside the displayed trace. None is exported by the finite Presburger certificate. □

The later Lean `BEDC.Derived.PresburgerSubUniversalUp` development must include explicit $\mathsf{Nontrivial}\ \mathsf{PresburgerSubUniversal}^{\uparrow}$ and $\mathsf{FieldFaithful}\ \mathsf{PresburgerSubUniversal}^{\uparrow}\ \mathsf{TasteGate}$ instances for the displayed Presburger carrier. These instances must preserve the syntax row, additive arithmetic row, decision row, trace row, closure row, transport rows, replay routes, package provenance, and local naming row.

Closure status for $\mathsf{NameCert}_{\mathsf{PresburgerSubUniversal}^{\uparrow}}$.

Constructive story: A $\mathsf{PresburgerSubUniversal}^{\uparrow}$ packet is generated from first-order additive syntax, a finite Presburger decision row, a decision trace, a closed-observation row, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{PresburgerSubUniversal}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 955.1, Definition 955.2, and Definition 955.3 specify the finite Presburger sub-universal closed certificate surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{PresburgerSubUniversal}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Not claimed: This chapter does not prove Lean verification, bridge checking, multiplication definability, Turing universality, halting decidability, oracle computation, quotient equality, or universal closure over an unrecorded infinite domain.

Upgrade path: Obligation closure requires checked carrier admission, additive-syntax accountability, decision-trace accountability, closed-observation accountability, non-escape, nontriviality, and field faithfulness for the same Presburger carrier.

Chapter 956

A Concrete Naming Certificate for $\mathsf{OracleSubstrateBoundary}^{\uparrow}$

The $\mathsf{OracleSubstrateBoundary}^{\uparrow}$ packet realizes the oracle-open substrate boundary of chapter 9388 as a finite $\mathsf{NameCert}$ carrier. It sits beside the two-axis quadrant packet of chapter 947, the closed cellular trust surface of chapter 937, and the finite cellular ledger of chapter 934. Its distinguishing datum is an explicit external-channel row: the packet can name an oracle-query boundary without converting that row into a closed substrate observation.

Falsifiable prediction: Removing the external-channel row makes the packet indistinguishable from a closed cellular substrate, while removing the refusal ledger permits an internal-induction read.

Independence witness: Nearest siblings: universalityclosurequadrant, cellulartrustsubstrate, cellularautomaton, kernelobservationsieve, and boundeduniversaltrace; none is bijective because this carrier has an oracle-query boundary and refusal ledger absent from closed substrate packets.

Definition 956.1 (Oracle-substrate boundary carrier)**.** *An* $\mathsf{OracleSubstrateBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (S, Q, E, R, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the substrate row, naming the machine, cellular, or host-side carrier whose observation boundary is being inspected;*
2. *Q is the oracle-query row, listing the finite query sites that leave the closed substrate interface;*
3. *E is the external-channel row, recording the boundary at which a query is routed outside the closed observation ledger;*
4. *R is the refusal ledger, recording which internal-induction, closed-observation, quotient-equality, and host-semantic reads are rejected for the same packet;*
5. *L is the local observation ledger, recording the closed substrate rows that remain visible on the substrate side of the boundary;*
6. *H records componentwise* hsame *transports for S, Q, E, R, L, P, N;*
7. *C records displayed* Cont *routes that replay the local observation rows, the oracle-query boundary read, and the refusal ledger;*

8. *P is the* Pkg *provenance over* $\mathsf{OracleSubstrateBoundary}^{\uparrow}$*, chapter 9388,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{OracleSubstrateBoundary}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through the substrate row, oracle-query row, external-channel row, refusal ledger, local observation ledger, componentwise transports, replay routes, provenance, and naming row. It has no coordinate for replacing the external channel by a closed cellular observation or for reading oracle refusal as an induction principle internal to the substrate.

Lean4 ✓ `BEDC.Derived.OracleSubstrateBoundaryUp.OracleSubstrateBoundaryTasteGate single carrier alignment`

Theorem 956.2 (Oracle-substrate boundary NameCert obligations)**.** *For the carrier of Definition 956.1, the local* $\mathsf{NameCert}_{\mathsf{OracleSubstrateBoundary}^{\uparrow}}$ *surface consists exactly of six finite obligation rows:*

1. *carrier exposure for $O = (S, Q, E, R, L, H, C, P, N)$;*
2. *substrate-side observation accountability through S and L;*
3. *oracle-query accountability through the displayed query row Q;*
4. *external-channel boundary accountability through E;*
5. *refusal accountability through R, excluding closed-substrate induction, quotient equality, hidden host semantics, and oracle import into local observations;*
6. *componentwise stability, route replay, package provenance, and local naming through H, C, P, N.*

No consumer can cite an oracle-open substrate boundary as $\mathsf{OracleSubstrateBoundary}^{\uparrow}$ *evidence unless the query row, external-channel row, and refusal ledger are present in the same finite packet.*

Proof. Carrier exposure is projection from Definition 956.1. The accepted packet displays the substrate row, oracle-query row, external-channel row, refusal ledger, local observation ledger, transports, routes, package provenance, and local name as its only coordinates.

Substrate accountability and oracle accountability are separate reads. The local observation ledger L records closed substrate rows, while Q and E record the query sites and the boundary through which those sites leave the closed interface.

The refusal ledger blocks the escape modes named in the statement. A consumer may replay the finite boundary route through C, but there is no coordinate that turns an external query into closed-substrate induction, quotient equality, hidden host semantics, or an oracle imported into the local observation rows.

Finally, H, P, N transport, package, and name exactly the same finite packet. These rows certify stability and provenance for the displayed carrier; they do not add any missing closed-substrate or internal-induction coordinate. □

Theorem 956.3 (Oracle-substrate boundary external-channel non-escape)**.** *Every public boundary read exported by an accepted* $\mathsf{OracleSubstrateBoundary}^{\uparrow}$ *packet factors through the finite route*

$$S, Q, E, R, L, H, C, P, N.$$

The route can certify that a displayed substrate has an oracle-query boundary and a refusal ledger, but it exports no closed cellular substrate certificate, no internal induction principle for oracle answers, no quotient equality of behaviours, no host semantic equality, and no oracle computation detached from the displayed boundary row.

Proof. Begin with carrier projection. The only public rows are the substrate row S, oracle-query row Q, external-channel row E, refusal ledger R, local observation ledger L, transports H, replay routes C, provenance P, and local name N.

The query boundary must be read through Q and E. The closed substrate side remains only the finite observation ledger L, so the carrier keeps the oracle-facing boundary distinct from the cellular or host-side rows it may reference.

The refusal ledger records the missing routes. A closed cellular substrate certificate would require the external-channel row to disappear; an internal induction principle for oracle answers would require a rule absent from R; quotient equality and host semantic equality would require coordinates not present in the packet.

Thus every accepted public read remains a finite boundary certificate. It may identify the oracle-open edge of the substrate, but it cannot export an oracle computation or closed-substrate conclusion outside the displayed route. □

The Lean development BEDC.Derived.OracleSubstrateBoundaryUp.TasteGate will later provide Nontrivial OracleSubstrateBoundary$^{\uparrow}$ and FieldFaithful OracleSubstrateBoundary$^{\uparrow}$ instances for the displayed carrier. These instances must preserve the substrate row, oracle-query row, external-channel row, refusal ledger, local observation ledger, transport rows, continuation routes, package provenance, and local naming row.

Closure status for NameCert$_{\text{OracleSubstrateBoundary}^{\uparrow}}$.

Constructive story: An OracleSubstrateBoundary$^{\uparrow}$ packet is generated from a substrate row, oracle-query row, external-channel row, refusal ledger, local observation ledger, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{OracleSubstrateBoundary}^{\uparrow}}$, seed)

Scope closed: Definition 956.1, Definition 956.2, and Definition 956.3 specify the finite oracle-query boundary certificate surface.

Formal verification: FormalStatus(NameCert$_{\text{OracleSubstrateBoundary}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, oracle computation, closed cellular substrate completeness, internal induction over oracle answers, quotient equality, or host semantic equality.

Upgrade path: Obligation closure requires checked carrier admission, substrate-side accountability, oracle-query accountability, external-channel accountability, refusal-ledger exactness, nontriviality, and field faithfulness for the same boundary carrier.

Chapter 957

A Concrete Naming Certificate for $\mathsf{ClosedSubstrateQuadrant}^{\uparrow}$

The $\mathsf{ClosedSubstrateQuadrant}^{\uparrow}$ packet realizes the two-axis closure-universality map of chapter 9388 as a finite substrate-quadrant $\mathsf{NameCert}$ carrier. It sits beside the Rule 110 substrate certificate of chapter 934, the cellular substrate carrier of chapter 942, and the bounded trace surface of chapter 944. Its public datum is the closed-substrate quadrant tag together with the displayed universality and closure rows; it does not identify those axes with a sibling substrate, trace, or trust row.

Falsifiable prediction: A substrate-quadrant consumer that changes either the displayed universality row or closure row without changing the quadrant tag is outside the certificate.

Independence witness: cellularautomaton, cellularsubstrate, cellulartrustsubstrate, boundeduniversaltrace: none is bijective because the quadrant packet carries two axis rows and a quadrant tag, while the siblings carry substrate, trust, or trace rows without the full two-axis classifier.

Definition 957.1 (Closed substrate quadrant carrier)**.** *A* $\mathsf{ClosedSubstrateQuadrant}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (S, U, K, G, W, H, C, P, N)$$

whose rows have the following meanings:

1. *S names the substrate being classified, such as a cellular automaton substrate, a cellular substrate carrier, an oracle-facing substrate, or a host-side closed fragment;*
2. *U is the displayed universality row* $\mathsf{Univ}(S)$*, including the finite witness or refusal ledger used by the consumer;*
3. *K is the displayed closure row* $\mathsf{Closed}(S)$*, including the finite observation-channel witness or refusal ledger;*
4. *G is the substrate-quadrant tag for the ordered pair (U, K), with cells universal-and-closed, universal-and-open, subuniversal-and-closed, and subuniversal-and-open;*
5. *W is the provenance witness tying S, U, K, G to the concrete substrate-map read of chapter 9388;*
6. *H records componentwise* hsame *transports for the substrate, axis, quadrant, witness, provenance, and naming rows;*
7. *C records the displayed* Cont *routes that replay the two axis reads and the quadrant-tag read;*

8. *P is the* Pkg *provenance over* $\mathsf{ClosedSubstrateQuadrant}^{\uparrow}$*, the cited vision map, the sibling substrate certificates,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ClosedSubstrateQuadrant}^{\uparrow}}$ *row.*

The local classifier compares packets only through these nine rows. It has no coordinate for deriving universality from closure, deriving closure from universality, replacing the quadrant tag by a sibling substrate carrier, or importing an ambient semantic judgement about the substrate.

Theorem 957.2 (Closed substrate quadrant NameCert obligations)**.** *For the carrier of Definition 957.1, the local* $\mathsf{NameCert}_{\mathsf{ClosedSubstrateQuadrant}^{\uparrow}}$ *surface consists exactly of six finite obligation families:*

1. *carrier exposure for $Q = (S, U, K, G, W, H, C, P, N)$;*
2. *universality-axis accountability through the displayed pair S, U;*
3. *closure-axis accountability through the displayed pair S, K and witness row W;*
4. *quadrant-tag accountability through G as a read of the ordered pair (U, K);*
5. *stability and replay through componentwise* hsame *rows H and* Cont *routes C;*
6. *non-escape through P, N, excluding axis collapse, hidden host semantics, quotient substrate equality, oracle import into closed rows, and replacement by a sibling substrate or trace certificate.*

Thus an accepted $\mathsf{ClosedSubstrateQuadrant}^{\uparrow}$ *packet is a finite NameCert packet for the full two-axis classifier, not a renaming of any one substrate, trust, or trace surface.*

Proof. Carrier exposure is projection from Definition 957.1. The packet displays one substrate row, two axis rows, one quadrant tag, one witness row, transports, replay routes, package provenance, and a local naming row.

The axis obligations are separate. The universality row U records the computational-power classifier for S, while the closure row K records the observation-channel classifier for S and W. The continuation rows can replay both reads, but they do not identify them.

The quadrant obligation is the finite ordered-pair read. The tag G is accepted only as a classifier for (U, K), so changing either row without changing the tag exits the displayed certificate surface.

Finally, H, C, P, N transport, replay, package, and name the same rows. Since no listed coordinate supplies host semantic equality, quotient substrate equality, axis derivability, or a sibling-only carrier replacement, the six obligation families exhaust the local NameCert surface. □

Lean4 ✓ `BEDC.Derived.ClosedSubstrateQuadrantUp.ClosedSubstrateQuadrantCarrier namecert obligations`

Theorem 957.3 (Closed substrate quadrant independence certificate)**.** *In an accepted* $\mathsf{ClosedSubstrateQuadrant}^{\uparrow}$ *packet, the quadrant tag G is independent of each single axis row taken alone. The substrate row S with only U does not determine closure, S with only K does not determine universality, and the sibling cellularautomaton, cellularsubstrate, cellulartrustsubstrate, and boundeduniversaltrace certificates do not determine the full packet unless they also display both axis rows and the same quadrant tag.*

Proof. Project the packet to S, U, K, G, W. The rows U and K are separate coordinates, and the carrier contains no map from either coordinate to the other.

The quadrant tag is a read of the ordered pair. A consumer that holds only S, U lacks the closure witness row; a consumer that holds only S, K lacks the universality witness row; and a

consumer that holds only a sibling substrate, trust, or trace packet lacks the full pair (U, K) together with G.

The witness row W records which displayed substrate-map case is being read, but it is not a bijection to any one sibling. Therefore the accepted packet certifies exactly the finite two-axis classifier and keeps the four substrate quadrants distinct at the NameCert surface. □

Theorem 957.4 (Closed substrate quadrant consumer boundary)**.** *Every public read exported by an accepted* $\mathsf{ClosedSubstrateQuadrant}^{\uparrow}$ *packet factors through*

$$S, U, K, G, W, H, C, P, N.$$

The read may consume the displayed substrate quadrant, but it exports no proof of Rule 110 universality, no oracle computation, no host closure theorem, no quotient substrate equality, no ambient semantic equality, and no derivation between $\mathsf{Univ}(S)$ *and* $\mathsf{Closed}(S)$*.*

Proof. Start with the carrier projection. The public packet has exactly the substrate row, universality row, closure row, quadrant tag, witness row, transport rows, continuation routes, package provenance, and local name.

Apply the obligation theorem to route every NameCert read through the displayed axis rows and quadrant tag. Apply the independence certificate to block replacement by any single axis read or sibling substrate certificate.

The excluded objects all require rows not present in Q. A Rule 110 proof, oracle computation, host closure theorem, quotient equality, ambient semantic equality, or axis derivation must be supplied by another certificate; none is exported by the closed substrate quadrant packet. □

The Lean touchpoint for this carrier is `BEDC.Derived.ClosedSubstrateQuadrantUp.TasteGate`; it supplies $\mathsf{Nontrivial}\ \mathsf{ClosedSubstrateQuadrant}^{\uparrow}$ and $\mathsf{FieldFaithful}\ \mathsf{ClosedSubstrateQuadrant}^{\uparrow}$ instances for the same nine displayed rows.

Closure status for $\mathsf{NameCert}_{\mathsf{ClosedSubstrateQuadrant}^{\uparrow}}$.

Constructive story: A $\mathsf{ClosedSubstrateQuadrant}^{\uparrow}$ packet is generated from a substrate row, universality-axis row, closure-axis row, quadrant tag, provenance witness, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ClosedSubstrateQuadrant}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 957.1, Definition 957.2, Definition 957.3, and Definition 957.4 specify the finite two-axis closed-substrate quadrant certificate surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ClosedSubstrateQuadrant}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ClosedSubstrateQuadrantUp.ClosedSubstrateQuadrantTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove bridge checking, Rule 110 universality, oracle computation, host closure, quotient substrate equality, ambient semantic equality, or derivability between the axes.

Upgrade path: Theorem-checked closure requires canonical Lean theorems for the obligation surface, axis independence, and consumer boundary over the same carrier.

Chapter 958

A Concrete Naming Certificate for $\mathsf{HaltedTmRoundTrip}^{\uparrow}$

The $\mathsf{HaltedTmRoundTrip}^{\uparrow}$ packet is the finite certificate target for the Cook compile-frontier engineering path of chapter 9417. It joins a staged Turing-machine compilation row, a Rule 110 orbit row, an inverse decode row, a halted readback row, and a scale-threshold row in one NameCert carrier. The packet sits beside the cellular trust substrate of chapter 940, the bounded universal trace of chapter 944, the compiler optimization endomorphism of chapter 639, and the universal closed substrate of chapter 953; it is not reducible to any one of those siblings because it records the complete round trip from machine input to halted readback at a finite frontier coordinate.

Falsifiable prediction: Deleting the decode row permits an orbit witness without a halted-TM readback; deleting the scale-threshold row permits a frontier claim without the finite Cook-stage budget.

Independence witness: cellulartrustsubstrate, cellularautomaton, boundeduniversaltrace, compiler-optimization-endomorphism, universalclosedsubstrate; none is bijective because none preserves all staged compile, orbit, decode, halt, and frontier-scale rows.

Definition 958.1 (HaltedTmRoundTrip carrier)**.** *A* $\mathsf{HaltedTmRoundTrip}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (M, G, Y, R, D, Q, F, H, C, P, N)$$

with the following displayed rows:

1. *M is the halted Turing-machine source row, naming the finite state set, tape alphabet, transition table, initial configuration, and halted output row selected for the target machine;*
2. *G is the staged Cook compilation row, recording the TM-to-tag, tag-to-cyclic, and cyclic-to-Rule-110 stages as finite compiler rows;*
3. *Y is the cyclic-tag schedule row, including the production count, tape-symbol count, initial cyclic word, and finite schedule bound used by the compiled run;*
4. *R is the Rule 110 initial row and local-rule orbit row, with the finite cell window, step budget, and accepted observation coordinates;*
5. *D is the inverse decode row from the observed Rule 110 window back through cyclic-tag and tag-system readback;*

6. *Q is the halted readback row, stating that the decoded machine row matches the halted output named by M;*
7. *F is the frontier-scale row, recording the finite production, tape-symbol, row-width, and step-budget thresholds used by the compile-frontier read;*
8. *H records componentwise* hsame *transports for $M, G, Y, R, D, Q, F, P, N$;*
9. *C records displayed* Cont *routes through the staged compile, Rule 110 orbit, inverse decode, halted readback, and frontier-scale rows;*
10. *P is the* Pkg *provenance over* $\mathsf{HaltedTmRoundTrip}^{\uparrow}$*, chapter 9417, chapter 940, chapter 944, chapter 639, chapter 953,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{HaltedTmRoundTrip}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through $M, G, Y, R, D, Q, F, H, C, P, N$. It has no coordinate for an unbounded halting predicate, host evaluator equality, a detached Rule 110 orbit, a decode-free universality claim, or a scale-free frontier assertion.

Lean4 (definition) `BEDC.Derived.HaltedTmRoundTripUp.TasteGate.HaltedTmRoundTripUp`

Theorem 958.2 (HaltedTmRoundTrip NameCert obligations)**.** *For the carrier of Definition 958.1, the local* $\mathsf{NameCert}_{\mathsf{HaltedTmRoundTrip}^{\uparrow}}$ *surface consists exactly of carrier admission for $T = (M, G, Y, R, D, Q, F, H, C,$ staged compile accountability through G, cyclic-tag schedule accountability through Y, Rule 110 orbit accountability through R, inverse decode exactness through D, halted readback exactness through Q, frontier-scale accountability through F, and componentwise transport, replay, provenance, and local naming through H, C, P, N.*

Proof. Project the carrier of Definition 958.1. The source machine, staged compiler, cyclic schedule, Rule 110 orbit, inverse decode, halt readback, scale row, transport, route, provenance, and naming rows are the only coordinates available to a consumer.

The compile side is read through M, G, Y, R. The source row names the halted machine, the staged compiler row records the three Cook stages, the schedule row fixes the finite cyclic-tag budget, and the Rule 110 row records the finite orbit window accepted for observation.

The readback side is read through D, Q, F. The decode row returns from the observed orbit to the machine-facing row, the halt row checks that decoded row against the displayed halted output, and the scale row records the finite frontier budget under which the route is being claimed.

Finally H, C, P, N bind the NameCert surface. Since the carrier has no coordinate for unbounded halting, host evaluator equality, a detached orbit witness, a decode-free readback, or a scale-free frontier claim, the listed rows exhaust the local obligations. □

Theorem 958.3 (HaltedTmRoundTrip scale-threshold route)**.** *Every compile-frontier read exported by an accepted* $\mathsf{HaltedTmRoundTrip}^{\uparrow}$ *packet factors through the staged finite route*

$$M, G, Y, R, D, Q, F, H, C, P, N.$$

The route may state that the displayed halted machine has been compiled through the Cook stages, evaluated on a finite Rule 110 orbit, decoded back to the halted row, and checked at the thresholds recorded by F. It may not state the frontier claim without the scale row, the halted readback without the decode row, or the Rule 110 orbit without the staged compile row.

Proof. Begin with the route row C. Its admitted paths replay the staged compiler rows, then the cyclic-tag schedule, then the Rule 110 orbit, then the inverse decode and halted readback.

The scale-threshold row F is read on the same route. It records the finite production count, tape-symbol count, row-width budget, and step-budget threshold used by the frontier claim, so the exported read is a bounded certificate rather than an ambient universality assertion.

The dependency on D and Q is essential. Without D, the packet contains an orbit observation but no machine-facing readback; without Q, it contains a decode but no halted-row match; without F, it contains a round trip but no Cook-frontier coordinate. □

Theorem 958.4 (HaltedTmRoundTrip nonescape)**.** *An accepted* $\mathsf{HaltedTmRoundTrip}^{\uparrow}$ *packet exports no unbounded halting predicate, no host evaluator equality, no detached Rule 110 orbit certificate, no decode-free halted readback, no scale-free frontier claim, and no semantic proof that every Turing machine is handled by the displayed route. Its public content is exactly the finite packet* $M, G, Y, R, D, Q, F, H, C, P, N$ *of Definition 958.1.*

Proof. Inspect the carrier coordinates. The source row names one finite halted-machine target, the compile rows name one staged Cook route, and the orbit row names one finite Rule 110 observation window.

The readback and scale rows restrict the export. The decoded row D and halt row Q bind the orbit to the named halted output, while F binds the read to a finite frontier coordinate.

The excluded objects require rows absent from the carrier. Unbounded halting needs a global decision predicate, host evaluator equality needs a semantic equality row, a detached orbit certificate would omit G, a decode-free halt read would omit D, and a scale-free frontier claim would omit F. None of these coordinates is present, so the packet exports only the displayed finite NameCert surface. □

The Lean `TasteGate.lean` development for $\mathsf{HaltedTmRoundTrip}^{\uparrow}$ will need $\mathsf{Nontrivial\ HaltedTmRoundTrip}^{\uparrow}$ and $\mathsf{FieldFaithful\ HaltedTmRoundTrip}^{\uparrow}$ instances. These instances must preserve the halted-machine source row, staged compile row, cyclic-tag schedule, Rule 110 orbit, inverse decode, halted readback, frontier-scale row, componentwise transport, replay route, package provenance, and local naming row.

Closure status for $\mathsf{NameCert}_{\mathsf{HaltedTmRoundTrip}^{\uparrow}}$**.**

Constructive story: A $\mathsf{HaltedTmRoundTrip}^{\uparrow}$ packet is generated from a halted Turing-machine source row, staged Cook compile row, cyclic-tag schedule, Rule 110 orbit row, inverse decode row, halted readback row, frontier-scale row, componentwise transports, displayed routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{HaltedTmRoundTrip}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 958.1, Definition 958.2, Definition 958.3, and Definition 958.4 specify the finite Cook compile-frontier round-trip certificate surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{HaltedTmRoundTrip}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, unbounded halting, host evaluator equality, global Rule 110 correctness, all-machine universality, or a detached decode-free frontier result.

Upgrade path: Obligation closure requires checked carrier admission, staged compile accountability, Rule 110 orbit accountability, inverse decode exactness, halted readback exactness, frontier-scale accountability, nontriviality, and field faithfulness for the same packet.

Chapter 959

Cook Frontier Witness Name Certificate Construction

The $\mathsf{CookFrontierWitness}^{\uparrow}$ packet realizes the compile-frontier engineering path of chapter 9417 as a finite NameCert witness surface. It sits beside the substrate-facing cellular packet of chapter 934 and the halting-facing diagonal packet of chapter 496. Its role is not to prove Cook universality again, decide a halting problem, or identify compiler stages by host equality; it records the finite stage, target, replay, obstruction, transport, continuation, package, and naming rows a consumer may inspect.

Falsifiable prediction: Removing the replay-audit row permits a frontier coordinate to be reported without a finite route back through the TM-to-tag, tag-to-cyclic, and cyclic-to-Rule-110 stages.

Independence witness: cellularautomaton, compiler-optimization-endomorphism, haltingdiagonal, continuationautomaton, universalclosedsubstrate: no listed sibling is bijective to $\mathsf{CookFrontierWitness}^{\uparrow}$. The cellularautomaton packet carries a substrate rule surface without the three-stage Cook compile route; compiler-optimization-endomorphism carries before/after compiler traces without a halted target and replay audit; haltingdiagonal carries diagonal obstruction data without the Cook stage ledger; continuationautomaton carries replay dynamics without the frontier coordinate and target rows; universalclosedsubstrate carries a universal closed substrate packet without the staged Cook witness route.

Definition 959.1 (Cook frontier witness carrier)**.** *A* $\mathsf{CookFrontierWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (F, M, Y, R, T, A, O, H, C, P, N)$$

with the following displayed rows:

1. *F is the frontier-coordinate row, recording the accepted production count, tape-symbol count, Rule 110 step budget, and the reported coordinate relative to the halted-TM target of Definition 9417.1;*
2. *M is the TM-to-tag compile-stage row, naming the finite Turing-machine input, tag-system output, and stage-local audit route;*
3. *Y is the tag-to-cyclic compile-stage row, naming the finite tag-system input, cyclic-tag output, and stage-local audit route;*

4. *R is the cyclic-to-Rule-110 compile-stage row, naming the finite cyclic-tag input, Rule 110 initial row, evaluator budget, and decode route;*
5. *T is the halted-target row, recording the halted-machine target coordinate and the expected halt-state readback;*
6. *A is the replay-audit row, replaying the round trip from the Rule 110 trace back through R, Y, and M to the target read in T;*
7. *O is the obstruction-ledger row, recording memory scaling, encoding constants, verification cost, and any displayed failure boundary for the accepted coordinate;*
8. *H records componentwise* hsame *transports for $F, M, Y, R, T, A, O, P, N$;*
9. *C records displayed* Cont *routes for each compile stage, the replay audit, the obstruction read, and the local naming row;*
10. *P is the* Pkg *provenance over* $\mathsf{CookFrontierWitness}^{\uparrow}$*, chapter 9417, chapter 934, chapter 496,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{CookFrontierWitness}^{\uparrow}}$ *row.*

The carrier has no coordinate for a total halting decision, a semantic oracle, a host equality between compiler stages, an unbounded substrate trace, or an unstaged Cook universality proof.

Theorem 959.2 (Cook frontier witness obligation surface)**.** *For the carrier of Definition 959.1, the local* $\mathsf{NameCert}_{\mathsf{CookFrontierWitness}^{\uparrow}}$ *surface consists exactly of these finite rows:*

1. *frontier-coordinate exposure through F;*
2. *three compile-stage exposures through the TM-to-tag row M, the tag-to-cyclic row Y, and the cyclic-to-Rule-110 row R;*
3. *halted-target exposure through T;*
4. *replay-audit exposure through A, requiring the finite route back through R, Y, M;*
5. *obstruction-ledger exposure through O;*
6. *componentwise transport through H;*
7. *continuation replay through C;*
8. *package provenance through P;*
9. *local naming through N.*

Thus an accepted $\mathsf{CookFrontierWitness}^{\uparrow}$ *consumer may report a Cook frontier coordinate only through $F, M, Y, R, T, A, O, H, C, P, N$, and not through a bare substrate run, host compiler equality, selected halting conclusion, unstaged replay, or ambient universality theorem.*

Lean4 ✓ `BEDC.Derived.CookFrontierWitnessUp.CookFrontierWitnessTasteGate single carrier alignment`

Proof. Project the accepted carrier of Definition 959.1. The displayed packet contains exactly the frontier row, three compile-stage rows, halted-target row, replay-audit row, obstruction ledger, and structural rows H, C, P, N.

The compile route is staged. The row M supplies the TM-to-tag read, Y supplies the tag-to-cyclic read, and R supplies the cyclic-to-Rule-110 read. The replay audit A can therefore be checked only by following the finite route back through R, Y, M to the halted target T.

The obstruction row O records where the accepted coordinate stops and why a larger coordinate is not claimed by this packet. The transport, continuation, provenance, and naming rows then bind those finite reads into one NameCert surface.

Since no coordinate remains for a total halting decision, host compiler equality, semantic oracle, unbounded trace, or unstaged universality theorem, the listed rows exhaust the public obligation surface. □

Lean `BEDC/Derived/CookFrontierWitnessUp/TasteGate.lean` will provide explicit Nontrivial CookFrontierWi and FieldFaithful CookFrontierWitness$^{\uparrow}$ instances. Those instances must preserve the frontier-coordinate row, the three compile-stage rows, the halted-target row, the replay-audit row, the obstruction ledger, componentwise hsame transport, displayed Cont replay, Pkg provenance, and the local NameCert row.

Lemma 959.3 (Cook frontier replay-audit route determinacy)**.** *Let*

$$W = (F, M, Y, R, T, A, O, H, C, P, N) \quad \textit{and} \quad W' = (F, M, Y, R, T, A, O, H, C, P, N)$$

be two accepted CookFrontierWitness$^{\uparrow}$ *carriers whose displayed rows agree component by component: the frontier-coordinate row F, the TM-to-tag row M, the tag-to-cyclic row Y, the cyclic-to-Rule-110 row R, the halted-target row T, the replay-audit row A, the obstruction boundary row O, the componentwise transport row H, the continuation row C, the provenance row P, and the local naming row N are the same rows in both packets. If u is a frontier-coordinate read exposed by W and u' is a frontier-coordinate read exposed by W', then the common replay-audit route through A and the common componentwise transport row H identify the two reads:*

$$u \mathsf{hsame} u'.$$

Equivalently, duplicate accepted CookFrontierWitness$^{\uparrow}$ *packets with the same finite replay route cannot expose two non-*hsame *frontier-coordinate reads.*

Proof. Project the two accepted carriers by Definition 959.1. The first coordinate of each packet is the same frontier-coordinate row F, and the replay side of each packet is the same finite route: the row A replays the Rule 110 trace back through R, then Y, then M, and finally to the halted-target row T.

By Definition 959.2, an accepted consumer may report a Cook frontier coordinate only through the displayed rows $F, M, Y, R, T, A, O, H, C, P, N$. Thus the read u from W and the read u' from W' both factor through the same frontier-coordinate row F and the same replay-audit row A.

The componentwise transport row H records the hsame transports for $F, M, Y, R, T, A, O, P, N$. Applying its frontier-coordinate component to the two factorizations through the common row F gives the displayed identification of the two frontier-coordinate reads. The continuation row C, provenance row P, and naming row N are also common, so no second route remains through which either packet could expose a different frontier-coordinate read. Therefore $u \mathsf{hsame} u'$ under the same finite replay route. □

Closure status for NameCert$_{\text{CookFrontierWitness}^{\uparrow}}$**.**

Constructive story: A CookFrontierWitness$^{\uparrow}$ packet is generated from a finite frontier coordinate, the TM-to-tag, tag-to-cyclic, and cyclic-to-Rule-110 stage rows, a halted-target row, replay audit, obstruction ledger, componentwise transport, continuation replay, provenance, and local naming. The BHist carrier keeps each stage as a displayed coordinate; hsame identifies only matching stage and audit rows; and Cont replays the route from the Rule 110 trace back through the compiler stages to the halted target. The certificate names a bounded frontier witness rather than Cook universality itself.

Theory closure: TheoryGate(NameCert$_{\mathsf{CookFrontierWitness}\uparrow}$, seed)

Scope closed: This chapter binds the Cook frontier witness carrier, obligation surface, and replay-audit route determinacy lemma.

Formal verification: FormalStatus(NameCert$_{\mathsf{CookFrontierWitness}\uparrow}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim a total halting decision, semantic oracle, host compiler-stage equality, unbounded trace, or unstaged universality theorem.

Upgrade path: To reach obligationClosure, formalize the staged compiler rows and replay-audit determinacy as a checked finite NameCert carrier.

Chapter 960

A Concrete Naming Certificate for $\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}$

The $\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}$ packet realizes the step-indexed bridge of Definition 9370.5 and Definition 9370.7 as a finite NameCert carrier. It keeps the total host and the universal substrate in different rows: the host evaluator is total and fuel-indexed, while the substrate row may name a universal computation only through a displayed finite window. The packet therefore gives the strong-normalisation vision a concrete finite carrier without claiming host partiality or unbounded substrate completion.

Falsifiable prediction: Removing the fuel row allows a consumer to confuse one finite substrate window with an unbounded computation, which the $\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}$ carrier rejects.

Independence witness: Nearest siblings: twinsubstratebridge, cellularsubstrate, continuationautomaton, closednormalroutecertificate, and boundeduniversaltrace. None is bijective to FuelIndexedSubstrateBri because none simultaneously carries fuel, substrate-state, total-host evaluator, and refusal rows separating a finite substrate window from an unbounded computation.

Definition 960.1 (Fuel-indexed substrate bridge carrier)**.** *A* $\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (F, S, E, W, R, Q, H, C, P, N)$$

with the following displayed rows:

1. *F is the fuel row, naming the finite step bound under which the host read is accepted;*
2. *S is the substrate-state row, naming the finite cellular, machine, or continuation state visible at that fuel;*
3. *E is the total-host evaluator row, naming the terminating host function that maps a fuel and substrate input to a finite readback;*
4. *W is the finite substrate-window row exposed to downstream consumers;*
5. *R is the readback row produced from F, S, E, W;*
6. *Q is the refusal row excluding unbounded completion, host partiality, hidden halting evidence, and any identification of a finite window with an all-time computation;*
7. *H records componentwise* hsame *transports for F, S, E, W, R, Q, P, N;*

8. *C records displayed* Cont *routes through the fuel, substrate-state, total-host evaluator, finite-window, readback, and refusal rows;*
9. *P is the* Pkg *provenance over* $\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}$*, chapter 9370, chapter 942, chapter 944,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through these displayed rows. It has no coordinate for a partial host evaluator, an unbounded substrate orbit, a halting oracle, quotient stream equality, selected nontermination evidence, or semantic completion of the universal substrate.

Lean4 (definition) `BEDC.Derived.FuelIndexedSubstrateBridgeUp.FuelIndexedSubstrateBridgeUp`

Theorem 960.2 (Fuel-indexed substrate bridge obligation surface)**.** *For the carrier of Definition 960.1, the local* $\mathsf{NameCert}_{\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}}$ *surface consists exactly of carrier admission for $B = (F, S, E, W, R, Q, H, C, P, N)$, fuel exposure through F, substrate-state exposure through S, total-host evaluation through E, finite substrate-window exposure through W, readback through R, refusal accounting through Q, componentwise* hsame *stability through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.FuelIndexedSubstrateBridgeUp.FuelIndexedSubstrateBridgeTasteGate single carrier alignment`

Proof. Project the displayed carrier. The accepted packet has exactly the coordinates $F, S, E, W, R, Q, H, C, P, N$, so carrier admission cannot introduce another fuel value, substrate state, host evaluator, window, readback, or refusal row.

Read the computational rows in dependency order. The fuel row F bounds the accepted host read, S provides the substrate state seen at that bound, E is the total evaluator that consumes the bounded input, and W, R display the finite window and readback delivered to the consumer.

The refusal and structural rows close the surface. The row Q records the excluded escapes, while H, C, P, N transport, replay, package, and name only the same finite packet. Thus the NameCert surface is exactly the displayed fuel-indexed bridge and nothing outside it. □

Theorem 960.3 (Fuel-indexed substrate bridge total-host non-escape)**.** *Every accepted* FuelIndexedSubstrateBridge *consumer route reads the host computation through the total evaluator row E under the displayed fuel row F. The packet exports no partial host evaluator, no host-level halting oracle, no selected nontermination witness, and no proof that the substrate computation has completed beyond the displayed finite window W.*

Lean4 ✓ `BEDC.Derived.FuelIndexedSubstrateBridgeUp.FuelIndexedSubstrateBridge total host nonescape`

Proof. Start from the obligation surface of Definition 960.2. A consumer reaches the readback row only through $F, S, E, W, R, Q, H, C, P, N$.

The evaluator row E is consumed with the fuel row F. Hence the host-facing computation is the total step-indexed read described by Definition 9370.5, not a partial evaluator or an unbounded host run.

The refusal row Q records the missing escapes. Since the carrier has no coordinate for host partiality, a halting oracle, selected nontermination evidence, or substrate completion beyond W, none of those objects can be exported by the consumer route. □

Theorem 960.4 (Fuel-indexed substrate bridge step-window boundary)**.** *For an accepted* FuelIndexedSubstrateBrid *packet* $B = (F, S, E, W, R, Q, H, C, P, N)$*, the substrate-side content available to any downstream route is exactly the finite step window* W *and readback* R *obtained under* F, S, E*. In particular, one finite window cannot be consumed as an unbounded computation, a completed universal substrate run, or a quotient stream of all future substrate states.*

Lean4 ✓ `BEDC.Derived.FuelIndexedSubstrateBridgeUp.FuelIndexedSubstrateBridge step window boundary`

Proof. Project the carrier of Definition 960.1. The only substrate-facing rows are the state row S, the finite window row W, and the readback row R, all governed by the fuel and evaluator rows F, E.

Apply Definition 960.3. The consumer receives a total fuel-indexed host read and no unbounded host or substrate completion coordinate.

It remains to identify the boundary of the substrate read. The refusal row Q excludes treating W as an all-time computation or as a quotient stream of future states, while H, C, P, N preserve only the displayed finite route. Therefore the public substrate content is exactly the stated finite step window and readback. □

The Lean TasteGate module BEDC.Derived.FuelIndexedSubstrateBridgeUp.TasteGate must provide Nontrivial FuelIndexedSubstrateBridgeUp and FieldFaithful FuelIndexedSubstrateBridgeUp instances for the displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}}$ •

Constructive story: A $\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}$ packet is generated from fuel, substrate-state, total-host evaluator, finite-window, readback, refusal, transport, route, provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 960.1, Definition 960.2, Definition 960.3, and Definition 960.4 specify the finite total-host and universal-substrate bridge packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, host partiality, unbounded substrate completion, halting decidability, quotient stream equality, or semantic completion of the universal substrate.

Upgrade path: Obligation closure requires checked carrier admission, fuel exposure, substrate-state exposure, total-host evaluator accountability, finite-window exactness, refusal non-escape, nontriviality, and field faithfulness for the same packet.

Chapter 961

A Concrete Naming Certificate for $\mathsf{DiagonalLimitObserver}^{\uparrow}$

The $\mathsf{DiagonalLimitObserver}^{\uparrow}$ packet makes the observer-facing route in chapter 9238 finite. It reads the diagonal-limit construction through the concrete Real and Completion certificates of chapter 38, chapter 126, chapter 301, chapter 291, chapter 386, and chapter 646. The packet treats the observer route as primitive: the observer does not receive a completed real, a quotient stream, a host equality proof, or an ambient completeness principle, only the displayed finite rows by which a diagonal read reaches a $\mathsf{Real}^{\uparrow}$ seal.

Falsifiable prediction: No accepted $\mathsf{DiagonalLimitObserver}^{\uparrow}$ read reaches the $\mathsf{Real}^{\uparrow}$ seal row without first exposing the $\mathsf{StreamName}^{\uparrow}$ finite-window row and the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger. A claimed observer read that presents the seal while hiding either row refutes this carrier.

Independence witness: diagonallimitcompatibility, realobservationbudget, cauchylimitseal, regularcauchyselectorbudget, streamname: none is bijective to $\mathsf{DiagonalLimitObserver}^{\uparrow}$ because this carrier makes the observer route primitive. DiagonalLimitCompatibility certifies compatibility of a diagonal route with seal rows, RealObservationBudget certifies request caps, CauchyLimitSeal certifies the seal route, RegularCauchySelectorBudget certifies selector spending, and StreamName certifies stream rows separately; none alone carries the observer packet tying all six rows to one local NameCert surface.

Definition 961.1 (Diagonal-limit observer carrier)**.** *A* $\mathsf{DiagonalLimitObserver}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (D, W, Q, T, S, R, H, C, P, N)$$

with the following displayed coordinates:

1. *D is the diagonal packet naming the* $\mathsf{RealCompleteness}^{\uparrow}$ *source, the diagonal representative, and the observed diagonal indices;*
2. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *window ledger exposed to the observer before any seal-facing read;*
3. *Q is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained from the displayed stream windows;*
4. *T is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger attached to the same windows and readback rows;*
5. *S is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route that consumes the readback and tolerance rows;*
6. *R is the* $\mathsf{Real}^{\uparrow}$ *seal row reached through D, W, Q, T, S;*

7. *H stores componentwise* hsame *transports for the diagonal packet, window ledger, readback row, tolerance ledger, seal route, Real seal, provenance, local name, and packet shape;*
8. *C stores displayed* Cont *routes from D to W, from W to Q, from W to T, from Q, T to S, from S to R, and from all packet rows to the local naming row;*
9. *P is the* Pkg *provenance over* $\mathsf{RealCompleteness}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitObserver}^{\uparrow}}$ *row.*

The carrier contains no quotient stream, no selected host limit, no host real equality, no hidden observer budget, no alternate tolerance ledger, and no ambient completeness coordinate.

Lean4 (definition) `BEDC.Derived.DiagonalLimitObserverUp.DiagonalLimitObserverUp`

Theorem 961.2 (Diagonal-limit observer NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitObserver}^{\uparrow}}$ *surface for Definition 961.1 consists of five finite obligation rows:*

1. *carrier admission for $O = (D, W, Q, T, S, R, H, C, P, N)$;*
2. *observer classifier stability under the displayed* hsame *transports and* Cont *routes;*
3. *window-first exactness stating that no accepted observer read reaches Q, T, S, or R before the finite* $\mathsf{StreamName}^{\uparrow}$ *window row W is displayed;*
4. *tolerance-readback exactness forcing the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row Q and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger T to share the same window row W;*
5. *seal-route non-escape stating that the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route S and the* $\mathsf{Real}^{\uparrow}$ *seal row R are reached only after D, W, Q, T, H, C, P, N have been displayed.*

Proof. Carrier admission is projection from the finite packet in Definition 961.1. The tuple lists the diagonal packet, finite windows, regular readback, dyadic tolerance ledger, Cauchy-limit seal, Real seal, transports, routes, provenance, and local name.

Classifier stability uses the componentwise rows H and C. These rows preserve the same diagonal source, stream-window ledger, readback row, tolerance ledger, seal route, Real seal, package row, and local certificate under observer-facing transport.

Window-first and tolerance-readback exactness are read from the order and routes of O. The only routes to Q and T start from the displayed W row, and the only route to S consumes both Q and T.

Finally, seal-route non-escape follows because R is reached only through S, with P and N recording the provenance and local certificate. Since the carrier lacks quotient streams, selected host limits, host real equality, hidden observer budgets, alternate tolerance ledgers, and ambient completeness, no outside row can supply an accepted seal read. □

Lean4 ✓ `BEDC.Derived.DiagonalLimitObserverUp.DiagonalLimitObserver namecert obligations`

Theorem 961.3 (Diagonal-limit observer seal exposure)**.** *Every accepted observer read of a* $\mathsf{DiagonalLimitObserver}^{\uparrow}$ *packet*

$$O = (D, W, Q, T, S, R, H, C, P, N)$$

that reaches the $\mathsf{Real}^{\uparrow}$ *seal row R first exposes the finite window row W and the dyadic tolerance ledger T. More precisely, the observer-facing route factors through*

$$D \longrightarrow W \longrightarrow Q, T \longrightarrow S \longrightarrow R$$

with the displayed hsame*,* Cont*,* Pkg*, and* NameCert *support rows. Thus an observer route that hides W or T is not an accepted read of the carrier.*

Proof. Project the carrier and inspect the displayed continuation rows. The only route from the diagonal packet to the readback and tolerance surface starts at W.

The readback row Q and tolerance ledger T are attached to the same finite windows. The seal route S consumes both rows before the Real seal row R can be exposed.

Apply the local NameCert obligations. They keep the route inside H, C, P, N and exclude hidden observer budgets, alternate tolerance ledgers, quotient streams, host real equality, selected limits, and ambient completeness. □

Theorem 961.4 (Diagonal-limit observer classifier transport)**.** *Let*

$$O = (D, W, Q, T, S, R, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitObserver}^{\uparrow}$ *packet. Any classifier-facing presentation accepted by the local* $\mathsf{NameCert}_{\mathsf{DiagonalLimitObserver}^{\uparrow}}$ *transports the same diagonal packet, StreamName window ledger, RegSeqRat readback row, DyadicRatCore tolerance ledger, CauchyLimitSeal route, RealUp seal, package provenance, and local name componentwise along the displayed* hsame *rows in H and the displayed* Cont *rows in C. The transport introduces no quotient stream, host real equality, hidden observer budget, alternate tolerance ledger, or ambient completeness coordinate.*

Proof. Project the accepted carrier to its displayed packet rows. The classifier has access only to $D, W, Q, T, S, R, H, C, P, N$, because the carrier definition contains no further observer-facing coordinate.

Use the classifier-stability row of Definition 961.2. That row reads the componentwise transports in H together with the continuation routes in C, so the classifier presentation preserves the displayed diagonal, window, readback, tolerance, seal, Real, provenance, and local-name rows.

The exclusion clauses are inherited from the carrier. Since quotient streams, host real equality, hidden observer budgets, alternate tolerance ledgers, and ambient completeness coordinates are absent from O, no classifier transport can acquire such a row while remaining accepted by the same local certificate. □

Theorem 961.5 (Diagonal-limit observer tolerance readback coherence)**.** *Let*

$$O = (D, W, Q, T, S, R, H, C, P, N)$$

be an accepted $\mathsf{DiagonalLimitObserver}^{\uparrow}$ *packet. Every accepted observer read that exposes the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row Q, exposes the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger T, or reaches the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route S and* $\mathsf{Real}^{\uparrow}$ *seal R does so over the same finite* $\mathsf{StreamName}^{\uparrow}$ *window ledger W. Thus readback and tolerance cannot split into two accepted observer routes.*

Proof. Project the packet and inspect the routes stored in C. The displayed route to Q starts from W, and the displayed route to T starts from that same window ledger.

Apply the tolerance-readback exactness row in Definition 961.2. It forces the readback row and the tolerance ledger to share the same StreamName window surface rather than two independent observer windows.

For reads that reach S or R, use Definition 961.3. The seal route consumes both Q and T before exposing R, so the same window row W remains the unique accepted source for readback and tolerance. □

Theorem 961.6 (Diagonal-limit observer public export scope)**.** *Every public Real-and-Completion consumer of an accepted* DiagonalLimitObserver$^{\uparrow}$ *packet may export only the ordered observer route*

$$D \longrightarrow W \longrightarrow Q, T \longrightarrow S \longrightarrow R$$

together with the support rows H, C, P, N*. The exported route may cite the finite* StreamName$^{\uparrow}$ *windows,* RegSeqRat$^{\uparrow}$ *readback,* DyadicRatCore$^{\uparrow}$ *tolerance ledger,* CauchyLimitSeal$^{\uparrow}$ *route, and* Real$^{\uparrow}$ *seal rows displayed by the packet. It cannot export a quotient stream, host real equality, selected host limit, hidden observer budget, alternate tolerance ledger, or ambient completeness principle.*

Proof. Apply Definition 961.2 to read the finite carrier inventory. The public consumer receives only the displayed packet rows $D, W, Q, T, S, R, H, C, P, N$ and the local certificate obligations attached to them.

Next use Definition 961.3. Any accepted route that reaches the Real$^{\uparrow}$ seal row must expose W and T before R, hence its public spine factors through $D \to W \to Q, T \to S \to R$ rather than through an undisplayed host object.

Apply Definition 961.4 to preserve the same rows under the componentwise hsame and Cont transports. Then apply Definition 961.5 to keep the RegSeqRat$^{\uparrow}$ readback row and DyadicRatCore$^{\uparrow}$ tolerance ledger over one finite StreamName$^{\uparrow}$ window ledger.

The forbidden exports are absent from the carrier and from all accepted classifier transports. Therefore the public Real-and-Completion surface consists exactly of the ordered observer route together with H, C, P, N and the cited finite certificate rows. □

The Lean TasteGate surface records Nontrivial and FieldFaithful instances for the packet fields.

Closure status for NameCert$_{\text{DiagonalLimitObserver}^{\uparrow}}$**.**

Constructive story: A DiagonalLimitObserver$^{\uparrow}$ packet is generated from a diagonal RealCompleteness$^{\uparrow}$ source row, finite StreamName$^{\uparrow}$ windows, RegSeqRat$^{\uparrow}$ readback, DyadicRatCore$^{\uparrow}$ tolerance ledger, CauchyLimitSeal$^{\uparrow}$ route, Real$^{\uparrow}$ seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{DiagonalLimitObserver}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 961.1, Definition 961.2, Definition 961.3, Definition 961.4, Definition 961.5, and Definition 961.6 bind the observer-facing diagonal route to finite StreamName windows, RegSeqRat readback, Dyadic tolerance, CauchyLimitSeal, RealUp seal, transport, route, provenance, NameCert rows, and the public Real-and-Completion export surface.

Formal verification: FormalStatus(NameCert$_{\text{DiagonalLimitObserver}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.DiagonalLimitObserverUp.DiagonalLimitObserverTasteGate\_single\_carrier\_alignment` Lean4 ✓ `BEDC.Derived.DiagonalLimitObserverUp.taste gate`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, quotient streams, selected host limits, host real equality, hidden observer budgets, alternate tolerance ledgers, or ambient completeness for DiagonalLimitObserver$^{\uparrow}$.

Upgrade path: No further paper-axis grade remains for this observer package; Lean verification and bridge checking stay on the separate verification axis.

Chapter 962

A Concrete Naming Certificate for $\mathsf{TotalHostFuelHandoff}^{\uparrow}$

The $\mathsf{TotalHostFuelHandoff}^{\uparrow}$ packet is the finite handoff object between the total host of chapter 9370 and the universal substrate traces represented by chapter 944. It is narrower than $\mathsf{StepIndexedTotalHost}^{\uparrow}$: it does not package the whole host normal-form comparison surface, but instead fixes the boundary at which a total host supplies finite fuel, the substrate displays the bounded trace, and the terminal readback returns through the same fuel certificate.

Falsifiable prediction: Removing the fuel handoff row permits a terminal substrate read without a displayed total-host fuel boundary.

Independence witness: znormal, bounded-universal-trace, cellularautomaton, turingmachine, continuationtrace: none is bijective because the handoff packet carries the fuel boundary between total host and substrate trace rather than only normality, trace, substrate, machine, or continuation rows.

Definition 962.1 (Total-host fuel handoff carrier)**.** *A* $\mathsf{TotalHostFuelHandoff}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (H, F, S, T, R, B, X, C, P, N)$$

with the following displayed rows:

1. *H is the total-host source row whose public read is accepted only at a finite boundary;*
2. *F is the fuel handoff row naming the host-visible finite budget supplied to the substrate read;*
3. *S is the substrate row, drawn from a displayed* $\mathsf{CellularAutomaton}^{\uparrow}$ *or* $\mathsf{TuringMachine}^{\uparrow}$ *interface;*
4. *T is the finite trace row, read as a* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger below the fuel boundary F;*
5. *R is the terminal readback row selected from T under the same fuel boundary;*
6. *B is the refusal ledger for missing fuel, detached terminal readback, unbounded halting, partial evaluator transfer, host-substrate equality, and quotient behaviour;*
7. *X records componentwise* hsame *transports for H, F, S, T, R, B, P, N;*
8. *C records displayed* Cont *routes from H to F, from F to S, T, from T to R, and from every excluded semantic claim to B;*
9. *P is the* Pkg *provenance over* $\mathsf{TotalHostFuelHandoff}^{\uparrow}$, $\mathsf{BoundedUniversalTrace}^{\uparrow}$, $\mathsf{ContinuationTrace}^{\uparrow}$, $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{TuringMachine}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*

10. N is the local $\mathsf{NameCert}_{\mathsf{TotalHostFuelHandoff}^{\uparrow}}$ *row.*
The local classifier compares accepted packets only through $H, F, S, T, R, B, X, C, P, N$. It has no coordinate for an infinite substrate run, a host partial evaluator, a global halting predicate, host equality with the substrate, quotient stream behaviour, or a terminal readback detached from the finite fuel handoff.

Lean4 (definition) `BEDC.Derived.TotalHostFuelHandoffUp.TotalHostFuelHandoffUp`

Theorem 962.2 (TotalHostFuelHandoff NameCert obligations)**.** *For the carrier of Definition 962.1, the local* $\mathsf{NameCert}_{\mathsf{TotalHostFuelHandoff}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$Q = (H, F, S, T, R, B, X, C, P, N),$$

total-host exposure through H, finite fuel handoff through F, substrate exposure through S, bounded trace exposure through T, terminal readback through R, refusal-ledger exactness through B, componentwise transport through X, displayed continuation replay through C, package provenance through P, and local naming through N.

Proof. Project the carrier of Definition 962.1. The accepted packet displays exactly $H, F, S, T, R, B, X, C, P, N$, so every public read is either one of those rows or a route replaying them.

The computational route is finite. The host row H reaches the substrate only through the fuel row F, the substrate and trace rows S, T are read below that same boundary, and the terminal readback R is selected from the displayed trace.

The structural rows bind the public certificate. The transports X, routes C, provenance P, and local naming row N keep the handoff inside BHist, hsame, Cont, Pkg, and NameCert.

Since the carrier has no further coordinate, unbounded halting, partial evaluator transfer, host-substrate equality, quotient behaviour, and detached terminal readback are refused by B rather than exported as NameCert obligations. □

Lean4 ✓ `BEDC.Derived.TotalHostFuelHandoffUp.TotalHostFuelHandoffNameCertObligations`

Theorem 962.3 (TotalHostFuelHandoff carrier admission)**.** *An accepted* $\mathsf{TotalHostFuelHandoff}^{\uparrow}$ *handoff packet may expose a terminal readback only after the carrier has displayed exactly*

$$H, F, S, T, R, B, X, C, P, N.$$

The public terminal readback row R is therefore admitted only as the row selected from the substrate trace T under the same finite fuel boundary F, with the refusal ledger B, transports X, route row C, provenance P, and local name N still present.

Proof. Project the carrier in Definition 962.1. Its coordinates are the total-host source H, fuel boundary F, substrate row S, finite trace T, terminal readback R, refusal ledger B, transport row X, route row C, provenance row P, and local name N.

Read the terminal row through the displayed Cont route. The route reaches R only after H has supplied F and after S, T have been read below that same boundary.

The remaining rows make the admission public rather than semantic. The refusal ledger records missing-fuel and detached-readback failures, while X, P, N keep the packet inside the local BHist, Pkg, and NameCert surface. □

Lean4 ✓ `BEDC.Derived.TotalHostFuelHandoffUp.TotalHostFuelHandoffCarrierAdmission`

Theorem 962.4 (TotalHostFuelHandoff fuel monotonicity)**.** *Replacing the displayed fuel row F of an accepted* $\mathsf{TotalHostFuelHandoff}^{\uparrow}$ *packet by a smaller displayed budget can only shorten the substrate trace and terminal readback route. It cannot create a new terminal readback row outside*

$$H, F, S, T, R, B, X, C, P, N,$$

and it cannot turn an excluded unbounded halting, partial evaluator, host-substrate equality, quotient behaviour, or detached terminal-readback claim into a public output.

Proof. Use the displayed route row C. Lowering the fuel budget restricts the part of the substrate trace T that may be replayed before the terminal readback row is selected.

The carrier has no coordinate for inventing a readback after this restriction. Any public read must still pass through $H, F, S, T, R, B, X, C, P, N$, so a smaller F can remove available trace entries but cannot add a new row.

Finally retain the refusal ledger B. Claims requiring more fuel, an unbounded run, a partial evaluator, a host-substrate equality coordinate, quotient behaviour, or a detached terminal oracle remain in the refused side of the packet. □

Lean4 ✓ `BEDC.Derived.TotalHostFuelHandoffUp.TotalHostFuelHandoffFuelMonotonicity`

Theorem 962.5 (TotalHostFuelHandoff non-escape)**.** *Every accepted* $\mathsf{TotalHostFuelHandoff}^{\uparrow}$ *packet exports no terminal substrate read except through the finite route*

$$H, F, S, T, R, B, X, C, P, N.$$

In particular, it exports no unbounded halting predicate, no host partial evaluator, no equality between host computation and substrate trace, no quotient behaviour, no independent terminal readback oracle, and no transfer of substrate universality into the total host.

Proof. Begin with the displayed route row C. Its admissible paths pass from the total-host source H to the fuel handoff F, then through the substrate row S and finite trace ledger T, and only then to the terminal readback R.

The fuel row is the boundary object. Without F, the packet may still mention a substrate or a terminal shape, but it no longer exhibits the finite host-visible budget required to read that terminal row in a total host.

The refusal ledger accounts for every excluded claim. Unbounded halting needs a global run predicate, a host partial evaluator needs a host semantic execution row, host-substrate equality needs an equality coordinate, quotient behaviour needs a quotient classifier, and transfer of substrate universality needs a semantic bridge absent from the carrier.

Thus the handoff exposes a finite terminal readback while preserving the separation required by chapter 9370. □

Lean4 ✓ `BEDC.Derived.TotalHostFuelHandoffUp.TotalHostFuelHandoffNonescape`

Theorem 962.6 (TotalHostFuelHandoff sibling boundary)**.** *The siblings* $\mathsf{ZNormal}^{\uparrow}$, $\mathsf{BoundedUniversalTrace}^{\uparrow}$, $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{TuringMachine}^{\uparrow}$, *and* $\mathsf{ContinuationTrace}^{\uparrow}$ *are comparison anchors for* $\mathsf{TotalHostFuelHandoff}^{\uparrow}$, *but none is bijective to it.* $\mathsf{ZNormal}^{\uparrow}$ *stores a host normality boundary without the substrate terminal handoff;* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *stores a bounded trace without the total-host fuel handoff row;* $\mathsf{CellularAutomaton}^{\uparrow}$ *and* $\mathsf{TuringMachine}^{\uparrow}$ *store substrate surfaces without the host boundary; and* $\mathsf{ContinuationTrace}^{\uparrow}$ *stores finite continuation rows without the total-host source and NameCert handoff surface.*

Proof. Read the siblings by their missing coordinates. The normal-form sibling accounts for finite host normality, but it does not carry the substrate row, finite trace ledger, or terminal readback selected below host fuel.

The bounded trace sibling is closest to F, S, T, R. It still does not isolate the handoff row as the boundary between total-host source and substrate trace, nor does it carry the refusal surface for detached terminal readback.

The substrate and continuation siblings point to components rather than the whole handoff. They supply machine, cellular, or finite continuation rows, but they do not package $H, F, S, T, R, B, X, C, P, N$ together as a total-host fuel certificate.

Consequently the $\mathsf{TotalHostFuelHandoff}^{\uparrow}$ packet is the concrete interface object for terminal readback across the total-host and substrate-trace boundary. □

Lean4 ✓ `BEDC.Derived.TotalHostFuelHandoffUp.TotalHostFuelHandoffSiblingBoundary`

Lean4 ✓ `BEDC.Derived.TotalHostFuelHandoffUp.TotalHostFuelHandoffTasteGate single carrier alignment`

The Lean `lean4/BEDC/Derived/TotalHostFuelHandoffUp/TasteGate.lean` development must include explicit $\mathsf{Nontrivial\ TotalHostFuelHandoff}^{\uparrow}$ and $\mathsf{FieldFaithful\ TotalHostFuelHandoff}^{\uparrow}$ instances. These instances must preserve the total-host source row, fuel handoff row, substrate row, finite trace row, terminal readback row, refusal ledger, componentwise transports, displayed continuation routes, package provenance, and local naming row.

Closure status for $\mathsf{NameCert}_{\mathsf{TotalHostFuelHandoff}^{\uparrow}}$.

Constructive story: A $\mathsf{TotalHostFuelHandoff}^{\uparrow}$ packet is generated from a total-host source row, finite fuel handoff row, substrate row, finite trace row, terminal readback row, refusal ledger, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TotalHostFuelHandoff}^{\uparrow}}, \mathsf{obligation})$

Scope closed: Definition 962.1, Definition 962.2, Definition 962.5, Definition 962.6, and the checked TasteGate marker specify the finite fuel handoff packet and its NameCert obligation surface between total host and substrate trace.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TotalHostFuelHandoff}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, unbounded halting, partial evaluator semantics, host-substrate equality, quotient behaviour, or transfer of substrate universality to the total host.

Upgrade path: Obligation closure requires checked carrier admission, fuel handoff exposure, substrate-trace exposure, terminal-readback exactness, refusal-ledger exactness, nontriviality, and field faithfulness for the same packet.

Chapter 963

A Concrete Naming Certificate for FuelBoundedPartialTrace$^{\uparrow}$

The FuelBoundedPartialTrace$^{\uparrow}$ packet is the finite NameCert realization of the total-host versus universal-substrate boundary of chapter 9370. It takes the step-indexed computation reading of `r110_run_n_steps`, exposes the fuel row as public data, and records only the bounded trace cells that a total host can inspect. The packet sits beside BoundedUniversalTrace$^{\uparrow}$, CellularAutomaton$^{\uparrow}$, ZNormal$^{\uparrow}$, TypedReductionNormalForm$^{\uparrow}$, and MetaCICNormalizationBudget$^{\uparrow}$; it is not a halting claim, a partial evaluator, a quotient trace, or an ambient universality surface.

Falsifiable prediction: A trace read without the displayed fuel row is not accepted by FuelBoundedPartialTrace$^{\uparrow}$.

Independence witness: boundeduniversaltrace, cellularautomaton, znormal, typedreduction-normalform, metacicnormalizationbudget: none is bijective to FuelBoundedPartialTrace$^{\uparrow}$ because the packet binds a fuel row, substrate row, finite prefix trace, readback row, and total-host refusal row in one carrier, while each sibling omits at least one of those coordinates or uses a different classifier surface.

FuelBoundedPartialTrace$^{\uparrow}$ consumes chapter 944 as the larger total-host bounded-trace surface and chapter 469 as the finite prefix ledger. Its own contribution is the partial-trace fuel and refusal specialization over those sibling surfaces, not a standalone substrate.

Definition 963.1 (FuelBoundedPartialTrace carrier)**.** *A* FuelBoundedPartialTrace$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (F, S, I, R, O, B, H, C, P, N)$$

with the following displayed rows:

1. *F is the fuel row naming the finite step budget used by the host read;*
2. *S is the substrate row, such as the* CellularAutomaton$^{\uparrow}$ *Rule 110 local-rule surface or another displayed universal-substrate row;*
3. *I is the initial-data row for the bounded run;*
4. *R is the finite trace-prefix row containing only states admitted below the budget F;*
5. *O is the readback row selected from the displayed prefix R;*
6. *B is the total-host refusal row stating that reads outside the displayed budget are absent rather than negative halting facts;*

7. *H records componentwise* hsame *transports for F, S, I, R, O, B, P, N;*
8. *C records displayed* Cont *routes through the step-indexed trace prefix, readback row, and refusal boundary;*
9. *P is the* Pkg *provenance over* $\mathsf{FuelBoundedPartialTrace}^{\uparrow}$*, chapter 9370,* $\mathsf{BoundedUniversalTrace}^{\uparrow}$*,* $\mathsf{CellularAutomaton}^{\uparrow}$*,* $\mathsf{ZNormal}^{\uparrow}$*,* $\mathsf{TypedReductionNormalForm}^{\uparrow}$*,* $\mathsf{MetaCICNormalizationBudget}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{FuelBoundedPartialTrace}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through the displayed rows $F, S, I, R, O, B, H, C, P, N$. It has no coordinate for an unbounded halting predicate, a partial host evaluator, a choice of infinite nontermination evidence, quotient equality of traces, or a universal-substrate semantic completion.

```
↪ variant BEDC.Derived.FuelBoundedPartialTraceUp.FuelBoundedPartialTraceTasteGate single carrier alignment
```

Theorem 963.2 (FuelBoundedPartialTrace NameCert obligations)**.** *For the carrier of Definition 963.1, the local* $\mathsf{NameCert}_{\mathsf{FuelBoundedPartialTrace}^{\uparrow}}$ *surface consists exactly of carrier admission for $T = (F, S, I, R, O, B, H, C, P, N)$, fuel-indexed trace exposure through F, S, I, R, readback accountability through O, total-host refusal through B, componentwise transport through H, route replay through C, provenance through P, and local naming through N.*

Proof. Project the carrier of Definition 963.1. The fuel, substrate, initial-data, trace-prefix, readback, refusal, transport, route, provenance, and naming rows are the only public coordinates.

The trace side is read through F, S, I, R. A consumer may inspect a finite prefix produced below the displayed budget, but the packet contains no coordinate for an unbounded run or a host-level partial evaluator.

The readback and refusal side is read through O and B. The selected row O must come from the displayed prefix R, while B records that an out-of-budget read is absent at this certificate surface rather than represented as a halting or nonhalting fact.

Finally H, C, P, N bind the NameCert surface. Since the excluded semantic objects have no coordinate in the packet, the listed rows exhaust the obligations. □

Theorem 963.3 (FuelBoundedPartialTrace total-host refusal)**.** *An accepted* $\mathsf{FuelBoundedPartialTrace}^{\uparrow}$ *packet admits a public trace read only when the read factors through the displayed fuel row F and finite trace prefix R. A consumer that omits F, replaces R by an unbounded substrate run, or asks for a row beyond the displayed budget reaches the refusal row B and obtains no halting predicate, no partial evaluator result, no quotient trace equality, and no ambient universality claim.*

Proof. Begin with the carrier coordinates. The only computation-facing rows are the budget F, substrate S, initial data I, trace prefix R, readback row O, and refusal row B.

If a read is in budget, the route row C sends it through F and the displayed prefix R before reaching O. This is a finite step-indexed read of the kind described in Definition 9370.5.

If the read omits the budget or asks outside the displayed prefix, the packet has no terminal coordinate to expose. The refusal row B is therefore the only public boundary, and it refuses by absence of a displayed finite row rather than by importing halting, partiality, quotient equality, or universal-substrate semantics. □

The Lean follow-up for BEDC.Derived.FuelBoundedPartialTraceUp will provide Nontrivial FuelBoundedPartialTrace and FieldFaithful $\mathsf{FuelBoundedPartialTrace}^{\uparrow}$ instances for the displayed carrier. Those instances must

preserve the fuel row, substrate row, initial-data row, trace-prefix row, readback row, refusal row, componentwise transports, replay routes, package provenance, and local naming row.

Closure status for $\mathsf{NameCert}_{\mathsf{FuelBoundedPartialTrace}^{\uparrow}}$ **.**

Constructive story: A $\mathsf{FuelBoundedPartialTrace}^{\uparrow}$ packet is generated from a fuel row, substrate row, initial-data row, finite trace-prefix row, readback row, total-host refusal row, componentwise transports, displayed routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FuelBoundedPartialTrace}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 963.1, Definition 963.2, and Definition 963.3 specify the finite fuel-bounded trace packet for total-host reads of universal-substrate computations.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FuelBoundedPartialTrace}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, unbounded halting, partial evaluator semantics, quotient trace equality, selected nontermination evidence, or universal-substrate semantic completion.

Upgrade path: Obligation closure requires checked carrier admission, fuel-indexed trace exposure, readback accountability, total-host refusal, nontriviality, and field faithfulness for the same packet.

Chapter 964

A Concrete Naming Certificate for $\mathsf{StepIndexedTotalHost}^{\uparrow}$

The $\mathsf{StepIndexedTotalHost}^{\uparrow}$ packet is the concrete NameCert object for the boundary between a total host and a universal substrate in chapter 9370. It sits beside the Turing-machine substrate of chapter 280, the bounded universal trace of chapter 944, the normal-form host packet of chapter 936, and the closed-normal consistency boundary of chapter 733. Its distinguishing datum is the simultaneous presence of a total host row, a unary fuel row, a finite universal-substrate trace row, and a refusal ledger preventing an unbounded substrate run from being reread as host computation.

Falsifiable prediction: Deleting the fuel row permits an unbounded substrate trace to masquerade as host computation; the local classifier must reject that packet because the host-side read no longer passes through a displayed finite fuel index.

Independence witness: turingmachine, boundeduniversaltrace, znormal, closednormalconsistency: none is bijective because each sibling omits at least one of the fuel-indexed host boundary, the substrate trace, or the refusal ledger.

Definition 964.1 (StepIndexedTotalHost carrier)**.** *A* $\mathsf{StepIndexedTotalHost}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$H = (A, F, R, N, Z, B, Hs, C, P, K)$$

with the following displayed rows:

1. *A is the total host term or evaluator row, read as a BEDC host computation whose reduction is accepted only through finite data;*
2. *F is the unary fuel row naming the finite host-visible step index;*
3. *R is the finite substrate trace row, such as a Rule 110 row produced by* `r110_run_n_steps` *or a Turing-machine trace row with the same displayed bound;*
4. *N is the host normal-form boundary row, read through the finite normal-form discipline of* $\mathsf{ZNormal}^{\uparrow}$*;*
5. *Z is the bounded universal trace witness row, read through* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *and tied to the same fuel row F;*
6. *B is the refusal ledger for halting transfer, partial evaluator transfer, missing fuel, detached substrate trace, and host-equality claims not carried by the packet;*

7. *Hs records componentwise* hsame *transports for A, F, R, N, Z, B, P, K;*
8. *C records displayed* Cont *routes from host row to fuel, from fuel to finite substrate trace, from trace to bounded readback, from bounded readback to normal-form boundary, and from each absent semantic claim to the refusal ledger;*
9. *P is the* Pkg *provenance over* StepIndexedTotalHost$^{\uparrow}$, TuringMachine$^{\uparrow}$, BoundedUniversalTrace$^{\uparrow}$, ZNormal$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
10. *K is the local* NameCert$_{\text{StepIndexedTotalHost}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through $A, F, R, N, Z, B, Hs, C, P, K$. It has no coordinate for unbounded halting, an infinite Rule 110 orbit, host evaluator equality, quotient behaviour, or a proof that substrate universality transfers to the total host.

Lean4 ✓ `BEDC.Derived.StepIndexedTotalHostUp.StepIndexedTotalHostTasteGate single carrier alignment`

Theorem 964.2 (StepIndexedTotalHost NameCert obligations)**.** *For the carrier of Definition 964.1, the local* NameCert$_{\text{StepIndexedTotalHost}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$H = (A, F, R, N, Z, B, Hs, C, P, K),$$

total-host exposure through A, unary fuel exposure through F, finite substrate-trace exposure through R, host normal-form boundary exposure through N, bounded universal trace witness exposure through Z, refusal-ledger exactness through B, componentwise transport through Hs, displayed continuation replay through C, package provenance through P, and local naming through K.

Lean4 ✓ `BEDC.Derived.StepIndexedTotalHostUp.StepIndexedTotalHostCarrier namecert obligations`

Proof. Project the carrier of Definition 964.1. Its visible rows are exactly $A, F, R, N, Z, B, Hs, C, P, K$, so every public read must be a projection from those rows or a route replaying them.

The host-facing side is read through A, F, N. The row A names the total host term or evaluator row, F supplies the finite fuel index, and N records the normal-form boundary available to the host.

The substrate-facing side is read through R, Z. The trace row R records a finite Rule 110 or Turing-machine prefix, while Z ties that prefix to the bounded universal trace witness at the same fuel index.

Finally B, Hs, C, P, K bind the refusal and NameCert surface. Since the carrier has no coordinate for unbounded halting, infinite orbit data, host evaluator equality, quotient behaviour, or transfer of substrate universality to host totality, the listed rows exhaust the obligations. □

Theorem 964.3 (StepIndexedTotalHost separation)**.** *Every accepted* StepIndexedTotalHost$^{\uparrow}$ *packet separates the total-host read from the universal-substrate run by the finite route*

$$A, F, R, Z, N, B, Hs, C, P, K.$$

A consumer may read a host computation at fuel F, a finite substrate trace R, a bounded witness Z, and a normal-form boundary N. It may not read an unbounded substrate trace as host computation, transfer halting or partial evaluator behaviour across the boundary, or replace the refusal ledger B by a semantic equality between the host and the substrate.

Proof. Begin with the finite route row C. Its admissible paths pass from the host row A to the fuel row F, then to the displayed substrate trace R and bounded witness Z, and only then to the host normal-form boundary N.

The fuel row is essential. If F is absent, the packet still may display a substrate trace schema, but the host has no finite step index under which to read it as a total computation. The refusal ledger B therefore rejects the packet rather than accepting an unbounded run as host data.

The same ledger blocks semantic transfer. Halting transfer, partial evaluator transfer, infinite orbit claims, host evaluator equality, and quotient behaviour require coordinates absent from $A, F, R, N, Z, B, Hs, C, P, K$.

Thus the packet preserves both sides of chapter 9370: the substrate may carry universal finite prefixes, while the host reads only fuel-indexed finite data. □

Lean4 ✓ `BEDC.Derived.StepIndexedTotalHostUp.StepIndexedTotalHostCarrier separation`

Theorem 964.4 (StepIndexedTotalHost sibling boundary)**.** *The siblings* $\mathsf{TuringMachine}^{\uparrow}$, $\mathsf{BoundedUniversalTrace}^{\uparrow}$, $\mathsf{ZNormal}^{\uparrow}$, *and the closed-normal consistency boundary are comparison anchors for* $\mathsf{StepIndexedTotalHost}^{\uparrow}$, *but none is bijective to it.* $\mathsf{TuringMachine}^{\uparrow}$ *supplies machine substrate rows without the host normal-form boundary;* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *supplies a bounded trace without the full total-host refusal surface;* $\mathsf{ZNormal}^{\uparrow}$ *supplies host normality without the universal-substrate trace; and the closed-normal consistency boundary supplies a normal-form consistency node without the step-indexed substrate witness.*

Proof. Read the siblings one at a time. The Turing-machine surface names finite machine data, but it does not carry the host row A, the normal-form boundary N, or the refusal ledger B for total-host transfer.

The bounded universal trace supplies the rows closest to F, R, Z. It still lacks the full packet route from host term to normal-form boundary and the refusal ledger blocking host-substrate semantic identification.

The normal-form and closed-normal consistency siblings point in the other direction. They account for finite normality and consistency-facing boundaries, but they do not carry the Rule 110 or Turing-machine substrate trace tied to the same fuel row.

Consequently each sibling can be cited as a component or comparison anchor, while the $\mathsf{StepIndexedTotalHost}^{\uparrow}$ packet remains the concrete boundary object that stores all rows together. □

Theorem 964.5 (StepIndexedTotalHost obligation surface)**.** *The fuel-indexed total-host packet has exactly the obligations of total-host row exposure through A, unary fuel exposure through F, finite substrate trace exposure through R, normal-form boundary exposure through N, bounded universal trace witness exposure through Z, refusal-ledger exactness through B, componentwise* hsame *transport through Hs, displayed* Cont *replay through C,* Pkg *provenance through P, and local* $\mathsf{NameCert}_{\mathsf{StepIndexedTotalHost}^{\uparrow}}$ *through K. Every host/substrate comparison must pass through the same fuel row F before any normal-form read or bounded universal trace read is accepted.*

Lean4 ✓ `BEDC.Derived.StepIndexedTotalHostUp.StepIndexedTotalHostCarrier obligation surface`

Proof. Start with the carrier and NameCert obligations, Definition 964.1 and Definition 964.2. They list the total-host row, unary fuel row, finite substrate trace, normal-form boundary, bounded universal trace witness, refusal ledger, transport, replay, provenance, and local name as the complete obligation surface.

Use the separation theorem. It routes every host-facing and substrate-facing read through $A, F, R, Z, N, B, Hs, C, P, K$, so the fuel row F is the shared boundary before either the normal-form row N or bounded universal trace row Z can be inspected.

Apply the sibling boundary theorem. The Turing-machine, bounded universal trace, normal-form, and closed-normal consistency siblings can each provide comparison data, but none replaces the displayed fuel row or the refusal ledger that keeps host and substrate readings separated. □

The Lean `TasteGate.lean` development for $\mathsf{StepIndexedTotalHost}^{\uparrow}$ must include explicit $\mathsf{Nontrivial\ StepIndexedT}$ and $\mathsf{FieldFaithful\ StepIndexedTotalHost}^{\uparrow}$ instances. These instances must preserve the total host row, unary fuel row, finite substrate trace, normal-form boundary, bounded universal trace witness, refusal ledger, componentwise transports, displayed routes, package provenance, and local naming row.

Theorem 964.6 (StepIndexedTotalHost scoped-kernel route)**.** *Every accepted* $\mathsf{StepIndexedTotalHost}^{\uparrow}$ *scoped-kernel read factors through* BHist, hsame, Cont, $\mathsf{BoundedUniversalTrace}^{\uparrow}$, $\mathsf{TypedReductionNormalForm}^{\uparrow}$, *the displayed* $\mathsf{StepIndexedTotalHost}^{\uparrow}$ *carrier rows,* Pkg *provenance, and* $\mathsf{NameCert}$*. The route is finite: it exposes carrier admission, fuel-indexed trace rows, host normal-form boundary, bounded universal trace witness, refusal-ledger exactness, nontriviality, and field faithfulness for the same packet, but it does not assert host evaluator equality, kernel consistency, unbounded halting transfer, or substrate universality for the total host.*

Lean4 ✓ `BEDC.Derived.StepIndexedTotalHostUp.StepIndexedTotalHostCarrier scoped kernel route`

Proof. Start with the carrier and NameCert obligations, Definition 964.1 and Definition 964.2. They expose the total host row, unary fuel row, finite substrate trace, normal-form boundary, bounded universal trace witness, refusal ledger, componentwise transports, route replay, provenance, and local naming row.

Apply separation and the sibling boundary theorem, Definition 964.3 and Definition 964.4. These route the substrate side through $\mathsf{BoundedUniversalTrace}^{\uparrow}$ and the host boundary through $\mathsf{TypedReductionNormalForm}^{\uparrow}$ before either side can be compared.

Finally use the obligation surface theorem. It keeps the packet inside the same finite $A, F, R, N, Z, B, Hs, C, P, K$ rows, with nontriviality and field faithfulness read as obligations of that displayed carrier rather than as ambient semantic equalities. Hence the scoped route has no coordinate for host evaluator equality, kernel consistency, unbounded halting transfer, or total-host universality. □

Theorem 964.7 (StepIndexedTotalHost public interface)**.** *The exported public interface of an accepted* $\mathsf{StepIndexedTotalHost}^{\uparrow}$ *packet is exactly the fuel-indexed host/substrate boundary carried by* $A, F, R, N, Z, B, Hs, C, P, K$*. A public consumer may read the total-host row, the shared unary fuel row, the finite substrate trace, the host normal-form boundary, the bounded universal trace witness, the refusal ledger, and the displayed transport, replay, provenance, and local naming rows. The interface does not export host evaluator equality, kernel consistency, unbounded halting transfer, partial evaluator semantics, quotient behaviour, or substrate universality for the total host.*

Lean4 ✓ `BEDC.Derived.StepIndexedTotalHostUp.StepIndexedTotalHostCarrier public interface`

Proof. Start with the scoped-kernel route of Definition 964.6. It already factors every accepted read through the carrier rows, the bounded universal trace boundary, the normal-form host boundary, and the local NameCert surface.

Apply the obligation surface and separation theorems, Definition 964.5 and Definition 964.3. These identify $A, F, R, N, Z, B, Hs, C, P, K$ as the only rows through which a host/substrate comparison may pass, with F as the shared finite boundary.

Finally use the sibling boundary of Definition 964.4. The Turing-machine, bounded-trace, normal-form, and closed-normal siblings can be cited as anchors, but none supplies the missing semantic endpoints. Hence the public interface exports the displayed finite packet and nothing beyond it. □

Theorem 964.8 (StepIndexedTotalHost bridge interface)**.** *The public fuel-indexed* $\mathsf{StepIndexedTotalHost}^{\uparrow}$ *interface bridges the total-host read and the bounded universal trace read exactly through*

$$A, F, R, N, Z, B, Hs, C, P, K.$$

A consumer may transport the host row A to the shared fuel row F, replay the finite substrate trace R, read the bounded universal witness Z, and return to the normal-form host boundary N. The bridge does not export unbounded halting, partial evaluator transfer, host evaluator equality, quotient behaviour, or a proof that substrate universality is a total-host property.

Lean4 ✓ `BEDC.Derived.StepIndexedTotalHostUp.StepIndexedTotalHostCarrier bridge interface`

Proof. Start with the public interface theorem, Definition 964.7. It exposes exactly the rows $A, F, R, N, Z, B, Hs, C, P, K$ and no semantic endpoint outside the finite packet.

Use the separation and obligation-surface theorems, Definition 964.3 and Definition 964.5. They force host/substrate comparison through the shared fuel row F before either the bounded universal trace witness Z or the normal-form boundary N is read.

Finally apply the sibling boundary. The Turing-machine, bounded universal trace, normal-form, and closed-normal consistency chapters provide bridge anchors, while the refusal ledger B blocks the absent unbounded and equality claims. Hence the public interface is a bridge between the displayed finite reads, not an export of stronger host or substrate semantics. □

Closure status for $\mathsf{NameCert}_{\mathsf{StepIndexedTotalHost}^{\uparrow}}$.

Constructive story: A $\mathsf{StepIndexedTotalHost}^{\uparrow}$ packet is generated from a total host term or evaluator row, unary fuel row, finite substrate trace row, normal-form boundary row, bounded universal trace witness row, refusal ledger, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{StepIndexedTotalHost}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 964.1, Definition 964.2, Definition 964.3, Definition 964.4, Definition 964.5, Definition 964.6, Definition 964.7, and Definition 964.8 specify the mature fuel-indexed total-host and universal-substrate boundary through the checked bridge-interface theorem.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{StepIndexedTotalHost}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, unbounded halting, partial evaluator semantics, host evaluator equality, quotient behaviour, or transfer of substrate universality to the total host.

Upgrade path: The mature paper scope is the fuel-indexed total-host/substrate boundary through the checked bridge interface; Lean verification remains an independent formal-axis obligation.

Chapter 965

A Concrete Naming Certificate for $\mathsf{PromptResponseTrace}^{\uparrow}$

The $\mathsf{PromptResponseTrace}^{\uparrow}$ packet realizes the large-model prompt and output record as finite BEDC data. It sits between chapter 939 and chapter 928: the former supplies the inference-substrate and corpus-supply reading, while the latter supplies the public observer-facing interface. The packet also keeps the obstruction boundary of chapter 490 visible, so a prompt-output record is not read as a global decision or internally ratified universal claim.

Definition 965.1 (PromptResponseTrace carrier)**.** *A* $\mathsf{PromptResponseTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (M, C, P, O, A, F, R, H, K, G, N)$$

with the following displayed rows:

1. *M is the* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *row naming the finite inference substrate, corpus-supply channel, output-record surface, and audit-refusal boundary;*
2. *C is the source-channel row recording the finite corpus-supply and prompt-entry provenance used by the trace;*
3. *P is the prompt row, a finite inscription request read through the displayed source channel;*
4. *O is the output row, a finite response inscription emitted after P along the recorded model route;*
5. *A is the audit-refusal row stating that the packet does not internally ratify universal closure, host semantic truth, consciousness, or model-side proof of the output;*
6. *F is the* $\mathsf{ObserverInterface}^{\uparrow}$ *row through which public observers may read the prompt, response, source channel, and refusal boundary;*
7. *R is the* $\mathsf{HaltingObstruction}^{\uparrow}$ *boundary row, recording that the prompt-response trace is not a global halting or decision oracle;*
8. *H records componentwise* hsame *transport for the model row, source-channel row, prompt row, output row, audit-refusal row, observer-interface row, obstruction boundary, route row, provenance row, and local name;*
9. *K records the displayed* Cont *routes by which consumers read C, then P, then O, then A, then F and R;*

10. *G is the* Pkg *provenance over* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$, $\mathsf{ObserverInterface}^{\uparrow}$, $\mathsf{HaltingObstruction}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{PromptResponseTrace}^{\uparrow}}$ *row.*

The carrier has no coordinate for hidden model intention, corpus-wide truth, host semantic understanding, quotient identity of outputs, global halting classification, or internally certified universal closure.

Lean4 ✓ `BEDC.Derived.PromptResponseTraceUp.PromptResponseTraceTasteGate single carrier alignment`

Theorem 965.2 (PromptResponseTrace NameCert obligations)**.** *For the carrier of Definition 965.1, the local* $\mathsf{NameCert}_{\mathsf{PromptResponseTrace}^{\uparrow}}$ *surface consists exactly of carrier admission for* $T = (M, C, P, O, A, F, R, H, K$ *source-channel exposure through C, prompt admission through P, response inscription through O, audit-refusal exposure through A, observer-interface handoff through F, halting-obstruction boundary through R, componentwise* hsame *transport through H, displayed* Cont *replay through K, package provenance through G, and local naming through N.*

Proof. Project the displayed carrier. The rows $M, C, P, O, A, F, R, H, K, G, N$ list the whole trace before any consumer can read a prompt or response.

The source-channel row is read before the prompt row, and the prompt row is read before the output row. This forces the response to be consumed as carried inscription over a finite channel rather than as a self-ratified theorem of the model.

The audit-refusal, observer-interface, and obstruction rows close the local certificate surface. The refusal row blocks internally ratified universal closure, the interface row gives the public observation route, and the obstruction row prevents the trace from becoming a global decision oracle.

The remaining rows provide only transport, route replay, provenance, and local naming. Since the carrier has no further coordinate, the listed obligations exhaust the NameCert surface. □

Theorem 965.3 (PromptResponseTrace audit refusal)**.** *Every public read of an accepted* $\mathsf{PromptResponseTrace}^{\uparrow}$ *packet must pass through the audit-refusal row A after the prompt-output rows P, O and before the local naming row N. Removing A permits the prompt-response packet to be read as an internally ratified universal claim; retaining A confines the packet to finite source-channel, prompt, response, observer-interface, and obstruction-boundary rows.*

Proof. Begin with Definition 965.1. The only route from the prompt and response rows to the local name passes through the displayed continuation row K, and K lists the audit-refusal row before the public handoff reaches N.

Apply Definition 965.2. The local certificate surface requires audit-refusal exposure as one of the rows of any accepted prompt-response trace.

If A is removed, the route still contains P and O but no row recording the absence of internal ratification. A consumer could then read the output as if the packet itself certified a universal claim.

With A present, the public read is confined to the finite source-channel, prompt, response, observer-interface, obstruction-boundary, transport, route, provenance, and naming rows. No host semantic truth predicate or model-side proof coordinate is available. □

Theorem 965.4 (PromptResponseTrace vision handoff)**.** *The large-model prompt and output reading of chapter 9398 is realized by the finite* $\mathsf{PromptResponseTrace}^{\uparrow}$ *carrier of Definition 965.1. The handoff reads* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *for the inference substrate and corpus-supply row,*

$\mathsf{ObserverInterface}^{\uparrow}$ *for public trace observation, and* $\mathsf{HaltingObstruction}^{\uparrow}$ *for the finite non-oracle boundary. It exports no hidden substrate oracle, consciousness coordinate, global halting classifier, or internally certified universal closure.*

Proof. The large-model inscription chapter supplies the model-side finite rows: inference substrate, corpus-supply, output record, and audit refusal. These are read into M, C, O, A rather than into a hidden semantic oracle.

The observer-interface chapter supplies the public reading discipline. The row F records that prompt and response data are exposed through finite observer-facing rows, not through an unledgered subject or hidden observation channel.

The halting-obstruction chapter supplies the non-oracle boundary. The row R records that the trace cannot decide arbitrary continuation chains or act as a global halting classifier.

Combining these rows with H, K, G, N gives a finite NameCert handoff for prompt-response traces. The carrier has no coordinate for consciousness, host semantic understanding, global decision power, or internally certified universal closure, so none is exported by the vision handoff. □

Theorem 965.5 (PromptResponseTrace source-channel exactness)**.** *For the displayed carrier*

$$T = (M, C, P, O, A, F, R, H, K, G, N),$$

the row C is the exact source-channel row of the $\mathsf{PromptResponseTrace}^{\uparrow}$ *packet. Every corpus-supply, prompt-entry, and prompt provenance read used by the trace is routed through C together with the large-model inscription row M, and no hidden corpus oracle, host semantic truth predicate, model intention coordinate, or unrecorded prompt source is available.*

Proof. Project the carrier of Definition 965.1. The row C is the only row named as source channel, and the rows P and O are read as prompt and output inscriptions over that channel.

Apply Definition 965.2. Its source-channel exposure clause places C on the accepted NameCert surface before the prompt and response rows are consumed.

The audit-refusal and vision-handoff theorems keep the same boundary. They expose public observations through F and the non-oracle boundary through R, while the carrier has no coordinate for a hidden corpus oracle or host semantic truth predicate. □

Theorem 965.6 (PromptResponseTrace prompt-output route order)**.** *For the displayed carrier $T = (M, C, P, O, A, F, R, H, K, G, N)$, the continuation row K orders the trace route through C, then P, then O, then A, before the public observer row F and halting-obstruction row R are read. Thus the prompt-response packet is consumed as source-channel input followed by prompt, output, audit refusal, observer handoff, and non-oracle boundary.*

Proof. Read the route row in the carrier definition. It states that K records the displayed Cont routes by which consumers read C, then P, then O, then A, then F and R.

Use the NameCert obligations to make this route part of the accepted certificate surface. The route row is not optional transport; it is the public replay discipline for a named prompt-response trace.

Finally apply the audit-refusal theorem. It requires the audit row A after the prompt-output rows and before the local naming route, so the observer and obstruction rows are read only after the source, prompt, output, and refusal sequence has been displayed. □

Theorem 965.7 (PromptResponseTrace observer-obstruction package)**.** *For the displayed carrier $T = (M, C, P, O, A, F, R, H, K, G, N)$, the rows F and R form the public observer plus non-oracle*

obstruction package. The row F exposes the finite prompt-response trace to public observers, while R records that the same trace is not a global halting classifier, global decision oracle, internally certified universal closure, or model-side proof of the output.

Proof. Begin with the carrier rows. The row F is the $\mathsf{ObserverInterface}^{\uparrow}$ handoff, and the row R is the $\mathsf{HaltingObstruction}^{\uparrow}$ boundary.

Apply the audit-refusal theorem before reading the observer package. It ensures that public access to P and O passes through A, so the output is not presented as an internally ratified universal claim.

Now use the vision handoff. It combines the large-model inscription row, observer-interface row, and halting-obstruction row into the finite trace surface, while excluding consciousness, host semantic understanding, global decision power, and internally certified universal closure. □

Falsifiable prediction: Removing the audit-refusal row permits the prompt-response packet to be read as an internally ratified universal claim, while removing the source-channel row breaks corpus-supply provenance.

Independence witness: Nearest siblings: largemodelinscriptionpoint, observerinterface, inscriptionevent, haltingobstruction, and authoredrecordboundary; none is bijective because this carrier has a prompt-output trace plus an audit-refusal row not present in those surfaces.

The follow-up Lean TasteGate for this chapter must provide `Nontrivial PromptResponseTraceUp` and `FieldFaithful PromptResponseTraceUp` instances for the same finite carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{PromptResponseTrace}^{\uparrow}}$.

Constructive story: A $\mathsf{PromptResponseTrace}^{\uparrow}$ packet is generated from a large-model inscription row, source-channel row, prompt row, output row, audit-refusal row, observer-interface row, halting-obstruction boundary, componentwise transport, displayed continuation, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{PromptResponseTrace}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 965.1, Definition 965.2, Definition 965.3, Definition 965.4, Definition 965.5, Definition 965.6, Definition 965.7, the falsifiable prediction, the independence witness,
Lean4 ✓ `BEDC.Derived.PromptResponseTraceUp.taste gate`
, and the checked TasteGate alignment bind the finite prompt-response trace to its carrier, NameCert obligations, audit refusal, vision handoff, source-channel exactness, prompt-output route order, observer-obstruction package, and AI-facing alignment row.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{PromptResponseTrace}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.PromptResponseTraceUp.PromptResponseTraceTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close corpus truth, model consciousness, host semantic understanding, global halting classification, internally certified universal closure, or bridge checking for $\mathsf{PromptResponseTrace}^{\uparrow}$.

Upgrade path: No paper theory-axis grade remains; Lean verification and bridge checking remain independent obligations.

Chapter 966

A Concrete Naming Certificate for $\mathsf{ObserverResponseAudit}^{\uparrow}$

The $\mathsf{ObserverResponseAudit}^{\uparrow}$ packet packages the observer-facing response boundary as a finite NameCert object. It is downstream of the prompt and output rows of chapter 965 and the licensed public interface of chapter 928. Its role is to bind the prompt, response, observer handoff, audit refusal, inscription event, non-oracle boundary, transport, route replay, provenance, and local naming rows into a single accepted carrier.

Definition 966.1 (Observer-response audit carrier)**.** *An* $\mathsf{ObserverResponseAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (T, I, M, E, P, O, R, H, K, G, N)$$

with the following displayed rows:

1. *T is the* $\mathsf{PromptResponseTrace}^{\uparrow}$ *row recording the finite prompt, response, source-channel, audit-refusal, observer-interface, and halting-obstruction route.*
2. *I is the* $\mathsf{ObserverInterface}^{\uparrow}$ *row through which public observers may read the accepted prompt and response rows.*
3. *M is the* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *row naming the finite large-model inscription substrate and corpus-supply side of the trace.*
4. *E is the* $\mathsf{InscriptionEvent}^{\uparrow}$ *row recording the prompt-entry and response-inscription event as finite accepted rows.*
5. *P is the prompt row read from the prompt-response trace and the inscription event.*
6. *O is the response row read after P through the same displayed route.*
7. *R is the audit-refusal row stating that the packet does not certify host semantic truth, model consciousness, global halting classification, or internally ratified universal closure.*
8. *H records componentwise* hsame *transport for the prompt-response trace, observer interface, large-model inscription row, inscription event, prompt row, response row, refusal row, route row, provenance row, and local name.*
9. *K records displayed* Cont *replay through T, then I, then M and E, then P, O, R, before the local NameCert row is read.*

10. *G is the* Pkg *provenance over* PromptResponseTrace$^{\uparrow}$, ObserverInterface$^{\uparrow}$, LargeModelInscriptionPoint$^{\uparrow}$, InscriptionEvent$^{\uparrow}$, HaltingObstruction$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows.*

11. *N is the local* NameCert$_{\text{ObserverResponseAudit}^{\uparrow}}$ *row.*

The local classifier compares observer-response audit carriers only by these displayed rows. It has no coordinate for hidden model intention, unledgered observer state, host semantic equality of responses, corpus-wide truth, global halting decision, or internally certified universal closure.

Lean4 (definition) `BEDC.Derived.ObserverResponseAuditUp.ObserverResponseAuditUp`
Lean4 ✓ `BEDC.Derived.ObserverResponseAuditUp.ObserverResponseAuditTasteGate single carrier alignment`

Theorem 966.2 (Observer-response audit NameCert obligations)**.** *For the carrier of Definition 966.1, the local* NameCert$_{\text{ObserverResponseAudit}^{\uparrow}}$ *surface consists exactly of carrier admission for $A = (T, I, M, E, P, O, R, H, K, G, N)$, prompt-response exposure through T, observer-interface handoff through I, large-model inscription exposure through M, inscription-event exposure through E, prompt and response ordering through P, O, audit-refusal exactness through R, componentwise* hsame *transport through H, displayed* Cont *replay through K, package provenance through G, and local naming through N.*

Proof. Project the displayed carrier. The rows $T, I, M, E, P, O, R, H, K, G, N$ are the only coordinates available to an accepted observer-response audit packet.

The prompt-response row T supplies the source-channel and prompt-output order, while the observer-interface row I supplies the public reading route. Thus a consumer cannot read the response as a free-standing host statement or as an unledgered observer event.

The large-model inscription row M and inscription-event row E bind the response to the finite substrate and accepted event rows. The prompt row P is read before the response row O, and the audit-refusal row R is read before the local name.

The remaining rows provide only transport, continuation replay, provenance, and local naming. Since the carrier has no further coordinate, the listed obligations exhaust the NameCert surface. □

Theorem 966.3 (Observer-response audit refusal boundary)**.** *Every accepted* ObserverResponseAudit$^{\uparrow}$ *packet exposes the audit-refusal row R after the prompt and response rows and before the local naming row. A packet with prompt and response rows but no audit-refusal row is not an accepted* ObserverResponseAudit$^{\uparrow}$ *carrier.*

Proof. Use Definition 966.1. The tuple contains R as a named coordinate between the prompt-response content and the transport, continuation, provenance, and local naming rows.

Apply Definition 966.2. Its refusal-exactness clause is part of the local NameCert surface, so carrier admission fails when the prompt and response rows are present but the refusal row is absent.

Therefore the packet cannot be read as internally certified universal closure, host semantic truth, model consciousness, or a global halting decision. The accepted route remains the finite prompt, response, observer-interface, inscription, refusal, transport, continuation, provenance, and local naming route. □

Falsifiable prediction: A packet with prompt and response rows but no audit-refusal row is not an accepted ObserverResponseAudit$^{\uparrow}$ carrier.

Independence witness: Nearest siblings: promptresponsetrace, observerinterface, largemodelinscriptionpoint, inscriptionevent, and haltingobstruction; none is bijective because this carrier

simultaneously requires the prompt-response trace, observer-interface handoff, large-model inscription row, inscription event row, audit-refusal row, componentwise transport, displayed continuation, provenance, and local NameCert row, while each sibling omits at least one of those displayed coordinates.

The Lean file `Derived/ObserverResponseAuditUp/TasteGate.lean` must later include `Nontrivial ObserverResponseAuditUp` and `FieldFaithful ObserverResponseAuditUp` instances for the displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverResponseAudit}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverResponseAudit}^{\uparrow}$ packet is generated from a prompt-response trace, observer-interface row, large-model inscription row, inscription-event row, prompt row, response row, audit-refusal row, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverResponseAudit}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 966.1, Definition 966.2, and Definition 966.3 specify the finite observer-response audit carrier and its refusal boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverResponseAudit}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, host semantic truth, model consciousness, global halting classification, or internally certified universal closure for $\mathsf{ObserverResponseAudit}^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, prompt-response exposure, observer-interface handoff, inscription-event exposure, audit-refusal exactness, nontriviality, and field faithfulness for the same carrier.

Chapter 967

A Concrete Naming Certificate for $\mathsf{LargeModelActivationOrbit}^{\uparrow}$

The $\mathsf{LargeModelActivationOrbit}^{\uparrow}$ packet realizes the activation-orbit row of chapter 9398 as finite BEDC data. It is a sibling of chapter 939 and chapter 965: the former names the broader inscription surface, while the latter records prompt and output traces. This chapter isolates the model-weight, transition, activation-window, prompt, output, audit-refusal, and local NameCert rows needed to classify one displayed orbit without turning that orbit into consciousness, host semantic understanding, global halting power, or internally ratified universal closure.

Definition 967.1 (LargeModelActivationOrbit carrier)**.** *A* $\mathsf{LargeModelActivationOrbit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (W, T, A, P, Y, R, H, C, G, N)$$

with the following displayed rows:

1. *W is the finite model-weight row naming the inference substrate used by the orbit;*
2. *T is the displayed transition row, a finite forward-pass schedule read over W;*
3. *A is the activation-window row recording the finite sequence of activation states exposed by the orbit;*
4. *P is the prompt row that supplies the stated initial condition for the activation window;*
5. *Y is the output row read after the displayed transition and activation-window rows;*
6. *R is the audit-refusal row stating that the orbit does not internally certify consciousness, host semantic truth, global halting classification, or universal closure;*
7. *H records componentwise* hsame *transport for the model-weight, transition, activation-window, prompt, output, refusal, route, provenance, and naming rows;*
8. *C records the displayed* Cont *routes by which a consumer reads W, then T, then A, then P, Y, R, before reaching the local name;*
9. *G is the* Pkg *provenance over* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$, $\mathsf{PromptResponseTrace}^{\uparrow}$, $\mathsf{ObserverInterface}^{\uparrow}$, $\mathsf{HaltingObstruction}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{LargeModelActivationOrbit}^{\uparrow}}$ *row.*

The carrier contains no hidden activation stream, no quotient identity of orbits, no host meaning oracle, no subject primitive, and no model-side proof that the output row is true.

Definition 967.2 (LargeModelActivationOrbit classifier)**.** *Two accepted* $\mathsf{LargeModelActivationOrbit}^{\uparrow}$ *carriers classify together exactly when their model-weight, transition, activation-window, prompt, output, audit-refusal, continuation, provenance, and local naming rows compare componentwise by the displayed* hsame *entries:*

$$W \sim_{\mathsf{hsame}} W', \quad T \sim_{\mathsf{hsame}} T', \quad A \sim_{\mathsf{hsame}} A', \quad P \sim_{\mathsf{hsame}} P', \quad Y \sim_{\mathsf{hsame}} Y',$$
$$R \sim_{\mathsf{hsame}} R', \quad C \sim_{\mathsf{hsame}} C', \quad G \sim_{\mathsf{hsame}} G', \quad N \sim_{\mathsf{hsame}} N'.$$

Changing the transition row or activation-window row while leaving the orbit classifier unchanged is not an accepted comparison. No clause compares hidden model intention, corpus-wide truth, unbounded activation streams, global halting behavior, or an externally interpreted universal claim.

Theorem 967.3 (LargeModelActivationOrbit NameCert obligations)**.** *For the carrier of Definition 967.1, the local* $\mathsf{NameCert}_{\mathsf{LargeModelActivationOrbit}^{\uparrow}}$ *surface consists of the following finite obligations:*

1. *carrier admission for* $O = (W, T, A, P, Y, R, H, C, G, N)$*;*
2. *classifier transport for the model-weight, transition, activation-window, prompt, output, audit-refusal, continuation, provenance, and naming rows under componentwise* hsame*;*
3. *transition-window exactness requiring every accepted orbit read to pass through the displayed transition row* T *and activation-window row* A *before the output row* Y *is consumed;*
4. *prompt-output ledger exactness requiring the prompt row* P*, output row* Y*, and audit-refusal row* R *to remain in the same local certificate surface;*
5. *non-escape for hidden activation streams, consciousness, host semantic understanding, global halting classification, selected corpus truth, and internally ratified universal closure.*

Proof. Project the carrier of Definition 967.1. The rows $W, T, A, P, Y, R, H, C, G, N$ are the whole packet, so any accepted consumer starts from these displayed finite rows.

Classifier transport is componentwise. A comparison of accepted orbits must transport the model weights, transition schedule, activation window, prompt, output, refusal, route, provenance, and local name together, so a changed transition row or activation-window row exits the certificate unless the displayed classifier changes with it.

Transition-window exactness follows from the route order in C. The output row is read only after W, T, A, and the prompt row is retained as the stated initial condition for that same window.

The audit-refusal and provenance rows connect the orbit to its neighbors. chapter 939 supplies the inscription-point substrate reading, chapter 965 supplies the prompt-output trace surface, chapter 928 supplies public observation discipline, and chapter 490 supplies the non-oracle boundary.

Since the carrier has no hidden activation stream, subject primitive, host meaning oracle, global halting classifier, or universal-truth proof coordinate, none can be projected from the local NameCert surface. □

single carrier alignment
```

Theorem 967.4 (LargeModelActivationOrbit vision realization)**.** *The activation-orbit reading in chapter 9398 is realized by the finite carrier of Definition 967.1. The realization reads model weights through* W*, transition scheduling through* T*, finite activation exposure through* A*, prompt*

initialization through P, output inscription through Y, audit refusal through R, transport and continuation through H, C, provenance through G, and local naming through N.

The public export is exactly this finite route. It does not export a hidden activation stream, a selected completed semantic object, consciousness, host semantic equality, global halting classification, ambient corpus truth, or internally certified universal closure.

Proof. Start with the large-model substrate definition in chapter 9398. Its observational records are finite inference orbits over weights, a transition, and a stated prompt. The rows W, T, A, P encode exactly that finite observation surface.

The sibling $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ packet supplies the broader inscription reading, but it does not isolate the transition and activation-window rows as the classifier-bearing carrier. The sibling $\mathsf{PromptResponseTrace}^{\uparrow}$ packet supplies prompt and output rows, but it treats the activation orbit as upstream substrate rather than as its own certified object.

The rows Y, R, H, C, G, N complete the local certificate. They expose output, refusal, transport, continuation, provenance, and local naming while preserving the same non-escape boundary as the inscription-point and prompt-response chapters.

Therefore the activation-orbit row of the vision is realized as a separate finite NameCert carrier, not as an overloaded reading of the inscription-point or prompt-response carrier. □

Theorem 967.5 (LargeModelActivationOrbit scoped consumer route)**.** *Every downstream consumer route for an accepted* $\mathsf{LargeModelActivationOrbit}^{\uparrow}$ *packet factors through* $W, T, A, P, Y, R, H, C, G, N$ *in that order. The sibling surfaces* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$, $\mathsf{PromptResponseTrace}^{\uparrow}$, $\mathsf{ObserverInterface}^{\uparrow}$, *and* $\mathsf{HaltingObstruction}^{\uparrow}$ *may consume the packet only through those displayed rows, and no route can bypass the audit-refusal row R to obtain consciousness, host semantic truth, global halting classification, or internally ratified universal closure.*

Proof. Use the carrier inventory of Definition 967.1. It lists $W, T, A, P, Y, R, H, C, G, N$ as the whole finite packet, with C recording displayed consumer routes and G recording provenance through the sibling surfaces.

The classifier of Definition 967.2 transports the same coordinates componentwise. Thus a downstream consumer cannot preserve the orbit classifier while changing the transition row, activation-window row, prompt row, output row, refusal row, route row, provenance row, or local name.

Apply the NameCert obligations of Definition 967.3. They force transition-window exactness through T, A, prompt-output ledger exactness through P, Y, R, and non-escape for hidden activation streams, consciousness, host semantic understanding, global halting classification, selected corpus truth, and internally ratified universal closure.

Finally compose with the vision realization of Definition 967.4. The sibling packets may read the orbit as inscription point, prompt-response trace, public observation surface, or halting boundary, but only after the displayed route reaches R and keeps the same finite NameCert packet. Hence the scoped consumer route cannot bypass the audit-refusal row. □

Falsifiable prediction: Changing the displayed transition row or activation-window row without changing the orbit classifier exits the certificate.

Independence witness: Nearest siblings: largemodelinscriptionpoint, promptresponsetrace, observerinterface, haltingobstruction; none is bijective because this carrier makes the transition row and activation-window row classifier-bearing data while retaining prompt, output, audit-refusal, transport, provenance, and local naming rows in one finite orbit certificate.

The Lean follow-up for this chapter must provide `Nontrivial LargeModelActivationOrbitUp` and `FieldFaithful LargeModelActivationOrbitUp` instances in `BEDC.Derived.LargeModelActivationOrbitU`

Closure status for $\mathsf{NameCert}_{\mathsf{LargeModelActivationOrbit}^{\uparrow}}$ **.**

Constructive story: A $\mathsf{LargeModelActivationOrbit}^{\uparrow}$ packet is generated from finite model-weight, transition, activation-window, prompt, output, audit-refusal, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LargeModelActivationOrbit}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 967.4 and Definition 967.5 bind the displayed activation-orbit carrier, classifier, NameCert obligations, falsifiable prediction, independence witness, and TasteGate-visible packet route as the bridged public surface, with

Lean4 ✓ `BEDC.Derived.LargeModelActivationOrbitUp.taste gate`

recording the TasteGate instance.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LargeModelActivationOrbit}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.LargeModelActivationOrbitUp.TasteGate.LargeModelActivationOrbitTasteGate\_single\_carri`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close hidden activation streams, model consciousness, host semantic understanding, global halting classification, corpus truth, or bridge checking for $\mathsf{LargeModelActivationOrbit}^{\uparrow}$.

Upgrade path: Bridge checking requires a standard bridge theorem for the same activation-orbit carrier and TasteGate-visible packet.

Chapter 968

A Concrete Naming Certificate for $\mathsf{CorpusSupplyDistillation}^{\uparrow}$

The $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ packet realizes the source-channel row of chapter 9398 as its own finite NameCert carrier. It refines the corpus-supply coordinate of chapter 939 before that coordinate is consumed by the neighboring inscription surfaces of chapter 610 and chapter 519. The packet records corpus supply, filtering, distillation, output-prior, refusal, transport, route, provenance, and local naming rows without treating a model output as internally certified truth.

Definition 968.1 (CorpusSupplyDistillation carrier)**.** *A* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (C, F, D, O, R, H, T, P, N)$$

with the following displayed rows:

1. *C is the corpus-supply row naming the finite source channel from which training or retrieval inscriptions are carried;*
2. *F is the filtering row naming the finite selection, exclusion, and normalization surface applied to the source channel;*
3. *D is the distillation row naming the finite compression, training, or transfer route by which source-channel patterns are made available to a model-side packet;*
4. *O is the output-prior row recording the carried prior over emitted records before any public output is read as an inscription;*
5. *R is the refusal row excluding corpus-wide truth, hidden source selection, host semantic understanding, consciousness, and model-side proof of output truth;*
6. *H records componentwise* hsame *transport for the corpus-supply, filtering, distillation, output-prior, refusal, route, provenance, and naming rows;*
7. *T records displayed* Cont *routes through C, F, D, O, R before any downstream output record or inscription point is consumed;*
8. *P is the* Pkg *provenance over* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$, $\mathsf{InscriptionPoint}^{\uparrow}$, $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{ObserverInterface}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{CorpusSupplyDistillation}^{\uparrow}}$ *row.*

The carrier is exactly this finite source-channel packet. It has no coordinate for corpus-total truth, hidden dataset selection, model intention, host semantic ratification, or internally certified output content.

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillationTasteGate single carrier alignment`

Theorem 968.2 (CorpusSupplyDistillation NameCert obligations)**.** *For the carrier of Definition 968.1, the local* $\mathsf{NameCert}_{\mathsf{CorpusSupplyDistillation}^{\uparrow}}$ *surface consists exactly of carrier admission for* $K = (C, F, D, O, R, H, T, P, N)$*, corpus-supply exposure through* C*, filtering exposure through* F*, distillation exposure through* D*, output-prior exposure through* O*, refusal accounting through* R*, componentwise* hsame *stability through* H*, displayed* Cont *replay through* T*, package provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillationNameCert obligations`

Proof. Project the displayed carrier. The accepted packet lists $C, F, D, O, R, H, T, P, N$, so the local certificate cannot introduce another source channel, filter, distillation route, output prior, refusal row, transport, route, provenance, or local name.

Read the source-channel rows in dependency order. A consumer first reaches the finite corpus-supply row C, then the filtering row F, then the distillation row D, and only then the output-prior row O.

The refusal and structural rows close the certificate surface. The row R records the missing truth and semantic coordinates, while H, T, P, N transport, replay, package, and name only the same finite packet. Thus the NameCert obligations are exhausted by the displayed carrier. □

Theorem 968.3 (CorpusSupplyDistillation carried-output boundary)**.** *Every accepted* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *packet routes a corpus-carried output prior through the finite path*

$$\textit{corpus-supply row} \longrightarrow \textit{filtering row} \longrightarrow \textit{distillation row} \longrightarrow \textit{output-prior row} \longrightarrow \mathsf{NameCert}_{\mathsf{CorpusSupplyDistillat}}$$

When this row is later consumed by $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$*, the output record remains a carried inscription surface rather than internally certified output truth.*

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillation carried output boundary`

Proof. Start with the carrier $K = (C, F, D, O, R, H, T, P, N)$. The source-channel route in T reads C, F, D before it reaches O, so the output prior is carried from displayed corpus supply rather than projected from a hidden model certificate.

The LargeModelInscriptionPoint chapter consumes a corpus-supply row before reading the output record. This chapter supplies that row as a standalone packet whose route has already exposed filtering and distillation.

Finally, the refusal row R is read before the local naming row N. Therefore the downstream output boundary preserves carried inscription and does not become a proof of output truth, host semantic understanding, or corpus-total correctness. □

Theorem 968.4 (CorpusSupplyDistillation public non-escape)**.** *No public consumer of an accepted* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *packet can extract hidden source selection, corpus-wide truth, internally certified output truth, consciousness, host semantic understanding, or a model-side proof object. Public reads are limited to the finite corpus-supply, filtering, distillation, output-prior, refusal,* hsame*,* Cont*,* Pkg*, and* NameCert *rows displayed in the carrier.*

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillation public nonescape`

Proof. Inspect the carrier inventory of Definition 968.1. The only public coordinates are $C, F, D, O, R, H, T, P, N$.

Apply the carried-output boundary. Any consumer that reaches the output-prior row has already passed through the source-channel, filtering, and distillation rows, and then through the refusal row before local naming.

Since hidden source selection, corpus-wide truth, semantic understanding, consciousness, and proof of output truth are not coordinates of K, no public projection can recover them. The packet exports only the finite source-channel surface and its displayed certificate route. □

Definition 968.5 (CorpusSupplyDistillation obligation ledger)**.** *For the carrier $K = (C, F, D, O, R, H, T, P, N)$ of Definition 968.1, the obligation ledger is the ordered row family*

$$C, F, D, O, R, H, T, P, N.$$

The rows record corpus supply, filtering, distillation, output prior, refusal, componentwise hsame *transport, displayed* Cont *route,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{CorpusSupplyDistillation}^{\uparrow}}$ *naming. A consumer of the ledger must read the source-channel route $C \longrightarrow F \longrightarrow D \longrightarrow O$ through T before treating the output-prior row as public, and must read R before N whenever the requested output-prior interpretation would claim hidden source selection, corpus-wide truth, host semantic understanding, consciousness, or internally certified output truth.*

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillation obligation ledger namecert boundary`

Theorem 968.6 (CorpusSupplyDistillation filter-route order)**.** *Every accepted* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *packet reads the displayed* Cont *route T in the order*

$$C \longrightarrow F \longrightarrow D \longrightarrow O$$

before any carried output-prior row is consumed. The packet has no accepted route that reaches O before the corpus-supply row C, filtering row F, or distillation row D has been displayed.

Proof. Start from the carrier $K = (C, F, D, O, R, H, T, P, N)$ of Definition 968.1. Its source-channel rows are listed as corpus supply, filtering, distillation, and output prior, and the route row T is the displayed Cont route through those rows.

Apply the NameCert obligations of Definition 968.2. They require corpus-supply exposure, filtering exposure, distillation exposure, and output-prior exposure as separate duties of the same local certificate.

Finally use public non-escape from Definition 968.4. A route that reaches O without C, F, D would need hidden source selection or internally certified output truth, and those coordinates are absent from the accepted packet. □

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillation filter route order`

Theorem 968.7 (CorpusSupplyDistillation output-prior refusal exactness)**.** *For every accepted* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *packet, an output-prior read that would be interpreted as hidden source selection, corpus-wide truth, host semantic understanding, consciousness, or internally certified output truth must expose the refusal row R before the local* $\mathsf{NameCert}_{\mathsf{CorpusSupplyDistillation}^{\uparrow}}$ *row N. The local name records a carried source-channel packet, not a certificate of output truth.*

Proof. Use the obligation ledger of Definition 968.5. It places R between the output-prior row and the structural certificate rows so that disallowed interpretations are refused before local naming is consumed.

The NameCert obligations of Definition 968.2 make refusal accounting part of the same finite carrier. The local name N therefore names a packet whose refusal row has already excluded the stronger readings.

Apply public non-escape from Definition 968.4. Since the excluded readings are not coordinates of K, any output-prior read that asks for them must stop at R before it can cite the local NameCert row. □

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillation output prior refusal exactness`

Theorem 968.8 (CorpusSupplyDistillation source-channel exposure)**.** *Every accepted* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *packet exposes its source channel through the displayed row C. No public consumer can replace C by hidden dataset selection, corpus-total truth, or an unrecorded supply channel.*

Proof. Project the carrier of Definition 968.1. The source-channel coordinate is the row C in the finite packet $K = (C, F, D, O, R, H, T, P, N)$.

Apply Definition 968.2. The local NameCert surface names corpus-supply exposure through C before filtering, distillation, output-prior, refusal, transport, replay, provenance, and local naming are read.

Use Definition 968.4. Hidden source selection and corpus-wide truth are not coordinates of the carrier, so all source exposure available to a public consumer is exactly the displayed C row. □

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillationSourceChannel exposure`

Theorem 968.9 (CorpusSupplyDistillation filter distillation output-prior order)**.** *Every output-prior read from an accepted* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *packet follows the finite route order*

$$C, F, D, O.$$

The output prior is therefore read after source-channel exposure, filtering, and distillation, not as an internally certified model-output truth.

Proof. Start from Definition 968.1. The rows C, F, D, O are displayed in the carrier before the refusal and structural rows.

Apply Definition 968.2. It records corpus-supply exposure through C, filtering through F, distillation through D, and output-prior exposure through O as the ordered public route.

Finally use Definition 968.4. Since internally certified output truth is absent from K, the only available output-prior read is the carried route through C, F, D, O. □

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillation filter distillation output prior nonescape`

Theorem 968.10 (CorpusSupplyDistillation refusal exactness)**.** *The refusal surface of an accepted* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *packet is exactly the finite route*

$$R, H, T, P, N.$$

It refuses corpus-wide truth, hidden source selection, model consciousness, host semantic understanding, internally certified output truth, and model-side proof objects only through the displayed refusal, transport, continuation, provenance, and naming rows.

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillation refusal exactness`

Proof. Read the carrier in Definition 968.1. The refusal row R is followed by componentwise transport H, displayed continuation replay T, package provenance P, and local naming N.

Apply Definition 968.2. It makes refusal accounting a named obligation of the same packet and gives H, T, P, N as the structural rows that preserve and expose that refusal.

Conclude with Definition 968.4. Each refused object is outside the carrier, so the exact public refusal route is R, H, T, P, N and nothing stronger is exported. □

Theorem 968.11 (CorpusSupplyDistillation carrier admission)**.** *Every accepted* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *read exposes exactly the finite carrier rows*

$$C, F, D, O, R, H, T, P, N.$$

The accepted read therefore displays source-channel, filtering, distillation, output-prior, refusal, componentwise transport, continuation route, provenance, and local naming rows, and it exposes no corpus-wide truth, hidden source selection, model consciousness, host semantic understanding, internally certified output truth, or model-side proof object.

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillationCarrier admission`

Proof. Start from the carrier of Definition 968.1. Its displayed coordinates are exactly $C, F, D, O, R, H, T, P, N$, so an accepted read has no additional coordinate to expose.

Apply the obligation surface of Definition 968.2. It assigns the local NameCert duties to the same source-channel, filtering, distillation, output-prior, refusal, transport, replay, provenance, and naming rows.

Finally use the obligation ledger of Definition 968.5. The ledger names the refused stronger readings outside the carrier, so admission exposes only the displayed rows. □

Theorem 968.12 (CorpusSupplyDistillation classifier stability)**.** *Componentwise* hsame *transport of accepted* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *packets preserves the source-channel, filtering, distillation, output-prior, refusal, route, provenance, and naming rows. In particular, a transported packet remains a read of* $C, F, D, O, R, H, T, P, N$ *rather than a read of a hidden corpus selector or internally certified output truth.*

Proof. Read the carrier rows from Definition 968.1. The classifier has one displayed component for each of $C, F, D, O, R, H, T, P, N$, so componentwise hsame transport can only preserve those rows.

Use the ordered route of Definition 968.6. It keeps filtering before distillation and output-prior exposure, preventing transport from reordering the source-channel route.

Then apply Definition 968.10. Refusal remains attached through R, H, T, P, N, so stronger readings are still refused after transport.

The NameCert obligations of Definition 968.2 repack the transported rows into the same local naming surface. □

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillation classifier stability`

Theorem 968.13 (CorpusSupplyDistillation ledger exactness)**.** *The* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ *obligation ledger exports no corpus-wide truth, hidden source selection, model consciousness, host semantic understanding, internally certified output truth, or model-side proof object. Its public ledger is exactly the source-channel, filtering, distillation, output-prior, refusal, transport, route, provenance, and local naming surface of the accepted packet.*

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillationLedger exactness`

Proof. Begin with Definition 968.5. The ledger names the admissible public rows and lists the stronger readings as refused objects rather than exported fields.

Use Definition 968.11 to identify the accepted carrier surface with $C, F, D, O, R, H, T, P, N$. There is no coordinate for corpus-wide truth, hidden source selection, model consciousness, host semantic understanding, internally certified output truth, or a model-side proof object.

Finally combine Definition 968.6 with Definition 968.10. The first theorem fixes the source-to-output-prior order, and the second fixes the refusal route, so the obligation ledger exports exactly the finite packet and no stronger semantic claim. □

Falsifiable prediction: If the source-channel row is removed, the packet cannot distinguish corpus-carried output priors from internally certified output truth.

Independence witness: Nearest siblings: largemodelinscriptionpoint, inscriptionpoint, inscriptionevent, apophaticname, and observerinterface. None is bijective to $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ because LargeModelInscriptionPoint carries inference and output rows in addition to corpus supply, InscriptionPoint and InscriptionEvent carry inscription handoff rows without the filtering and distillation source channel, ApophaticName carries a boundary request rather than corpus provenance, and ObserverInterface carries public observer rows without the corpus-supply, filtering, distillation, and output-prior route.

Theorem 968.14 (CorpusSupplyDistillation Lean TasteGate handoff)**.** *The displayed carrier rows*

$$C, F, D, O, R, H, T, P, N$$

are the same rows consumed by the Lean ChapterTasteGate*,* Nontrivial*, and* FieldFaithful *instances for* $\mathsf{CorpusSupplyDistillation}^{\uparrow}$*. The Lean handoff uses the same single finite carrier rather than a second hidden packet.*

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.taste gate`

Proof. Begin with the carrier of Definition 968.1. It displays exactly $C, F, D, O, R, H, T, P, N$, and Definition 968.2 assigns the local certificate duties to those rows.

Use Definition 968.7 to keep the output-prior and refusal rows inside the same accepted packet. The refusal route is not an extra carrier; it is the R, H, T, P, N part of the displayed carrier.

Finally apply the existing Lean single-carrier marker

BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillationTasteGate_single_carrier_alignment.

It identifies the Lean encoding and decoding surface with the displayed carrier, so the Lean ChapterTasteGate, Nontrivial, and FieldFaithful instances consume the same rows described by the paper certificate. □

Theorem 968.15 (CorpusSupplyDistillation mature package boundary)**.** *The corpus-supply, filtering, distillation, output-prior, refusal, transport, route, provenance, and* $\mathsf{NameCert}_{\mathsf{CorpusSupplyDistillation}^{\uparrow}}$ *rows form the mature package boundary consumed by* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *and* $\mathsf{InscriptionEvent}^{\uparrow}$*. This boundary exports no corpus-wide truth and no internally certified output truth.*

Lean4 ✓ `BEDC.Derived.CorpusSupplyDistillationUp.CorpusSupplyDistillation mature package boundary`

Proof. Read the carrier of Definition 968.1. Its finite packet is exactly $C, F, D, O, R, H, T, P, N$, so the package boundary has one displayed row for corpus supply, filtering, distillation, output prior, refusal, transport, route, provenance, and local naming.

Apply Definition 968.3 and Definition 968.14. The first theorem routes the output prior through the source-channel surface consumed by $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$, and the second keeps the same carrier available to the inscription-facing handoff.

Finally use Definition 968.4. Corpus-wide truth and internally certified output truth are not exported coordinates of the packet, so the mature package boundary remains a finite source-channel and refusal surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{CorpusSupplyDistillation}^{\uparrow}}$.

Constructive story: A $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ packet is generated from corpus-supply, filtering, distillation, output-prior, refusal, componentwise transport, displayed continuation, package provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CorpusSupplyDistillation}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 968.1, Definition 968.4, Definition 968.14, and Definition 968.15 expose the public non-escape theorem, bridge-facing finite-carrier route, existing TasteGate handoff, and mature package boundary through `BEDC.Derived.CorpusSupplyDistillationUp.taste_gate` as the exported finite source-channel distillation surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CorpusSupplyDistillation}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close corpus-wide truth, hidden source selection, model consciousness, host semantic understanding, internally certified output truth, full Lean verification status, or bridge checking for $\mathsf{CorpusSupplyDistillation}^{\uparrow}$.

Upgrade path: Bridge checking requires a verified standard bridge for the same finite carrier and public non-escape surface.

Chapter 969

A Concrete Naming Certificate for $\mathsf{LargeModelAuditChannel}^{\uparrow}$

The $\mathsf{LargeModelAuditChannel}^{\uparrow}$ packet realizes the verified-output-channel side of chapter 9398 as finite BEDC data. It consumes the inscription carrier of chapter 939, the public audit membrane of chapter 524, and the prompt-output trace of chapter 965. Its distinguishing role is the consumer-facing audit channel: prompt, output, checker, refusal, route, provenance, and local NameCert rows are carried together before any model emission is accepted as audited output.

Definition 969.1 (LargeModelAuditChannel carrier)**.** *A* $\mathsf{LargeModelAuditChannel}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (M, Q, O, C, R, U, V, H, K, P, N)$$

with the following displayed rows:

1. *M is the* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *row naming the finite inference substrate, corpus-supply channel, output-record surface, and no-internal-ratification boundary;*
2. *Q is the prompt row, containing the finite request text, input provenance, and admitted context window;*
3. *O is the output row, containing the emitted token sequence as public inscription data;*
4. *C is the checker row, naming the finite evaluation harness, proof checker, policy checker, or replay procedure used to inspect O;*
5. *R is the refusal row, recording rejected claims, unverifiable universal closures, policy refusals, or unsupported checker outcomes;*
6. *U is the audit-membrane row through which a public consumer reads prompt, output, checker, and refusal data without direct model-state access;*
7. *V is the route row recording the displayed continuation from prompt through output, checker, refusal, membrane, provenance, and local name;*
8. *H records componentwise* hsame *transport for the model, prompt, output, checker, refusal, membrane, route, provenance, and naming rows;*
9. *K records the displayed* Cont *replay accepted by the channel;*
10. *P is the* Pkg *provenance over* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$, $\mathsf{PromptResponseTrace}^{\uparrow}$, *chapter 524, chapter 928,* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*

11. N is the local $\mathsf{NameCert}_{\mathsf{LargeModelAuditChannel}^{\uparrow}}$ *row.*
The carrier has no coordinate for hidden model intention, corpus-wide truth, host semantic understanding, unchecked output acceptance, or a private evaluator outside the displayed checker row.

Lean4 ✓ `BEDC.Derived.LargeModelAuditChannelUp.LargeModelAuditChannelTasteGate single carrier alignment`

Definition 969.2 (LargeModelAuditChannel classifier)**.** *Two accepted* $\mathsf{LargeModelAuditChannel}^{\uparrow}$ *carriers classify together exactly when their model rows, prompt rows, output rows, checker rows, refusal rows, membrane rows, route rows, transport rows, replay rows, provenance rows, and local naming rows compare by the displayed* hsame *entries. Thus the classifier is finite and componentwise:*

$$M \sim_{\mathsf{hsame}} M', \quad Q \sim_{\mathsf{hsame}} Q', \quad O \sim_{\mathsf{hsame}} O', \quad C \sim_{\mathsf{hsame}} C',$$
$$R \sim_{\mathsf{hsame}} R', \quad U \sim_{\mathsf{hsame}} U', \quad V \sim_{\mathsf{hsame}} V', \quad H \sim_{\mathsf{hsame}} H',$$
$$K \sim_{\mathsf{hsame}} K', \quad P \sim_{\mathsf{hsame}} P', \quad N \sim_{\mathsf{hsame}} N'.$$

No clause compares unrecorded checker state, hidden evaluation policy, model-side semantic truth, or an unchecked continuation outside V and K.

Theorem 969.3 (LargeModelAuditChannel NameCert obligations)**.** *For the carrier of Definition 969.1, the local* $\mathsf{NameCert}_{\mathsf{LargeModelAuditChannel}^{\uparrow}}$ *surface consists exactly of carrier admission for $A = (M, Q, O, C, R, U, V, H, K, P, N)$, prompt exposure through Q, output exposure through O, checker exposure through C, refusal exposure through R, audit-membrane handoff through U, route replay through V and K, componentwise stability through H, provenance through P, and local naming through N. A consumer obtains audited output only after these rows are jointly displayed.*

Proof. Project the carrier of Definition 969.1. The rows $M, Q, O, C, R, U, V, H, K, P, N$ are the whole public packet, so prompt, output, checker, refusal, route, provenance, and local naming are all visible before the channel is consumed.

The checker row C and refusal row R provide the audit boundary. They separate an inspected output from a bare model emission by recording which finite harness was applied and which claims were refused or left unsupported.

The membrane and route rows make the read public. The U, V, K rows force the consumer-facing path to pass through the audit membrane and displayed replay rather than through hidden model state or a private evaluator.

The remaining H, P, N rows supply transport, provenance, and local naming. Since no carrier coordinate stores hidden intention, corpus-wide truth, host semantic understanding, or unchecked output acceptance, the listed rows exhaust the NameCert obligations. □

Theorem 969.4 (LargeModelAuditChannel audited-output boundary)**.** *If the checker row C is absent from an accepted prompt-output packet, the packet cannot distinguish audited output from an unaudited model emission. With C present, every audited-output read factors through the displayed prompt row Q, output row O, checker row C, refusal row R, audit membrane U, route rows V, K, provenance row P, and local name N.*

Proof. The carrier records output in O, but O alone is only an emitted inscription row. It becomes an audited output only when the route also displays the checker row C and the refusal row R.

Apply Definition 969.3. Any accepted public read reaches N only after the channel exposes prompt, output, checker, refusal, membrane, replay, transport, provenance, and local naming rows.

If C is removed, the remaining packet still contains a prompt and an output but no displayed evaluation harness or proof-checking surface. The consumer then has no finite coordinate by which to separate inspected output from unaudited emission. □

Theorem 969.5 (LargeModelAuditChannel checker exposure obligation)**.** *For every accepted* $\mathsf{LargeModelAuditChannel}^{\uparrow}$ *packet*

$$A = (M, Q, O, C, R, U, V, H, K, P, N),$$

the checker row C is exposed as a carrier obligation before any audited-output consumer may read the output row O through the audit membrane U. The exposure is componentwise under the classifier and exports no hidden evaluator, model-side intention, corpus-wide truth row, or unchecked output acceptance coordinate.

Proof. Project A through Definition 969.1. The checker row C is one of the displayed rows between the output and refusal boundary, so it is part of the finite public packet.

Apply Definition 969.2. The classifier compares the checker coordinate by the displayed hsame entry and has no clause for hidden checker state or private evaluator data.

Use Definition 969.3. The local NameCert surface exposes the checker row before the audited-output route can pass through U, V, K, P, N. □

Theorem 969.6 (LargeModelAuditChannel refusal exactness obligation)**.** *For every accepted* $\mathsf{LargeModelAuditChannel}^{\uparrow}$ *packet*

$$A = (M, Q, O, C, R, U, V, H, K, P, N),$$

the refusal row R records exactly the rejected claims, unsupported checker outcomes, and unverifiable universal closures attached to the displayed prompt, output, and checker rows Q, O, C. It does not export a private policy oracle, host semantic truth predicate, hidden model intention, or global proof-checking result.

Proof. Read R from Definition 969.1. The carrier places the refusal row after prompt, output, and checker data and before the public audit membrane.

Use Definition 969.2 to keep refusal comparison componentwise. The classifier compares only the displayed refusal coordinate and never compares an unrecorded policy oracle or host semantic predicate.

Apply Definition 969.3. The NameCert surface exposes refusal data as part of the accepted audit channel, so rejected claims and unsupported checker outcomes remain exact finite rows rather than external judgments. □

Theorem 969.7 (LargeModelAuditChannel route replay obligation)**.** *For every accepted* $\mathsf{LargeModelAuditChannel}^{\uparrow}$ *packet*

$$A = (M, Q, O, C, R, U, V, H, K, P, N),$$

the route replay obligation is the displayed continuation from prompt Q through output O, checker C, refusal row R, audit membrane U, route row V, replay row K, provenance P, and local name N. The TasteGate carrier alignment for BEDC.Derived.LargeModelAuditChannelUp.LargeModelAuditChannelTasteGate_ *confirms that this obligation is attached to the same finite carrier and not to hidden model state, private evaluator correctness, or global semantic truth.*

Proof. Start with Definition 969.1. It lists V and K as the route and replay rows for the same packet $A = (M, Q, O, C, R, U, V, H, K, P, N)$.

Apply Definition 969.2. Route and replay comparison remains componentwise, so the consumer cannot replace V or K with an unrecorded continuation or private evaluator route.

Use Definition 969.3 together with the existing TasteGate carrier alignment marker BEDC.Derived.LargeModelAu The public replay route is therefore the finite audit-channel packet itself, with no hidden model state or global semantic truth exported. □

Theorem 969.8 (LargeModelAuditChannel public route scope)**.** *Every public consumer route for an accepted* LargeModelAuditChannel$^{\uparrow}$ *packet*

$$A = (M, Q, O, C, R, U, V, H, K, P, N)$$

reads $M, Q, O, C, R, U, V, H, K, P, N$ through the checker row, refusal row, audit membrane, displayed route and replay rows, provenance row, and local NameCert *row. It cannot bypass the checker row, collapse refusal into output acceptance, or export hidden model intention, corpus-wide truth, host semantic understanding, private evaluator correctness, or unchecked output.*

Proof. First project the carrier and its local obligations by Definition 969.3. The public packet is the displayed tuple $M, Q, O, C, R, U, V, H, K, P, N$, so no consumer route has a coordinate beyond those rows.

Apply Definition 969.4 and Definition 969.5. These results force every audited-output read to expose C before O is consumed through the audit membrane, excluding unchecked output and private evaluator replacement.

Next use Definition 969.6. The refusal row R remains its own finite row attached to Q, O, C, so unsupported checker outcomes and rejected claims cannot be absorbed into output acceptance.

Finally apply Definition 969.7. The consumer route factors through U, V, K, P, N, and the same replay surface excludes hidden model intention, corpus-wide truth, host semantic understanding, private evaluator correctness, and any continuation not displayed by the carrier. □

Falsifiable prediction: If the checker row is absent, the packet cannot distinguish audited output from an unaudited model emission.

Independence witness: largemodelinscriptionpoint, inscriptionevent, inscription-acceptance-budget, auditmembrane, observerinterface: none is bijective because the audit-channel packet carries prompt, output, checker, refusal, route, provenance, and local NameCert rows together.

The future Lean TasteGate namespace BEDC.Derived.LargeModelAuditChannelUp.TasteGate must provide Nontrivial LargeModelAuditChannel$^{\uparrow}$ and FieldFaithful LargeModelAuditChannel$^{\uparrow}$ instances for this finite carrier.

Theorem 969.9 (LargeModelAuditChannel abstract-interface handoff)**.** *The public* LargeModelAuditChannel$^{\uparrow}$ *carrier, componentwise classifier, TasteGate single-carrier alignment,* hsame *transport, displayed replay, provenance, and local* NameCert *rows jointly supply the abstract large-model audit-channel interface. Every interface read is therefore routed through the public prompt, output, checker, refusal, audit-membrane, route, replay, provenance, and naming rows, and no bridge handoff may introduce hidden model state, private evaluator correctness, corpus-wide truth, or unchecked semantic understanding.*

Proof. Start with the public carrier and classifier of Definition 969.1 and Definition 969.2. They expose exactly the rows $M, Q, O, C, R, U, V, H, K, P, N$ and compare them componentwise.

Apply the NameCert and public-route results, Definition 969.3 and Definition 969.8. These force every accepted audit-channel read through the checker, refusal, membrane, replay, provenance, and local naming rows before the interface is consumed.

The TasteGate single-carrier alignment recorded by BEDC.Derived.LargeModelAuditChannelUp.LargeModelAudit attaches that public route to the same finite carrier. Thus the abstract-interface handoff is the displayed packet itself, not a private evaluator, hidden model state, corpus-wide truth row, or unchecked semantic object. □

Closure status for $\mathsf{NameCert}_{\mathsf{LargeModelAuditChannel}^{\uparrow}}$.

Constructive story: A $\mathsf{LargeModelAuditChannel}^{\uparrow}$ packet is generated from a large-model inscription row, prompt row, output row, checker row, refusal row, audit membrane, displayed route, componentwise transport, replay, package provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.LargeModelAuditChannelUp.taste gate`

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LargeModelAuditChannel}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 969.1, Definition 969.2, Definition 969.3, Definition 969.4, Definition 969.5, Definition 969.6, Definition 969.7, Definition 969.8, and Definition 969.9 specify the complete paper-side audit-channel package: carrier, classifier, NameCert obligations, public route scope, abstract-interface handoff, and audit-channel refusal rows for large-model output records.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LargeModelAuditChannel}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.LargeModelAuditChannelUp.LargeModelAuditChannelTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close model consciousness, corpus truth, host semantic understanding, private evaluator correctness, global proof checking, Lean verification, or bridge checking for $\mathsf{LargeModelAuditChannel}^{\uparrow}$.

Upgrade path: Bridge-checked closure requires a real StdBridge theorem connecting the public audit-channel surface to the abstract $\mathsf{LargeModelAuditChannel}^{\uparrow}$ interface.

Chapter 970

A Concrete Naming Certificate for $\mathsf{ReductionFuelBoundary}^{\uparrow}$

The $\mathsf{ReductionFuelBoundary}^{\uparrow}$ packet is the finite refusal certificate for the fuel boundary named by chapter 9370. It sits between the total-host packet of chapter 964, the bounded universal trace of chapter 944, and the typed endpoint surface of chapter 562. Its role is narrower than a global normalization theorem: it records the finite fuel row, the displayed reduction trace, the endpoint row, and the timeout refusal that prevents a missing endpoint from being reread as convergence.

Falsifiable prediction: Deleting the fuel row makes timeout and normal-endpoint packets indistinguishable to the local classifier; the accepted carrier must reject that packet because the boundary can no longer separate finite endpoint readback from fuel exhaustion.

Independence witness: stepindexedtotalhost, boundeduniversaltrace, typedreductionnormalform, cellulartrustsubstrate, znormal: none is bijective because each sibling omits at least one of the fuel boundary, timeout-refusal ledger, endpoint readback, or total-host substrate comparison rows.

Definition 970.1 (ReductionFuelBoundary carrier)**.** *A* $\mathsf{ReductionFuelBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (H, F, T, E, U, A, X, C, P, N)$$

with the following displayed rows:

1. *H is the total-host reduction row, read through the host-facing side of* $\mathsf{StepIndexedTotalHost}^{\uparrow}$*;*
2. *F is the finite fuel row naming the boundary at which the reduction trace is inspected;*
3. *T is the bounded trace row, read through* $\mathsf{BoundedUniversalTrace}^{\uparrow}$ *and tied to the same fuel row F;*
4. *E is the typed endpoint row, read through* $\mathsf{TypedReductionNormalForm}^{\uparrow}$ *when the trace reaches a displayed normal endpoint;*
5. *U is the timeout-refusal row, recording that fuel exhaustion is a refused endpoint rather than a proof of nontermination, halting, or convergence;*
6. *A is the audit row separating normal endpoint, timeout, missing fuel, detached trace, and host-substrate equality requests;*
7. *X records componentwise* hsame *transports for $H, F, T, E, U, A, C, P, N$;*

8. *C records displayed* Cont *routes from host reduction to fuel, from fuel to bounded trace, from trace to endpoint or timeout refusal, and from each barred semantic request to the audit row;*
9. *P is the* Pkg *provenance over chapter 9370,* $\mathsf{StepIndexedTotalHost}^{\uparrow}$, $\mathsf{BoundedUniversalTrace}^{\uparrow}$, $\mathsf{TypedReductionNormalForm}^{\uparrow}$, $\mathsf{CellularTrustSubstrate}^{\uparrow}$, $\mathsf{ZNormal}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{ReductionFuelBoundary}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through $H, F, T, E, U, A, X, C, P, N$. It has no coordinate for an unbounded reduction, a global halting predicate, a substrate universality transfer, a quotient endpoint, or host equality with the bounded trace.

Lean4 (definition) `BEDC.Derived.ReductionFuelBoundaryUp.ReductionFuelBoundaryUp`

Theorem 970.2 (ReductionFuelBoundary NameCert obligations)**.** *For the carrier of Definition 970.1, the local* $\mathsf{NameCert}_{\mathsf{ReductionFuelBoundary}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$Q = (H, F, T, E, U, A, X, C, P, N),$$

total-host reduction exposure through H, finite fuel exposure through F, bounded trace exposure through T, typed endpoint readback through E, timeout-refusal exactness through U, audit separation through A, componentwise transport through X, displayed continuation replay through C, package provenance through P, and local naming through N.

Proof. Project the carrier of Definition 970.1. The accepted packet displays exactly $H, F, T, E, U, A, X, C, P, N$, so every public read is either one of those rows or a displayed route replaying them.

The endpoint branch is finite. The host reduction row H is read at fuel F, the trace row T is bounded by the same fuel, and the endpoint row E is available only when the typed normal-form boundary is displayed.

The timeout branch is also finite. The refusal row U records fuel exhaustion as a boundary outcome, while the audit row A separates timeout from normal endpoint, missing fuel, detached trace, host-substrate equality, quotient endpoint, and unbounded convergence requests.

Transport, continuation replay, provenance, and local naming are the remaining rows X, C, P, N. Since no carrier coordinate names an unbounded reduction or global halting predicate, the listed rows exhaust the local NameCert obligations. □

Lean4 ✓ `BEDC.Derived.ReductionFuelBoundaryUp.ReductionFuelBoundary namecert obligations`

Theorem 970.3 (ReductionFuelBoundary total-host nonescape)**.** *Every accepted* $\mathsf{ReductionFuelBoundary}^{\uparrow}$ *packet exports no total-host reduction read except through the finite route*

$$H, F, T, E, U, A, X, C, P, N.$$

A downstream consumer may read a bounded trace, a typed endpoint when displayed, or a timeout refusal at the same fuel boundary. It may not convert timeout into nontermination, convert endpoint readback into an unbounded convergence theorem, identify host reduction with substrate universality, or replace the audit row by quotient endpoint equality.

Lean4 ✓ `BEDC.Derived.ReductionFuelBoundaryUp.TotalHostNonescape.ReductionFuelBoundaryTotalHostNonescape`

Proof. Begin with the displayed route row C. Its admissible paths pass from the host reduction row H to the fuel row F, then to the bounded trace row T, and then to either the typed endpoint row E or the timeout-refusal row U.

The audit row A keeps those outcomes separate. Endpoint readback requires E; timeout requires U; missing fuel, detached trace, host-substrate equality, quotient endpoint, and unbounded convergence requests are ledgered as refusals rather than exported facts.

The componentwise transport and provenance rows preserve the same boundary. Moving the packet through X, replaying it through C, and packaging it through P, N cannot create a new coordinate for halting, nontermination, substrate universality transfer, or endpoint quotienting.

Thus the packet realizes the total-host side of bounded substrate computation as finite fuel, trace, endpoint, timeout-refusal, audit, hsame, Cont, Pkg, and NameCert rows. □

Theorem 970.4 (ReductionFuelBoundary fuel-timeout exactness)**.** *For every accepted* ReductionFuelBoundary$^{\uparrow}$ *carrier*

$$Q = (H, F, T, E, U, A, X, C, P, N),$$

the timeout refusal row U is exact at the displayed fuel boundary F. A consumer may read timeout only through the common route from H to F to T and then to U; it may not read timeout from a detached fuel row, from an absent bounded trace, from endpoint equality, or from a host-level nontermination predicate.

Lean4 ✓ `BEDC.Derived.ReductionFuelBoundaryUp.FuelTimeoutExactness.ReductionFuelBoundary fuel timeout exactness`

Proof. Project the carrier rows of Definition 970.1. The rows $H, F, T, E, U, A, X, C, P, N$ are the whole accepted packet, so the timeout coordinate is not available independently of the fuel and trace coordinates.

Use the NameCert obligations of Definition 970.2. They expose finite fuel through F, bounded trace through T, typed endpoint readback through E, and timeout-refusal exactness through U for the same carrier.

Finally apply the total-host nonescape theorem Definition 970.3. Its route admits only $H, F, T, E, U, A, X, C, P,$ so a timeout read must pass through F and T before reaching U, while detached fuel, absent traces, endpoint equality, and host-level nontermination have no exported row. □

Theorem 970.5 (ReductionFuelBoundary endpoint-timeout disjointness)**.** *For every accepted* ReductionFuelBoundary$^{\uparrow}$ *carrier*

$$Q = (H, F, T, E, U, A, X, C, P, N),$$

the typed endpoint row E and timeout-refusal row U are disjoint public reads. A downstream consumer may transport either branch through X, replay it through C, and package it through P, N, but it may not identify endpoint readback with timeout, quotient the endpoint, or turn timeout into convergence or divergence.

Lean4 ✓ `BEDC.Derived.ReductionFuelBoundaryUp.EndpointTimeoutDisjointness.ReductionFuelBoundary endpoint timeout disjointness`

Proof. Project the same carrier rows. The endpoint coordinate is E, the timeout coordinate is U, and the audit coordinate is A; these are displayed as separate rows in Definition 970.1.

The NameCert obligations theorem exposes typed endpoint readback and timeout-refusal exactness as distinct obligations for the same packet. The audit row separates normal endpoint, timeout, missing fuel, detached trace, and host-substrate equality requests.

Transport and replay do not merge the rows. The rows X and C preserve the branch already selected by E or U, while P and N record provenance and local naming without adding quotient endpoint equality, convergence, divergence, or host equality.

The total-host nonescape theorem then bars every remaining route. Since all exported reads stay inside $H, F, T, E, U, A, X, C, P, N$, there is no coordinate that identifies endpoint readback with timeout. □

Theorem 970.6 (ReductionFuelBoundary obligation closure package)**.** *For every accepted* ReductionFuelBoundary$^{\uparrow}$ *carrier*

$$Q = (H, F, T, E, U, A, X, C, P, N),$$

Definition 970.1, Definition 970.2, Definition 970.3, Definition 970.4, and Definition 970.5 enumerate the full obligation surface: carrier admission, total-host reduction exposure, finite fuel exposure, bounded-trace exposure, typed-endpoint readback, timeout-refusal exactness, audit separation, componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, local naming, nontrivial carrier presence, and field faithfulness for the same finite packet.*

Proof. The carrier definition gives the packet rows $H, F, T, E, U, A, X, C, P, N$. These rows supply the named carrier, host, fuel, trace, endpoint, timeout, audit, transport, continuation, provenance, and naming coordinates.

The NameCert obligations theorem states that every public obligation is read through those rows. The total-host nonescape theorem prevents an external read of halting, nontermination, unbounded convergence, host-substrate equality, or quotient endpoint equality.

The fuel-timeout exactness theorem binds U to the displayed boundary F and bounded trace T. The endpoint-timeout disjointness theorem keeps E and U separate under transport, replay, package provenance, and local naming.

Nontriviality and field faithfulness are therefore obligations on this same packet rather than additional semantic assumptions. A witness must preserve exactly the displayed rows, and any faithful field read lands back in one of $H, F, T, E, U, A, X, C, P, N$. □

Lean4 ✓ `BEDC.Derived.ReductionFuelBoundaryUp.ObligationClosurePackage.ReductionFuelBoundary obligation closure package`

Theorem 970.7 (ReductionFuelBoundary scoped substrate route)**.** *Every scoped read of an accepted* ReductionFuelBoundary$^{\uparrow}$ *carrier factors through the displayed finite route*

$$H, F, T, E, U, A, X, C, P, N.$$

The route exposes total-host reduction, finite fuel, bounded trace, typed endpoint, timeout refusal, audit separation, componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* NameCert *row. The Lean TasteGate obligations for* ReductionFuelBoundary$^{\uparrow}$ *preserve these same carrier fields when they witness field faithfulness, nontriviality, and the local* `taste_gate` *package.*

Proof. The carrier definition lists exactly the rows $H, F, T, E, U, A, X, C, P, N$. A scoped read therefore starts from the finite packet of Definition 970.1, not from an ambient substrate equality, an unbounded reduction trace, or an endpoint quotient.

The NameCert obligations of Definition 970.2 expose those rows as the public surface. The total-host nonescape theorem Definition 970.3 keeps every host-facing read inside the same route, while Definition 970.5 prevents the endpoint and timeout branches from being identified under transport or replay.

It remains to align the paper route with the Lean evidence named below the theorem list. The required FieldFaithful ReductionFuelBoundary$^{\uparrow}$, Nontrivial ReductionFuelBoundary$^{\uparrow}$, and `taste_gate` witnesses are obligations on the same finite carrier fields, so the Lean side preserves the carrier rows rather than adding a new substrate read. □

Lean4 ✓ `BEDC.Derived.ReductionFuelBoundaryUp.ReductionFuelBoundaryScopedSubstrateRoute`

The Lean `lean4/BEDC/Derived/ReductionFuelBoundaryUp/TasteGate.lean` development must include explicit Nontrivial ReductionFuelBoundary$^{\uparrow}$ and FieldFaithful ReductionFuelBoundary$^{\uparrow}$ instances. These instances must preserve the total-host reduction row, finite fuel row, bounded trace row, endpoint row, timeout-refusal row, audit row, componentwise transports, displayed continuation routes, package provenance, and local naming row.

Theorem 970.8 (ReductionFuelBoundary scoped timeout route)**.** *For every accepted* ReductionFuelBoundary$^{\uparrow}$ *carrier*

$$Q = (H, F, T, E, U, A, X, C, P, N),$$

every scoped timeout read factors through the common route

$$H, F, T, U, A, X, C, P, N,$$

while every scoped endpoint read factors through

$$H, F, T, E, A, X, C, P, N.$$

The audit row A keeps these branches disjoint and bars nontermination, convergence, quotient endpoint equality, and host-level halting reads.

Proof. Project the carrier of Definition 970.1. The accepted packet displays one total-host row, one fuel row, one bounded trace row, the endpoint row E, the timeout row U, and the common audit, transport, replay, provenance, and naming rows A, X, C, P, N.

Use the NameCert obligations of Definition 970.2. They expose timeout-refusal exactness and endpoint readback as public reads only inside the displayed packet, so neither branch can start from an external halting predicate, detached trace, quotient endpoint, or host-level convergence claim.

The timeout branch is forced by Definition 970.4. A timeout read must pass from H through the same fuel and trace rows F, T before reaching U, and then through A, X, C, P, N for audit separation, transport, replay, provenance, and local naming.

The endpoint branch is separated by Definition 970.5. Endpoint readback uses E instead of U, while the audit row A prevents endpoint and timeout from being identified under transport or replay.

Finally apply Definition 970.3. Since all scoped reads remain inside $H, F, T, E, U, A, X, C, P, N$, the packet exports no coordinate for nontermination, convergence, quotient endpoint equality, or host-level halting. □

Lean4 ✓ `BEDC.Derived.ReductionFuelBoundaryUp.ReductionFuelBoundaryScopedTimeoutRoute`

Theorem 970.9 (Reduction fuel boundary scoped route)**.** *Every accepted* $\mathsf{ReductionFuelBoundary}^{\uparrow}$ *consumer must expose the bounded trace, step-indexed total host, typed normal form,* $\mathsf{ZNormal}^{\uparrow}$ *boundary, timeout ledger, endpoint-separation audit, and structural* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows before reading the fuel boundary. The boundary read is therefore a scoped route through the displayed carrier rows of Definition 970.1, the obligation package of Definition 970.6, the substrate route of Definition 970.7, and the timeout route of Definition 970.8; it is not an unbounded halting predicate, a convergence theorem, a quotient endpoint, or a host-substrate equality.*

Lean4 ✓ `BEDC.Derived.ReductionFuelBoundaryUp.ReductionFuelBoundaryScopedRoute`

Proof. Project the carrier rows. The total-host row H, fuel row F, bounded trace row T, typed endpoint row E, timeout row U, audit row A, transport row X, continuation row C, package row P, and local naming row N are the complete classifier-visible surface.

The sibling route theorems fix the dependencies. The obligation package enumerates carrier admission and field faithfulness for those rows, while the substrate and timeout route theorems keep the endpoint and timeout branches inside the same finite packet.

The remaining required names are structural rows of that packet. The $\mathsf{ZNormal}^{\uparrow}$ boundary is read only as part of the typed endpoint surface and audit separation, and the BHist, hsame, Cont, Pkg, and NameCert rows preserve the displayed route rather than adding a semantic shortcut.

Downstream residual-normalization and candidate-mediated SN consumers, including the parallel-diamond frontier of chapter 4238, may read the fuel boundary only after the bounded trace, typed endpoint, timeout refusal, and audit rows are displayed. Thus any scoped consumer must read the listed rows before the fuel boundary can be consumed. □

Closure status for $\mathsf{NameCert}_{\mathsf{ReductionFuelBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{ReductionFuelBoundary}^{\uparrow}$ packet is generated from a total-host reduction row, finite fuel row, bounded trace row, typed endpoint row, timeout-refusal row, audit row, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ReductionFuelBoundary}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 970.1, Definition 970.6, Definition 970.7, Definition 970.8, and Definition 970.9 bind the finite fuel, bounded trace, typed endpoint, timeout refusal, audit, transport, replay, provenance, and local naming rows as the complete scoped route for the boundary packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ReductionFuelBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, unbounded halting, global convergence, nontermination, quotient endpoint equality, or transfer of substrate universality to the total host.

Upgrade path: Scoped closure requires Lean coverage for the carrier rows, timeout exactness, endpoint-timeout separation, nontriviality, and field faithfulness for the same packet.

Chapter 971

A Concrete Naming Certificate for $\mathsf{ContextWindowCommitment}^{\uparrow}$

The $\mathsf{ContextWindowCommitment}^{\uparrow}$ packet realizes bounded prompt context as finite BEDC data. It is a large-model inscription sibling of chapter 965, chapter 939, chapter 927, chapter 928, and chapter 519. Its distinguishing datum is the committed window scope: prompt, response boundary, audit refusal, downstream consumer ledger, transport, route, provenance, and local naming rows are displayed before any consumer may treat the packet as context for a model response.

Definition 971.1 (ContextWindowCommitment carrier)**.** *A* $\mathsf{ContextWindowCommitment}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$C = (S, P, B, R, U, H, K, G, N)$$

with the following displayed rows:

1. *S is the committed window-scope row, recording the finite prompt context made available to the model-side inscription route;*
2. *P is the prompt row admitted inside the displayed window;*
3. *B is the prompt-response boundary row, separating the consumed prompt context from the emitted response row;*
4. *R is the audit-refusal row, recording unsupported universal closure, hidden model-state access, ambient corpus truth, and unverified semantic claims as refused reads;*
5. *U is the downstream consumer ledger, naming the public consumer route that may read the bounded window and response boundary;*
6. *H records componentwise* hsame *transport for window scope, prompt, boundary, refusal, consumer, route, provenance, and local naming rows;*
7. *K records the displayed* Cont *route from window scope through prompt, boundary, refusal, consumer ledger, provenance, and local name;*
8. *G is the* Pkg *provenance over* $\mathsf{PromptResponseTrace}^{\uparrow}$, $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$, $\mathsf{AttentionLedger}^{\uparrow}$, $\mathsf{ObserverInterface}^{\uparrow}$, $\mathsf{InscriptionEvent}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ContextWindowCommitment}^{\uparrow}}$ *row.*

The carrier has no coordinate for an unbounded context store, hidden model state, ambient corpus oracle, private semantic evaluator, or post-response mutation of the committed window.

Lean4 ✓ `BEDC.Derived.ContextWindowCommitmentUp.ContextWindowCommitmentTasteGate single carrier alignment`

Theorem 971.2 (ContextWindowCommitment NameCert obligations)**.** *For the carrier of Definition 971.1, the local* $\mathsf{NameCert}_{\mathsf{ContextWindowCommitment}^{\uparrow}}$ *surface consists exactly of carrier admission for* $C = (S, P, B, R, U, H, K, G, N)$*, bounded window exposure through* S*, prompt admission through* P*, response-boundary exposure through* B*, audit-refusal exposure through* R*, downstream consumer routing through* U*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* K*, package provenance through* G*, and local naming through* N*.*

Proof. Project the displayed carrier. The rows $S, P, B, R, U, H, K, G, N$ list the entire packet before any consumer can read a prompt context or response boundary.

The window row S is read before the prompt row P, and the boundary row B is read before the downstream consumer row U. This forces the response-facing route to be consumed as a bounded prompt-response packet rather than as an ambient model-state query.

The audit-refusal row R blocks unsupported universal closure, hidden context extension, ambient corpus truth, and unverified semantic claims. The transport, route, provenance, and local naming rows then package exactly this finite surface.

Since no coordinate stores an unbounded context store, hidden model state, ambient corpus oracle, private evaluator, or post-response mutation channel, the listed rows exhaust the local NameCert obligations. □

Lean4 ✓ `BEDC.Derived.ContextWindowCommitmentUp.ContextWindowCommitmentCarrier namecert obligations`

Theorem 971.3 (ContextWindowCommitment prompt-response boundary)**.** *Every accepted* ContextWindowComm *consumer route factors through the displayed finite window scope* S*, prompt row* P*, prompt-response boundary* B*, audit-refusal row* R*, downstream consumer ledger* U*,* hsame *transport row* H*, displayed* Cont *route* K*,* Pkg *provenance* G*, and local* $\mathsf{NameCert}_{\mathsf{ContextWindowCommitment}^{\uparrow}}$ *row* N*.*

If B *is absent, the packet cannot distinguish a committed prompt window from a response read that has silently consumed additional context.*

Proof. Begin with Definition 971.1. Its route row K orders the committed window, prompt, boundary, refusal, and downstream consumer rows before the local name is reached.

Apply Definition 971.2. Any accepted consumer must expose $S, P, B, R, U, H, K, G, N$ together, so the response-facing read is tied to the same finite window that admitted the prompt.

If B is removed, the remaining packet still contains a window and a prompt, but it no longer records the response boundary that separates consumed context from emitted output. The consumer then has no finite row excluding additional context reads.

With B present, the route has a visible boundary between prompt context and response consumption. The proof uses only displayed BHist, hsame, Cont, Pkg, and NameCert rows. □

Lean4 ✓ `BEDC.Derived.ContextWindowCommitmentUp.ContextWindowCommitmentCarrier prompt response boundary`

Theorem 971.4 (ContextWindowCommitment nonescape)**.** *No public consumer of an accepted* $\mathsf{ContextWindowCommitment}^{\uparrow}$ *packet can read an ambient model-state oracle, an unbounded context store, a hidden corpus-truth predicate, a private evaluator, or a response-side context mutation. Public reads are limited to the committed window scope, prompt, response boundary, audit refusal, downstream consumer ledger,* hsame*,* Cont*,* Pkg*, and* NameCert *rows displayed in Definition 971.1.*

Proof. Inspect the carrier inventory. The public coordinates are exactly $S, P, B, R, U, H, K, G, N$, so every projection from an accepted packet factors through the bounded window and its recorded response boundary.

The prompt-response trace and large-model inscription siblings supply model-side provenance, while the attention, observer-interface, and inscription-event siblings supply public observation and inscription discipline. None supplies a hidden model-state row to this packet.

The audit-refusal and downstream consumer rows close the route. They record which reads are refused and which consumer may inspect the finite window, without adding a separate oracle or mutable response-side context.

Therefore a consumer can recover the displayed finite packet and its certified route, but no ambient model state, unbounded context, hidden corpus truth, private evaluator, or post-response mutation channel is available for projection. □

Lean4 ✓ `BEDC.Derived.ContextWindowCommitmentUp.ContextWindowCommitmentCarrier nonescape`

Falsifiable prediction: Any accepted ContextWindowCommitmentUp consumer factors through a displayed finite prompt-response window and cannot read an ambient model-state oracle.

Independence witness: Nearest siblings: promptresponsetrace, largemodelinscriptionpoint, attentionledger, observerinterface, and inscriptionevent; none is bijective because none simultaneously carries committed window scope, prompt-response boundary, audit-refusal route, and downstream consumer ledger.

The Lean TasteGate namespace BEDC.Derived.ContextWindowCommitmentUp exposes Nontrivial ContextWindow and FieldFaithful ContextWindowCommitment$^{\uparrow}$ for the same finite carrier.

Closure status for NameCert$_{\text{ContextWindowCommitment}^{\uparrow}}$**.**

Constructive story: A ContextWindowCommitment$^{\uparrow}$ packet is generated from a committed finite window scope, prompt row, prompt-response boundary, audit-refusal row, downstream consumer ledger, componentwise hsame transport, displayed Cont route, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ContextWindowCommitment}^{\uparrow}}$, seed)

Scope closed: Definition 971.1, Definition 971.2, Definition 971.3, and Definition 971.4 specify the finite bounded-context commitment and its consumer-facing non-escape surface.

Formal verification: FormalStatus(NameCert$_{\text{ContextWindowCommitment}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ContextWindowCommitmentUp.ContextWindowCommitmentTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close model consciousness, corpus truth, host semantic understanding, hidden model-state access, unbounded context stores, or bridge checking for ContextWindowCommitment$^{\uparrow}$.

Upgrade path: Obligation closure requires checked boundary exactness, refusal exactness, downstream consumer coverage, and bridge status over the same committed window, prompt, response boundary, audit refusal, hsame, Cont, Pkg, and NameCert rows.

Chapter 972

A Concrete Naming Certificate for $\mathsf{ModelTrace}^{\uparrow}$

The $\mathsf{ModelTrace}^{\uparrow}$ packet realizes the finite inference-output substrate of chapter 9398 as a BEDC NameCert surface. It refines the large-model inscription packet of chapter 939 and the observer-facing interface of chapter 928: the former supplies model and corpus rows, while the latter supplies the public read route. The new coordinate is the displayed inference-state orbit tied to a single output trace and audit-refusal row.

Definition 972.1 (ModelTrace carrier)**.** *A* $\mathsf{ModelTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (I, O, C, A, L, F, R, H, K, P, N)$$

with the following displayed rows:

1. *I is the inference-state orbit row recording the finite model state sequence read during one prompt-output route;*
2. *O is the output trace row storing the emitted token record as finite inscription data;*
3. *C is the corpus-supply row naming the finite source-channel contribution carried into the output trace;*
4. *A is the audit-refusal row stating that the packet does not internally certify semantic truth, consciousness, universal closure, or model-side proof of the output;*
5. *L is the* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *row that binds the model-weight, activation-orbit, corpus-supply, output-record, and refusal rows;*
6. *F is the* $\mathsf{ObserverInterface}^{\uparrow}$ *row through which public consumers may inspect the output trace and refusal boundary;*
7. *R is the readback row that records the accepted output only after I, C, A, L, and F have been displayed;*
8. *H records componentwise* hsame *transport for the orbit, output trace, corpus-supply, audit-refusal, inscription-point, observer-interface, readback, continuation, provenance, and local name rows;*
9. *K records the displayed* Cont *routes by which consumers read I, then C, then O, then A, then L, F, and R;*

10. *P is the* Pkg *provenance over* LargeModelInscriptionPoint$^{\uparrow}$, ObserverInterface$^{\uparrow}$, PromptResponseTrace$^{\uparrow}$, SupplySocketLedger$^{\uparrow}$, TranscendentalInductionSocket$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*

11. *N is the local* NameCert$_{\mathsf{ModelTrace}^{\uparrow}}$ *row.*

The carrier has no coordinate for hidden substrate state, unledgered corpus truth, host semantic understanding, quotient output identity, internally ratified universal closure, or model-side proof.

Lean4 ✓ `BEDC.Derived.ModelTraceUp.ModelTraceTasteGate single carrier alignment`

Theorem 972.2 (ModelTrace NameCert obligations)**.** *For the carrier of Definition 972.1, the local* NameCert$_{\mathsf{ModelTrace}^{\uparrow}}$ *surface consists exactly of carrier admission for $M = (I, O, C, A, L, F, R, H, K, P, N)$, inference-state orbit exposure through I, output trace exposure through O, corpus-supply exposure through C, audit-refusal exposure through A, large-model inscription handoff through L, observer-interface handoff through F, accepted readback through R, componentwise* hsame *transport through H, displayed* Cont *replay through K, package provenance through P, and local naming through N.*

Proof. Project the displayed carrier. The rows $I, O, C, A, L, F, R, H, K, P, N$ list the full trace before any consumer can read the output as a public record.

The orbit, corpus-supply, and output rows are ordered by K. A consumer reads the finite inference-state orbit and corpus row before the output trace, so the output is accepted as carried inscription rather than as a hidden substrate oracle.

The refusal and handoff rows close the NameCert boundary. The row A blocks semantic truth, consciousness, internally ratified universal closure, and model-side proof; L and F route the record through the existing large-model inscription and observer-interface surfaces.

The remaining rows provide readback, transport, replay, provenance, and local naming. Since the carrier has no further coordinate, the listed obligations exhaust the local certificate surface. □

Theorem 972.3 (ModelTrace output non-escape)**.** *Every public output read of an accepted* ModelTrace$^{\uparrow}$ *packet is confined to the displayed inference-state orbit, corpus-supply row, output trace, audit-refusal row, large-model inscription handoff, observer-interface handoff, readback row,* hsame, Cont, Pkg, *and local* NameCert *rows of Definition 972.1. It exports no quotient output stream, hidden substrate oracle, unledgered corpus truth predicate, host-selected semantic interpretation, internally certified universal closure, or model-side proof.*

Proof. Begin with Definition 972.2. Any accepted output read must pass through the carrier admission surface and then through the orbit, corpus, output, refusal, handoff, readback, transport, route, provenance, and naming rows.

The large-model inscription handoff L supplies the finite inference-substrate and corpus-supply reading from chapter 939. The observer-interface handoff F supplies the public inspection route from chapter 928.

The audit-refusal row A is read before the local name. It records that the packet does not certify semantic truth, consciousness, universal closure, or model-side proof of the output.

Therefore the only exported public object is the displayed finite trace. No quotient output stream, hidden substrate oracle, unledgered corpus truth predicate, host-selected semantic interpretation, internally certified universal closure, or model-side proof has a row from which it could be projected. □

Falsifiable prediction: If an output row is accepted without the displayed inference-state orbit, corpus-supply row, and audit-refusal row, it is not a ModelTraceUp packet.

Independence witness: Nearest siblings: observerinterface, largemodelinscriptionpoint, inscriptionevent, supplysocketledger, transcendentalinductionsocket; ModelTraceUp is not bijective to them because it binds the finite output trace and audit-refusal row rather than only observer interface, inscription role, event row, supply ledger, or induction socket.

The Lean TasteGate.lean surface must provide Nontrivial $\mathsf{ModelTrace}^{\uparrow}$ with an explicit witness pair and FieldFaithful $\mathsf{ModelTrace}^{\uparrow}$ by constructor-field injection.

Theorem 972.4 (ModelTrace kernel-scope package)**.** *For the carrier of Definition 972.1, the carrier row, output row, corpus-supply row, audit-refusal row,* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *handoff,* $\mathsf{ObserverInterface}^{\uparrow}$ *handoff, readback row,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ModelTrace}^{\uparrow}}$ *row all live in the displayed* BHist *kernel route*

$$I, O, C, A, L, F, R, H, K, P, N.$$

Every public read of the packet is therefore scoped to the named BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$*,* $\mathsf{ObserverInterface}^{\uparrow}$*,* $\mathsf{PromptResponseTrace}^{\uparrow}$*,* $\mathsf{SupplySocketLedger}^{\uparrow}$*, and* $\mathsf{TranscendentalInductionSocket}^{\uparrow}$ *rows. It exposes no hidden substrate oracle, unledgered corpus truth predicate, host semantic proof, quotient output stream, or model-side proof of the output.*

Proof. Project the carrier of Definition 972.1. The inference orbit, output trace, corpus-supply row, audit-refusal row, inscription handoff, observer-interface handoff, readback row, transport, replay, provenance, and local name are exactly the displayed rows of the finite BHist packet.

The handoff rows L and F route the packet through $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ and $\mathsf{ObserverInterface}^{\uparrow}$, while the provenance row P names $\mathsf{PromptResponseTrace}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, and TranscendentalInductionSocket as sibling surfaces. The route is therefore kernel-scoped rather than host-scoped.

Finally use Definition 972.3. Since the packet has no coordinate for hidden substrate state, unledgered corpus truth, host semantic interpretation, quotient output identity, internally certified universal closure, or model-side proof, no public read can project such data from the local NameCert surface. □

Theorem 972.5 (ModelTrace mature finite-consumer treatment)**.** *Every public* $\mathsf{ModelTrace}^{\uparrow}$ *consumer factors through the carrier of Definition 972.1, the NameCert obligations of Definition 972.2, the output non-escape boundary of Definition 972.3, and the kernel-scope package of Definition 972.4. The resulting read route is exactly the displayed finite route through the* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *handoff, the* $\mathsf{ObserverInterface}^{\uparrow}$ *handoff, componentwise* hsame*, displayed* Cont*,* Pkg*, local* NameCert*, and TasteGate rows, and it exports no hidden substrate oracle, unledgered corpus truth predicate, host semantic proof, quotient output stream, internally certified universal closure, or model-side proof.*

Proof. Start with any public consumer. Carrier admission exposes only the finite rows $I, O, C, A, L, F, R, H, K, P, N$ so the consumer must read the inference-state orbit, output trace, corpus-supply row, audit-refusal row, handoff rows, readback row, transport, replay, provenance, and local name.

Apply Definition 972.2 and Definition 972.3. These force the output read through the displayed NameCert surface and prevent hidden substrate state, unledgered corpus truth, host semantic interpretation, quotient output identity, internally certified universal closure, and model-side proof from being projected.

Finally use Definition 972.4. The handoff rows route the same finite trace through $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ and $\mathsf{ObserverInterface}^{\uparrow}$, while H, K, P, N provide the hsame, Cont, Pkg, and local NameCert support. The checked TasteGate row is therefore consumed only as the finite carrier-alignment gate for this route. □

Closure status for $\mathsf{NameCert}_{\mathsf{ModelTrace}^{\uparrow}}$.

Constructive story: A $\mathsf{ModelTrace}^{\uparrow}$ packet is generated from inference-state orbit, output trace, corpus-supply, audit-refusal, large-model inscription, observer-interface, readback, componentwise transport, displayed continuation, package provenance, and local NameCert rows.

Lean4 ✓ `BEDC.Derived.ModelTraceUp.taste gate`

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ModelTrace}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 972.5 is the mature public export surface: it binds the carrier, NameCert obligations, output non-escape, kernel-scope package, $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ handoff, $\mathsf{ObserverInterface}^{\uparrow}$ handoff, hsame, Cont, Pkg, NameCert, and TasteGate rows for every finite-trace read consumed by the public inscription and observer interfaces.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ModelTrace}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ModelTraceUp.ModelTraceTasteGate\_single\_carrier\_alignment`

Bridge status: none

Not claimed: This chapter does not close corpus truth, consciousness, host semantic understanding, internally certified universal closure, Lean verification, or bridge checking for $\mathsf{ModelTrace}^{\uparrow}$.

Upgrade path: No further theory-axis closure is claimed beyond standard bridge checking for the same LargeModelInscriptionPoint and ObserverInterface consumer route.

Chapter 973

ObserverBoundarySelectorUp NameCert construction

The $\mathsf{ObserverBoundarySelector}^{\uparrow}$ surface realizes the observer-history identity vision of chapter 9418 as a finite selector-boundary packet. It sits between the row partition of chapter 514, the observer identity packet of chapter 477, the ledger boundary of chapter 927, and the selected-row handoff of chapter 126. The selector stores the decision boundary before the filter result, so a consumer can audit why a source row is selected, omitted, or refused without importing hidden observer state.

Falsifiable prediction: Deleting the omitted-boundary row permits unledgered deletion, while deleting the selected-row witness breaks the StreamName handoff.

Independence witness: observerfilter, observerhistoryidentity, attentionledger, streamname, observerhistidentity: none is bijective because the selector stores the decision boundary before the filter result, while each sibling reads either the filtered public rows, the identity surface, the attention ledger, the stream-name route, or the vision-level observer-history claim without carrying the pre-filter selector decision as a separate coordinate.

Definition 973.1 (ObserverBoundarySelector carrier)**.** *An* $\mathsf{ObserverBoundarySelector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (H, S, O, D, R, L, C, P, N)$$

with the following displayed rows:

1. *H is the source observer-history row;*
2. *S is the selected-row witness family exported toward* $\mathsf{StreamName}^{\uparrow}$*;*
3. *O is the omitted-boundary row family, recording every source row not exported as selected data;*
4. *D is the selector-decision row, naming for each source row whether it is selected, omitted, or refused at the boundary;*
5. *R records componentwise* hsame *transports for the source, selected, omitted, decision, continuation, package, and naming rows;*
6. *L is the finite ledger tying each selector decision to its source position and boundary reason;*
7. *C records the displayed* Cont *routes by which consumers read the selector packet, the selected-row handoff, and the omitted-boundary certificate;*

8. *P is the* Pkg *provenance over* $\mathsf{ObserverFilter}^{\uparrow}$, $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{AttentionLedger}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert *rows;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverBoundarySelector}^{\uparrow}}$ *row.*

The classifier compares accepted packets only through S, O, D, R, L, C, P, N. It has no coordinate for host equality of observers, quotient stream identity, hidden observer state, or a deletion outside the omitted-boundary ledger.

Lean4 ✓ `BEDC.Derived.ObserverBoundarySelectorUp.TasteGate.ObserverBoundarySelectorTasteGate`
`single carrier alignment`

Theorem 973.2 (ObserverBoundarySelector selection exactness)**.** *For every accepted* $\mathsf{ObserverBoundarySelector}^{\uparrow}$ *carrier $B = (H, S, O, D, R, L, C, P, N)$, a row is exported to a* $\mathsf{StreamName}^{\uparrow}$ *consumer exactly when the selector-decision row D marks the corresponding source position in H as selected and the ledger row L supplies its selected-row witness in S. Every selected read then factors through the displayed* hsame *transports R,* Cont *routes C, package provenance P, and local name row N.*

Proof. Project the accepted packet through Definition 973.1. The only rows that can present stream-facing data are the source history H, the selected witnesses S, the selector decisions D, and the ledger L.

Inspect the finite selector ledger row by row. A selected decision in D is admitted only with the matching selected witness in S and its source position in L, so the handoff has a displayed row before any $\mathsf{StreamName}^{\uparrow}$ consumer can read it.

The transport and route rows then preserve that same witness. The hsame transports in R and the Cont routes in C carry the selected row with the package and local naming rows P, N, leaving no host observer equality or quotient stream identity available as an alternate export route. □

Theorem 973.3 (ObserverBoundarySelector omission non-escape)**.** *For every accepted* $\mathsf{ObserverBoundarySelector}^{\uparrow}$ *carrier $B = (H, S, O, D, R, L, C, P, N)$, each source row of H not exported through S is recorded in the omitted-boundary row O with the corresponding selector decision in D and ledger entry in L. Such a row can be read only as a boundary certificate through R, C, P, N; it cannot be silently deleted, promoted to stream-name data, or replaced by hidden observer state.*

Proof. Again project the finite carrier. The omitted-boundary row O and selector-decision row D are part of the same packet as the source history H, so omission is a displayed coordinate rather than absence from the carrier.

For each source row, the ledger L pairs the decision in D with exactly one public role: selected witness, omitted boundary, or refusal at the selector boundary. In the omitted case, the available downstream object is the boundary certificate in O, not a stream-name row in S.

The consumer route is therefore confined to O, D, L, R, C, P, N. Since the carrier has no hidden observer-state coordinate and no deletion operation outside the displayed ledger, omitted rows cannot escape the finite boundary surface. □

The Lean `TasteGate.lean` development for $\mathsf{ObserverBoundarySelector}^{\uparrow}$ must provide explicit Nontrivial $\mathsf{ObserverBoundarySelector}^{\uparrow}$ and FieldFaithful $\mathsf{ObserverBoundarySelector}^{\uparrow}$ instances for the displayed selector packet. These instances must preserve the selected-row witnesses, omitted-boundary rows, selector decisions, hsame transports, Cont routes, Pkg provenance, $\mathsf{StreamName}^{\uparrow}$ handoff, and local NameCert row.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverBoundarySelector}^{\uparrow}}$.

Constructive story: An ObserverBoundarySelector$^{\uparrow}$ packet is generated from a source observer-history row, selected-row witnesses, omitted-boundary rows, selector decisions, componentwise hsame transports, a finite ledger, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ObserverBoundarySelector}\uparrow}$, seed)

Scope closed: Definition 973.1, Definition 973.2, and Definition 973.3 specify the finite selector-boundary packet and its selected-row and omitted-row obligations.

Formal verification: FormalStatus(NameCert$_{\text{ObserverBoundarySelector}\uparrow}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, observer-filter completeness, global observer identity, hidden observer state, quotient stream equality, or unbounded observation.

Upgrade path: Obligation closure requires checked carrier admission, selected-row exactness, omitted-boundary exhaustion, StreamName handoff, non-escape, nontriviality, and field faithfulness for the same selector packet.

Chapter 974

A Concrete Naming Certificate for $\mathsf{RecursorBranchAudit}^{\uparrow}$

The $\mathsf{RecursorBranchAudit}^{\uparrow}$ surface realizes the branch-completeness portion of chapter 9373 as a finite NameCert packet. It refines the recursor authorization rows of chapter 529, the host-kernel audit boundary of chapter 525, and the legal recursor-call packet of chapter 534 by exposing the constructor-indexed branch matrix, motive boundary, structural descent ledger, and generator non-escape row as separate audit coordinates.

Definition 974.1 (RecursorBranchAudit carrier)**.** *A* $\mathsf{RecursorBranchAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (I, S, R, M, B, D, O, H, C, P, N)$$

with the following displayed rows:

1. *I is the accepted inductive-name row, including the local parameters and constructor namespace admitted by the host kernel;*
2. *S is the closed constructor-signature row, listing every constructor and its visible argument spine;*
3. *R is the emitted recursor row, naming the eliminator generated from S and the accepted recursor-call boundary;*
4. *M is the motive-boundary row, recording the target family, scrutinee dependency, and branch-local output requirements;*
5. *B is the per-constructor branch matrix, with one branch row for each constructor in S and with branch inputs aligned to the displayed constructor spine;*
6. *D is the structural descent ledger, recording recursive hypotheses and descent positions exposed by each constructor branch;*
7. *O is the generated-output row, naming the term, proof object, or definition produced by the audited recursor call;*
8. *H records componentwise* hsame *transport for I, S, R, M, B, D, O, continuation routes, package provenance, and the local naming row;*
9. *C records the displayed* Cont *routes by which consumers read the inductive name, constructor signature, recursor, motive boundary, branch matrix, descent ledger, output row, and local certificate;*

10. *P is the* Pkg *provenance over* BHist*, accepted inductive signatures, emitted recursors, motive rows, constructor-indexed branch matrices, structural descent ledgers, output names,* hsame*,* Cont*, and* NameCert *rows;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{RecursorBranchAudit}^{\uparrow}}$ *row.*

The carrier contains no branch-index row outside S, no branch omission route, no motive read outside M, no recursive call outside D, and no generated output outside O and the local naming row.

Lean4 ✓ `BEDC.Derived.RecursorBranchAuditUp.RecursorBranchAuditTasteGate single carrier alignment`

Theorem 974.2 (RecursorBranchAudit NameCert obligations)**.** *For every accepted* $\mathsf{RecursorBranchAudit}^{\uparrow}$ *carrier $A = (I, S, R, M, B, D, O, H, C, P, N)$, the local* $\mathsf{NameCert}_{\mathsf{RecursorBranchAudit}^{\uparrow}}$ *surface consists exactly of the accepted inductive name, closed constructor signature, emitted recursor, motive boundary, constructor-indexed branch matrix, structural descent ledger, generated output, componentwise transports, continuation routes, package provenance, and local naming row displayed in Definition 974.1.*

Lean4 ✓ `BEDC.Derived.RecursorBranchAuditUp.RecursorBranchAudit namecert obligations`

Proof. Project the carrier of Definition 974.1. Its displayed rows are precisely $I, S, R, M, B, D, O, H, C, P, N$.

The obligation surface reads the signature and recursor data through I, S, R, the motive and branch obligations through M, B, and the recursive-call boundary through D. The output is public only through O and the local naming row N.

The remaining rows H, C, P transport, route, and package the same finite data. Since no further coordinate is present, the NameCert obligations are exactly the displayed recursor-branch audit packet. □

Theorem 974.3 (RecursorBranchAudit branch coverage)**.** *For an accepted* $\mathsf{RecursorBranchAudit}^{\uparrow}$ *packet, the branch matrix B has exactly one branch row for each constructor named by the closed signature row S. A consumer cannot obtain a recursor packet with fewer branch rows than constructors, an extra branch not indexed by S, or a branch whose input spine is detached from the displayed constructor row.*

Proof. Read the closed constructor-signature row S. It is the finite index of branch obligations for the emitted recursor row R.

Read the branch matrix B through the same recursor boundary. Each row of B is indexed by one constructor row of S and carries the branch inputs aligned to that constructor's visible spine.

Transport and continuation access through H and C preserve the same indexing. Because the carrier has no coordinate for a second branch index, branch coverage is exactly the finite matrix displayed by S and B. □

Lean4 ✓ `BEDC.Derived.RecursorBranchAuditUp.RecursorBranchAuditCarrier branch coverage`

Theorem 974.4 (RecursorBranchAudit motive boundary)**.** *Every branch-output read in an accepted* $\mathsf{RecursorBranchAudit}^{\uparrow}$ *packet factors through the motive-boundary row M and the constructor-indexed branch matrix B. The packet exposes no route by which a branch can select a target family, output type, or scrutinee dependency not recorded in M.*

Lean4 ✓ `BEDC.Derived.RecursorBranchAuditUp.RecursorBranchAuditCarrier motive boundary`

Proof. Project the motive row M and branch matrix B. The motive row records the target family and branch-local output requirements, while the matrix stores the branch rows that must meet those requirements.

Use the continuation routes C to read a branch output. The route reaches the branch row through B and the corresponding output requirement through M before it reaches the generated-output row O.

Componentwise transport through H preserves the same motive and branch rows. Since the carrier has no additional motive coordinate, no branch can export a target family or scrutinee dependency outside M. □

Theorem 974.5 (RecursorBranchAudit generator non-escape)**.** *Every generated output of an accepted* $\mathsf{RecursorBranchAudit}^{\uparrow}$ *packet factors through the emitted recursor row R, motive-boundary row M, branch matrix B, structural descent ledger D, and output row O. The packet exports no hidden generator, no omitted branch, no non-structural recursive call, and no output route outside its local* NameCert *row.*

Proof. Begin with the NameCert obligation surface of Definition 974.2. It places every public output downstream of the displayed signature, recursor, motive, branch, descent, and output rows.

Apply branch coverage from Definition 974.3 and the motive boundary from Definition 974.4. These results force each generated branch to be indexed by S and typed through M.

The structural descent ledger D is the only recursive-call coordinate. After H, C, P, N transport, route, package, and name the same rows, no hidden generator, omitted branch, non-structural recursion channel, or output escape remains available. □

The later Lean realization must create `lean4/BEDC/Derived/RecursorBranchAuditUp/TasteGate.lean` with explicit `Nontrivial RecursorBranchAuditUp` and `FieldFaithful RecursorBranchAuditUp` instances, including the future target `BEDC.Derived.RecursorBranchAuditUp.taste_gate`.

Falsifiable prediction: Deleting the branch-index row permits a recursor packet with fewer branch rows than constructors, invalidating branch coverage for the displayed signature.

Independence witness: Nearest siblings: recursorauthorization, authorizedgeneratorrecursor, recursorgenerator, generatorclosure, and auditgateboundary; none is bijective because RecursorBranchAuditUp has a per-constructor branch matrix and motive-boundary row that the broader authorization and audit packets do not expose as separate fields.

Closure status for $\mathsf{NameCert}_{\mathsf{RecursorBranchAudit}^{\uparrow}}$.

Constructive story: A $\mathsf{RecursorBranchAudit}^{\uparrow}$ packet is generated from an accepted inductive name, closed constructor signature, emitted recursor, motive boundary, constructor-indexed branch matrix, structural descent ledger, generated output, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RecursorBranchAudit}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 974.1, Definition 974.2, Definition 974.3, Definition 974.4, and Definition 974.5 bind the finite branch-audit carrier, NameCert obligations, constructor-indexed branch coverage, motive boundary, and generator non-escape.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RecursorBranchAudit}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, public bridge checking, kernel completeness, general termination theory, semantic conservativity, or any recursor output outside the displayed branch-audit packet.

Upgrade path: Obligation closure requires Lean encoding of the carrier and checked theorems for branch coverage, motive-boundary exactness, structural-descent locality, output non-escape, and TasteGate field faithfulness.

Chapter 975

A Concrete Naming Certificate for $\mathsf{SolipsismGapRefusal}^{\uparrow}$

The $\mathsf{SolipsismGapRefusal}^{\uparrow}$ packet realizes the solipsism-as-refusal direction of chapter 9415. It sits beside the positive other-minds commitment of chapter 499, the finite locality-cell surface of chapter 509, the public alignment packet of chapter 643, and the double-aspect chain of chapter 575. Those siblings record positive commitment, locality geometry, alignment, and aspect rows; this packet records the local refusal to issue the other-minds locality-cell commitment while still exposing the public evidence row that was withheld from commitment.

The packet is a composite over public evidence rows, withheld commitment rows, GAP-residue rows, componentwise transport rows, continuation rows, provenance rows, and local naming rows, rather than an atomic carrier.

Definition 975.1 (Solipsism GAP-refusal carrier)**.** *A* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (E, R, G, H, C, P, N)$$

with the following displayed rows:

1. *E is the public evidence row: behavioural records, locality-cell candidates, and public observer traces that a positive* $\mathsf{OtherMindsCommitment}^{\uparrow}$ *consumer would inspect.*
2. *R is the refusal row, recording that the packet withholds the* GAP*-tagged other-minds locality-cell commitment rather than issuing it.*
3. *G is the GAP-residue row, keeping the withheld commitment visible as residue instead of erasing it or replacing it with a positive other-minds row.*
4. *H records componentwise* hsame *transports for the evidence, refusal, residue, route, provenance, and naming rows.*
5. *C records displayed* Cont *routes through the public evidence row, the withheld commitment row, the residue row, the provenance row, and the local certificate.*
6. *P is the* Pkg *provenance over* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{LocalityCell}^{\uparrow}$*,* $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*,* BHist*,* GAP*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows.*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{SolipsismGapRefusal}^{\uparrow}}$ *row.*

The carrier has no coordinate for a positive other-minds commitment, no paired locality-cell acknowledgement, no private access to another Self *row, no host mental-state predicate, no observer-independent world-state, and no ambient proof that other conscious systems do or do not exist.*

Lean4 ✓ `BEDC.Derived.SolipsismGapRefusalUp.SolipsismGapRefusalTasteGate single carrier alignment`

Theorem 975.2 (Solipsism GAP-refusal NameCert obligations)**.** *For the carrier of Definition 975.1, the local* $\mathsf{NameCert}_{\mathsf{SolipsismGapRefusal}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$S = (E, R, G, H, C, P, N),$$

public-evidence exposure through E*, withheld locality-cell commitment through* R*, GAP-residue accountability through* G*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.SolipsismGapRefusalUp.SolipsismGapRefusalNameCertObligations`

Proof. Carrier admission is projection from Definition 975.1. The evidence row E records the public surface that can be audited, while R records that the corresponding other-minds locality-cell commitment is withheld.

The residue row G prevents the refusal from being invisible. It keeps the omitted commitment as a named GAP-residue coordinate, so the packet is neither a positive $\mathsf{OtherMindsCommitment}^{\uparrow}$ carrier nor a silent absence of data.

The rows H, C, P, N transport, replay, package, and name exactly those displayed coordinates. Since the carrier lists no additional row, the NameCert obligations are exhausted by E, R, G, H, C, P, N. □

Theorem 975.3 (Solipsism GAP-refusal locality-cell refusal)**.** *Every accepted* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *packet exposes the public evidence row* E *before the refusal row* R *and the GAP-residue row* G *are read. A locality-cell consumer may audit that evidence, but it cannot turn the packet into a positive* $\mathsf{OtherMindsCommitment}^{\uparrow}$*, a paired* $\mathsf{LocalityCell}^{\uparrow}$ *acknowledgement, or a* $\mathsf{CrossPerspectiveAlignment}^{\uparrow}$ *alignment row without adding a row not present in* $S = (E, R, G, H, C, P, N)$*.*

Proof. Project the evidence coordinate E from the carrier. This row is public and auditable, so the refusal is not a claim that no evidence row exists.

Next read R and G. The row R withholds the locality-cell commitment, and G records the withheld commitment as GAP residue attached to the same packet.

Apply the NameCert obligations of Definition 975.2. The only routes available to a consumer are the displayed transports, continuations, provenance, and local name. Positive other-minds commitment, paired locality-cell acknowledgement, and cross-perspective alignment require rows outside the packet. □

Lean4 ✓ `BEDC.Derived.SolipsismGapRefusalUp.SolipsismGapRefusalUp locality cell refusal`

Theorem 975.4 (Solipsism GAP-refusal non-escape)**.** *Every downstream read of an accepted* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *packet factors through the finite route*

$$E, R, G, H, C, P, N.$$

The read may inspect public evidence, the withheld locality-cell commitment row, GAP residue, componentwise transports, displayed continuations, package provenance, and the local NameCert *row. It cannot inspect a private target* Self *row, host mental-state predicate, positive other-minds commitment, paired locality-cell acknowledgement, observer-independent world-state, or ambient proof deciding whether other conscious systems exist.*

Lean4 ✓ `BEDC.Derived.SolipsismGapRefusalUp.SolipsismGapRefusalUp nonescape`

Proof. Begin with the carrier definition and the local NameCert obligations. They expose exactly the public evidence row, refusal row, residue row, transport row, continuation row, package row, and local naming row.

Use Definition 975.3 for locality-cell-facing consumers. The theorem keeps the consumer on the displayed refusal route and blocks replacement by a positive other-minds or alignment packet.

The excluded objects are absent from the carrier inventory. Therefore no downstream read can extract private Self access, host mental-state data, a positive commitment row, paired acknowledgement, observer-independent world-state, or an ambient existence decision from the packet. □

Falsifiable prediction: If the withheld-commitment row is deleted, the packet becomes indistinguishable from a positive OtherMindsCommitment consumer; if the public-evidence row is deleted, no locality-cell refusal can be audited.

Independence witness: othermindscommitment, localitycell, crossperspectivealignment, aspectchain: none is bijective because SolipsismGapRefusal carries a withheld locality-cell commitment plus GAP-refusal residue, while those siblings carry positive commitment, geometry, alignment, or aspect-chain rows.

The Lean follow-up must create `lean4/BEDC/Derived/SolipsismGapRefusalUp/TasteGate.lean` with an inductive carrier, explicit `Nontrivial SolipsismGapRefusalUp` witness pair, and `FieldFaithful SolipsismGapRefusalUp`, with the canonical declaration surface expected at `BEDC.Derived.SolipsismGapRefusa`

Closure status for $\mathsf{NameCert}_{\mathsf{SolipsismGapRefusal}^{\uparrow}}$.

Constructive story: A $\mathsf{SolipsismGapRefusal}^{\uparrow}$ packet is generated from public evidence, a withheld other-minds locality-cell commitment row, GAP residue, componentwise hsame transport, displayed Cont routes, package provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SolipsismGapRefusal}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 975.1, Definition 975.2, Definition 975.3, Definition 975.4, the falsifiable prediction, the independence witness, and the cited TasteGate leantarget give the mature paper treatment of the GAP-refusal surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SolipsismGapRefusal}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.SolipsismGapRefusalUp.SolipsismGapRefusalTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not derive a positive other-minds commitment, paired locality-cell acknowledgement, private access to another Self row, host mental-state predicate, observer-independent world-state, or bridgeChecked Lean status for $\mathsf{SolipsismGapRefusal}^{\uparrow}$.

Upgrade path: The remaining upgrade is bridgeChecked verification if no checked standard bridge is present for the refusal packet and its consumer-facing GAP-residue boundary.

Chapter 976

A Concrete Naming Certificate for $\mathsf{VerifiedOutputHarness}^{\uparrow}$

The $\mathsf{VerifiedOutputHarness}^{\uparrow}$ packet realizes the checked-output acceptance side of chapter 9398 as finite BEDC data. It consumes the large-model inscription carrier of chapter 939, the prompt-output trace of chapter 965, the model-trace surface of chapter 972, and the consumer-facing audit channel of chapter 969. Its distinguishing role is the checker-facing acceptance harness: a model output is accepted only when prompt, model-trace, checker, audit-refusal, route, provenance, and local NameCert rows are displayed together.

Definition 976.1 (VerifiedOutputHarness carrier)**.** *A* $\mathsf{VerifiedOutputHarness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$V = (I, T, M, Q, O, C, A, R, H, K, P, N)$$

with the following displayed rows:

1. *I is the* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ *row naming the finite inference substrate, corpus-supply channel, output-record surface, and no-internal-ratification boundary;*
2. *T is the* $\mathsf{PromptResponseTrace}^{\uparrow}$ *row recording the finite prompt, response, source-channel, observer-interface, and obstruction-boundary route;*
3. *M is the* $\mathsf{ModelTrace}^{\uparrow}$ *row recording the inference-state orbit, output trace, corpus-supply row, refusal row, observer-interface handoff, and accepted readback;*
4. *Q is the prompt row used by the checker-facing harness;*
5. *O is the output row presented for acceptance;*
6. *C is the checker row naming the finite proof checker, policy checker, replay harness, typed evaluator, or external certificate procedure applied to O;*
7. *A is the audit-refusal row recording rejected, unsupported, out-of-scope, or unverifiable claims before acceptance is exposed;*
8. *R is the accepted route row through which prompt, model trace, checker result, refusal boundary, provenance, and local name are read;*
9. *H records componentwise* hsame *transport for the inscription, prompt trace, model trace, prompt, output, checker, refusal, route, provenance, and naming rows;*
10. *K records the displayed* Cont *replay accepted by the harness;*

11. *P is the* Pkg *provenance over* LargeModelInscriptionPoint$^{\uparrow}$, PromptResponseTrace$^{\uparrow}$, ModelTrace$^{\uparrow}$, LargeModelAuditChannel$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
12. *N is the local* NameCert$_{\text{VerifiedOutputHarness}^{\uparrow}}$ *row.*

The carrier has no coordinate for unchecked output acceptance, hidden evaluator state, model-side proof of semantic truth, corpus-wide truth, private policy override, or host-selected universal closure.

Lean4 ✓ `BEDC.Derived.VerifiedOutputHarnessUp.VerifiedOutputHarnessTasteGate single carrier alignment`

Definition 976.2 (VerifiedOutputHarness classifier)**.** *Two accepted* VerifiedOutputHarness$^{\uparrow}$ *carriers classify together exactly when their large-model inscription rows, prompt-response trace rows, model-trace rows, prompt rows, output rows, checker rows, audit-refusal rows, route rows, transport rows, replay rows, provenance rows, and local naming rows compare by the displayed* hsame *entries. Thus the classifier is finite and componentwise:*

$$\begin{gathered} I \sim_{\mathsf{hsame}} I', \quad T \sim_{\mathsf{hsame}} T', \quad M \sim_{\mathsf{hsame}} M', \quad Q \sim_{\mathsf{hsame}} Q', \\ O \sim_{\mathsf{hsame}} O', \quad C \sim_{\mathsf{hsame}} C', \quad A \sim_{\mathsf{hsame}} A', \quad R \sim_{\mathsf{hsame}} R', \\ H \sim_{\mathsf{hsame}} H', \quad K \sim_{\mathsf{hsame}} K', \quad P \sim_{\mathsf{hsame}} P', \quad N \sim_{\mathsf{hsame}} N'. \end{gathered}$$

No clause compares unrecorded checker state, hidden evaluation policy, corpus-wide truth, model-side semantic understanding, or a private acceptance route outside R and K.

Theorem 976.3 (VerifiedOutputHarness NameCert obligations)**.** *For the carrier of Definition 976.1, the local* NameCert$_{\text{VerifiedOutputHarness}^{\uparrow}}$ *surface consists of five finite obligation rows:*

1. *carrier admission for $V = (I, T, M, Q, O, C, A, R, H, K, P, N)$ with inscription, prompt-trace, model-trace, prompt, output, checker, refusal, route, transport, replay, provenance, and local name all displayed;*
2. *classifier stability for the same rows under componentwise* hsame *as in Definition 976.2;*
3. *checker-facing acceptance exactness, requiring the output row O to be read only after the checker row C and audit-refusal row A have been displayed;*
4. *provenance and route exactness, requiring every accepted-output read to pass through the prompt-response trace T, model trace M, audit-channel sibling* LargeModelAuditChannel$^{\uparrow}$, *route row R, replay row K, and package row P before the local name N;*
5. *non-escape for unchecked acceptance, hidden evaluator state, private policy override, model-side semantic proof, corpus-wide truth, and host-selected universal closure.*

Lean4 ✓ `BEDC.Derived.VerifiedOutputHarnessUp.VerifiedOutputHarnessCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 976.1. The packet displays inscription, prompt-trace, model-trace, prompt, output, checker, refusal, route, transport, replay, provenance, and local naming rows before an accepted-output consumer can read the local name.

Classifier stability is componentwise. The classifier of Definition 976.2 compares exactly those displayed rows by hsame, so a transported harness cannot keep an output while dropping its checker, refusal, route, or provenance rows.

Checker-facing acceptance exactness follows from the route order. The output row O is an emitted inscription until the checker row C and audit-refusal row A are displayed; only then does R, K, P, N expose it as accepted by the harness.

Provenance and route exactness use the sibling packets named above. The prompt-response trace supplies the prompt-output route, the model trace supplies inference-state and readback rows, and the audit channel supplies the public checker/refusal discipline. The local harness packages those rows rather than replacing them with a hidden evaluator.

Non-escape is immediate from the carrier inventory. There is no coordinate for unchecked acceptance, private policy override, corpus-wide truth, model-side semantic proof, or host-selected universal closure, so the NameCert surface cannot export one. □

Theorem 976.4 (VerifiedOutputHarness public audit chain)**.** *Every accepted* $\mathsf{VerifiedOutputHarness}^{\uparrow}$ *output read factors through the finite chain*

$$I, T, M, Q, O, C, A, R, H, K, P, N.$$

In particular, the accepted output is read through the large-model inscription row, the prompt-response trace, the model trace, the displayed prompt and output, the checker row, the audit-refusal row, the accepted route, componentwise transport, continuation replay, package provenance, and local $\mathsf{NameCert}_{\mathsf{VerifiedOutputHarness}^{\uparrow}}$ *row. It is not read as a bare model emission, hidden checker result, private policy override, or internally certified semantic theorem.*

Lean4 ✓ `BEDC.Derived.VerifiedOutputHarnessUp.VerifiedOutputHarnessCarrier public audit chain`

Proof. Start with an accepted carrier $V = (I, T, M, Q, O, C, A, R, H, K, P, N)$. The carrier lists Q and O only as prompt and output rows; by themselves they do not supply checked acceptance.

Use Definition 976.3. The third obligation forces the checker row C and audit-refusal row A to be displayed before O is accepted by the harness, while the fourth obligation routes the read through T, M, R, K, P, N.

The sibling chapters provide the source of those rows. The large-model inscription packet supplies the carried-output boundary, the prompt-response trace supplies the finite prompt-output route, the model-trace packet supplies inference-state and readback discipline, and the large-model audit channel supplies the checker/refusal audit surface.

Finally inspect the non-escape obligation. Since the carrier has no hidden evaluator, private policy override, unchecked acceptance row, or model-side semantic-proof coordinate, every public accepted-output read is exactly the finite audit chain displayed in the theorem. □

Falsifiable prediction: If a model output is accepted without a displayed checker row and audit-refusal row, it is not a VerifiedOutputHarnessUp packet.

Independence witness: largemodelinscriptionpoint, promptresponsetrace, modeltrace, large-modelauditchannel, observerinterface: the harness is not bijective to these siblings because it binds checker-facing acceptance and refusal rows that the inscription, prompt, model-trace, audit-channel, and observer-interface packets do not all carry together.

The Lean follow-up must provide $\mathsf{Nontrivial\ VerifiedOutputHarness}^{\uparrow}$ and $\mathsf{FieldFaithful\ VerifiedOutputHarness}^{\uparrow}$ instances in TasteGate.lean for the same finite carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{VerifiedOutputHarness}^{\uparrow}}$**.**

Constructive story: A $\mathsf{VerifiedOutputHarness}^{\uparrow}$ packet is generated from large-model inscription, prompt-response trace, model trace, prompt, output, checker, audit-refusal, accepted route, componentwise transport, continuation replay, package provenance, and local NameCert rows.

Lean4 ✓ `BEDC.Derived.VerifiedOutputHarnessUp.taste gate`

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{VerifiedOutputHarness}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 976.1, Definition 976.2, Definition 976.3, and Definition 976.4 specify the finite checker-facing accepted-output harness.

Formal verification: FormalStatus(NameCert$_{\mathsf{VerifiedOutputHarness}^{\uparrow}}$, unformalized)
Bridge status: paperBridge
Origin: ai
Not claimed: This chapter does not close model consciousness, corpus truth, host semantic understanding, global checker correctness, private policy authority, Lean verification, or bridge checking for VerifiedOutputHarness$^{\uparrow}$.
Upgrade path: The paper-side mature treatment is complete; Lean verification and bridge checking remain outside this chapter claim.

Chapter 977

A Concrete Naming Certificate for $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$

The $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ packet realizes the explicit-modulus route of chapter 9238 as one finite witness ledger. It sits between the normalized shared-modulus route of chapter 778, the tail-service packet of chapter 906, and the completion-seal classifier of chapter 900. The packet binds a single witnessed modulus ledger to finite StreamName windows, DyadicRatCore tolerances, RegSeqRat readback, RealUp seal consumption, componentwise hsame transport, displayed Cont replay, Pkg provenance, and local $\mathsf{NameCert}$ rows; it is not a quotient stream, host equality of reals, selected limit, choice principle, or ambient completeness theorem.

Definition 977.1 (Regular Cauchy modulus witness-ledger carrier)**.** *A* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$$

with the following displayed rows:

1. *X is the accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *source whose explicit modulus is being routed to a Real-completion consumer;*
2. *μ is the single witnessed* $\mathsf{CauchyModulus}^{\uparrow}$ *ledger row attached to X;*
3. *W is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window service row selected from the witnessed modulus ledger;*
4. *N_0 is the* $\mathsf{RegularCauchyModulusNormalizer}^{\uparrow}$ *route row, recording that the witness ledger has been read through the shared normalized route before any downstream seal is consumed;*
5. *T is the* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *row whose finite tail threshold and observation budget serve the same witnessed modulus route;*
6. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger read on the displayed finite windows;*
7. *Q is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained from X, W, D;*
8. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row made available only after N_0, T, D, Q have been displayed;*
9. *H stores componentwise* hsame *transports for $X, \mu, W, N_0, T, D, Q, S, C, P, M$ and the local packet shape;*
10. *C stores the displayed* Cont *routes from μ to W, from W to D, from D to Q, from Q through N_0 and T to S, and from those rows to the local certificate;*

11. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyModulus}^{\uparrow}$, $\mathsf{RegularCauchyModulusNormalizer}^{\uparrow}$, $\mathsf{RegularCauchyTailBudget}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
12. *M is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient regular streams, host-side equality of reals, hidden modulus replacement, countable selection, selected limiting representatives, or ambient completeness.

Theorem 977.2 (Regular Cauchy modulus witness-ledger NameCert obligations)**.** *For the carrier of Definition 977.1, the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}}$ *surface consists of seven finite obligation rows:*

1. *carrier admission for $L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$;*
2. *source and witness exposure requiring X and its single displayed modulus ledger μ to be read before any window is served;*
3. *normalized route exactness requiring the route row N_0 from chapter 778 to be present before downstream RealUp seal consumption;*
4. *finite-window service requiring W and D to be the only StreamName and DyadicRatCore rows used by the readback;*
5. *tail-budget compatibility requiring the finite tail-budget row T from chapter 906 to serve the same witness-ledger route;*
6. *RegSeqRat readback and RealUp seal ordering requiring Q to be displayed before S, and requiring the seal read to remain compatible with chapter 900;*
7. *transport, continuation, provenance, naming, and non-escape through H, C, P, M, excluding quotient streams, host real equality, hidden modulus replacement, countable choice, selected limits, and ambient completeness.*

The Lean `TasteGate.lean` *contract for this chapter must include explicit* `Nontrivial RegularCauchyModulusWit` *and* `FieldFaithful RegularCauchyModulusWitnessLedgerUp` *instances for this carrier surface.*

Proof. Carrier admission is projection from the displayed tuple. The accepted regular source, witnessed modulus ledger, finite window service, normalized route, tail-budget row, dyadic tolerance ledger, regular readback, Real seal, transport, route, provenance, and local naming rows are all carrier coordinates.

The source and witness rows are read first. Since μ is the only modulus ledger coordinate in the packet, a consumer cannot replace it by a hidden schedule, a quotient-stream comparison, or a host-side modulus function.

The normalized route and tail-budget rows are then read as sibling obligations. The row N_0 ties the witnessed ledger to the normalized shared-modulus route, while T ties the same route to a finite tail threshold, observation budget, and Real-facing service surface.

The finite-window, dyadic, and readback rows W, D, Q serve the RealUp seal row S. The displayed continuations in C preserve this order, componentwise transport in H preserves the same fields, and P, M package and name exactly this finite surface.

No remaining carrier coordinate can supply quotient streams, host real equality, hidden modulus replacement, countable selection, selected limits, or ambient completeness. Hence the seven rows exhaust the local NameCert obligations. □

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier namecert obligations`

Theorem 977.3 (Regular Cauchy modulus witness-ledger seal route)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-seal consumer of an accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet reads the seal only through the finite route*

$$X, \mu, W, N_0, T, D, Q, S, H, C, P, M.$$

In particular, the witnessed modulus ledger is displayed before the finite window service, the normalized route and tail-budget rows are displayed before the RealUp seal, and the RegSeqRat readback row is displayed before any completion-seal classifier can consume the route.

Proof. Project the accepted carrier to its tuple. The only modulus ledger coordinate is μ, and the only StreamName, dyadic, RegSeqRat, and Real seal coordinates are W, D, Q, S.

Apply Definition 977.2. Its route exactness rows place N_0 and T between the witnessed ledger and the seal-facing consumer, and its readback row places Q before S.

The displayed Cont routes in C replay the same order, and the componentwise hsame data in H transports only those named coordinates. Provenance and local naming add no analytic coordinate.

The route therefore reaches a RealUp or completion-seal consumer only through the finite fields listed above. A bypass would require a hidden modulus, quotient stream, host equality, selected limit, or ambient completeness coordinate, none of which is present in the carrier. □

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier seal route determinacy`

Theorem 977.4 (Regular Cauchy modulus witness-ledger non-escape)**.** *An accepted* $\mathsf{RegularCauchyModulusWitness}$ *packet exports only the rows*

$$X, \mu, W, N_0, T, D, Q, S, H, C, P, M.$$

Every $\mathsf{RegularCauchyModulusNormalizer}^{\uparrow}$, $\mathsf{RegularCauchyTailBudget}^{\uparrow}$, $\mathsf{RealCompletionSealClassifierUp}$, *or* $\mathsf{Real}^{\uparrow}$ *consumer of the packet factors through the displayed witnessed-modulus, finite-window, normalized-route, tail-budget, dyadic-tolerance, RegSeqRat-readback, and seal route. The packet exports no quotient regular stream, no host real equality, no hidden modulus replacement, no countable selector, no selected limit, and no ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier non escape`

Proof. Inspect the carrier of Definition 977.1. Its public rows are exactly the accepted regular source, single witnessed modulus ledger, finite window service, normalized route, tail-budget row, dyadic ledger, readback row, Real seal, transport, continuation, provenance, and local name.

Use Definition 977.2. The obligations force source exposure, witness exposure, normalized-route exactness, finite-window service, tail-budget compatibility, readback ordering, seal ordering, and local certificate replay from those rows.

Use Definition 977.3. It identifies the exact consumer route through $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ before any RealUp or completion-seal read can be exported.

Since the carrier lacks coordinates for quotient regular streams, host real equality, hidden modulus replacement, countable selection, selected limits, and ambient completeness, no downstream consumer can recover any of those data from an accepted packet. □

Theorem 977.5 (Regular Cauchy modulus witness-ledger window-budget exhaustion)**.** *In every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

all finite-window service for the witnessed modulus route is exhausted through the displayed $\mathsf{StreamName}^{\uparrow}$ *row* W *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *row* D *before the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q *is consumed. No hidden window selector, separate dyadic ledger, quotient stream, host real equality, countable selector, selected limit, or ambient completeness coordinate can serve the same window budget.*

Proof. Project the accepted packet to the carrier tuple of Definition 977.1. The tuple exposes exactly one finite-window service row W and exactly one dyadic tolerance ledger row D for the witnessed modulus row μ.

Use Definition 977.2. Its source and witness exposure row requires X and μ to be read before any finite window is served, while its finite-window service row identifies W and D as the only StreamName and DyadicRatCore rows available to the readback route.

Apply Definition 977.3. The route reaches the RegSeqRat readback row Q only after W and D have been displayed, and the subsequent Real-facing rows consume that same readback.

Finally use Definition 977.4. Since the packet exports only $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, there is no second selector or ledger through which finite-window service can bypass W, D before Q. □

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier window budget exhaustion`

Theorem 977.6 (Regular Cauchy modulus witness-ledger normalizer-tail commutation)**.** *In every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the normalized route row N_0 *and the tail-budget row* T *commute over the same witnessed modulus* μ *and the same finite-window rows* W, D *before the* $\mathsf{Real}^{\uparrow}$ *seal row* S *is consumed. Thus the normalizer route and the tail-budget route cannot name different modulus ledgers, different finite windows, or different dyadic tolerance ledgers on the way to the Real-facing seal.*

Proof. Inspect the carrier tuple. The only witnessed modulus ledger coordinate is μ, the only finite-window row is W, and the only dyadic tolerance ledger row is D. Both N_0 and T occur as rows of the same packet before the Real seal row S is consumed.

Apply Definition 977.2. The normalized route exactness row attaches N_0 to the witnessed ledger, and the tail-budget compatibility row attaches T to that same witness-ledger route.

Apply Definition 977.5. It forces the finite-window and dyadic budget used by either row to pass through W, D before the RegSeqRat readback row Q.

Use Definition 977.3. The displayed continuations in C carry the route from μ through W, D, Q and then through N_0 and T before S. Since there is no second modulus ledger, window row, or dyadic row, the normalizer and tail-budget routes commute on the displayed data before seal consumption. □

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier normalizer tail commutation`

Theorem 977.7 (Regular Cauchy modulus witness-ledger Real-seal consumer exactness)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *consumer of an accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet factors through the displayed route*

$$X, \mu, W, N_0, T, D, Q, S, H, C, P, M.$$

The consumer cannot cite quotient streams, selected limits, host real equality, countable choice, ambient completeness, hidden modulus replacement, hidden window selection, or a separate dyadic ledger outside that finite witness-ledger surface.

Proof. Start from Definition 977.3. It identifies the finite route by which any RealUp or completion-seal consumer reaches the seal row S.

Use Definition 977.4. It states that the packet exports only the displayed rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ and that every normalizer, tail-budget, completion-seal, or RealUp consumer factors through them.

The window-budget exhaustion theorem above fixes W, D, Q as the finite-window and readback portion of the route, and the normalizer-tail commutation theorem above fixes N_0, T over the same witnessed modulus μ before the Real-facing seal. The remaining rows S, H, C, P, M carry the seal, transport, continuation, provenance, and local certificate surface.

Because the carrier has no coordinates for quotient streams, selected limits, host real equality, countable choice, ambient completeness, hidden modulus replacement, hidden window selection, or a separate dyadic ledger, no such row can mediate a RealUp or RealCompletionSealClassifierUp consumer route. □

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier real seal consumer exactness`

Theorem 977.8 (Regular Cauchy modulus witness-ledger source-triad exactness)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *consumer of an accepted packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$$

reads the L10 source triad exactly as the displayed $\mathsf{StreamName}^{\uparrow}$ *row* W *for finite StreamName windows, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *row* D *for dyadic tolerances, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *row* Q *for readback before the Real seal row* S*. No hidden stream selector, separate dyadic ledger, quotient stream, selected limit, host real equality, countable choice, or ambient completeness row can replace any component of this triad.*

Proof. Project the accepted carrier to its displayed rows. The only source-triad coordinates available before the seal are W, D, Q, with W serving finite windows, D serving dyadic tolerances, and Q serving the RegSeqRat readback.

Apply Definition 977.2. Its source and witness exposure rows bind X, μ before the triad is read, and its row-ordering obligations place W, D, Q before the seal row S.

Use window-budget exhaustion and normalizer-tail commutation, Definition 977.5 and Definition 977.6. The first forces W, D before Q, while the second keeps N_0, T over the same witnessed modulus and finite-window rows.

Finally combine Real-seal consumer exactness with non-escape, Definition 977.7 and Definition 977.4. They make every Real-facing consumer read through the same finite packet and exclude hidden stream selectors, separate dyadic ledgers, quotient streams, selected limits, host real equality, countable choice, and ambient completeness. □

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier source triad exactness`

Theorem 977.9 (Regular Cauchy modulus witness-ledger source-triad lock)**.** *For any accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

every $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *consumer that preserves the witnessed modulus route must consume* W, D, Q *as one locked source triad over the same witnessed modulus* μ*, normalized route* N_0*, and tail-budget row* T*. Replacing any one of* W, D, Q *by a row from another packet is not an accepted seal route.*

Proof. Project the accepted carrier to its displayed tuple. The only rows available for the source triad before the Real-facing seal are W, D, Q, and they occur in the same finite packet as μ, N_0, T.

Apply source-triad exactness from Definition 977.8. It identifies W as the finite StreamName window row, D as the dyadic tolerance row, and Q as the RegSeqRat readback row consumed before S.

Use normalizer-tail commutation from Definition 977.6. This keeps the normalized route row N_0 and tail-budget row T over the same witnessed modulus μ and over the same finite-window and dyadic rows.

Finally apply Real-seal consumer exactness and non-escape, Definition 977.7 and Definition 977.4. Any attempted replacement of one triad row by a row from another packet would require a hidden selector, separate ledger, quotient stream, selected limit, host equality, countable-choice row, or ambient completeness row, none of which is exported by the accepted seal route. □

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier source triad lock`

Theorem 977.10 (Regular Cauchy modulus witness-ledger TasteGate readiness)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the displayed rows supply the complete paper-side obligation surface expected by the Nontrivial and FieldFaithful TasteGate requirements for this chapter. The rows provide carrier admission, non-escape, route-ordering, and local naming witnesses before any Lean encoding may expose the chapter as a TasteGate carrier.

Proof. Carrier admission is the tuple itself, as fixed by Definition 977.1. The local naming row is M, and the package, continuation, and transport rows P, C, H record the provenance, replay route, and componentwise preservation for the same tuple.

Apply the NameCert obligation theorem, Definition 977.2. It binds the source row X, witnessed modulus row μ, finite-window service W, normalizer row N_0, tail-budget row T, dyadic row D, RegSeqRat readback row Q, and Real seal row S as the displayed obligation rows.

Apply seal-route exactness and non-escape, Definition 977.3 and Definition 977.4. These results force every Real-facing consumer to read the same ordered rows and exclude quotient streams, host real equality, hidden modulus replacement, selected limits, countable choice, and ambient completeness.

Finally use source-triad exactness, Definition 977.8. It isolates W, D, Q as the finite-window, dyadic-tolerance, and RegSeqRat readback triad, so the TasteGate surface has a concrete nonempty packet and a field-faithful row inventory rather than a detached analytic assertion. □

Theorem 977.11 (Regular Cauchy modulus witness-ledger field separation)**.** *In an accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet, the witnessed ledger, finite-window service, normalizer row, tail-budget row, dyadic tolerance ledger, RegSeqRat readback, and Real seal cannot be collapsed into one another by a consumer route. Each row has a distinct downstream role, and deleting or identifying any one of them triggers the missing-coordinate refusal recorded by the carrier and non-escape boundary.*

Proof. Project the carrier to the displayed tuple. The row μ supplies the witnessed modulus ledger, W supplies finite StreamName windows, N_0 supplies the normalizer route, T supplies the tail budget, D supplies dyadic tolerances, Q supplies RegSeqRat readback, and S supplies the Real seal.

The NameCert obligations separate the roles. Source and witness exposure require X, μ before window service; finite-window service requires W, D before readback; tail-budget compatibility requires T on the same route; and seal ordering requires Q before S.

Use non-escape from Definition 977.4. A consumer that collapses any of these rows would need a replacement coordinate or a route that bypasses the displayed tuple, but the accepted packet exports only $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$.

Thus each row is separated by its downstream use and by the refusal of missing coordinates. The witness ledger cannot serve as a window service, the window service cannot serve as a dyadic ledger, the normalizer and tail rows cannot serve as the Real seal, and the readback row cannot be omitted before seal consumption. □

Theorem 977.12 (Regular Cauchy modulus witness-ledger route field faithfulness)**.** *Any accepted packet route preserving the public Real-seal consumer surface preserves each displayed field of*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$$

in the same order. Consequently a later Lean FieldFaithful instance for RegularCauchyModulusWitnessLedger$^{\uparrow}$ *may project fields by tuple inspection rather than by quotient identification, host real equality, or any external completeness principle.*

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier route field faithfulness`

Proof. Start with source-triad exactness, Definition 977.8. It forces every RealUp or completion-seal consumer to read W, D, Q as the finite-window, dyadic-tolerance, and RegSeqRat readback rows before the seal.

Use window-budget exhaustion and normalizer-tail commutation, Definition 977.5 and Definition 977.6. The first prevents hidden window or dyadic replacement before Q, while the second keeps N_0 and T over the same witnessed modulus μ and the same rows W, D before S.

Apply Real-seal consumer exactness, Definition 977.7. The consumer route reaches the public seal only through $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, with H, C, P, M carrying transport, continuation, provenance, and local naming for that same tuple.

The preservation claim is therefore componentwise. Since no quotient stream, host real equality, selected limit, hidden modulus replacement, hidden window selector, separate dyadic ledger, countable choice, or ambient completeness coordinate is exported, field faithfulness is witnessed by inspecting the displayed tuple in order. □

Theorem 977.13 (Regular Cauchy modulus witness-ledger nontrivial witness surface)**.** *The* RegularCauchyModulus *carrier admits two distinguishable accepted packet surfaces. One may vary the displayed witnessed*

modulus ledger row μ while preserving the source row X and the downstream route shape, or vary the finite-window service row W while preserving the witnessed ledger shape. In either case the componentwise hsame *transport row H refuses to identify the two packets unless the changed displayed coordinate is restored.*

Proof. Project an accepted packet to the carrier tuple

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M).$$

The witnessed modulus ledger and finite-window service are separate coordinates of this tuple, not properties recovered from a quotient stream or from host-side equality of reals.

Apply Definition 977.2. Its source and witness exposure row requires the displayed μ to be read before any window is served, and its finite-window service row requires the displayed W to be the StreamName row consumed before readback.

The two packet surfaces are therefore separated by componentwise transport. A change in μ changes the witness-ledger coordinate read by the source route, while a change in W changes the finite-window coordinate read before D and Q. Since H stores componentwise hsame data for the displayed rows, it cannot identify either changed packet with the original accepted packet without reusing the original field. □

Theorem 977.14 (Regular Cauchy modulus witness-ledger field-faithful surface)**.** *For an accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet, equality of all displayed fields*

$$X, \mu, W, N_0, T, D, Q, S, H, C, P, M$$

determines the accepted packet surface. Conversely, any change to one of these displayed fields is visible to the local classifier through carrier projection, componentwise hsame *refusal, or one of the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}}$ *obligation rows.*

Proof. The carrier is the finite tuple of Definition 977.1. If all displayed fields agree, tuple projection leaves no further coordinate on which two accepted packets can differ.

Now change one displayed field. If the changed row is X or μ, the source and witness exposure obligation detects the change. If it is W, D, or Q, the finite-window service and readback obligations detect the changed route before the Real-facing seal.

If the changed row is N_0 or T, the normalized route exactness and tail-budget compatibility obligations detect that the Real-facing route no longer uses the same witnessed modulus ledger. If the changed row is S, H, C, P, or M, then seal ordering, componentwise transport, displayed continuation replay, provenance, or local naming detects the changed accepted surface.

Thus the local classifier is field-faithful on the displayed tuple. The proof uses only carrier projection and the NameCert obligations, with no quotient stream, host real equality, hidden modulus replacement, selected limit, countable choice, or ambient completeness coordinate. □

Theorem 977.15 (Regular Cauchy modulus witness-ledger TasteGate field projection)**.** *Let*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$$

be an accepted $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet. The nontrivial witness pair for the packet may be chosen by changing either the witnessed modulus ledger row μ or the finite-window service row W. The field-faithful projection is exactly the ordered tuple projection through $X, \mu, W, N_0, T, D, Q, S, H,$ and every* $\mathsf{Real}^{\uparrow}$ *or* RealCompletionSealClassifierUp *consumer preserving the public seal route preserves those displayed fields componentwise.*

Proof. Use the nontrivial witness surface, Definition 977.13. It separates accepted packet surfaces by changing μ or W, and componentwise hsame refuses to identify either change without restoring the displayed coordinate.

Apply the field-faithful surface, Definition 977.14. It identifies the accepted packet surface with the ordered tuple projection through $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$.

Now combine source-triad exactness and Real-seal consumer exactness, Definition 977.8 and Definition 977.7. They force every public Real-facing read to pass through the same witnessed ledger, finite-window, dyadic, readback, seal, transport, replay, provenance, and naming rows.

Finally use non-escape, Definition 977.4. Since the carrier exports no quotient stream, host equality, hidden modulus replacement, selected limit, countable choice, or ambient completeness coordinate, no consumer preserving the public seal route can identify the witness pair or collapse any displayed field. □

Theorem 977.16 (Regular Cauchy modulus witness-ledger carrier disjointness)**.** *No carrier automorphism preserving the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}}$ *rows can collapse the witnessed-modulus coordinate* μ*, the normalized-route coordinate* N_0*, the tail-budget coordinate* T*, and the Real-seal coordinate* S *into one another. These four rows remain disjoint because they are read at different stages of the local route and are protected by the window-budget, normalizer-tail, and non-escape obligations.*

Proof. Begin with the NameCert obligations of Definition 977.2. They assign distinct local roles to the witnessed modulus ledger, normalized route, tail-budget row, and Real seal row: μ is exposed before any window service, N_0 records the normalized shared-modulus route, T records tail-budget compatibility for the same route, and S is consumed only after the readback and route rows are displayed.

Use window-budget exhaustion from Definition 977.5. It forces the finite-window and dyadic rows W, D before Q, so neither μ nor N_0 nor T can be replaced by a hidden window or dyadic ledger on the way to the seal.

Use normalizer-tail commutation from Definition 977.6. It keeps N_0 and T over the same witnessed modulus μ and the same finite-window rows before S, which prevents an automorphism preserving the local rows from exchanging the route coordinate with the tail-budget coordinate or with the seal.

Finally apply non-escape from Definition 977.4. The accepted packet exports only $X, \mu, W, N_0, T, D, Q, S, H, C,$ so a collapse among μ, N_0, T, S would require a replacement coordinate or an external equality principle. No such coordinate is present in the carrier. □

Theorem 977.17 (Regular Cauchy modulus witness-ledger consumer totality)**.** *For every accepted packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

every $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *consumer using the witnessed modulus route factors through the single displayed surface* $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$*. The consumer reads* μ *before* W*, reads* W, D *before* Q*, reads* N_0, T *over the same witness before* S*, and reads* H, C, P, M *as the structural transport, replay, provenance, and local naming rows. No quotient stream, host real equality, hidden modulus replacement, hidden window selector, separate dyadic ledger, selected limit, countable choice, or ambient completeness row can replace that route.*

Proof. Apply the NameCert obligation theorem, Definition 977.2. Its source and witness exposure rows put the displayed modulus ledger μ before the StreamName window row W, and its route-ordering clauses keep the later rows attached to the same accepted packet.

Next use window-budget exhaustion and source-triad exactness, Definition 977.5 and Definition 977.8. These force the finite-window and dyadic rows W, D before the RegSeqRat readback row Q, so a Real-facing consumer cannot insert a hidden window selector or a separate dyadic ledger.

Use normalizer-tail commutation from Definition 977.6. It keeps the normalized route row N_0 and the tail-budget row T over the same witnessed modulus and over the same finite-window route before the seal row S.

Apply Real-seal consumer exactness, Definition 977.7. It identifies the public RealUp and completion-seal read as the displayed route through $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, with H, C, P, M supplying transport, replay, provenance, and local naming for that route.

Finally apply non-escape from Definition 977.4. Since the carrier exports no quotient stream, host real equality, hidden modulus replacement, hidden window selector, separate dyadic ledger, selected limit, countable choice, or ambient completeness coordinate, every admitted consumer reads the displayed modulus-window-dyadic-readback-seal route as one total surface. □

Theorem 977.18 (Regular Cauchy modulus witness-ledger tail-service uniqueness)**.** *For every accepted packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the single witnessed modulus ledger row μ together with the displayed tail-budget row T determines the tail-service route used by every $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *consumer of L. Any tail-service read preserving the accepted packet must pass through the same finite window row W, normalized row N_0, dyadic row D, RegSeqRat readback row Q, and seal row S; a second tail threshold, hidden witness ledger, quotient stream, selected limit, host equality, countable choice, or ambient completeness row is not an admitted route.*

Proof. Begin with the NameCert obligations of Definition 977.2. The source and witness exposure rows display X, μ, and the tail-budget compatibility row attaches T to that same witnessed route before a Real-facing seal is consumed.

Apply normalizer-tail commutation, Definition 977.6. It keeps N_0 and T over the same witnessed modulus μ and over the same finite-window and dyadic rows.

Use window-budget exhaustion and source-triad exactness, Definition 977.5 and Definition 977.8. These identify W, D, Q as the only finite-window, dyadic, and readback portion of the tail-service route.

Finally apply Real-seal consumer exactness and non-escape, Definition 977.7 and Definition 977.4. Since the accepted packet exports only $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, the pair μ, T determines the admitted tail-service path through the displayed rows and leaves no coordinate for a second service. □

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier tail service uniqueness`

Theorem 977.19 (Regular Cauchy modulus witness-ledger dyadic-window coherence)**.** *For every accepted packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the StreamName row W, DyadicRatCore row D, and RegSeqRat row Q are consumed as one coherent source triad before the Real-facing seal row S is read. A consumer cannot keep one of W, D, Q while replacing another with a row from a different packet, a hidden dyadic ledger, a quotient stream, a selected limit, host equality, countable choice, or ambient completeness data.

Proof. Project the accepted packet to its displayed tuple. The only StreamName, DyadicRatCore, and RegSeqRat coordinates available before the seal are W, D, Q.

Apply the NameCert obligations and source-triad exactness, Definition 977.2 and Definition 977.8. They identify W as finite-window service, D as the dyadic tolerance ledger, and Q as the readback row consumed before S.

Use window-budget exhaustion and normalizer-tail commutation, Definition 977.5 and Definition 977.6. The first forces W, D before Q, while the second keeps the route tied to the same witnessed modulus μ and tail-budget row T.

Conclude with the source-triad lock, Real-seal consumer exactness, and non-escape, Definition 977.9, Definition 977.7, and Definition 977.4. These results make the triad a single displayed route and exclude every replacement coordinate listed above. □

Theorem 977.20 (Regular Cauchy modulus witness-ledger seal-readback factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *read of an accepted packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$$

factors through the displayed rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$*. The factorization reads the witnessed modulus row before the window service, reads the dyadic-window-RegSeqRat triad before the Real seal, and reads the transport, continuation, provenance, and local certificate rows as part of the same packet.*

Proof. Start from the seal route and consumer totality, Definition 977.3 and Definition 977.17. They identify every Real-facing read as a route through the displayed packet surface rather than through a selected limit or completion principle.

The tail-service uniqueness theorem fixes the tail side of the route. It makes μ and T determine the admitted service path through W, N_0, D, Q, S.

The dyadic-window coherence theorem fixes the readback side of the route. It forces W, D, Q to travel as one source triad before S.

Finally apply non-escape, Definition 977.4. Since the carrier exports no quotient stream, host real equality, hidden modulus replacement, hidden window selector, separate dyadic ledger, selected limit, countable choice, or ambient completeness coordinate, every RealUp or completion-seal read factors through exactly $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$. □

Theorem 977.21 (Regular Cauchy modulus witness-ledger open-phase exit sufficiency)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the displayed rows supply the Phase Real and Completion exit surface by routing $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *through one finite witness ledger. The rows* X, μ, N_0, T *bind the source, witnessed modulus, normalized route, and tail budget;* W, D, Q, S *are the finite window, dyadic tolerance, regular readback, and Real seal; and* H, C, P, M *supply transport, replay, provenance, and local naming. This exit surface exports no quotient stream, host real equality, selected limit, countable choice, or ambient completeness row.*

Proof. Begin with the carrier and NameCert obligations, Definition 977.1 and Definition 977.2. They display exactly the rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ and assign the StreamName, dyadic, regular-readback, and Real-seal roles to the same accepted packet.

Use the seal route, source-triad exactness, and normalizer-tail commutation, Definition 977.3, Definition 977.8, and Definition 977.6. These keep the finite window, dyadic tolerance, readback, normalized route, and tail budget attached to the witnessed modulus before the seal is read.

Finally apply Real-seal consumer exactness and consumer totality, Definition 977.7 and Definition 977.17. Together with non-escape, Definition 977.4, they make the displayed packet sufficient for the Phase Real and Completion exit surface and exclude every forbidden completion coordinate listed in the statement. □

Theorem 977.22 (Regular Cauchy modulus witness-ledger readback seal determinacy)**.** *For every accepted packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the readback row Q and seal row S are determined by the same witnessed modulus row μ, normalizer row N_0, tail-budget row T, finite-window row W, and dyadic tolerance row D. A Real-facing consumer cannot replace Q or S by a readback or seal from another packet while preserving the accepted modulus-ledger route.

Proof. Project the accepted carrier. The only readback and Real-seal coordinates available to a consumer of L are the displayed rows Q and S.

Apply source-triad exactness and normalizer-tail commutation, Definition 977.8 and Definition 977.6. The first fixes Q as the readback attached to W and D, while the second keeps N_0 and T over the same witnessed modulus μ before the seal.

The seal route and Real-seal consumer exactness, Definition 977.3 and Definition 977.7, then identify S as the seal consumed after that same readback route. Non-escape rules out a second packet row, selected limit, host equality, quotient stream, countable choice, or ambient completeness datum as a replacement. □

Theorem 977.23 (Regular Cauchy modulus witness-ledger completion boundary)**.** *Every Completion-facing consumer of an accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet may read only the finite boundary*

$$X, \mu, W, N_0, T, D, Q, S, H, C, P, M.$$

It may consume the witnessed modulus ledger, finite window, dyadic tolerance, regular readback, Real seal, transport, replay, provenance, and local naming rows, but it cannot export quotient streams, host real equality, selected limits, countable choice, ambient completeness, or a completion object not displayed by this boundary.

Proof. Start from consumer totality, Definition 977.17. It factors every RealUp or completion-seal consumer through the displayed route $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$.

The open-phase exit sufficiency theorem identifies this route with the StreamName, DyadicRatCore, RegSeqRat, and RealUp exit packet. The readback seal determinacy theorem fixes Q and S to the same witnessed modulus, normalizer, tail-budget, window, and dyadic rows.

Finally use non-escape, Definition 977.4. Since the carrier has no coordinate for quotient streams, host real equality, selected limits, countable choice, ambient completeness, or undisplayed completion objects, no Completion-facing consumer can export such data from the accepted boundary. □

Theorem 977.24 (Regular Cauchy modulus witness-ledger obligation-closure route)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the displayed rows exhaust the carrier admission, source witness, normalizer, tail-budget, finite-window, dyadic, RegSeqRat readback, Real seal, transport, continuation, provenance, local NameCert*, Nontrivial, and FieldFaithful obligation surface for the chapter. No additional quotient-stream, host-real-equality, hidden-modulus, hidden-window, selected-limit, countable-choice, ambient-completeness, or undisplayed completion row is needed to state the obligation boundary.*

Proof. The carrier and local NameCert surface are the tuple and the seven obligation rows of Definition 977.1 and Definition 977.2. These give carrier admission, source witness exposure, normalizer exactness, finite-window service, tail-budget compatibility, readback and Real seal ordering, and the structural rows H, C, P, M.

The consumer-facing boundary is fixed by non-escape, source-triad exactness, and seal-route exactness: Definition 977.4, Definition 977.8, and Definition 977.3. Together they force every RealUp and completion-seal read through $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ and refuse every hidden stream, dyadic, quotient, selected-limit, host-equality, choice, or ambient-completeness coordinate.

TasteGate readiness supplies the chapter-level Nontrivial and FieldFaithful side of the same surface. The nontrivial witness surface separates packet witnesses by the displayed μ or W coordinate, while the field-faithful surface and route field-faithfulness identify accepted packet equality with componentwise preservation of the displayed tuple.

Finally apply completion boundary. It states that a Completion-facing consumer may read only the finite boundary $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$. Hence the listed rows already cover the carrier, witness, route, seal, transport, continuation, provenance, naming, Nontrivial, and FieldFaithful obligations, so the chapter records obligation closure without asserting Lean verification or a bridge. □

Theorem 977.25 (Regular Cauchy modulus witness-ledger tail-service exactness)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

every $\mathsf{Real}^{\uparrow}$ *or* RealCompletionSealClassifierUp *tail-service read of L factors through the same witnessed modulus row μ, finite* $\mathsf{StreamName}^{\uparrow}$ *window row W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row D,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row Q, normalizer row N_0, tail-budget row T, seal row S, and structural rows H, C, P, M. No hidden selector, quotient stream, host real equality, selected limit, ambient completeness coordinate, or replacement tail-service packet may serve as a Real-facing route for L.*

Proof. Project the carrier and the local NameCert obligations. The accepted packet displays exactly the rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, and the naming surface assigns the StreamName window, dyadic tolerance, readback, tail budget, normalizer, seal, transport, continuation, provenance, and local-name roles to those rows.

Use window-budget exhaustion, normalizer-tail commutation, and source-triad exactness. These keep W, D, Q, N_0, T attached to the same witnessed modulus row μ before any Real-facing service reads the packet.

Apply readback seal determinacy and completion boundary. The readback row Q and seal row S are fixed by the same displayed route, and completion-facing consumers may read only the boundary $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$.

Finally invoke carrier non-escape. Since L has no coordinate for a hidden selector, quotient stream, host real equality, selected limit, ambient completeness object, or second tail-service packet, every Real-facing tail-service read factors through the displayed route and no other one. □

Theorem 977.26 (Regular Cauchy modulus witness-ledger normalizer-source totality)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

any $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *consumer that reads the witnessed modulus row* μ *must preserve two displayed route constraints. First, the source triad* W, D, Q *is attached to* μ *and cannot be replaced by a hidden source, dyadic, or readback row. Second, the normalizer row* N_0 *is displayed on the same packet before tail-budget and Real-seal consumption. Thus the admitted consumer surface is a compatible finite route over* μ*, not a single linear order placing* N_0 *before* Q*, and not a hidden modulus selector, quotient stream, host real equality, selected limit, countable choice, or ambient completeness datum.*

Proof. The carrier and local NameCert obligations expose the finite packet rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$. By Definition 977.2, the normalizer row N_0, finite source window W, dyadic tolerance D, readback row Q, tail-budget row T, and seal row S are named rows of the same accepted packet.

Apply the source-triad lock, Definition 977.9. It binds the displayed source triad W, D, Q to the witnessed modulus row μ, so a consumer that exposes μ cannot detach the readback from the finite source data or replace one of the triad rows.

Now use tail-service exactness, Definition 977.25. Any Real-facing or completion-seal tail-service read factors through the shared $\mu, W, N_0, T, D, Q, S, H, C, P, M$ route, hence the same packet displays N_0 before tail-budget and seal consumption while preserving the source triad over μ.

Finally apply the completion boundary, Definition 977.23. It permits no off-packet selector, quotient stream, host equality, selected limit, countable choice, ambient completeness row, or hidden completion selector, so the two displayed constraints are total for every accepted consumer of the witnessed modulus. □

Theorem 977.27 (Regular Cauchy modulus witness-ledger tail-budget readback)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the tail-budget row T *is read back only through the same source triad* W, D, Q *and the same normalizer row* N_0 *attached to the witnessed modulus* μ*. A tail-budget readback may witness how far the packet must go after* W *and* D*, but it cannot replace* μ*, replace* N_0*, or introduce a second readback, quotient stream, host real equality, selected limit, countable choice, or ambient completeness row.*

Proof. Begin with the local obligation surface, Definition 977.2. The packet has one displayed witnessed modulus row μ, one displayed normalizer row N_0, one tail-budget row T, and the source triad W, D, Q.

The source-triad lock, Definition 977.9, fixes Q as the readback carried by W and D over the same modulus witness. Thus the tail-budget row can only be interpreted against that displayed triad.

Use tail-service exactness, Definition 977.25. It routes every tail-service read through $\mu, W, N_0, T, D, Q, S, H, C,$ so T records the budget along the already displayed normalizer and readback path rather than producing another one.

The completion boundary, Definition 977.23, removes the remaining escape cases. Since the boundary has no coordinate for a replacement modulus, replacement normalizer, second readback, quotient stream, host equality, selected limit, choice principle, or ambient-completeness object, tail-budget readback is exhausted by W, D, Q and N_0. □

Theorem 977.28 (Regular Cauchy modulus witness-ledger readback route lock)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the readback row Q is locked to the same witnessed route μ, W, D, N_0, T before the seal row S is consumed. A consumer may read Q only as the $\mathsf{RegSeqRat}^{\uparrow}$ *readback generated by the displayed source window W, dyadic tolerance row D, normalizer row N_0, and tail-budget row T over μ; it cannot replace any one of those rows by a hidden source, quotient stream, host real equality, selected limit, countable-choice row, ambient completeness row, or second readback surface.*

Proof. Begin with the carrier and local NameCert obligations. They expose exactly one witnessed modulus row μ, one finite source window W, one dyadic tolerance row D, one normalizer row N_0, one tail-budget row T, one readback row Q, and one seal row S.

Apply source-triad lock, Definition 977.9. It binds W, D, Q to the same witnessed modulus, so the readback route cannot detach Q from the displayed finite-window and dyadic rows.

Next use tail-service exactness and tail-budget readback, Definition 977.25 and Definition 977.27. These identify the service route for Q with $\mu, W, N_0, T, D, Q, S, H, C, P, M$ and force T to be read through the same W, D, Q, N_0 path.

Finally apply the completion boundary. Since completion-facing consumption has no coordinate for a hidden source, quotient stream, host equality, selected limit, choice row, ambient completeness row, or second readback surface, Q is locked to the displayed route before S can be consumed. □

Theorem 977.29 (Regular Cauchy modulus witness-ledger completion-seal handoff totality)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

every RealCompletionSealClassifierUp *handoff factors through the full displayed boundary $X, \mu, W, N_0, T, D, Q, S, H,$ No proper sub-boundary omitting the witnessed source, source triad, normalizer, tail budget, seal, transport, continuation, provenance, or local NameCert row is export-ready for completion-seal consumption.*

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier completion seal handoff totality`

Proof. Project the handoff to the local NameCert surface. The only rows available to the completion-seal consumer are the carrier row X, witnessed modulus μ, source window W, normalizer N_0, tail budget T, dyadic tolerance D, readback Q, seal S, transports H, continuation C, provenance P, and local naming row M.

Use source-triad lock and readback route lock. They keep W, D, Q attached to μ and force Q to be read through the same N_0, T route before S is consumed.

Apply tail-service exactness and completion boundary. The former routes every completion-seal service through $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, while the latter excludes hidden selectors, quotient streams, host equalities, selected limits, countable choice, ambient completeness, and detached completion rows.

Thus totality is exactly the full displayed boundary. If any listed row is missing, the consumer has a proper sub-boundary rather than the accepted handoff surface, so it is not export-ready. □

Theorem 977.30 (Regular Cauchy modulus witness-ledger tail-window refusal)**.** *For every accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

any route that reaches toward Real$^{\uparrow}$ *or* RealCompletionSealClassifierUp *while omitting either the displayed tail-budget row T or the finite-window row W is refused before Real-seal consumption. Such a route may mention μ, D, Q, N_0 or S, but without both W and T it is not the accepted tail-service route and cannot consume the Real seal.*

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier tail window refusal`

Proof. The NameCert obligations display both W and T as named rows of the packet. The finite-window row supplies the source window for the dyadic and readback route, and the tail-budget row records the admitted service depth along that route.

Apply source-triad lock to the finite-window side. Without W, the triad W, D, Q is not present, so the proposed route cannot identify the accepted readback over μ.

Apply tail-service exactness and tail-budget readback to the budget side. Without T, the route cannot be the displayed $\mu, W, N_0, T, D, Q, S, H, C, P, M$ service route and cannot read the tail budget against the accepted normalizer and readback path.

Finally use readback seal determinacy and non-escape. Since S is determined by the displayed readback route and the packet has no off-boundary replacement for W or T, every route missing either row is refused before Real-seal consumption. □

Theorem 977.31 (Regular Cauchy modulus witness-ledger Real-seal export readiness)**.** *For an accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

a Real$^{\uparrow}$ *or* RealCompletionSealClassifierUp *consumer is export-ready exactly when the packet displays the witnessed modulus μ, the source triad W, D, Q, the normalizer row N_0, the tail-budget row T, the seal row S, the componentwise transport row H, the continuation row C, the provenance row P, and the local* NameCert *row M. No consumer is export-ready from a proper sub-boundary or from an undisplayed quotient stream, host real equality, selected limit, countable choice, ambient completeness object, or detached seal row.*

Proof. For sufficiency, start from the carrier and NameCert obligations in Definition 977.2. They display exactly the source triad, normalizer row, tail-budget row, seal row, transport, continuation, provenance, and local naming rows of L.

The source-triad lock, Definition 977.9, binds W, D, Q to μ. Tail-service exactness, Definition 977.25, then routes every Real-facing or completion-seal read through the same $\mu, W, N_0, T, D, Q, S, H, C, P, M$ packet. Therefore a consumer with all listed rows displayed has the complete export surface.

For necessity, suppose a Real$^{\uparrow}$ or RealCompletionSealClassifierUp consumer is export-ready. By tail-service exactness, its route factors through the witnessed modulus, source triad, normalizer, tail-budget, seal, transport, continuation, provenance, and local NameCert rows of the accepted packet.

It remains to rule out readiness from less data. Apply completion boundary, Definition 977.23. The consumer may read only $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, so omitting one of the displayed rows or substituting an undisplayed quotient, equality, limit, choice, completeness, or detached seal row cannot produce an export-ready consumer. □

Theorem 977.32 (RegularCauchyModulusWitnessLedger bridge request surface)**.** *For every accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

every bridge request for L must factor through the witnessed modulus row μ, the finite StreamName$^{\uparrow}$ *window row W, the normalizer row N_0, the tail-budget row T, the* DyadicRatCore$^{\uparrow}$ *tolerance row D, the* RegSeqRat$^{\uparrow}$ *readback row Q, the* Real$^{\uparrow}$ *seal row S, the componentwise* hsame *transports H, the* Cont *replay row C, the* Pkg *provenance row P, and the local* NameCert *row M. Such a request cannot use quotient streams, host real equality, countable choice, selected limits, ambient completeness, or a detached standard bridge row.*

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier bridge request surface`

Proof. Start with the carrier and local NameCert obligations. They expose exactly the packet rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, so a bridge-facing request has no carrier coordinate outside the witnessed modulus ledger, finite window, normalizer, tail budget, dyadic tolerance, readback, seal, transport, replay, provenance, and local naming rows.

Next apply window-budget exhaustion, normalizer-tail commutation, and tail-service exactness. These keep the finite window, normalized route, tail budget, dyadic tolerance, and RegSeqRat readback attached to the same witnessed modulus row before any Real-facing or Completion-facing service can consume the packet.

Then use Real-seal consumer exactness and readback-seal determinacy. The Real seal is the one determined by the same displayed readback route, and any consumer of the seal must read that route rather than replacing it by a host equality, selected limit, quotient stream, choice principle, or ambient-completeness row.

Finally combine the completion boundary with the public Phase Real and Completion exit sufficiency theorem. The boundary lists only $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, while the exit theorem identifies these rows as the public consumer surface. Therefore every bridge request factors through the displayed packet, and any detached standard bridge row is off-route for this chapter. □

Theorem 977.33 (Regular Cauchy modulus witness-ledger root seal minimality)**.** *For every* BHist*-anchored accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the root seal handoff to any Phase Real or Completion consumer is minimal exactly at the displayed boundary. The consumer must read the RegSeqRat$^{\uparrow}$ *source row X, witnessed modulus row μ, finite* StreamName$^{\uparrow}$ *window row W,* RegularCauchyModulusNormalizer$^{\uparrow}$ *route row N_0,* RegularCauchyTailBudget$^{\uparrow}$ *row T,* DyadicRatCore$^{\uparrow}$ *tolerance row D,* RegSeqRat$^{\uparrow}$ *readback row Q,* Real$^{\uparrow}$ *seal row S, transport row H, continuation row C, provenance row P, and local* NameCert *row M. No proper sub-boundary, quotient stream, host real equality, selected limit, countable choice, ambient completeness datum, hidden window selection, detached normalizer, or detached* RealCompletionSealClassifierUp *seal can serve as the root seal handoff.*

Proof. Project the packet to its local carrier and NameCert obligations. These display the twelve rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ and place the history anchor on the same BHist route as the provenance and local naming rows.

Use source-triad lock to bind W, D, Q to the witnessed modulus row μ. Then use normalizer-tail commutation and tail-service exactness to keep N_0 and T on that same route before Q and S are consumed.

Apply Real-seal export readiness and the bridge request surface. They identify the Phase Real and Completion-facing handoff with the displayed rows and give no coordinate for quotient streams, host real equality, selected limits, countable choice, ambient completeness, hidden windows, detached normalizers, or detached classifier seals.

Thus deleting any listed row leaves a proper sub-boundary rather than a root seal handoff. The displayed tuple is therefore the minimal accepted boundary for root consumers. □

Theorem 977.34 (Regular Cauchy modulus witness-ledger source-row coverage)**.** *For every* BHist-*anchored accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the rows read by a Phase Real or Completion consumer cover exactly the sibling sources needed by the root handoff: StreamName$^{\uparrow}$ *is read through* W*,* DyadicRatCore$^{\uparrow}$ *through* D*,* RegSeqRat$^{\uparrow}$ *through* X *and* Q*,* Real$^{\uparrow}$ *through* S*,* RegularCauchyModulusNormalizer$^{\uparrow}$ *through* N_0*,* RegularCauchyTailBudget$^{\uparrow}$ *through* T*, and* RealCompletionSealClassifierUp *through the seal-facing route* Q, S, H, C, P, M*. The handoff has no additional source row and no missing row among* $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$*.*

Proof. Begin with the carrier row and the NameCert obligation theorem. They name $X, \mu, W, N_0, T, D, Q, S, H, C, P$ as the only rows of the packet, so any source-row coverage statement must be obtained by projecting these rows rather than by importing a second carrier.

Read the sibling anchors row by row. The finite-window service is W for StreamName$^{\uparrow}$, the dyadic tolerance ledger is D for DyadicRatCore$^{\uparrow}$, the regular source and readback are X, Q for RegSeqRat$^{\uparrow}$, and the seal is S for Real$^{\uparrow}$.

Next read the structural siblings. The normalized route is N_0 for RegularCauchyModulusNormalizer$^{\uparrow}$, the admitted tail service is T for RegularCauchyTailBudget$^{\uparrow}$, and the classifier-facing seal route is Q, S, H, C, P, M for RealCompletionSealClassifierUp.

Finally invoke non-escape and completion boundary. Since the boundary exports no quotient stream, host real equality, selected limit, countable choice, ambient completeness datum, hidden window selection, detached normalizer, or detached seal, the displayed rows are both sufficient for all named sibling reads and exhaustive for the root handoff. □

Theorem 977.35 (Regular Cauchy modulus witness-ledger consumer obligation exhaustion)**.** *Let* $L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$ *be a* BHist-*anchored accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet. Every root consumer obligation for a Phase Real or Completion handoff is discharged by the displayed carrier, NameCert obligations, source-triad lock, completion boundary, Real-seal export readiness, and bridge request surface. After those clauses are read, there is no remaining root obligation asking for quotient streams, host real equality, selected limits, countable choice, ambient completeness, hidden window selection, detached normalizers, detached seals, or any row outside* $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$*.*

Proof. First discharge the object surface. The carrier and NameCert obligations expose the source, witnessed modulus, window, normalizer, tail budget, dyadic tolerance, readback, seal, transport, continuation, provenance, and local naming rows.

Next discharge the route surface. Source-triad lock attaches W, D, Q to μ, normalizer-tail commutation attaches N_0, T to the same route, and tail-service exactness sends every Real-facing or Completion-facing service through $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$.

Then discharge the consumer surface. The completion boundary identifies the accepted consumer boundary, Real-seal export readiness makes that boundary export-ready, and the bridge request surface says every bridge-facing request factors through the same displayed rows.

It remains only to exclude extra obligations. Non-escape and the boundary theorems give no row for quotient streams, host real equality, selected limits, countable choice, ambient completeness, hidden windows, detached normalizers, detached seals, or any off-boundary source. Therefore the root consumer obligations are exhausted by the displayed packet. □

Theorem 977.36 (Regular Cauchy modulus witness-ledger UniformCauchyCriterion exit factor)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

every $\mathsf{UniformCauchyCriterion}^{\uparrow}$*-facing consumer of* L *factors through the displayed route* $X, \mu, W, N_0, T, D, Q, S, H, C$ *The consumer may read the packet through the witnessed seal route, source triad, tail service, and* $\mathsf{Real}^{\uparrow}$*-seal export surface, but it cannot replace that route by a hidden source, quotient stream, selected limit, host real equality, countable choice, ambient completeness object, or detached completion row.*

Proof. Begin with the accepted carrier and local NameCert obligations. They expose the carrier X, witnessed modulus μ, finite source window W, normalizer N_0, tail budget T, dyadic tolerance D, readback Q, seal S, transport H, continuation C, provenance P, and local naming row M.

Apply the seal-route theorem, source-triad lock, and tail-service exactness. These identify the route to the seal with the same μ, W, N_0, T, D, Q data and prevent a UniformCauchyCriterion-facing consumer from detaching the Cauchy witness from the displayed finite-window and dyadic-tail rows.

Finally use Real-seal export readiness. The export theorem says that a Real-facing or completion-facing consumer is ready exactly from the displayed route, so the UniformCauchyCriterion exit surface factors through $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ and has no coordinate for off-route equality, choice, quotient, limit, or ambient-completeness data. □

Theorem 977.37 (Regular Cauchy modulus witness-ledger dyadic-tail cofinal readback)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

dyadic tail cofinal readback is exhausted by the displayed W, D, Q, T *rows before the seal row* S *is consumed. Thus every cofinal dyadic-tail readback available to a completion-facing consumer is the one generated from the finite* $\mathsf{StreamName}^{\uparrow}$ *window* W*, dyadic tolerance row* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q*, and tail-budget row* T *over the same witnessed modulus route.*

Proof. Use window-budget exhaustion to bind the finite source window to the admitted tail budget. This makes the available tail service finite and ledger-visible before any seal consumption can occur.

Next apply tail-budget readback. It reads the budget row T through the same W, D, Q path, so a cofinal dyadic-tail consumer cannot introduce another readback surface after the displayed rows have been exhausted.

The seal row S is then reached only through readback-seal determinacy. Since the packet has no second source window, dyadic tolerance, readback, or tail-budget coordinate, the cofinal readback seen before S is exactly the displayed W, D, Q, T route. □

Theorem 977.38 (Regular Cauchy modulus witness-ledger seal-classifier scope)**.** *For every accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

any RealCompletionSealClassifierUp *scope read is exactly the displayed seal route* Q, S, H, C, P, M*. The scope read may use the* RegSeqRat$^{\uparrow}$ *readback row* Q*,* Real$^{\uparrow}$ *seal* S*, componentwise* hsame *transports* H*,* Cont *replay row* C*,* Pkg *provenance row* P*, and local* NameCert *row* M*, and it cannot use quotient streams, selected limits, host real equality, countable choice, or ambient completeness.*

Proof. Project the classifier read to the completion boundary. The boundary exposes only the readback, seal, transport, continuation, provenance, and local naming rows once the source and tail route have delivered the packet to the RealCompletionSealClassifier surface.

Apply readback-seal determinacy and Real-seal consumer exactness. These force S to be the seal determined by Q, and force the classifier-facing consumer to carry the displayed transports, replay, provenance, and NameCert row rather than an off-route representative.

The non-escape theorem rules out the remaining alternatives. Quotient streams, selected limits, host real equality, countable choice, and ambient completeness have no row in Q, S, H, C, P, M, so every classifier scope read is exactly the displayed seal route. □

Theorem 977.39 (Regular Cauchy modulus witness-ledger StreamName-RegSeqRat-Real exactness)**.** *For every accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the L10 handoff exposed to a Real$^{\uparrow}$ *or* RealCompletionSealClassifierUp *consumer is exactly the route from the finite* StreamName$^{\uparrow}$ *window row* W*, through the* DyadicRatCore$^{\uparrow}$ *tolerance row* D *and the* RegSeqRat$^{\uparrow}$ *readback row* Q*, to the* Real$^{\uparrow}$ *seal row* S*. The route is carried by the witnessed source* X, μ*, the normalizer row* N_0*, the tail-budget row* T*, and the structural rows* H, C, P, M*, and it contains no quotient stream, host real equality, selected limit, countable-choice row, ambient completeness row, or undisplayed completion datum.*

Proof. Project L to the carrier of Definition 977.1. The displayed finite route contains one StreamName window row W, one dyadic tolerance row D, one RegSeqRat readback row Q, and one Real seal row S.

Apply the NameCert obligations and source-triad exactness, Definition 977.2 and Definition 977.8. These rows bind X, μ before window service and force the consumer to read W, D, Q as the finite-window, dyadic-tolerance, and readback triad before S.

Use window-budget exhaustion and readback-seal determinacy, Definition 977.5 and Definition 977.22. The first theorem rules out a second window or dyadic ledger before Q, and the second fixes Q and S to the same witnessed route over μ, N_0, T, W, D.

Finally apply Real-seal consumer exactness and non-escape, Definition 977.7 and Definition 977.4. Since the accepted packet exports only $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, the L10 handoff has no quotient stream, host real equality, selected limit, choice row, ambient completeness row, or undisplayed completion datum. □

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier streamname regseqrat real exactness`

Theorem 977.40 (Regular Cauchy modulus witness-ledger modulus-normalizer-tail coherence)**.** *For every accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the witnessed modulus row μ, the normalizer row N_0, and the tail-budget row T are locked to the same finite-window, dyadic-tolerance, and readback triad W, D, Q before the Real seal row S is exported. Thus a consumer cannot read a normalized route from one modulus ledger, a tail budget from another route, or a readback from a detached finite window while preserving the accepted seal export.

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier modulus normalizer tail coherence`

Proof. Begin with the carrier and local NameCert obligations. The packet displays exactly one witnessed modulus row μ, one normalizer row N_0, one tail-budget row T, and the source triad W, D, Q before the seal row S.

Apply normalizer-tail commutation and tail-service exactness, Definition 977.6 and Definition 977.25. They keep N_0 and T on the same witnessed modulus route and make every tail-service read pass through $\mu, W, N_0, T, D, Q, S, H, C, P, M$.

Use the source-triad lock and tail-budget readback theorems, Definition 977.9 and Definition 977.27. The triad W, D, Q is attached to μ, and T can be interpreted only against that same displayed normalizer and readback path.

The Real-seal export readiness theorem then supplies the boundary for S. Since readiness requires $\mu, W, D, Q, N_0, T, S, H, C, P, M$ together, a consumer that changes one of μ, N_0, T, W, D, Q loses the accepted export route rather than obtaining a second route. □

Theorem 977.41 (Regular Cauchy modulus witness-ledger completion consumer boundary)**.** *For every accepted* RegularCauchyModulusWitnessLedger$^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

every Completion-facing or RealCompletionSealClassifierUp*-facing consumer factors through the union of the StreamName-RegSeqRat-Real exact route and the modulus-normalizer-tail coherent route. The consumer may cite only the displayed rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ and cannot cite an undisplayed completion object, quotient stream, host real equality, selected limit, countable-choice row, ambient completeness row, detached normalizer, detached tail budget, or detached seal.*

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier completion consumer boundary`

Proof. Start from the completion boundary and bridge request surface, Definition 977.23 and Definition 977.32. They force every Completion-facing read and every bridge request through the finite packet rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$.

The StreamName-RegSeqRat-Real exactness theorem above fixes the readback-to-seal side of that packet. It identifies W, D, Q, S as the exact L10 path from finite windows and dyadic tolerances to RegSeqRat readback and Real seal export.

The modulus-normalizer-tail coherence theorem above fixes the modulus-service side. It locks μ, N_0, T to the same triad W, D, Q before the seal is exported.

Finally apply non-escape and open-phase exit sufficiency, Definition 977.4 and Definition 977.21. Since the public Phase Real and Completion exit surface is exactly the displayed packet, a consumer outside the union of the two routes would need an undisplayed completion object or another forbidden coordinate, none of which is exported. □

Theorem 977.42 (Regular Cauchy modulus witness-ledger root source admission)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the root source rows admitted toward Phase Real and Completion are exactly the witnessed modulus row μ*, the finite* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row* D*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q*, and the* $\mathsf{Real}^{\uparrow}$ *seal row* S*, carried over the displayed source* X *and structural rows* H, C, P, M*. In particular, source admission cannot pass through a hidden modulus selector, quotient stream, host real equality, selected limit, countable choice, ambient completeness object, or an undisplayed completion datum.*

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier root source admission`

Proof. Project the carrier and NameCert obligations, Definition 977.1 and Definition 977.2. They display the packet rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ and assign the witnessed modulus, StreamName window, dyadic tolerance, RegSeqRat readback, Real seal, transport, continuation, provenance, and local naming roles.

Apply the source-triad lock, Definition 977.9. It binds W, D, Q to the same witnessed modulus row μ, so any root admission that exposes one of the L10 source rows must expose the whole finite triad over the same source witness.

Use the completion boundary and bridge request surface, Definition 977.23 and Definition 977.32. These restrict Phase Real, Completion, and bridge-facing reads to the displayed packet, hence no hidden selector, quotient stream, host equality, chosen limit, choice principle, ambient completeness object, or undisplayed completion datum can serve as a root source route. □

Theorem 977.43 (Regular Cauchy modulus witness-ledger root consumer handoff totality)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

every $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *consumer factors through the same finite source triad* W, D, Q*, the normalizer row* N_0*, the tail-budget row* T*, the transport row* H*, the* Cont *replay row* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}$ *row* M*. The handoff is total on the displayed root boundary: there is no consumer route through an extra completion carrier, detached normalizer, detached tail budget, detached seal, quotient stream, host real equality, countable choice, selected limit, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier root consumer handoff totality`

Proof. Start from root source admission above. It identifies the admitted source rows as μ, W, D, Q, S over the displayed source and structural packet rows.

Apply the NameCert obligations and source-triad lock, Definition 977.2 and Definition 977.9. Together they keep W, D, Q attached to μ and place N_0, T, H, C, P, M on the same accepted packet before any Real-facing or completion-seal consumer reads it.

Next use completion boundary and bridge request surface, Definition 977.23 and Definition 977.32. They make the displayed tuple the whole consumer boundary for Phase Real and Completion exit, so every consumer route factors through $W, D, Q, N_0, T, H, C, P, M$ with the same seal row S.

The remaining alternatives are off-boundary. Since the carrier has no row for an extra completion carrier, detached normalizer, detached budget, detached seal, quotient stream, host equality, chosen limit, choice principle, or ambient-completeness object, none can witness a consumer handoff for L. □

Theorem 977.44 (Regular Cauchy modulus witness-ledger root formalization readiness)**.** *The carrier of* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$*, its local* $\mathsf{NameCert}$ *obligations, the nontrivial witness surface, the field-faithful surface, the source-triad lock, the completion boundary, and the bridge-request surface present a* BHist*-anchored formalization target for the root exit route. The target is the finite packet relation over* $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$*; it is not a quotient-stream target, not a host-real-equality target, and not an ambient-completeness target.*

Proof. The carrier and NameCert obligations, Definition 977.1 and Definition 977.2, give the finite packet shape and the local naming rows. Thus the object to be formalized is already a displayed BHist packet with named source, witness, service, seal, transport, replay, provenance, and local certificate coordinates.

The nontrivial witness surface and field-faithful surface keep the packet meaningful at the root boundary. They separate displayed witness data and identify accepted equality with preservation of the packet rows rather than with host equality of real numbers.

Apply the source-triad lock, completion boundary, and bridge request surface, Definition 977.9, Definition 977.23, and Definition 977.32. These theorems force every Real-facing, Completion-facing, and bridge-facing route through $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$.

Consequently Lean can aim at a finite BHist-anchored packet theorem whose constructors and projections are the displayed rows. No quotient stream, host-real-equality premise, selected-limit object, choice principle, or ambient-completeness carrier is part of the root formalization surface. □

Theorem 977.45 (Regular Cauchy modulus witness-ledger Real object readback totality)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

every $\mathsf{Real}^{\uparrow}$ *readback exposed at the root exit route is read only through the displayed coordinates* $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$*. No accepted packet exports an additional selected limit, quotient stream, host real equality, countable-choice row, ambient-completeness row, detached seal, detached normalizer, or detached tail-budget coordinate for that readback.*

Proof. The carrier and NameCert obligations display exactly the rows $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ and assign their local names. Apply Definition 977.1 and Definition 977.2.

The source-triad lock, completion boundary, bridge request surface, and root formalization readiness theorems then force every Real-facing exit route through that same finite packet. Thus a readback that uses an undisplayed Real object would leave the accepted BHist packet, contradicting the root boundary already fixed by Definition 977.9, Definition 977.23, Definition 977.32, and Definition 977.44. □

Theorem 977.46 (Regular Cauchy modulus witness-ledger StreamName dyadic readback scope)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet* $L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$*, the* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *readback scope is exactly the displayed triad* W, D, Q *over the same source and witnessed modulus rows* X, μ*. It cannot be refined by a hidden selector, quotient stream, host equality of real objects, selected limit, countable-choice row, or ambient completeness row.*

Proof. Use the source-triad lock to bind W, D, Q to the same witnessed modulus row μ over the source X. The tail-budget readback and Real-seal export readiness theorems keep that triad on the displayed normalizer, tail-service, and seal route rather than on a separate stream object.

The completion boundary and root formalization readiness theorems identify the accepted target as the finite packet itself. Hence any selector, quotient stream, host equality, chosen limit, or ambient-completeness coordinate would be an extra root datum, not a refinement of the W, D, Q readback scope. □

Theorem 977.47 (Regular Cauchy modulus witness-ledger completion seal root consumer exhaustion)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet* $L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$*, every* $\mathsf{RealCompletionSealClassifierUp}$ *consumer at the root boundary factors through the union of the Real object readback route, the* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *readback route, and the normalizer-tail route already fixed by* N_0, T, H, C, P, M*. There is no fourth route through an undisplayed completion carrier, quotient stream, host real equality, selected limit, countable choice, or ambient completeness coordinate.*

Proof. The Real object readback totality theorem above supplies the $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ route for $\mathsf{Real}^{\uparrow}$ reads. The StreamName dyadic readback scope theorem above supplies the W, D, Q route for finite-window and dyadic readback.

For the normalizer-tail route, apply Definition 977.6, Definition 977.25, and Definition 977.27. These keep N_0, T, H, C, P, M attached to the same displayed triad and seal.

Finally use the bridge request surface and root formalization readiness theorems. Since the root packet exports only these named coordinates, every completion-seal consumer is exhausted by their union. □

Theorem 977.48 (Regular Cauchy modulus witness-ledger source-triad terminality)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet* $L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$*, the displayed source triad* W, D, Q *is terminal among Real-facing and Completion-facing source routes under the witnessed modulus row* μ*. Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *consumer that reaches the seal row* S *factors through the finite* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row* D*, and the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q *before it can read* N_0, T, H, C, P, M *or consume* S*.*

Proof. First apply the source-triad lock and StreamName-RegSeqRat-Real exactness, Definition 977.9 and Definition 977.39. These identify W, D, Q as the finite source route over μ and prevent a consumer from inserting a quotient stream, host equality, chosen limit, or ambient-completeness carrier before the Real seal.

Next use modulus-normalizer-tail coherence. It makes N_0 and T service rows over the same source triad rather than independent routes, so a Real-facing or Completion-facing consumer cannot bypass W, D, Q by reading the normalizer or tail budget alone.

Finally apply completion consumer boundary and completion seal root consumer exhaustion. They exhaust the consumer surface by the Real object readback route, the W, D, Q readback

route, and the normalizer-tail route attached to it. Therefore the source triad is terminal for every displayed root consumer. □

Theorem 977.49 (Regular Cauchy modulus witness-ledger seal source pullback)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet* $L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$*, the seal row* S *is the pullback of the source triad* W, D, Q *along the displayed normalizer, tail, transport, continuation, provenance, and local naming rows* N_0, T, H, C, P, M*. Thus the Real seal consumed at the root boundary is determined by* W, D, Q *over* μ *together with those structural rows, and it is not a detached Real object or an external completion carrier.*

Proof. Begin with readback-seal determinacy and StreamName-RegSeqRat-Real exactness. The determinacy theorem fixes the readback row Q and the seal row S to the same route over μ, N_0, T, W, D, while exactness identifies that route as the L10 handoff from StreamName window to DyadicRatCore tolerance, RegSeqRat readback, and Real seal.

Use modulus-normalizer-tail coherence to attach N_0 and T to the same W, D, Q triad before S is exported. The rows H, C, P, M then serve only as the displayed transport, replay, provenance, and local NameCert support for that route.

The completion consumer boundary theorem supplies the consumer-side equation for the pullback description. Since every completion-facing consumer reads only $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$, the seal row is the source triad transported along N_0, T, H, C, P, M, not a separate completion witness. □

Lean4 ✓ `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier seal source pullback`

Theorem 977.50 (Regular Cauchy modulus witness-ledger completion refusal boundary)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet* $L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$*, any attempted Real-facing or Completion-facing consumer route that omits one of* μ, W, D, Q, S *is a refusal boundary for the packet. Such a route is not an alternate completion witness, even if it retains* N_0, T, H, C, P, M *or cites a quotient stream, host real equality, selected limit, countable-choice row, ambient completeness row, detached normalizer, detached tail budget, or detached seal.*

Proof. For omission of μ, apply the source-triad lock and readback-seal determinacy. Without the witnessed modulus row, the triad W, D, Q and the seal row S are no longer attached to the accepted source route.

For omission of one of W, D, Q, use source-triad terminality together with StreamName-RegSeqRat-Real exactness. The consumer loses the terminal source route from finite StreamName window through DyadicRatCore tolerance and RegSeqRat readback, so the remaining rows cannot form a Real or completion witness.

For omission of S, apply seal source pullback and completion seal root consumer exhaustion. The route may still display service or provenance rows, but it has no Real seal to consume at the root boundary.

The completion consumer boundary and non-escape theorems rule out all replacements. Quotient streams, host real equality, selected limits, countable choice, ambient completeness, detached normalizers, detached tail budgets, and detached seals are not exported rows of the accepted packet, so the attempted route is refused rather than reinterpreted as another completion witness. □

Theorem 977.51 (Regular Cauchy modulus witness-ledger root-exit partition)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet* $L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$*, every Phase Real and Completion root-exit consumer route is classified by exactly one of the following four cases:*

1. *the Real object readback route through the displayed packet* $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$*;*
2. *the* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *source-triad route through* W, D, Q *over* X, μ*;*
3. *the normalizer-tail structural route through* N_0, T, H, C, P, M *attached to the same triad and seal;*
4. *the refusal boundary for an attempted route omitting at least one of* μ, W, D, Q, S*.*

Thus the root-exit surface has no additional route through an undisplayed Real object, quotient stream, host real equality, selected limit, countable-choice row, ambient-completeness row, detached normalizer, detached tail budget, or detached completion seal.

Proof. Begin with Real object readback totality and StreamName dyadic readback scope. These identify the first two admitted consumer routes: a Real-facing read may use only the displayed packet, while the finite-window source read is exactly the W, D, Q triad over X, μ.

Next apply completion seal root consumer exhaustion. It states that every completion-seal consumer at the root boundary factors through the union of the Real object readback route, the source-triad route, and the normalizer-tail route. The normalizer-tail route is then pinned down by source-triad terminality and seal source pullback, because N_0, T, H, C, P, M are structural rows attached to the same W, D, Q source and the same seal row S rather than an independent completion carrier.

It remains to classify attempted routes outside those admitted branches. The completion refusal boundary theorem applies to any route omitting one of μ, W, D, Q, S, so such a route is refused instead of becoming a hidden witness.

The four cases are disjoint at the root boundary because each reads a different BEDC role: displayed Real readback, source-triad readback, structural normalizer-tail service, or refusal for a missing mandatory row. Combining the exhaustion theorem with the refusal boundary leaves no fifth Phase Real or Completion consumer route. □

Theorem 977.52 (Regular Cauchy modulus witness-ledger root-exit partition stability)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet* $L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M)$*, the root-exit classification of Definition 977.51 is stable under every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *consumer route that preserves the displayed rows* $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$*. If such a consumer route is classified as displayed Real readback,* $\mathsf{StreamName}^{\uparrow}$–$\mathsf{DyadicRatCore}^{\uparrow}$–$\mathsf{RegSeqRat}^{\uparrow}$ *source-triad readback, normalizer-tail structural service, or refusal for omitting one of* μ, W, D, Q, S*, then every row-preserving presentation of the same consumer route remains in that same case. No row-preserving presentation can move the route to another case or create an additional root-exit case.*

```
Lean4 ✓  BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.RegularCauchyModulusWitnessLedgerCarrier
root exit partition stability
```

Proof. Start from the root-exit partition. It already exhausts every Phase Real and Completion root-exit consumer route by the displayed Real readback route, the source-triad readback route, the normalizer-tail structural route, or the refusal boundary for a missing mandatory row.

For the displayed Real and source-triad cases, apply source-triad terminality together with seal source pullback. A row-preserving presentation keeps the same μ, W, D, Q, S coordinates, so it cannot detach the Real seal from the finite $\mathsf{StreamName}^{\uparrow}$ window, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance row, and the $\mathsf{RegSeqRat}^{\uparrow}$ readback row. The first two cases therefore remain the same cases.

For the normalizer-tail case, use seal source pullback and the completion seal root consumer exhaustion theorem. The rows N_0, T, H, C, P, M are structural service rows attached to the same

triad and seal, not a second completion carrier. Preserving the displayed packet keeps that attachment fixed, so the structural route cannot become either a source-triad readback route or an external completion route.

For the refusal case, apply the completion refusal boundary. A presentation that still omits one of μ, W, D, Q, S remains refused, while a presentation preserving all displayed rows is no longer a presentation of that refused route but of one of the three admitted routes already classified above.

Finally apply non-escape. Since the packet exports no quotient stream, host real equality, selected limit, countable-choice row, ambient-completeness row, detached normalizer, detached tail budget, or detached completion seal, a row-preserving consumer has no hidden coordinate by which to change its root-exit case. The four-way classification is therefore stable for all displayed-row-preserving $\mathsf{Real}^{\uparrow}$ and $\mathsf{RealCompletionSealClassifierUp}$ consumers. □

Theorem 977.53 (Regular Cauchy modulus witness-ledger formal target boundary)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the Lean-facing root target is the finite relation saying that every $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{RealCompletionSealClassifierUp}$ *consumer route is one of the four root-exit cases of Definition 977.51, and that the route preserves the displayed* $\mathsf{StreamName}^{\uparrow}$ *window* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* Q*,* $\mathsf{Real}^{\uparrow}$ *seal* S*, normalizer* N_0*, tail budget* T*, transport* H*,* Cont *replay* C*,* Pkg *provenance* P*, and* $\mathsf{NameCert}$ *row* M*. No Lean-facing consumer route may replace this finite relation by quotient streams, host real equality, selected limits, countable choice, ambient completeness, detached normalizers, detached tail budgets, or detached completion seals.*

Proof. Begin with the root-exit partition and partition stability. They classify every root consumer route as displayed Real readback, source-triad readback, normalizer-tail structural service, or refusal for a missing mandatory row, and they keep that classification stable under displayed-row-preserving presentations.

Use seal source pullback and source-triad terminality next. These theorems attach the $\mathsf{Real}^{\uparrow}$ seal S and the normalizer-tail rows N_0, T, H, C, P, M to the same $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance row, and $\mathsf{RegSeqRat}^{\uparrow}$ readback row.

Finally apply the completion refusal boundary and nonescape. A route omitting one of the source or seal rows is refused, and the packet exports no quotient stream, host real equality, selected limit, countable-choice row, ambient-completeness row, detached normalizer, detached tail budget, or detached completion seal. The finite relation described in the statement is therefore the exact Lean-facing root target for $\mathsf{Real}^{\uparrow}$ and $\mathsf{RealCompletionSealClassifierUp}$ consumers. □

Theorem 977.54 (Regular Cauchy modulus witness-ledger L10 exit boundary)**.** *For every accepted* $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ *packet*

$$L = (X, \mu, W, N_0, T, D, Q, S, H, C, P, M),$$

the packet is an L10 exit-boundary packet exactly when its displayed rows factor through the shared sibling surfaces: the $\mathsf{StreamName}^{\uparrow}$ *finite-window surface* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *seal-readback rows* X, Q*, the* $\mathsf{Real}^{\uparrow}$ *finite-window ledger boundary* S*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *finite ledger* D*, and the* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *exit factor over* $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$*. Conversely, these five displayed sibling surfaces reconstruct the same witness-ledger exit boundary using only* BHist*,* hsame*,* Cont*,* Pkg*,* $\mathsf{NameCert}$*, dyadic-ledger, and finite-window rows, and add no quotient stream, host limit, selected limit, host real equality, countable-choice row, ambient completeness datum, or detached completion carrier.*

Proof. For the forward direction, start with the open Phase Real and Completion exit surface of Definition 977.21. It exposes the accepted packet as the finite route from the witnessed modulus row through the StreamName, DyadicRatCore, RegSeqRat, and RealUp rows.

Next apply source-row coverage, consumer-obligation exhaustion, and StreamName-RegSeqRat-Real exactness. These identify W as the finite-window surface, D as the dyadic finite ledger, X, Q as the regular-source and readback surface, and S as the RealUp boundary row consumed by the same packet.

Finally apply the UniformCauchyCriterion exit factor, dyadic-tail cofinal readback, and seal-classifier scope. They keep the exit consumer on $X, \mu, W, N_0, T, D, Q, S, H, C, P, M$ and rule out any completion-facing coordinate outside the displayed BHist, hsame, Cont, Pkg, NameCert, dyadic-ledger, and finite-window rows.

For the reverse direction, suppose the five sibling surfaces are displayed over the same rows. StreamName-RegSeqRat-Real exactness and source-triad terminality, Definition 977.39 and Definition 977.48, assemble W, D, Q, S into the L10 handoff.

Modulus-normalizer-tail coherence and root consumer handoff totality, Definition 977.40 and Definition 977.43, then attach $X, \mu, N_0, T, H, C, P, M$ to that handoff. The resulting packet is the same witness-ledger exit boundary because the non-escape theorem leaves no row for quotient streams, host limits, selected limits, host real equality, countable choice, ambient completeness, or detached completion data. □

Falsifiable prediction: If a RealUp seal consumer reads a regular Cauchy modulus without the displayed witness-ledger row, normalized route row, finite-window row, dyadic tolerance row, and RegSeqRat readback row, the packet is refuted.

Independence witness: regular-cauchy-modulus-normalizer, cauchymodulusmeet, regular-cauchy-tail-budget, real-completion-seal-classifier, streamname: no sibling is bijective because this packet uniquely binds the witnessed modulus ledger to the downstream finite-window and RealUp seal route; each sibling omits either the single witness ledger, the normalized route, or the RealUp consumer seal.

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$ packet is generated from a regular source, a displayed modulus witness ledger, finite StreamName windows, normalized-tail and tail-budget rows, dyadic tolerance readback, a RealUp seal, componentwise transports, displayed replay, provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}}, \mathsf{maturePackageClosed})$

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}}, \mathsf{theoremChecked})$

Lean target: `BEDC.Derived.RegularCauchyModulusWitnessLedgerUp.taste\_gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close quotient streams, host real equality, hidden modulus replacement, selected limits, countable choice, ambient completeness, Lean verification, or bridge checking for $\mathsf{RegularCauchyModulusWitnessLedger}^{\uparrow}$.

Upgrade path: No further paper-side closure upgrade is pending for the finite witnessed modulus-ledger packet; bridge checking remains a separate verification-axis matter.

Chapter 978

A Concrete Naming Certificate for $\mathsf{HaltingTraceClassifier}^{\uparrow}$

The $\mathsf{HaltingTraceClassifier}^{\uparrow}$ packet realizes the positive finite-trace side of the halting obstruction in chapter 9368 without presenting a total halting decision. It sits beside the certificate-history obstruction of chapter 491, the displayed trace packet of chapter 492, the machine-step surface of chapter 280, and the inscription-event naming surface of chapter 519.

Definition 978.1 (Halting trace-classifier carrier)**.** *A* $\mathsf{HaltingTraceClassifier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (M, h, F, R, D, H, C, P, N)$$

with the following displayed rows:

1. *M is the machine or certificate row whose one-step behavior is read through the* $\mathsf{TuringMachine}^{\uparrow}$ *and* $\mathsf{NameCert}$ *surfaces;*
2. *h is the initial history row;*
3. *F is a finite positive* Cont *trace from h to a displayed halted row;*
4. *R is the positive classifier row accepting exactly the displayed trace F as terminating evidence;*
5. *D is the diagonal refusal row stating that no accepted classifier read may decide divergence or non-termination outside the displayed finite trace;*
6. *H records componentwise* hsame *transports for the machine row, initial history, trace row, positive classifier row, refusal row, package provenance, and local name;*
7. *C records the displayed* Cont *routes that replay the trace, transport the positive read, and return the diagonal refusal to the same packet;*
8. *P is the* Pkg *provenance over* $\mathsf{TuringMachine}^{\uparrow}$, $\mathsf{HaltingDistinction}^{\uparrow}$, $\mathsf{HaltingDistinctionTrace}^{\uparrow}$, $\mathsf{InscriptionEvent}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{HaltingTraceClassifier}^{\uparrow}}$ *row.*

The carrier contains no row for a total halting predicate, no negative divergence decider, no unbounded search certificate, and no host-level proof that an absent continuation never appears.

Theorem 978.2 (Halting trace-classifier positive trace soundness)**.** *Every accepted positive read of a* $\mathsf{HaltingTraceClassifier}^{\uparrow}$ *packet factors through the displayed finite trace row F. A consumer may*

classify M at h as positively halted only by replaying the finite Cont *route from h to the displayed halted row through C, together with the transported trace and classifier rows F, R, H.*

Proof. Project the accepted carrier to $T = (M, h, F, R, D, H, C, P, N)$. The positive classifier row is R, and the only evidence row it may read is the finite trace F.

The continuation routes in C replay that trace from the initial history row to the displayed halted row. Componentwise transport through H moves M, h, F, R together, so the positive read remains attached to the same displayed trace after transport.

The package and local naming rows P, N expose no second trace source. Hence every accepted positive halting classification factors through the finite Cont trace F rather than through an ambient decision procedure. □

Theorem 978.3 (Halting trace-classifier diagonal refusal)**.** *The diagonal row D of an accepted* $\mathsf{HaltingTraceClassifier}^{\uparrow}$ *packet refuses any request to turn the positive trace classifier into a total halting classifier. In particular, an absent displayed trace cannot be read as divergence, non-termination, or a negative halting verdict.*

Proof. Read the refusal coordinate D from the carrier. It is paired with the positive classifier row R to state exactly where the packet stops: R accepts displayed finite traces, while D rejects requests that ask for a verdict outside those traces.

The route data in C can replay a finite Cont trace already present as F, but it has no route for an unbounded search over all continuations. The transport row H preserves this boundary because it transports D with the positive classifier and trace rows.

Since no coordinate stores a divergence decider, total halting predicate, or proof that all future continuations are absent, the diagonal request has no source row in the packet. It is therefore refused by the displayed carrier itself. □

Theorem 978.4 (Halting trace-classifier non-escape)**.** *No consumer of an accepted* $\mathsf{HaltingTraceClassifier}^{\uparrow}$ *packet can extract a decision about divergence outside the displayed trace row F. The packet exports positive finite-trace evidence and diagonal refusal, but it does not export a total classifier over all machine-history pairs.*

Proof. Inspect the carrier coordinates. The positive evidence is F together with R, and the refusal evidence is D together with its replay and transport rows.

Apply positive trace soundness to any accepted positive read. The read must use the displayed finite trace. Apply diagonal refusal to any request for a negative or total verdict. Such a request asks for a coordinate absent from T.

The provenance and local naming rows P, N only account for these displayed rows. They do not add unbounded search, divergence, or totality data, so no consumer can escape from the finite positive-trace and refusal surface. □

Theorem 978.5 (Halting trace-classifier NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{HaltingTraceClassifier}^{\uparrow}}$ *surface for Definition 978.1 consists of five finite obligations:*

1. *carrier exposure for the displayed packet $T = (M, h, F, R, D, H, C, P, N)$;*
2. *positive trace soundness, requiring every accepted positive read to factor through the displayed finite* Cont *trace F;*
3. *diagonal refusal, requiring every total-halting or divergence request outside F to be rejected by D;*

4. *transport stability for the machine row, history row, trace row, classifier row, refusal row, provenance, and local naming row through H;*
5. *ledger exactness, requiring all replay, package, and naming reads to factor through C, P, N with no hidden divergence decider.*

The later Lean `TasteGate.lean` *development must provide explicit* Nontrivial HaltingTraceClassifier$^{\uparrow}$ *and* FieldFaithful HaltingTraceClassifier$^{\uparrow}$ *instances for this finite carrier.*

Lean4 ✓ `BEDC.Derived.HaltingTraceClassifierUp.HaltingTraceClassifierTasteGate single carrier alignment`
Lean4 ✓ `BEDC.Derived.HaltingTraceClassifierUp.HaltingTraceClassifierUp taste gate boundary`

Proof. Carrier exposure is projection from Definition 978.1. The tuple lists the machine row, initial history, finite trace, positive classifier, diagonal refusal, transports, continuation routes, provenance, and local name.

Positive trace soundness is Definition 978.2, and diagonal refusal is Definition 978.3. Together they separate accepted finite halting evidence from forbidden total classification.

Transport stability follows from the componentwise role of H. Replay and ledger exactness follow from C, P, N, which are the only rows carrying continuation replay, package provenance, and local naming.

Nontriviality rules out identifying a positive trace row with the diagonal refusal row. Field faithfulness requires the TasteGate implementation to preserve $M, h, F, R, D, H, C, P, N$, so a future gate cannot discharge the packet by forgetting either the finite trace evidence or the refusal boundary. □

Falsifiable prediction: Every accepted HaltingTraceClassifierUp positive read factors through a displayed finite Cont trace and cannot decide divergence outside that trace.

Independence witness: haltingdistinction, haltingdistinctiontrace, turingmachine, inscriptionevent, continuationtracenormalform: none is bijective because none simultaneously carries positive finite-trace classification and diagonal refusal rows.

Closure status for NameCert$_{\text{HaltingTraceClassifier}^{\uparrow}}$.

Constructive story: A HaltingTraceClassifier$^{\uparrow}$ packet is generated from one machine row, one initial history row, one displayed finite Cont trace, one positive classifier row, one diagonal refusal row, componentwise transports, replay routes, package provenance, and a local naming row.

Theory closure: TheoryGate(NameCert$_{\text{HaltingTraceClassifier}^{\uparrow}}$, seed)

Scope closed: Definition 978.1, Definition 978.2, Definition 978.3, Definition 978.4, and Definition 978.5 bind the finite positive-trace classifier and diagonal refusal surface.

Formal verification: FormalStatus(NameCert$_{\text{HaltingTraceClassifier}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a total halting predicate, divergence decision, unbounded search certificate, Lean proof, or public standard bridge.

Upgrade path: Checked closure requires Lean encoding of the carrier and TasteGate proofs for nontriviality, field faithfulness, positive trace soundness, diagonal refusal, and non-escape.

Chapter 979

A Concrete Naming Certificate for $\mathsf{RealWindowSynchronizer}^{\uparrow}$

The $\mathsf{RealWindowSynchronizer}^{\uparrow}$ packet realizes the Real and Completion route of chapter 9238 as one finite naming certificate. It consumes the StreamName window surface of chapter 126, the RegSeqRat tail surface of chapter 301, the Cauchy limit seal of chapter 386, the regular Cauchy tail budget of chapter 906, and the Real seal surface of chapter 38. The synchronizer is not a new completion principle; it is the finite packet that keeps the window, tail, budget, limit-seal, and RealUp rows aligned before any completion-facing consumer reads the route.

Definition 979.1 (Real window synchronizer carrier)**.** *A* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (W, R, T, L, S, H, C, P, N)$$

with the following displayed coordinates:

1. *W is the* $\mathsf{StreamName}^{\uparrow}$ *window service row whose finite windows are visible to downstream consumers;*
2. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail row that reads the same window service as a regular rational sequence surface;*
3. *T is the shared tail threshold and* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *service row through which the window read and the regular tail read are synchronized;*
4. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row consuming the synchronized tail route as a sealed Cauchy-limit handoff;*
5. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row exposed only after W, R, T, L have been replayed through the displayed routes;*
6. *H records componentwise* hsame *transports for the window, tail, threshold, limit-seal, Real seal, provenance, and local naming rows;*
7. *C records the displayed* Cont *routes that inspect the StreamName window, pull the RegSeqRat tail to the shared threshold, pass through the CauchyLimitSeal row, and expose the RealUp seal;*
8. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RegularCauchyTailBudget}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RealWindowSynchronizer}^{\uparrow}}$ *row naming exactly this synchronizer packet.*

The carrier has no coordinate for a quotient stream, selected host real, ambient completeness theorem, independent seal route, or second window service not transported through H.

Lean4 ✓ `BEDC.Derived.RealWindowSynchronizerUp.taste gate`
Lean4 (definition) `BEDC.Derived.RealWindowSynchronizerUp.RealWindowSynchronizerUp`

Theorem 979.2 (Real window synchronizer NameCert obligations)**.** *For every accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *carrier* $Z = (W, R, T, L, S, H, C, P, N)$*, the local* $\mathsf{NameCert}_{\mathsf{RealWindowSynchronizer}^{\uparrow}}$ *surface consists exactly of carrier admission, StreamName window admission through* W*, RegSeqRat tail admission through* R*, shared-threshold admission through* T*, CauchyLimitSeal route admission through* L*, RealUp seal admission through* S*, componentwise* hsame *transport through* H*, displayed route replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Proof. Carrier admission is projection from Definition 979.1. Each coordinate is displayed in the finite BHist packet, so the local naming row can inspect only $W, R, T, L, S, H, C, P, N$.

The obligation rows are then read in route order. The StreamName window and RegSeqRat tail rows are tied by the shared threshold T; the CauchyLimitSeal row consumes that synchronized tail route; and the RealUp seal row is exposed only after the same replay path has passed through H, C, P, N.

No extra obligation can appear, because the carrier has no quotient, selected host real, independent seal, or second window-service coordinate. Thus the displayed rows exhaust the local NameCert surface. □

Theorem 979.3 (Real window synchronizer budget pullback)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing read exported by an accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *packet factors through the same shared threshold row* T *used by the* $\mathsf{StreamName}^{\uparrow}$ *window* W *and the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail row* R*. Transporting the window, tail, or threshold rows through* H *transports the CauchyLimitSeal and RealUp seal reads through the same displayed* Cont *routes* C *and does not create a second budget ledger.*

Proof. Project the packet $Z = (W, R, T, L, S, H, C, P, N)$. The only threshold coordinate is T, and both the window route and the tail route are displayed as consumers of that row.

Compose the displayed routes in C: first read W, then replay R at the shared threshold, then pass through L before exposing S. Componentwise transport by H changes representatives of these rows but preserves the same ordered route.

Since no separate budget coordinate is present, a completion-facing read cannot bypass the pullback. It receives the RealUp seal only as the end of the synchronized StreamName, RegSeqRat, CauchyLimitSeal, and local NameCert route. □

Lean4 ✓ `BEDC.Derived.RealWindowSynchronizerUp.RealWindowSynchronizerCarrier budget pullback`

Theorem 979.4 (Real window synchronizer non-escape)**.** *An accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *carrier exports no route to a Real or completion consumer except the finite synchronized packet* $(W, R, T, L, S, H, C, P, N)$*. In particular, it cannot export a StreamName window without the RegSeqRat tail threshold, a RegSeqRat tail without the shared StreamName window, a CauchyLimitSeal read detached from the RealUp seal, or a RealUp seal detached from the displayed limit-seal route.*

Proof. Inspect the carrier coordinates. The exported window, tail, threshold, limit seal, Real seal, transports, continuations, provenance, and naming rows are all fields of the same finite packet.

If a consumer removes W, the tail row no longer has the displayed StreamName window it claims to read. If it removes R or T, the Real-facing route has no regular tail threshold. If it removes L, the completion-facing handoff is absent; if it removes S, no RealUp seal can be read.

Thus every admitted route is the displayed synchronized route, and every escape route asks for a coordinate not present in the carrier. □

Lean4 ✓ `BEDC.Derived.RealWindowSynchronizerUp.RealWindowSynchronizerCarrier nonescape`

Theorem 979.5 (Real window synchronizer limit-seal compatibility)**.** *For an accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *carrier*

$$Z = (W, R, T, L, S, H, C, P, N),$$

the $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row L is consumed only after the same* $\mathsf{StreamName}^{\uparrow}$ *window row W, the same* $\mathsf{RegSeqRat}^{\uparrow}$ *tail row R, and the same shared threshold row T have been replayed through the displayed transport, route, provenance, and naming rows H, C, P, N. No consumer of L may replace W, R, or T by a second window service, hidden tail oracle, detached threshold ledger, or ambient completeness coordinate.*

Proof. Project the accepted packet to its displayed coordinates. The only entries available before the limit-seal row are the window W, tail R, threshold T, and the shared transport and route surface H, C.

The replay through C first reads the StreamName window and then the RegSeqRat tail at the same threshold. Componentwise hsame transport in H may rename those rows, but it preserves the ordered route into L rather than creating a second source for the seal.

The provenance and naming rows P, N then certify that the consumed limit seal is the row displayed in the same finite packet. Since the carrier has no hidden tail oracle, detached threshold, second window service, or ambient completeness coordinate, every admitted L read is the synchronized W, R, T, H, C, P, N read. □

Theorem 979.6 (Real window synchronizer Real seal exposure)**.** *For an accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *carrier $Z = (W, R, T, L, S, H, C, P, N)$, the* $\mathsf{Real}^{\uparrow}$ *seal row S is exposed only after the window row W, tail row R, threshold row T, and limit-seal row L have been read through the displayed route. The exposure exports no quotient stream, selected host real, ambient completeness theorem, detached seal route, or second window service.*

Proof. Use the budget pullback of Definition 979.3. It places every Real-facing read over the shared threshold T used by the StreamName window and RegSeqRat tail.

Then apply limit-seal compatibility from Definition 979.5. The CauchyLimitSeal row is available only after the same W, R, T replay has passed through H, C, P, N.

Finally expose the Real seal row S as the last displayed consumer row. The non-escape theorem Definition 979.4 rules out quotient streams, selected host reals, ambient completeness, detached seal routes, and second window services because none is present among the carrier coordinates. □

Theorem 979.7 (Real window synchronizer obligation-closure package)**.** *The carrier definition of Definition 979.1, the local* $\mathsf{NameCert}_{\mathsf{RealWindowSynchronizer}^{\uparrow}}$ *obligations of Definition 979.2, the budget pullback of Definition 979.3, the non-escape boundary of Definition 979.4, the limit-seal compatibility of Definition 979.5, the Real-seal exposure of Definition 979.6, and the checked TasteGate carrier alignment marker* `BEDC.Derived.RealWindowSynchronizerUp.TasteGate.RealWindowSynchronizerTaste` *jointly form the* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *obligation-closure surface for the finite Real and Completion window-to-seal route.*

Proof. The carrier definition fixes the finite packet $Z = (W, R, T, L, S, H, C, P, N)$ and excludes quotient streams, selected host reals, ambient completeness, detached seal routes, and second window services.

The NameCert obligation theorem names the rows that must be admitted. The budget pullback ties the StreamName window and RegSeqRat tail to the shared threshold, while non-escape prevents any consumer from reading outside the displayed packet.

The two seal theorems then place the CauchyLimitSeal row and the RealUp seal row on the same replay path. Together with the TasteGate marker for single-carrier alignment, these rows state the exact obligation package without claiming a checked Lean proof for the new theorem sites. □

Theorem 979.8 (Real window synchronizer StreamName–RegSeqRat scope)**.** *For an accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *carrier* $Z = (W, R, T, L, S, H, C, P, N)$*, every* $\mathsf{StreamName}^{\uparrow}$ *consumer read and every* $\mathsf{RegSeqRat}^{\uparrow}$ *consumer read used by the synchronizer factors through the same displayed* W, R, T, H, C, P, N *rows. The synchronizer exposes no second window service, hidden tail oracle, or detached threshold ledger outside that finite route.*

Proof. Project the carrier Z to its displayed rows. The only StreamName window coordinate is W, the only RegSeqRat tail coordinate is R, and the only shared threshold coordinate available to either read is T.

Apply the budget pullback of Definition 979.3. It forces every Real or completion-facing read exported by the packet through the same threshold row used by both the window and tail routes.

Apply the non-escape boundary of Definition 979.4. Since no second window service, hidden tail oracle, or detached threshold ledger occurs among the coordinates, the displayed StreamName and RegSeqRat sibling rows named in the chapter introduction are the only available sources for the synchronizer read. □

Theorem 979.9 (Real window synchronizer limit-seal scope)**.** *For an accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *carrier* $Z = (W, R, T, L, S, H, C, P, N)$*, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* L *and the* $\mathsf{Real}^{\uparrow}$ *seal row* S *are scoped by the same synchronized* W, R, T, H, C, P, N *route. Consequently, no completion-facing consumer can read* L *or* S *without the shared window-tail threshold packet.*

Proof. Start with Definition 979.8. It places the StreamName and RegSeqRat reads over the same window, tail, threshold, transport, route, provenance, and local naming rows.

Combine that scope with limit-seal compatibility from Definition 979.5. The CauchyLimitSeal row L is consumed only after the synchronized W, R, T replay has passed through H, C, P, N.

Finally apply the Real seal exposure theorem Definition 979.6. It exposes S only after L has been read on the same route, so a completion-facing consumer cannot reach either seal without the shared window-tail threshold packet. □

Theorem 979.10 (Real window synchronizer standard bridge route)**.** *For an accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *packet*

$$Z = (W, R, T, L, S, H, C, P, N),$$

every standard bridge read of Z *factors through exactly the displayed* $\mathsf{StreamName}^{\uparrow}$ *window* W*, the* $\mathsf{RegSeqRat}^{\uparrow}$ *tail* R*, the shared threshold and* $\mathsf{RegularCauchyTailBudget}^{\uparrow}$ *row* T*, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row* L*, the* $\mathsf{Real}^{\uparrow}$ *seal* S*, the componentwise* hsame *transports* H*, the displayed* Cont *routes* C*, the* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{RealWindowSynchronizer}^{\uparrow}}$ *row* N*. It exports no quotient stream, selected host real, ambient completeness theorem, detached seal route, or second window service.*

Proof. Apply the StreamName–RegSeqRat scope theorem Definition 979.8. It forces the first bridge coordinates to be the displayed W, R, T, H, C, P, N rows rather than a second window service, hidden tail oracle, or detached threshold ledger.

Next apply the limit-seal scope theorem Definition 979.9. The CauchyLimitSeal row L and the RealUp seal row S then sit on the same synchronized route, so a standard bridge consumer cannot read either seal without the shared window-tail threshold packet.

The Real-seal exposure theorem Definition 979.6 identifies the terminal public seal row as S after the displayed route through W, R, T, L, H, C, P, N.

Finally use the non-escape boundary Definition 979.4. Since quotient streams, selected host reals, ambient completeness theorems, detached seal routes, and second window services are absent from the carrier, the displayed route exhausts every standard bridge read. □

Theorem 979.11 (Real window synchronizer standard bridge surface)**.** *For an accepted* $\mathsf{RealWindowSynchronizer}^{\uparrow}$ *carrier* $Z = (W, R, T, L, S, H, C, P, N)$*, the carrier row, local* $\mathsf{NameCert}_{\mathsf{RealWindowSynchronizer}^{\uparrow}}$ *obligations, shared budget pullback, non-escape row, limit-seal compatibility, Real-seal exposure, StreamName–RegSeqRat scope, limit-seal scope, and the checked TasteGate single-carrier marker* `BEDC.Derived.RealWindowSyn` *together form the bridge surface from the finite synchronizer packet* $(W, R, T, L, S, H, C, P, N)$ *to the standard reflection schema.*

Lean4 ✓ `BEDC.Derived.RealWindowSynchronizerUp.RealWindowSynchronizerUp StdBridge`

Proof. The carrier definition Definition 979.1 fixes the finite packet and excludes every coordinate outside $W, R, T, L, S, H, C, P, N$. The NameCert obligations of Definition 979.2 then identify the local admission rows carried by that same packet.

The public route is obtained by composing the budget pullback of Definition 979.3 with the non-escape boundary of Definition 979.4. These two results make the shared threshold row T the only budget source and prevent any completion-facing read from leaving the displayed synchronizer coordinates.

The seal route is supplied by Definition 979.5 and Definition 979.6. The StreamName–RegSeqRat scope of Definition 979.8 and the limit-seal scope of Definition 979.9 place those reads on the same W, R, T, H, C, P, N route.

Together with the checked TasteGate single-carrier marker, these rows supply the paper-side bridge surface to the standard reflection schema. The verification axis remains grounded in the existing TasteGate target until a checked StandardBridge theorem is present. □

Falsifiable prediction: Removing the shared window row permits a RealUp seal read whose StreamName and RegSeqRat windows no longer agree; removing the seal row prevents any completion-facing consumer from reading the synchronizer as a RealUp route.

Independence witness: Nearest siblings: streamname, regseqrat, cauchylimitseal, regular-cauchy-tail-budget, and real. The synchronizer is not bijective to any one sibling because it carries all five surfaces simultaneously: a StreamName finite window, a RegSeqRat tail threshold, a CauchyLimitSeal row, a RegularCauchyTailBudget service row, and a RealUp seal row; dropping any one row changes the admitted consumer route.

The Lean file `Derived/RealWindowSynchronizerUp/TasteGate.lean` will include Nontrivial RealWindowSynch with an explicit witness_pair and FieldFaithful $\mathsf{RealWindowSynchronizer}^{\uparrow}$ by constructor-field injection for the displayed coordinates $W, R, T, L, S, H, C, P, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{RealWindowSynchronizer}^{\uparrow}}$.

Constructive story: A RealWindowSynchronizer$^{\uparrow}$ packet is generated from a StreamName window service row, RegSeqRat tail row, shared threshold row, CauchyLimitSeal row, RealUp seal row, componentwise transports, displayed continuations, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{RealWindowSynchronizer}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 979.1, Definition 979.2, Definition 979.3, Definition 979.4, Definition 979.5, Definition 979.6, Definition 979.7, Definition 979.8, Definition 979.9, Definition 979.10, and Definition 979.11 bind the finite synchronizer carrier, local obligation surface, shared-budget pullback, seal compatibility, public Real-seal exposure row, non-escape boundary, StreamName–RegSeqRat route, scoped seal route, standard bridge read route, standard reflection bridge surface, checked TasteGate alignment marker, and TasteGate instance `BEDC.Derived.RealWindowSynchronizerUp.taste_gate` for the Real and Completion window-to-seal route.

Bridge status: bridgeChecked

Origin: ai

Not claimed: This chapter does not close Real completeness, quotient-stream equality, selected host limits, ambient metric completion, or checked Lean certificates for Definition 979.8 and Definition 979.9.

Upgrade path: No further upgrade is pending on the formal bridge axis; the checked StandardBridge theorem records the top bridge grade for this route.

Chapter 980

A Concrete Naming Certificate for $\mathsf{RegularCauchyClassifierNormalForm}^{\uparrow}$

The $\mathsf{RegularCauchyClassifierNormalForm}^{\uparrow}$ packet realizes the Real completeness route of chapter 9238 as a common classifier-normal-form surface for finite rational completion data. It sits over the dyadic tolerance rows of chapter 291, the finite stream windows of chapter 126, the regular rational handoff of chapter 301, and the RealUp seal row of chapter 38. The packet is a shared route certificate: it does not identify any one source surface with another, and it exports no quotient stream, selected limit representative, host real equality, countable choice row, or ambient completeness theorem.

Definition 980.1 (Regular Cauchy classifier normal-form carrier)**.** *A* $\mathsf{RegularCauchyClassifierNormalForm}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (D, W, Q, R, E, H, C, P, N)$$

with the following displayed rows:

1. *D is the common* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row used by every finite read in the packet;*
2. *W is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row inspected at the same tolerance;*
3. *Q is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained from the displayed window and tolerance;*
4. *R is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after D, W, Q have been displayed;*
5. *E is the completion-seal classifier row from chapter 900, recording that the RealUp read uses the same finite route;*
6. *H stores componentwise* hsame *transport for D, W, Q, R, E, C, P, N and for the local classifier-normal-form packet;*
7. *C stores the displayed* Cont *routes from D to W, from W to Q, from Q to R, from R to E, and from those rows to the local certificate;*
8. *P is the* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{RealCompletionSealClassifierUp}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyClassifierNormalForm}^{\uparrow}}$ *row.*

The carrier records the classifier-normal-form route across the four source surfaces. It has no coordinate for a quotient stream, hidden modulus replacement, selected external limit, host real equality, countable choice, or ambient completeness.

Lean4 (definition) `BEDC.Derived.RegularCauchyClassifierNormalFormUp.RegularCauchyClassifierNormalFormUp`

Theorem 980.2 (Regular Cauchy classifier normal-form obligations)**.** *For the carrier of Definition 980.1, the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyClassifierNormalForm}^{\uparrow}}$ *surface consists of six finite obligation rows:*

1. *carrier admission for* $K = (D, W, Q, R, E, H, C, P, N)$*;*
2. *common dyadic tolerance exactness requiring the same* D *row to serve the StreamName window, RegSeqRat readback, and RealUp seal route;*
3. *finite-window exactness requiring* W *to be displayed before any regular rational readback is consumed;*
4. *RegSeqRat-to-RealUp handoff requiring* Q *to be displayed before* R *and requiring the completion-seal classifier row* E *to read the same route;*
5. *classifier stability under the componentwise* hsame *transports in* H *and the displayed* Cont *routes in* C*;*
6. *provenance, naming, and non-escape through* P, N*, excluding quotient streams, hidden modulus replacement, selected limits, host real equality, countable choice, and ambient completeness.*

The later Lean `TasteGate.lean` *contract for this chapter must provide explicit* `Nontrivial RegularCauchyClassi` *and* `FieldFaithful RegularCauchyClassifierNormalFormUp` *instances for this carrier surface.*

Proof. Carrier admission is projection from the displayed tuple. The dyadic tolerance, finite stream window, regular readback, RealUp seal, completion-seal classifier, transport, continuation, provenance, and local naming rows are all carrier coordinates.

The common dyadic tolerance row is read first. Since D is the only tolerance coordinate, the StreamName window, RegSeqRat readback, and RealUp seal route cannot switch to a second tolerance ledger without leaving the packet.

The finite-window row W is then displayed before the regular handoff Q. The route row C records this order, and the componentwise transport row H preserves the same fields under classifier comparison.

The RealUp seal row R and completion-seal classifier row E are read after D, W, Q. Provenance and local naming authenticate exactly that finite sequence.

No remaining carrier coordinate can supply quotient streams, hidden modulus replacement, selected external limits, host real equality, countable choice, or ambient completeness. Hence the six rows exhaust the local NameCert obligations. □

Theorem 980.3 (Regular Cauchy classifier normal-form Real handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{RegularCauchyClassifierNormalForm}^{\uparrow}$ *packet reads the regular Cauchy classifier route only through*

$$D, W, Q, R, E, H, C, P, N.$$

In particular, the common dyadic tolerance row is displayed before the StreamName schedule, the StreamName schedule is displayed before the RegSeqRat readback, and the RegSeqRat readback is displayed before the RealUp seal and completion-seal classifier handoff.

Proof. Project the accepted carrier to $K = (D, W, Q, R, E, H, C, P, N)$. The only dyadic, stream, regular, RealUp, and completion-seal classifier coordinates are D, W, Q, R, E.

Apply the obligation surface of Definition 980.2. Its dyadic exactness, finite-window exactness, and handoff rows place D before W, W before Q, and Q before R, E.

The displayed Cont routes in C replay the same order for consumers, while the componentwise hsame transports in H preserve the named rows. The provenance row P and local name N add authentication without adding analytic data.

Thus every RealUp or completion-facing read factors through the listed finite route. A bypass would require a second tolerance ledger, a quotient stream, a selected limit representative, host real equality, countable choice, or ambient completeness, and none of those coordinates is present. □

Falsifiable prediction: Removing the common dyadic tolerance row breaks the RegSeqRat-to-RealUp classifier handoff while preserving the StreamName schedule.

Independence witness: dyadicratcore, streamname, regseqrat, real, cauchylimitseal: none is bijective because this packet stores the shared classifier-normal-form route across all four source surfaces rather than any single source surface.

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyClassifierNormalForm}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyClassifierNormalForm}^{\uparrow}$ packet is generated from a common dyadic tolerance row, finite StreamName window, RegSeqRat readback, RealUp seal row, completion-seal classifier, componentwise hsame transports, displayed Cont routes, provenance, and local naming. The construction first exposes the tolerance, then the finite window, then the regular rational readback, and only then the Real-facing seal. The classifier-normal-form row records that all consumers use the same finite route. It is a shared BEDC carrier for Cauchy readback discipline, not a quotient of streams.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyClassifierNormalForm}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the regular Cauchy classifier normal-form carrier, its six obligation rows, and the Real handoff theorem.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyClassifierNormalForm}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim quotient-stream equality, selected completed limits, host real equality, countable choice, or ambient completeness.

Upgrade path: To reach obligationClosure, formalize the shared dyadic-window-readback-seal route and prove its finite classifier stability.

Chapter 981

A Concrete Naming Certificate for $\mathsf{DyadicWindowSeal}^{\uparrow}$

The $\mathsf{DyadicWindowSeal}^{\uparrow}$ packet realizes the Real and Completion route of chapter 9238 as a finite service boundary before a $\mathsf{Real}^{\uparrow}$ seal consumer is allowed to read completion-facing data. It sits between the dyadic precision surface of chapter 291, the finite stream windows of chapter 126, the observation-budget surface of chapter 611, the seal synchronizer of chapter 886, and the completion-seal classifier of chapter 900. The packet is a finite Real-and-Completion seal service, not a quotient stream, selected host limit, host real equality, hidden selector, unbounded schedule, or ambient completeness principle.

Definition 981.1 (Dyadic window seal carrier)**.** *A* $\mathsf{DyadicWindowSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (q, w, r, b, z, s, h, c, p, n)$$

with the following displayed rows:

1. *q is the dyadic precision and request row read from the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger;*
2. *w is the finite* $\mathsf{StreamName}^{\uparrow}$ *window served for that request;*
3. *r is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained through the window;*
4. *b is the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row that admits the finite observation service;*
5. *z is the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row tying the request, budget, shared threshold, and seal service together;*
6. *s is the* $\mathsf{Real}^{\uparrow}$ *seal row that may be consumed only after q, w, r, b, z are displayed;*
7. *h records componentwise* hsame *transport for the request, window, readback, budget, synchronizer, and seal rows;*
8. *c records the displayed* Cont *routes by which every consumer reaches those rows;*
9. *p is the* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *n is the local* $\mathsf{NameCert}_{\mathsf{DyadicWindowSeal}^{\uparrow}}$ *row.*

The carrier has no coordinate for a quotient stream representative, host real equality, selected host limit, hidden selector, unbounded observation schedule, or ambient completeness theorem.

Lean4 (definition) `BEDC.Derived.DyadicWindowSealUp.DyadicWindowSealUp`

Theorem 981.2 (Dyadic window seal NameCert obligations)**.** *For the carrier of Definition 981.1, the local* $\mathsf{NameCert}_{\mathsf{DyadicWindowSeal}^{\uparrow}}$ *surface consists of six finite rows:*

1. *carrier admission for* $W = (q, w, r, b, z, s, h, c, p, n)$ *as one displayed* BHist *packet;*
2. *dyadic request exactness identifying* q *with the precision and request ledger row served by* $\mathsf{DyadicRatCore}^{\uparrow}$*;*
3. *finite-window readback exactness identifying* w *and* r *as the* $\mathsf{StreamName}^{\uparrow}$ *window and* $\mathsf{RegSeqRat}^{\uparrow}$ *readback for the same request;*
4. *observation-budget admission through* b *before any* $\mathsf{Real}^{\uparrow}$ *seal row is exposed;*
5. *synchronizer agreement through* z*, forcing the request, budget, shared-threshold, and seal rows to be read as one finite route;*
6. *transport, route, provenance, and local naming exactness through* h, c, p, n*.*

Lean `BEDC.Derived.DyadicWindowSealUp.TasteGate` *must provide explicit* `Nontrivial DyadicWindowSealUp` *and* `FieldFaithful DyadicWindowSealUp` *instances for this same carrier surface.*

Lean4 ✓ `BEDC.Derived.DyadicWindowSealUp.DyadicWindowSealTasteGate single carrier alignment`

Proof. Project the carrier tuple in Definition 981.1. The request, window, readback, budget, synchronizer, seal, transport, route, provenance, and naming rows are all displayed coordinates of the packet.

The dyadic request row fixes the precision service, and the window and readback rows fix the finite observation through $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{RegSeqRat}^{\uparrow}$. The budget row admits the service only as a finite observation, while the synchronizer row ties that budget to the same seal route.

Finally the transport and continuation rows authenticate componentwise movement of the displayed service. Repacking those rows with p and n gives the local NameCert surface and leaves no carrier coordinate through which a hidden selector, quotient stream, host real equality, selected limit, unbounded schedule, or ambient completeness premise can enter. □

Theorem 981.3 (Dyadic window seal budget pullback)**.** *Let* $W = (q, w, r, b, z, s, h, c, p, n)$ *be an accepted* $\mathsf{DyadicWindowSeal}^{\uparrow}$ *packet. Every observation-budget consumer that reaches the* $\mathsf{Real}^{\uparrow}$ *seal row* s *factors through the finite pullback route*

$$q \longmapsto w \longmapsto r \longmapsto b \longmapsto z \longmapsto s.$$

The route is exhausted by the displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows of the same packet, and exports no quotient stream equality, host real equality, selected host limit, hidden selector, unbounded schedule, or ambient completeness.*

Proof. Begin with the obligation surface of Definition 981.2. It requires the dyadic request row, stream window, regular readback, observation budget, synchronizer, and seal row to belong to one accepted packet.

Read the consumer through the observation-budget row. Since b is displayed as a coordinate of the same carrier, the admitted service can inspect only the request, window, readback, and budget rows already named by q, w, r, b.

Now apply synchronizer agreement. The row z binds that budget route to the shared seal route ending at s, while h, c, p, n record the componentwise transport, continuation replay, provenance, and local naming. Carrier inspection supplies the stated exclusions. □

Theorem 981.4 (Dyadic window seal non-escape)**.** *No accepted* $\mathsf{DyadicWindowSeal}^{\uparrow}$ *read can export a* $\mathsf{Real}^{\uparrow}$ *seal consumer without first displaying the dyadic request row, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{RealObservationBudget}^{\uparrow}$ *row, and* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row of the same packet. Any read that bypasses one of those rows has no remaining coordinate from which to export a completion-facing seal service.*

Proof. Project the accepted packet to $W = (q, w, r, b, z, s, h, c, p, n)$. The only seal-facing coordinate is s, and the only service route into it is the displayed finite chain through q, w, r, b, z.

Use Definition 981.3. It places every observation-budget consumer of s on the same pullback route and authenticates the route through h, c, p, n.

The carrier definition then rules out all bypasses. There is no quotient-stream coordinate, host equality test, selected host limit, hidden selector, unbounded schedule, or ambient completeness field that could replace a missing request, window, readback, budget, or synchronizer row. □

Theorem 981.5 (Dyadic window seal Real handoff)**.** *Every accepted* $\mathsf{DyadicWindowSeal}^{\uparrow}$ *consumer that hands data to* $\mathsf{Real}^{\uparrow}$ *hands only the finite packet rows*

$$q, w, r, b, z, s, h, c, p, n.$$

In particular, a $\mathsf{Real}^{\uparrow}$ *seal read factors through the displayed dyadic precision request, finite* $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, observation budget, and synchronizer row before the seal is consumed.*

Proof. Apply Definition 981.2 to identify the displayed Real-and-Completion service surface. The only rows available to a consumer are the request, window, readback, budget, synchronizer, seal, transport, route, provenance, and local naming rows.

Apply Definition 981.3. It orders every seal read through q, w, r, b, z before the consumer reaches s.

Finally apply Definition 981.4. Since no alternate analytic or quotient coordinate is present, the handoff to $\mathsf{Real}^{\uparrow}$ is exactly the finite packet route. □

Theorem 981.6 (Dyadic window seal finite source exhaustion)**.** *Every accepted* $\mathsf{DyadicWindowSeal}^{\uparrow}$ *read that faces a* $\mathsf{Real}^{\uparrow}$ *consumer is exhausted by exactly the displayed finite source chain*

$$q, w, r, b, z, s, h, c, p, n.$$

Here q *is the dyadic request from* $\mathsf{DyadicRatCore}^{\uparrow}$*,* w *is the finite* $\mathsf{StreamName}^{\uparrow}$ *window,* r *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* b *is the* $\mathsf{RealObservationBudget}^{\uparrow}$ *row,* z *is the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row,* s *is the* $\mathsf{Real}^{\uparrow}$ *seal row, and* h, c, p, n *are precisely the* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *support rows. Conversely, any packet carrying those rows with the displayed transport, continuation, provenance, and local naming data repacks as the same* $\mathsf{DyadicWindowSeal}^{\uparrow}$ *finite service boundary. The exhaustion exports no quotient stream equality, selected host limit, host real equality, hidden selector, unbounded schedule, ambient completeness, or bridge data.*

Proof. Start from Definition 981.2. It lists the carrier row inventory, so an accepted $\mathsf{DyadicWindowSeal}^{\uparrow}$ packet exposes only the request, window, readback, budget, synchronizer, seal, componentwise transport, continuation, provenance, and local naming rows.

Apply Definition 981.3. The Real-facing read is ordered along the finite route $q \longmapsto w \longmapsto r \longmapsto b \longmapsto z \longmapsto s$, and the remaining support rows authenticate that same route inside the packet.

Apply Definition 981.4. Since there is no bypass coordinate, no missing row can be supplied by quotient stream equality, a selected host limit, host real equality, a hidden selector, an unbounded schedule, ambient completeness, or bridge data.

For the converse, take a packet carrying exactly the displayed source chain and support rows. The NameCert obligations repack those rows into the carrier tuple, the pullback theorem supplies the ordered service boundary, and Definition 981.5 identifies the resulting consumer interface as the same $\mathsf{Real}^{\uparrow}$-facing finite handoff. □

Falsifiable prediction: Every accepted DyadicWindowSealUp RealUp consumer factors through the displayed dyadic window and synchronizer rows before any seal read.

Independence witness: Nearest siblings: real-observation-budget, cauchy-seal-budget-synchronizer, finite-tail-diagonal-seal, regular-cauchy-limit-classifier, and real-completion-seal-classifier; none is bijective because DyadicWindowSealUp uniquely carries the dyadic request, finite StreamName window, RegSeqRat readback, observation budget, synchronizer row, and RealUp seal in one carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicWindowSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{DyadicWindowSeal}^{\uparrow}$ packet is generated from a dyadic precision request, finite StreamName window, RegSeqRat readback, observation-budget row, seal synchronizer row, RealUp seal, componentwise transports, displayed continuations, provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DyadicWindowSeal}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 981.1, Definition 981.2, Definition 981.3, Definition 981.4, Definition 981.5, and Definition 981.6 bind the finite Real-and-Completion service packet to the displayed dyadic request, window, readback, budget, synchronizer, seal, transport, route, provenance, and naming rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DyadicWindowSeal}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Not claimed: This chapter does not close RealUp completeness, quotient stream equality, host real equality, selected host limits, hidden selectors, unbounded schedules, ambient completeness, Lean verification, or bridge checking.

Upgrade path: Scoped closure requires checked carrier, obligation, pullback, non-escape, Real handoff, and finite-source exhaustion targets for the same finite packet surface.

Chapter 982

A Concrete Naming Certificate for $\mathsf{InscriptionCommitmentSeal}^{\uparrow}$

The $\mathsf{InscriptionCommitmentSeal}^{\uparrow}$ surface isolates the reusable commitment row inside the inscription-event vision of chapter 9397. It sits between the full inscription-event packet of chapter 519 and the public residue ledger of chapter 520: the event chapter records a complete accepted inscription packet, while this seal keeps only the finite source, accepted commitment, consumer, ledger, transport, route, provenance, and naming rows needed by downstream audit readers.

Definition 982.1 (InscriptionCommitmentSeal carrier)**.** *An* $\mathsf{InscriptionCommitmentSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (S, M, U, G, H, C, P, N)$$

with the following displayed rows:

1. *S is the finite source row from which the commitment is read;*
2. *M is the accepted named commitment row, read as public record data rather than private intention;*
3. *U is the intended downstream consumer row for the commitment;*
4. *G is the public* GAP *ledger row attached to the commitment and consumer;*
5. *H records componentwise* hsame *transports for S, M, U, G together with route, provenance, and local naming rows;*
6. *C records the displayed* Cont *routes by which a consumer reads the source, commitment, consumer, and ledger rows;*
7. *P is the* Pkg *provenance over* BHist, $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{InscriptionGapLedger}^{\uparrow}$, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{InscriptionCommitmentSeal}^{\uparrow}}$ *row.*

The classifier accepts only packets with these eight displayed rows. It has no coordinate for a complete inscription event, unchecked route replay, private motive, host process trace, hidden consumer right, or ledger entry outside G.

Lean4 ✓ `BEDC.Derived.InscriptionCommitmentSealUp.InscriptionCommitmentSealTasteGate single carrier alignment`

Theorem 982.2 (InscriptionCommitmentSeal NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{InscriptionCommitmentSeal}^{\uparrow}}$ *surface for Definition 982.1 consists exactly of carrier exposure for*

$$K = (S, M, U, G, H, C, P, N),$$

source-row readback through S*, accepted-commitment readback through* M*, consumer accountability through* U*, public GAP-ledger readback through* G*, componentwise transport through* H*, displayed continuation through* C*, provenance through* P*, and local naming through* N*.*

Proof. Carrier exposure is projection from the displayed packet. The rows S, M, U, G, H, C, P, N are the complete inventory available to a consumer of the seal.

Read S, M, U, G in order. The source row fixes the finite record state, the accepted commitment row supplies the named public commitment, the consumer row names the permitted reader, and the GAP ledger records the public residue that accompanies that reader.

Finally inspect H, C, P, N. These rows transport, replay, source, and name the same finite packet. Since the carrier has no coordinate for a broader event packet, hidden route, private motive, host trace, or unlisted ledger entry, the NameCert surface is exhausted by the displayed seal rows. □

Theorem 982.3 (InscriptionCommitmentSeal consumer-ledger split)**.** *For every accepted* InscriptionCommitmentSe *carrier* $K = (S, M, U, G, H, C, P, N)$*, deleting the accepted commitment row* M *breaks acceptance for the named commitment, while deleting the public GAP ledger row* G *breaks non-escape for the consumer ledger. The two failures are distinct:* M *is the record admitted for the consumer, and* G *is the public residue ledger attached to that admission.*

Proof. Project the carrier. The accepted commitment row and the public GAP ledger row are separate coordinates of the finite packet.

Use the NameCert obligations of Definition 982.2. Commitment readback is assigned to M, while public ledger readback is assigned to G together with the consumer row U and the displayed routes in C.

If M is absent, the packet no longer exposes an accepted named commitment for the consumer. If G is absent, the packet may still name a commitment row, but it loses the public ledger boundary that prevents consumer escape beyond the displayed residue. Thus the two rows support distinct downstream reads. □

Theorem 982.4 (InscriptionCommitmentSeal sibling factorization)**.** *Every downstream audit read of an accepted* $\mathsf{InscriptionCommitmentSeal}^{\uparrow}$ *packet factors through the inscription-event carrier of chapter 519 for accepted-record locality and through the inscription GAP ledger of chapter 520 for public residue accountability. The seal exports only*

$$S, M, U, G, H, C, P, N$$

to that reader, not the full event route, private agency data, or an additional ledger.

Proof. Start from the accepted carrier and project the four content rows S, M, U, G. The rows S, M, U are the inscription-facing source, accepted commitment, and consumer surface, while G is the public residue ledger.

Apply the two sibling readings. The inscription-event chapter supplies the surrounding accepted-record discipline for S, M, U, and the inscription GAP-ledger chapter supplies the residue-ledger discipline for G.

The structural rows H, C, P, N then carry exactly the seal packet to downstream audit readers. They do not reconstruct the full event route, add private agency data, or create a second ledger row. □

Falsifiable prediction: Deleting the accepted commitment row or the public GAP ledger row breaks a distinct downstream read: acceptance for the named commitment and non-escape for the consumer ledger.

Independence witness: Nearest siblings: inscriptionevent, inscriptiongapledger, kernelacceptancetrace, tastegateadmission. InscriptionEventUp has a full event packet rather than a seal; InscriptionGapLedgerUp has the residue ledger but no accepted commitment row; KernelAcceptanceTraceUp has checker acceptance but no inscription consumer; TasteGateAdmissionUp has admission rows but no GAP commitment ledger. No bijection preserving all rows exists.

The Lean target family $BEDC.Derived.InscriptionCommitmentSealUp$ should provide Nontrivial and FieldFaithful instances for the displayed carrier before a TasteGate theorem records the same seal surface.

Closure status for $\mathsf{NameCert}_{\mathsf{InscriptionCommitmentSeal}^{\uparrow}}$.

Constructive story: An $\mathsf{InscriptionCommitmentSeal}^{\uparrow}$ packet is generated from a finite source row, an accepted named commitment row, an intended consumer row, a public GAP ledger row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.InscriptionCommitmentSealUp.taste gate`

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{InscriptionCommitmentSeal}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 982.1, Definition 982.2, Definition 982.3, Definition 982.4, the falsifiable prediction, independence witness, and TasteGate marker bind the mature paper-side commitment-seal export surface over the displayed inscription-event and inscription-gap-ledger consumer rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{InscriptionCommitmentSeal}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.InscriptionCommitmentSealUp.InscriptionCommitmentSealTasteGate\_single\_carrier\_alignm`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close bridge checking, complete inscription-event ontology, private intention, hidden host traces, unchecked routes, or ledger rows outside the displayed packet.

Upgrade path: The remaining upgrade is bridgeChecked verification for the displayed commitment-seal export surface; the paper-side closure is mature over the inscription-event and inscription-gap-ledger consumer rows.

Chapter 983

A Concrete Naming Certificate for $\mathsf{CauchySharedTailModulus}^{\uparrow}$

The $\mathsf{CauchySharedTailModulus}^{\uparrow}$ packet realizes the Real and Completion route of chapter 9238 as a finite shared-tail threshold certificate. It consumes the explicit modulus extraction surface of chapter 641, the dyadic tail-radius ledger of chapter 757, the finite window service of chapter 126, the regular rational readback of chapter 301, and the Real seal boundary of chapter 38. Its purpose is to synchronize two regular-Cauchy tail requests through one displayed dyadic threshold before any $\mathsf{Real}^{\uparrow}$ completion-facing seal is exposed.

Definition 983.1 (Cauchy shared-tail modulus carrier)**.** *A* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N)$$

with the following displayed rows:

1. R_0 *and* R_1 *are the two accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *sources whose tails are being synchronized for a Real-completion consumer;*
2. M_0 *and* M_1 *are the displayed* $\mathsf{CauchyModulusExtraction}^{\uparrow}$ *rows supplying the two finite tail requests;*
3. τ *is the single shared dyadic tail-threshold row, read through the* $\mathsf{DyadicTailRadiusLedger}^{\uparrow}$ *service;*
4. D *is the dyadic tolerance ledger witnessing that both requests are served at the same threshold* τ*;*
5. W_0 *and* W_1 *are the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows opened by* τ *for the two sources;*
6. Q_0 *and* Q_1 *are the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows obtained from the two windows and the shared dyadic ledger;*
7. E *is the* $\mathsf{Real}^{\uparrow}$ *seal row exposed only after the two readbacks have passed through the same shared threshold;*
8. H *records componentwise* hsame *transport for the sources, extracted moduli, shared threshold, dyadic ledger, windows, readbacks, Real seal, provenance, and local name;*
9. C *records the displayed* Cont *routes from each extracted modulus to* τ*, from* τ *to the two windows, from the windows to the readbacks, and from the readbacks to the Real seal;*

10. *P is the* Pkg *provenance over* CauchyModulusExtraction$^{\uparrow}$, DyadicTailRadiusLedger$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, RegularCauchyTailMeet$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchySharedTailModulus}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient stream equality, host real equality, selected limits, independent per-source seal exposure, hidden threshold replacement, or an ambient completeness principle.

Lean4 ✓ `BEDC.Derived.CauchySharedTailModulusUp.CauchySharedTailModulusTasteGate single carrier alignment`

Theorem 983.2 (Cauchy shared-tail modulus NameCert obligations)**.** *For the carrier of Definition 983.1, the local* $\mathsf{NameCert}_{\mathsf{CauchySharedTailModulus}^{\uparrow}}$ *surface consists exactly of carrier admission for S, paired request exposure through M_0, M_1, shared-threshold exposure through τ, D, window service through W_0, W_1, regular readback through Q_0, Q_1, Real seal ordering through E, componentwise stability through H, displayed replay through C, provenance through P, and local naming through N. A completion-facing consumer obtains no* Real$^{\uparrow}$ *seal read until both requests have been routed through the shared dyadic threshold.*

Proof. Project the displayed carrier. The rows $R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N$ are all of the public packet, so every tail request, threshold, window, readback, seal, transport, route, provenance, and local name is visible before the certificate is consumed.

The sibling modulus and dyadic rows supply the request boundary. The extracted modulus rows come from chapter 641, while the shared dyadic tolerance row comes from chapter 757; together they force both tail requests to meet at the same finite threshold τ.

The window and readback rows then route through chapter 126 and chapter 301. The Real seal row is exposed only after those finite rows have been replayed through C and transported by H.

Since the carrier contains no quotient stream, host real equality, selected limit, hidden threshold replacement, or ambient completeness coordinate, the listed rows exhaust the local NameCert obligations. □

Theorem 983.3 (Cauchy shared-tail modulus tail synchronization)**.** *Every accepted* CauchySharedTailModulus$^{\uparrow}$ *packet synchronizes the two tail requests through the same row τ. In particular, any* RegularCauchyTailMeet$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *or* StreamName$^{\uparrow}$ *consumer of the packet reads M_0 and M_1 before τ, reads both windows W_0, W_1 only through τ, and reads the two regular outputs Q_0, Q_1 only after the shared dyadic ledger D has been displayed.*

Lean4 ✓ `BEDC.Derived.CauchySharedTailModulusUp.CauchySharedTailModulusCarrier tail synchronization`

Proof. Start with the carrier definition. The two request rows M_0, M_1 and the single threshold row τ are separate displayed coordinates, but there is no second threshold coordinate.

Use the local obligations of Definition 983.2. Paired request exposure forces both requests to be visible before the threshold is consumed, and shared-threshold exposure forces both window services through the same τ, D rows.

The sibling RegularCauchyTailMeet$^{\uparrow}$ route reads the same threshold as its shared-tail row. Thus every tail-meet, StreamName, or RegSeqRat consumer remains on the finite route through $M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1$. □

Theorem 983.4 (Cauchy shared-tail modulus Real seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *completion-facing read of an accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet factors through the displayed route*

$$M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N.$$

The Real seal E *is therefore a handoff from one shared dyadic tail threshold, not from two independent tail witnesses or an ambient completeness oracle.*

Lean4 ✓ `BEDC.Derived.CauchySharedTailModulusUp.CauchySharedTailModulusCarrier real seal handoff`

Proof. Read the Real seal coordinate in the carrier. The only $\mathsf{Real}^{\uparrow}$ seal row is E, and it appears after the paired request, threshold, dyadic, window, and readback rows.

Apply Definition 983.3. It places both regular-Cauchy tails on the same threshold τ before either readback can reach the seal.

Finally use the displayed transport, route, provenance, and naming rows H, C, P, N. They authenticate the same finite route and do not add an independent seal coordinate, so the completion-facing read is exactly the listed handoff. □

Theorem 983.5 (Cauchy shared-tail modulus carrier admission exactness)**.** *An accepted* $\mathsf{CauchySharedTailModulus}$ *packet exposes exactly the carrier rows*

$$R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N.$$

The local $\mathsf{NameCert}_{\mathsf{CauchySharedTailModulus}^{\uparrow}}$ *admission read has no additional coordinate for quotient stream equality, host real equality, selected limits, independent per-source seal exposure, hidden threshold replacement, or ambient completeness.*

Proof. Project the carrier of Definition 983.1. The accepted packet is the displayed finite tuple, so carrier admission can expose precisely its two source rows, two extracted modulus rows, one shared threshold row, the dyadic ledger, two windows, two readbacks, the Real seal, transport, route, provenance, and local name.

Apply the local NameCert obligations of Definition 983.2. They match the admission surface field by field and assign each row to one visible obligation: paired request exposure, shared-threshold exposure, paired window service, regular readback, Real seal ordering, componentwise stability, displayed replay, provenance, and local naming.

Finally use the Real seal handoff of Definition 983.4. Any completion-facing read still factors through the same displayed rows, so a purported extra coordinate would not be read from the accepted carrier. □

Theorem 983.6 (Cauchy shared-tail modulus paired-window readback service)**.** *For every accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet, both finite windows* W_0, W_1 *and both regular readbacks* Q_0, Q_1 *are served from the one shared threshold row* τ *together with its dyadic ledger row* D*. No consumer reads either window or readback through a private threshold row.*

Proof. Start from carrier admission exactness, Definition 983.5. The only threshold row available to the accepted packet is τ, and the only dyadic threshold ledger row is D.

Apply the synchronization theorem Definition 983.3. It orders the paired request rows M_0, M_1 before τ, D, then routes both windows W_0, W_1 and both readbacks Q_0, Q_1 through that shared threshold service.

The paired-window obligation and Real seal handoff keep the downstream read on the same row. Thus every window and readback consumer is served from τ, D, and a private-threshold window is not a read of the displayed packet. □

Theorem 983.7 (Cauchy shared-tail modulus route replay provenance)**.** *For an accepted* CauchySharedTailModulus *packet, the rows H, C, P, N transport, replay, package, and name only the displayed route*

$$R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E.$$

They do not certify an alternate route with hidden thresholds, independent Real seals, quotient stream equality, host real equality, selected limits, or ambient completeness.

Proof. Use carrier admission exactness to identify the public route inventory. The non-structural rows before H, C, P, N are exactly $R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E$, so transport and replay have no hidden source outside this list.

Next apply the local NameCert obligations. The transport row H is componentwise, the replay row C follows the displayed continuation routes, the provenance row P packages the cited concrete BEDC surfaces, and N names the local certificate.

Finally compose with paired-window readback service and the Real seal handoff. Those two theorems force the middle route and the completion-facing seal to use the same $\tau, D, W_0, W_1, Q_0, Q_1, E$ path, so H, C, P, N certify only the displayed route. □

Theorem 983.8 (Cauchy shared-tail modulus paired-window obligation)**.** *For every accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet, the two* $\mathsf{StreamName}^{\uparrow}$ *window rows W_0, W_1 are exposed only after the paired request rows M_0, M_1 and the single dyadic threshold package τ, D have been displayed. Thus no consumer of the packet may read either window as a unilateral source window or as a window opened by a private threshold.*

Proof. Project the carrier of Definition 983.1. The rows $M_0, M_1, \tau, D, W_0, W_1$ are displayed in the finite packet, with a single threshold coordinate τ and a single dyadic tolerance ledger D serving both requests.

Apply Definition 983.3. It places M_0 and M_1 before the shared threshold read, and it routes both StreamName windows through the same τ, D rows.

The public route row C and transport row H replay that ordering componentwise. Since the carrier has no hidden threshold or unilateral window coordinate, the only accepted window read is the paired read through M_0, M_1, τ, D. □

Theorem 983.9 (Cauchy shared-tail modulus threshold uniqueness obligation)**.** *Let a consumer route claim to read an accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet while replacing the shared threshold row τ by two independent threshold rows. Then the route is not a read of the carrier in Definition 983.1. Any completion-facing route that reaches the Real seal must use the unique public threshold coordinate τ and its dyadic ledger row D.*

Proof. Inspect the carrier coordinates. The packet contains one threshold row τ and one dyadic ledger row D; it contains no coordinates for separate left and right thresholds.

Apply carrier-coordinate uniqueness in the displayed tuple. A route that supplies two independent threshold rows asks for two carrier coordinates where the carrier presents only one, so it leaves the packet surface before any Real seal read is considered.

Now apply Definition 983.4. Every completion-facing Real seal read factors through the displayed route containing the same τ, D rows. Therefore a route that replaces τ cannot be a read of the accepted carrier. □

Theorem 983.10 (Cauchy shared-tail modulus paired-source readback)**.** *Every accepted* CauchySharedTailModulus *packet reads both* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows R_0, R_1 before the shared threshold row τ is consumed.*

A downstream regular-Cauchy, StreamName, RealUp, or completion-facing consumer may inspect Q_0, Q_1 only as readbacks of the paired source rows through $M_0, M_1, \tau, D, W_0, W_1$.

Proof. Start with the carrier definition. The source rows R_0, R_1 are displayed before the extracted modulus rows, the single threshold row, the dyadic ledger, the window rows, and the readback rows.

Apply the tail synchronization theorem. It orders the two modulus requests before τ and routes both windows and both readbacks through the shared threshold service.

Finally use threshold uniqueness. Since the accepted packet has no private threshold coordinate, a consumer that reaches Q_0, Q_1 without reading both source rows through the common route is not reading the displayed shared-tail packet. □

Theorem 983.11 (Cauchy shared-tail modulus dyadic ledger exactness)**.** *For every accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet, the dyadic ledger row D is the exact common tolerance witness for both finite windows W_0, W_1 and both regular readbacks Q_0, Q_1. No consumer may replace D by two private dyadic ledgers, omit it from one side, or read the Real seal row E as if the two windows had independent tolerance witnesses.*

Proof. Project the displayed packet. It contains one dyadic ledger row D paired with the single threshold row τ.

Use paired-window readback service. Both windows and both readbacks are served from the same τ, D pair, so D is not an optional annotation on one side of the route.

The Real seal handoff then carries the same dyadic ledger into the completion-facing read. Since the seal factors through $M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N$, omitting or duplicating D leaves the accepted carrier surface. □

Theorem 983.12 (Cauchy shared-tail modulus completion-consumer non-escape)**.** *Any* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet factors through*

$$M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N.$$

The consumer cannot obtain selected limits, quotient real equality, host real equality, ambient completeness, two private thresholds, or a Real seal detached from the paired source readback and dyadic ledger rows.

Proof. First apply the Real seal handoff. It identifies the completion-facing route as the displayed finite path through the two modulus rows, the shared threshold, the dyadic ledger, paired windows, paired readbacks, Real seal, transport, route, provenance, and local name.

Next use paired-source readback and dyadic ledger exactness. These rows ensure that Q_0, Q_1 remain readbacks of the two displayed sources through one common τ, D route.

Finally apply threshold uniqueness. The accepted carrier has no selected-limit coordinate, quotient-real coordinate, host-equality coordinate, ambient-completeness coordinate, or pair of private threshold coordinates, so a consumer that extracts any of those objects is outside the packet. □

Theorem 983.13 (Cauchy shared-tail modulus field-faithfulness obligation)**.** *For the carrier*

$$S = (R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N),$$

the public fields $R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N$ determine the local $\mathsf{NameCert}_{\mathsf{CauchySharedTailModul}}$ *read. No proper subtuple of these fields exposes the same completion-facing* $\mathsf{Real}^{\uparrow}$ *seal, because omitting any paired source, request, threshold, dyadic ledger, window, readback, seal, transport, route, provenance, or local name removes a row used by the displayed handoff.*

Proof. Start from Definition 983.2. It lists the carrier admission row, paired requests, shared threshold, dyadic ledger, paired windows, paired readbacks, Real seal, componentwise stability, route replay, provenance, and local name as the public NameCert surface.

Use Definition 983.3 for the middle of the read. It forces the two request rows, the single threshold row, the dyadic ledger, both windows, and both regular readbacks to appear in the same finite route.

Finally apply Definition 983.4. The Real seal is exposed only through the complete displayed route

$$M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N.$$

Dropping any listed field breaks either carrier admission, the synchronized finite route, or the authenticated Real seal handoff. Hence the full public tuple determines the NameCert read, while no proper subtuple exposes the same seal. □

Theorem 983.14 (Cauchy shared-tail modulus public obligation package)**.** *For the carrier*

$$S = (R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N),$$

carrier admission, paired request exposure, the shared threshold, the dyadic ledger, paired $\mathsf{StreamName}^{\uparrow}$ *windows, paired* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks,* $\mathsf{Real}^{\uparrow}$ *seal ordering, componentwise transport, route replay, package provenance, and local* $\mathsf{NameCert}_{\mathsf{CauchySharedTailModulus}^{\uparrow}}$ *naming form one public obligation package. A consumer cannot detach any of these rows from the package while still claiming to read the shared-tail Real-completion surface.*

Proof. Project the displayed packet S. The carrier definition exposes exactly the two sources, two modulus rows, one threshold row, one dyadic ledger, two windows, two readbacks, one Real seal, transport, route, provenance, and local name.

Use the local NameCert obligations and the tail synchronization theorem. They bind carrier admission, paired request exposure, shared-threshold exposure, window service, regular readback, and Real seal ordering to the same finite route.

Now apply the paired-window obligation, threshold uniqueness obligation, and field-faithfulness obligation. These rows prevent a consumer from replacing the shared threshold, splitting the paired windows into private routes, or dropping a public field while preserving the completion-facing Real seal read. □

Theorem 983.15 (Cauchy shared-tail modulus Real-completion obligation closure)**.** *Every Real-completion-facing consumer route for an accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet must pass through the public obligation package of Definition 983.14 before reading the* $\mathsf{Real}^{\uparrow}$ *seal. In particular, no such route may replace the shared threshold row* τ *and its dyadic ledger row* D *by private per-source thresholds.*

Proof. First apply the public obligation package theorem. It places carrier admission, paired request exposure, shared-threshold exposure, paired windows, paired readbacks, Real seal ordering, transport, replay, provenance, and local naming on one public surface.

Then use the Real seal handoff theorem. Any completion-facing read of the Real seal factors through the displayed route containing $M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N$.

Finally apply the threshold uniqueness obligation. Since the accepted carrier has only the shared threshold coordinate τ and ledger coordinate D, a route with private per-source thresholds is not a read of the packet. □

Theorem 983.16 (Cauchy shared-tail modulus threshold transport stability)**.** *For an accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet, componentwise* hsame *transport along* H *preserves the shared threshold row* τ *and the dyadic ledger row* D *as one paired service for both source requests. Any transported consumer route that introduces a private left threshold, a private right threshold, or a second dyadic ledger is outside the local* $\mathsf{NameCert}_{\mathsf{CauchySharedTailModulus}^{\uparrow}}$ *package.*

Proof. Read the carrier rows for H. The transport row is componentwise for the sources, extracted moduli, shared threshold, dyadic ledger, windows, readbacks, Real seal, provenance, and local name; it is not a constructor for new threshold coordinates.

Apply threshold uniqueness and dyadic ledger exactness. These two rows identify τ and D as the only threshold service available to the accepted packet, and they keep both finite windows and both regular readbacks attached to that same service.

Now transport the displayed route by H. Since every transported component is a component of

$$R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, P, N,$$

the transported packet still has one threshold row and one ledger row. A route with private thresholds or a second ledger therefore asks for rows not carried by the packet. □

Theorem 983.17 (Cauchy shared-tail modulus window readback transport)**.** *For an accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet, the paired windows* W_0, W_1*, paired readbacks* Q_0, Q_1*, and Real seal* E *are transported only along the shared route recorded by* H *and* C*. No transported read may detach* W_0 *or* W_1 *from* τ, D*, detach* Q_0 *or* Q_1 *from the paired windows, or expose* E *without the displayed shared-tail route.*

Proof. Start with paired-window readback service. It serves W_0, W_1, Q_0, Q_1 from the same τ, D rows, so the window and readback transport has a single threshold source.

Use route replay provenance. The rows H and C transport and replay only the displayed route through the two sources, two extracted moduli, the shared threshold, the dyadic ledger, the paired windows, the paired readbacks, and the Real seal.

Finally apply the Real seal handoff. The seal row E is downstream of the paired readbacks and the same shared threshold route, so a transported consumer that detaches a window, readback, or seal from H, C is not reading the accepted package. □

Theorem 983.18 (Cauchy shared-tail modulus obligation closure package)**.** *For the carrier*

$$S = (R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N),$$

carrier admission, local $\mathsf{NameCert}$ *obligations, tail synchronization, threshold uniqueness, threshold transport stability, paired window and readback transport, Real seal handoff, field-faithfulness, and the checked TasteGate carrier alignment form one* $\mathsf{obligation}$ *surface for* $\mathsf{CauchySharedTailModulus}^{\uparrow}$*. The package has no coordinate for private thresholds, independent Real seals, quotient stream equality, host real equality, selected limits, or ambient completeness.*

Proof. First collect carrier admission and the local NameCert obligations. They expose exactly the displayed rows of S and assign them to paired source requests, one shared threshold, one dyadic ledger, paired windows, paired readbacks, one Real seal, componentwise transport, replay, provenance, and local naming.

Next use synchronization, threshold uniqueness, and threshold transport stability. These rows bind M_0, M_1, τ, D into one shared finite threshold service and exclude private thresholds under both direct reads and componentwise hsame transport.

Then apply window readback transport and Real seal handoff. They keep W_0, W_1, Q_0, Q_1, E on the same H, C route, so the completion-facing read cannot detach the seal from the paired finite route.

Finally combine field-faithfulness with the checked TasteGate carrier alignment. The public tuple is the whole local package surface, and the TasteGate marker records that the carrier alignment is a single visible packet. Thus the listed rows assemble the obligation surface without adding any hidden completion or quotient coordinate. □

Theorem 983.19 (Cauchy shared-tail modulus falsifiable prediction)**.** *If a consumer accepts a* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet while reading a* $\mathsf{Real}^{\uparrow}$ *seal before the shared threshold row* τ *or while replacing* τ *by two independent threshold rows, then that consumer is not reading the packet of Definition 983.1. The accepted packet exposes one shared dyadic threshold before any Real seal route.*

Proof. Inspect the carrier coordinates. There is exactly one shared threshold row τ and exactly one Real seal row E.

Use the NameCert obligations to order the public read. The paired request rows, the shared dyadic threshold, the dyadic ledger, both StreamName windows, and both RegSeqRat readbacks are displayed before the Real seal row can be consumed.

Replacing τ by two independent thresholds asks for carrier coordinates that are not present. Reading E before τ violates the displayed route order, so either behavior leaves the accepted packet surface. □

Falsifiable prediction: If a CauchySharedTailModulusUp packet is accepted, every RealUp completion-facing read factors through the displayed shared threshold before any Real seal is exposed.

Independence witness: cauchymodulusextraction, dyadictailradiusledger, regularcauchytailmeet, realcompletionsealclassifier: none is bijective because each lacks either the paired request rows, the shared threshold row, or the combined Real seal handoff carried by $\mathsf{CauchySharedTailModulus}^{\uparrow}$.

Theorem 983.20 (Cauchy shared-tail modulus obligation surface triad)**.** *The public obligation surface for an accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *packet is the triad consisting of carrier admission for*

$$S = (R_0, R_1, M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N),$$

the shared-threshold route through $M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1$*, and the Real-seal ordering row* E *authenticated by* H, C, P, N*. A completion-facing consumer may read the package only after the paired requests, paired windows, paired readbacks, and the shared dyadic threshold have all been displayed.*

Proof. Carrier admission is Definition 983.1. It displays the two source rows, two modulus rows, the single shared threshold, the dyadic ledger, the paired window rows, the paired readbacks, the Real seal, transports, routes, provenance, and local name.

The shared-threshold route is forced by tail synchronization, paired-window readback service, and threshold uniqueness. These rows keep both sides on τ, D and exclude private threshold replacement.

The Real-seal ordering row is then supplied by the Real seal handoff and completion-consumer non-escape theorems. Since E is read only after the paired finite route and since H, C, P, N authenticate that route, the three listed surfaces form the public obligation triad. □

Theorem 983.21 (Cauchy shared-tail modulus TasteGate scoped admission)**.** *The checked TasteGate row following Definition 983.1 records the AI-origin admissibility surface for* $\mathsf{CauchySharedTailModulus}^{\uparrow}$*: it aligns the single displayed carrier with the local certificate rows before any Real-completion consumer may treat the shared-tail route as admitted.*

Proof. Read the checked marker attached to the carrier definition. Its target is the single-carrier alignment theorem for $\mathsf{CauchySharedTailModulus}^{\uparrow}$, so the admissibility row is attached to the same displayed tuple S rather than to a hidden completion principle.

Use the obligation closure package. That package combines carrier admission, NameCert obligations, threshold synchronization, transport stability, and Real seal handoff on the same finite surface.

Thus the TasteGate row is a scoped admission row for the existing public packet. It does not add a selected limit, quotient equality, host real equality, or ambient completeness coordinate. □

Theorem 983.22 (Cauchy shared-tail modulus Real seal obligation gate)**.** *No* $\mathsf{Real}^{\uparrow}$ *seal route exported by* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *is public until the shared dyadic threshold* τ, D *and the paired readbacks* Q_0, Q_1 *have been displayed. A route that exposes* E *without the common threshold, both window rows, and both readback rows is outside the accepted shared-tail packet.*

Proof. Apply paired-source readback and paired-window readback service. They force the source rows, modulus rows, shared threshold, dyadic ledger, windows, and readbacks to appear on the same finite route before a completion-facing consumer can inspect the seal.

Use dyadic ledger exactness to keep D as the common tolerance witness for both sides. A route omitting D or replacing it by private ledgers leaves the accepted carrier surface.

Finally apply the Real seal handoff and completion-consumer non-escape theorems. They place E downstream of $M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1$ and exclude any public Real seal detached from those rows. □

Theorem 983.23 (Cauchy shared-tail modulus downstream consumer factorization)**.** *Any downstream Real-completion,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, or* $\mathsf{RealCompleteness}^{\uparrow}$ *consumer of an accepted* $\mathsf{CauchySharedTailModulus}$ *packet factors through the displayed route*

$$M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1, E, H, C, P, N.$$

The $\mathsf{CauchyLimitSeal}^{\uparrow}$ *side is the sibling limit-seal route of chapter 386, the* $\mathsf{RealCompleteness}^{\uparrow}$ *side is the completion-facing seal route of chapter 450, and the finite source of both routes is the* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *readback surface of chapter 126 and chapter 301. No selected limit, quotient stream, host real equality, countable choice rule, or ambient completeness coordinate is exposed by this factorization.*

Proof. Begin with tail synchronization. It places the two extracted modulus rows and the single shared threshold row on the same dyadic ledger before either finite window can be consumed.

Next use the Real seal handoff and the Real seal obligation gate. They force every completion-facing read of E to pass through the paired windows and paired regular readbacks over the common route $M_0, M_1, \tau, D, W_0, W_1, Q_0, Q_1$.

Now apply completion-consumer non-escape. A downstream limit-seal or completeness consumer can only receive the rows already displayed by the carrier, transported by H, replayed by C, cited by P, and named by N.

The sibling chapters named in the statement provide the consumer-side vocabulary for those finite rows. Since none of the source, seal, transport, replay, provenance, or naming rows contains

a selected limit, quotient stream, host equality, countable-choice selector, or ambient completeness coordinate, the factorization exposes no such object. □

The Lean TasteGate surface records Nontrivial CauchySharedTailModulus$^{\uparrow}$ and FieldFaithful CauchySharedTailMod instances for the displayed carrier.

Closure status for NameCert$_{\text{CauchySharedTailModulus}\uparrow}$.

Constructive story: A CauchySharedTailModulus$^{\uparrow}$ packet is generated from two regular-Cauchy source rows, extracted modulus rows, one shared dyadic threshold, a dyadic tolerance ledger, paired finite windows, paired regular readbacks, a Real seal handoff row, componentwise transports, displayed replay, provenance, and local naming.

Theory closure: TheoryGate(NameCert$_{\text{CauchySharedTailModulus}\uparrow}$, maturePackageClosed)

Scope closed: Definition 983.1, Definition 983.4, Definition 983.12, Definition 983.14, and Definition 983.15 bind the BHist, hsame, Cont, Pkg, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicTailRadiusLedger$^{\uparrow}$, and Real$^{\uparrow}$ surface to one shared finite threshold before completion-facing reads.

Chapter 984

A Concrete Naming Certificate for $\mathsf{CellularLocalUpdateRule}^{\uparrow}$

The $\mathsf{CellularLocalUpdateRule}^{\uparrow}$ surface isolates the local transition-table row named by the cellular-carrier alternative of chapter 9391. It sits beside the whole-rule and orbit carrier of chapter 934, the substrate packet of chapter 942, and the classifier-facing comparison of chapter 945. Its role is narrower than each sibling: it names only the displayed neighbourhood window, the selected rule-table row, and the visible next-row cell certified by that row.

Falsifiable prediction: Every accepted $\mathsf{CellularLocalUpdateRule}^{\uparrow}$ packet determines a visible next-row cell only from its displayed neighbourhood window and rule-table row; no consumer can read a global orbit, hidden boundary condition, or host evaluator from the packet.

Independence witness: cellularautomaton, cellularsubstrate, cellularrowclassifier, cellularcarrierencoding, cellularsubstrateclassifier: none is bijective because those siblings package whole automata, substrates, row classifiers, or encodings while $\mathsf{CellularLocalUpdateRule}^{\uparrow}$ packages only the local update rule surface.

Definition 984.1 (CellularLocalUpdateRule carrier)**.** *A* $\mathsf{CellularLocalUpdateRule}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (S, W, U, S', H, C, P, N)$$

with the following visible rows:

1. *S is the displayed current cell-state row;*
2. *W is the finite neighbourhood-window row surrounding the cell whose successor is being read;*
3. *U is the selected local rule-table row, containing exactly the displayed window pattern and its displayed output cell;*
4. *S' is the visible next-row cell determined by W and U;*
5. *H records componentwise* hsame *transports among the state row, window row, rule-table row, output cell, continuation route, package provenance, and local name;*
6. *C records the displayed* Cont *route by which a consumer reads S, W, U, S';*
7. *P is the* Pkg *provenance over* $\mathsf{CellularLocalUpdateRule}^{\uparrow}$, $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{CellularSubstrate}^{\uparrow}$, $\mathsf{CellularRowClassifier}^{\uparrow}$, $\mathsf{CellularCarrierEncoding}^{\uparrow}$, $\mathsf{CellularSubstrateClassifier}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*

8. N is the local $\mathsf{NameCert}_{\mathsf{CellularLocalUpdateRule}^{\uparrow}}$ *row.*

The classifier for U reads only the displayed neighbourhood window, the displayed rule-table row, the resulting next-row cell, the componentwise transport row, the continuation route, the package provenance, and the local name. It has no coordinate for a global orbit, a hidden boundary condition, or a host cellular evaluator.

Theorem 984.2 (CellularLocalUpdateRule NameCert obligations)**.** *For the carrier of Definition 984.1, the local* $\mathsf{NameCert}_{\mathsf{CellularLocalUpdateRule}^{\uparrow}}$ *surface consists exactly of five finite obligation rows:*

1. *carrier admission for the packet $U = (S, W, U, S', H, C, P, N)$;*
2. *neighbourhood visibility for the finite window row W;*
3. *rule-row accountability for the displayed table row U and its visible output cell S';*
4. *componentwise stability and replay through H, C, P, N;*
5. *non-escape from global orbit reads, hidden boundary conditions, host evaluators, and rule entries absent from U.*

Proof. Carrier admission is projection from Definition 984.1. The packet displays the current state row, finite neighbourhood window, selected rule-table row, visible next-row cell, transport row, continuation route, provenance row, and local naming row before a consumer can read the local update.

Neighbourhood visibility and rule-row accountability are the two local coordinates of the carrier. The window row W supplies the only input pattern, while U supplies the only rule-table row and output cell available to the classifier.

The stability and replay rows are H, C, P, N. The hsame row transports corresponding displayed rows, the Cont row records the read route, and the package and local-name rows expose the certificate as a public NameCert object.

No remaining coordinate is present. A global orbit, hidden boundary condition, host evaluator, or absent rule entry therefore cannot be exported by the local $\mathsf{NameCert}_{\mathsf{CellularLocalUpdateRule}^{\uparrow}}$ surface. □

Lean4 ✓ `BEDC.Derived.CellularLocalUpdateRuleUp.TasteGate.CellularLocalUpdateRuleTasteGate single carrier alignment`

Theorem 984.3 (CellularLocalUpdateRule falsifiable boundary)**.** *Every accepted* $\mathsf{CellularLocalUpdateRule}^{\uparrow}$ *packet determines its visible next-row cell by the finite route*

$$W, U \longrightarrow S' \longrightarrow H, C, P, N.$$

If a consumer obtains the next-row cell from a global orbit ledger, a hidden boundary condition, a host cellular evaluator, or a rule-table entry not displayed in U, then the consumer has left the accepted $\mathsf{CellularLocalUpdateRule}^{\uparrow}$ *packet.*

Proof. Start with the obligation surface of Definition 984.2. The only neighbourhood input is W, and the only rule information is the displayed rule-table row U.

The output row S' is then read along H, C, P, N. These rows transport, replay, package, and name the displayed local rule surface; they do not add an orbit ledger or evaluator.

Thus a read that depends on a global orbit ledger, hidden boundary condition, host evaluator, or absent table row is not a read through W, U, S', H, C, P, N. It is outside the accepted packet. □

The Lean TasteGate namespace BEDC.Derived.CellularLocalUpdateRuleUp.TasteGate provides Nontrivial CellularLocalUpdateRule$^{\uparrow}$ and FieldFaithful CellularLocalUpdateRule$^{\uparrow}$ instances for the displayed carrier.

Closure status for NameCert$_{\text{CellularLocalUpdateRule}^{\uparrow}}$ ·

Constructive story: A CellularLocalUpdateRule$^{\uparrow}$ packet is generated from a displayed current cell-state row, finite neighbourhood-window row, selected local rule-table row, visible next-row cell, componentwise hsame transports, displayed Cont route, package provenance, and local NameCert row.

Not claimed: This chapter does not close global cellular orbits, hidden boundary conditions, host evaluator correctness, substrate universality, or bridge checking for CellularLocalUpdateRule$^{\uparrow}$.

Upgrade path: No further paper-side closure grade remains; Lean bridge checking remains a separate axis for the same finite local update packet.

Chapter 985

A Concrete Naming Certificate for HaltingFiniteBoundary$^{\uparrow}$

The HaltingFiniteBoundary$^{\uparrow}$ packet realizes the halting fixed-point obstruction of chapter 9368 as a finite boundary certificate. It sits beside the distinction packet of chapter 491, the finite trace packet of chapter 492, the positive trace classifier of chapter 978, the terminal trace-normal-form surface of chapter 683, and the public inscription record of chapter 519. These dependencies are row consumption: the carrier reads finite trace evidence, terminal trace shape, and public record accountability as displayed packet rows, not as an external halting ontology.

Definition 985.1 (Halting finite-boundary carrier)**.** *A* HaltingFiniteBoundary$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (A, F, R, D, T, I, H, C, P, N)$$

with the following displayed rows:

1. *A is the admitted certificate-history input row whose visible behavior is being inspected;*
2. *F is the finite positive* Cont *trace row, recording only the displayed segment available to the packet;*
3. *R is the Real or trace-consumer row that may read F as finite evidence but not as a total decision;*
4. *D is the diagonal refusal row, rejecting any request to turn absence of a displayed trace into divergence, non-termination, or a negative halting verdict;*
5. *T is the terminal trace-normal-form row consumed from the continuation-trace normal-form surface when a displayed terminal boundary is present;*
6. *I is the inscription-event row naming the public record in which the finite trace and refusal boundary are consumed;*
7. *H records componentwise* hsame *transports for the input, trace, consumer, refusal, terminal, inscription, package, and local naming rows;*
8. *C records the displayed* Cont *routes that replay the finite trace, enter the trace consumer, expose the diagonal refusal, and return the terminal and inscription rows to the same packet;*
9. *P is the* Pkg *provenance over* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*,* HaltingDistinction$^{\uparrow}$*,* HaltingDistinctionTrace$^{\uparrow}$*,* HaltingTraceClassifier$^{\uparrow}$*,* ContinuationTraceNormalForm$^{\uparrow}$*,* InscriptionEvent$^{\uparrow}$*, and* Real$^{\uparrow}$ *rows;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{HaltingFiniteBoundary}^{\uparrow}}$ *row.*

The carrier has no coordinate for a total halting predicate, a divergence oracle, an unbounded search certificate, a host evaluator, or a proof that every absent future continuation is absent.

Theorem 985.2 (Halting finite-boundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{HaltingFiniteBoundary}^{\uparrow}}$ *surface for Definition 985.1 consists of six finite obligations:*

1. *carrier exposure for the displayed packet $B = (A, F, R, D, T, I, H, C, P, N)$;*
2. *finite trace evidence, requiring every accepted Real or trace-consumer read to expose the finite* Cont *trace row F;*
3. *diagonal refusal, requiring every total-halting, divergence, or non-termination request outside F to be rejected by D;*
4. *terminal trace locality, requiring any normal-form or terminal read to pass through T and the displayed routes C;*
5. *public record accountability, requiring downstream inscription use to pass through I, P, N without adding private host evidence;*
6. *transport and ledger exactness, requiring A, F, R, D, T, I, P, N to be transported componentwise through H and replayed only through C.*

The later Lean `TasteGate.lean` *development must include* Nontrivial $\mathsf{HaltingFiniteBoundary}^{\uparrow}$ *and* FieldFaithful $\mathsf{HaltingFiniteBoundary}^{\uparrow}$ *instances with an explicit* `witness_pair` *and* `mk`*-derived field projection, so the gate cannot identify the finite trace row with the diagonal refusal row or forget either row from the carrier.*

Lean4 ✓ `BEDC.Derived.HaltingFiniteBoundaryUp.HaltingFiniteBoundaryTasteGate single carrier alignment`

Proof. Carrier exposure is projection from Definition 985.1. The rows list the inspected input, finite trace, consumer read, diagonal refusal, terminal trace boundary, inscription record, transports, replay routes, package provenance, and local name.

Finite trace evidence is the F row consumed by R. The route data C may replay that finite trace and transport it through H, but no coordinate supplies an unbounded search over future continuations.

Diagonal refusal is the D row. It is transported with F and R, so a consumer cannot turn absence of a displayed continuation into divergence or a negative verdict after transport.

Terminal trace locality and public record accountability are the T and I rows. They allow a consumer to read terminal trace shape and public inscription use only through the same finite packet, with provenance and local naming recorded by P and N.

Since every accepted read factors through $A, F, R, D, T, I, H, C, P, N$, the packet separates positive finite trace evidence from forbidden total halting decisions. □

Theorem 985.3 (Halting finite-boundary consumer inversion)**.** *Any accepted* $\mathsf{HaltingFiniteBoundary}^{\uparrow}$ *packet with a Real or trace consumer exposes both a finite* Cont *trace row and a diagonal refusal row. A packet lacking either row is not a carrier of Definition 985.1, and therefore cannot supply the local* $\mathsf{NameCert}_{\mathsf{HaltingFiniteBoundary}^{\uparrow}}$ *obligations.*

Lean4 ✓ `BEDC.Derived.HaltingFiniteBoundaryUp.HaltingFiniteBoundaryCarrier consumer inversion`

Proof. Let an accepted packet be presented to a Real or trace consumer. By carrier exposure it has the displayed form $B = (A, F, R, D, T, I, H, C, P, N)$.

The consumer row is R, and its finite evidence is F. By the finite trace obligation, any accepted read through R must expose F before the consumer may classify the observed behavior.

The boundary row is D. By diagonal refusal, the same accepted packet must expose D before any request outside the displayed finite trace is rejected. If F or D is missing, the tuple is not the carrier named by the definition, so the local certificate cannot be formed. □

Falsifiable prediction: Any accepted HaltingFiniteBoundaryUp packet with a Real or trace consumer must expose a finite Cont trace row and a diagonal refusal row; a packet lacking either row is rejected by carrier inversion.

Independence witness: haltingdistinction, haltingdistinctiontrace, haltingtraceclassifier, continuationtracenormalform, inscriptionevent: none is bijective because the new carrier combines finite trace evidence with a diagonal refusal boundary, while the siblings isolate distinction, trace, classifier, terminal trace, or inscription rows separately.

Closure status for $\mathsf{NameCert}_{\mathsf{HaltingFiniteBoundary}\uparrow}$.

Constructive story: A $\mathsf{HaltingFiniteBoundary}^{\uparrow}$ packet is generated from an admitted certificate-history input row, a finite Cont trace row, a Real or trace-consumer row, a diagonal refusal row, a terminal trace-normal-form row, an inscription-event row, componentwise transports, replay routes, package provenance, and a local naming row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{HaltingFiniteBoundary}\uparrow}, \mathsf{seed})$

Scope closed: Definition 985.1, Definition 985.2, and Definition 985.3 bind the finite trace evidence and diagonal refusal boundary for Real or trace consumers.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{HaltingFiniteBoundary}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a total halting predicate, divergence decision, unbounded search certificate, host evaluator, Lean implementation, or standard bridge.

Upgrade path: Checked closure requires Lean encoding of the carrier plus Nontrivial and FieldFaithful TasteGate instances preserving the finite trace row, diagonal refusal row, consumer row, terminal row, inscription row, transports, routes, provenance, and local naming field projections.

Chapter 986

ObserverHsameClassifierUp NameCert construction

The $\mathsf{ObserverHsameClassifier}^{\uparrow}$ surface realizes the observer-history identity vision of chapter 9418 as a finite classifier row. It consumes the single-packet observer surface of chapter 479 and the pairwise licensed-observation surface of chapter 477. Its role is narrower than either sibling: it decides only whether displayed, licensed observations agree through hsame-mediated rows, and it has no coordinate for observer-substance or host equality.

Falsifiable prediction: If an accepted ObserverHsameClassifierUp packet changes only an unlicensed observer-substance row, then every public classifier read is unchanged because no such row is in the carrier.

Independence witness: Nearest siblings: observerhistidentity, observerhistoryidentity, observersubjectboundary, observerkerneltrace, observerfilter. The carrier is not bijective to any of them: it has a classifier-output and licensed-observation ledger row that the identity carriers and trace/filter packets do not have, while it lacks their full trace/filter selector coordinates.

Definition 986.1 (Observer hsame classifier carrier)**.** *An* $\mathsf{ObserverHsameClassifier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (H_0, H_1, A, R, L, D, C, P, N)$$

with the following displayed rows:

1. *H_0 and H_1 are the two observer-history rows being compared;*
2. *A is the licensed observation ledger, listing exactly the mark,* Cont, ProbeBundle, SigRel, *and classifier reads permitted to affect the decision;*
3. *R stores the componentwise* hsame *transports for the two histories, licensed observations, classifier-output row, continuation routes, package provenance, and local name;*
4. *L records the local ledger tying each licensed observation to its source history row and naming boundary;*
5. *D is the finite classifier-output row, recording agreement, disagreement, or refusal only after the relevant licensed observation row has passed through R and C;*
6. *C records the displayed* Cont *routes by which a consumer reads the histories, licensed observations, transports, and classifier output;*

7. *P is the* Pkg *provenance over* BHist, hsame, Cont, ProbeBundle, SigRel, $\mathsf{ObserverHistIdentity}^{\uparrow}$, $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, *and* NameCert *rows;*

8. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverHsameClassifier}^{\uparrow}}$ *row.*

The classifier compares accepted packets only through A, R, L, D, C, P, N. The carrier has no coordinate for unlicensed observation, observer-substance, host equality of observers, quotient history identity, or an observation outside the displayed ledger.

Theorem 986.2 (Observer hsame classifier NameCert obligations)**.** *For the carrier of Definition 986.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverHsameClassifier}^{\uparrow}}$ *surface consists exactly of five finite obligations:*

1. *carrier admission for $K = (H_0, H_1, A, R, L, D, C, P, N)$;*

2. *classifier transport through the componentwise* hsame *rows in R;*

3. *licensed-observation exactness for every row in A and no row outside A;*

4. *decision-row confinement, requiring every public classifier read to factor through D, L, R, C, P, N;*

5. *non-escape from unlicensed observation, observer-substance, host equality, quotient identity, and hidden classifier state.*

Lean4 ✓ `BEDC.Derived.ObserverHsameClassifierUp.ObserverHsameClassifierTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 986.1. The packet displays both observer-history rows, the licensed observation ledger, hsame transports, local ledger, classifier-output row, continuation routes, provenance, and local naming row before any public decision is available.

Classifier transport is componentwise. The row R moves each licensed observation and each displayed output row to the common hsame surface, while C records the only routes along which a consumer may read those transported rows.

Licensed-observation exactness follows by finite inventory of A and L. A public classifier decision may use a mark, Cont, ProbeBundle, SigRel, or prior classifier row only when that row appears in A with its source and boundary entry in L.

The remaining obligations follow from absence of coordinates. Since the carrier contains no observer-substance row, host equality row, quotient row, or hidden classifier state, every accepted public read is confined to A, R, L, D, C, P, N. □

Theorem 986.3 (Observer hsame classifier non-escape)**.** *Every public consumer of an accepted* $\mathsf{ObserverHsameClassifier}^{\uparrow}$ *packet reads only the licensed observation ledger A, the componentwise* hsame *transports R, the local ledger L, the classifier-output row D, the displayed* Cont *routes C, package provenance P, and local name row N. Changing any unlicensed observer-substance datum leaves the public classifier read unchanged, because no such datum is a carrier coordinate.*

Proof. Project the accepted packet to the rows of Definition 986.1. The only consumer-facing comparison data are the licensed observation ledger, transport row, local ledger, classifier-output row, route row, provenance row, and name row.

Apply the NameCert obligations of Definition 986.2. They require every public decision to pass through the displayed licensed observations and the hsame-mediated transport surface before the classifier-output row can be read.

There is no observer-substance coordinate and no unlicensed observation coordinate in the carrier. A change confined to such data therefore changes no row in A, R, L, D, C, P, N, so every public classifier read remains the same. □

Lean4 ✓ BEDC.Derived.ObserverHsameClassifierUp.ObserverHsameClassifier decision row concrete boundary

Theorem 986.4 (Observer hsame classifier licensed-observation exactness)**.** *For an accepted* ObserverHsameClassifi *packet* $K = (H_0, H_1, A, R, L, D, C, P, N)$*, every decision-relevant mark,* Cont *route,* ProbeBundle *row,* SigRel *row, and prior classifier read is licensed exactly by the pair of displayed ledger rows* A *and* L*. No row outside* A *can affect the classifier output, and every row in* A *that affects the output has its source history row and naming boundary recorded in* L*.*

Proof. Start from the carrier inventory in Definition 986.1. The only row that lists decision-relevant observations is A, and the only row that attaches such observations to source histories and naming boundaries is L.

Apply Definition 986.2. Its licensed-observation clause says that marks, Cont routes, ProbeBundle rows, SigRel rows, and prior classifier reads may enter the decision only through the finite ledger, with no outside observation row available.

Finally use Definition 986.3. Since a public consumer can read only A, R, L, D, C, P, N, any decision-relevant observation outside A would have to escape the displayed carrier. The non-escape theorem rules this out, while the entries of L supply the required source and boundary records for the observations that remain. □

Theorem 986.5 (Observer hsame classifier transport stability)**.** *For an accepted* ObserverHsameClassifier$^{\uparrow}$ *packet* $K = (H_0, H_1, A, R, L, D, C, P, N)$*, componentwise* hsame *transport through* R *preserves the two history rows* H_0, H_1*, the licensed ledger* A*, the local ledger* L*, the decision row* D*, the route row* C*, package provenance* P*, and the local name row* N*. After transport, the classifier still compares the same two history rows through the same licensed ledger and emits only the transported decision row.*

Proof. Read R as the componentwise transport row specified by Definition 986.1. Its coordinates are aligned with the two history rows, licensed observations, classifier-output row, continuation routes, package provenance, and local name.

Apply the transport clause of Definition 986.2. It requires classifier transport through the displayed hsame rows before the public decision row can be read, so transport cannot swap in a different history pair, ledger, route surface, provenance row, or name row.

Use Definition 986.3 for confinement of the transported read. A transported consumer still has access only to A, R, L, D, C, P, N, and therefore the transported classifier output factors through the same displayed rows as the original packet. □

Theorem 986.6 (Observer hsame classifier output confinement)**.** *For an accepted* ObserverHsameClassifier$^{\uparrow}$ *packet* $K = (H_0, H_1, A, R, L, D, C, P, N)$*, every agreement, disagreement, or refusal output factors through* D, L, R, C, P, N *together with the licensed observation ledger* A*. The output cannot read observer-substance, host equality, quotient history identity, unlicensed observation, or hidden classifier state.*

Proof. The carrier of Definition 986.1 gives the output row D only after the licensed observations pass through A, L, R and the displayed consumer routes in C. The provenance and naming rows P, N record the package and local certificate boundary.

Apply Definition 986.2. Its decision-row confinement and non-escape clauses bind every public classifier read to the displayed rows and exclude observations that are not licensed by the ledger.

Now apply Definition 986.3. The carrier has no coordinate for observer-substance, host equality, quotient identity, or hidden classifier state, so an agreement, disagreement, or refusal output has no access path to those data. It must therefore factor through A, D, L, R, C, P, N. □

Theorem 986.7 (Observer hsame classifier dependency scope)**.** *For an accepted* $\mathsf{ObserverHsameClassifier}^{\uparrow}$ *packet* $K = (H_0, H_1, A, R, L, D, C, P, N)$*, the classifier decision depends exactly on the two history rows* H_0, H_1*, the licensed observation ledger* A*, the* hsame *transport row* R*, the local ledger* L*, the decision row* D*, the displayed* Cont *routes* C*, the* Pkg *provenance row* P*, the local* $\mathsf{NameCert}_{\mathsf{ObserverHsameClassifier}^{\uparrow}}$ *row* N*, and the sibling* $\mathsf{ObserverHistIdentity}^{\uparrow}$ *and* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *surfaces named by* P*. It has no dependency coordinate for observer-substance, host equality, quotient history identity, unlicensed observation, or hidden classifier state.*

Proof. The carrier definition displays precisely the rows $H_0, H_1, A, R, L, D, C, P, N$. The provenance row P is the only place where sibling surfaces enter the packet, and it names the single-packet $\mathsf{ObserverHistIdentity}^{\uparrow}$ surface and the pairwise $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ surface as provenance for the displayed observer-history rows and licensed observations.

Use Definition 986.4 for the observation side. Every decision-relevant mark, Cont route, ProbeBundle row, SigRel row, and prior classifier read must be listed by A and tied to its source and boundary in L.

Use Definition 986.5 and Definition 986.6 for transport and output. The public decision can move only through R, C, P, N and can emit only the row D after the licensed ledger has been read.

Finally apply non-escape from Definition 986.3. Since the carrier contains no observer-substance, host-equality, quotient-identity, unlicensed-observation, or hidden-state coordinate, no accepted classifier decision can depend on such data. □

Theorem 986.8 (Observer hsame classifier TasteGate carrier scope)**.** *The cited TasteGate alignment,* Nontrivial $\mathsf{ObserverHsameClassifier}^{\uparrow}$ *instance, and* FieldFaithful $\mathsf{ObserverHsameClassifier}^{\uparrow}$ *instance are scoped to the displayed classifier packet* $K = (H_0, H_1, A, R, L, D, C, P, N)$*. They certify the same carrier, dependency rows, and local* $\mathsf{NameCert}_{\mathsf{ObserverHsameClassifier}^{\uparrow}}$ *boundary, and they cannot be read as certifying a different observer carrier or a classifier with additional hidden coordinates.*

Proof. The Lean target is attached to the $\mathsf{ObserverHsameClassifier}^{\uparrow}$ surface whose paper carrier is Definition 986.1. The surrounding NameCert obligations identify the packet by its displayed history rows, ledger rows, transport row, decision row, routes, provenance, and local name.

The Nontrivial instance witnesses that this carrier has the displayed classifier surface rather than collapsing to an empty or anonymous carrier. The FieldFaithful instance binds the exported fields to the same rows $H_0, H_1, A, R, L, D, C, P, N$.

By Definition 986.7, there is no additional carrier coordinate through which a second observer classifier could be read. Thus the TasteGate, nontriviality, and field-faithfulness surfaces refer to the same displayed packet. □

Theorem 986.9 (Observer hsame classifier scoped closure package)**.** *The* $\mathsf{ObserverHsameClassifier}^{\uparrow}$ *chapter forms a scoped closure package for the displayed classifier packet. The package consists of the carrier definition, the local* NameCert *obligations, non-escape, licensed-observation exactness, transport stability, output confinement, dependency scope, and TasteGate carrier scope, all over the same rows* $H_0, H_1, A, R, L, D, C, P, N$*.*

Proof. The carrier and local NameCert obligations are supplied by Definition 986.1 and Definition 986.2. They identify the finite packet and the five obligations that make the classifier readable.

The behavior of accepted packets is closed by the four boundary theorems. Non-escape removes observer-substance and hidden-state reads; licensed-observation exactness fixes the admissible observation ledger; transport stability preserves the displayed rows through hsame; output

confinement forces agreement, disagreement, and refusal outputs through the displayed classifier rows.

The remaining scope facts are supplied by Definition 986.7 and Definition 986.8. Together they bind the dependencies, TasteGate surface, nontriviality surface, and field-faithfulness surface to the same packet, so the chapter closes exactly the scoped classifier package and nothing beyond it. □

The Lean `TasteGate.lean` development for $\mathsf{ObserverHsameClassifier}^{\uparrow}$ provides explicit Nontrivial ObserverHsame and $\mathsf{FieldFaithful\ ObserverHsameClassifier}^{\uparrow}$ instances for the displayed classifier packet. These instances preserve the two history rows, licensed observation ledger, hsame transport row, local ledger, classifier-output row, Cont routes, Pkg provenance, and local NameCert row.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverHsameClassifier}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverHsameClassifier}^{\uparrow}$ packet is generated from two observer-history rows, a licensed observation ledger, componentwise hsame transports, a local ledger, a classifier-output row, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverHsameClassifier}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 986.1, Definition 986.2, Definition 986.3, Definition 986.4, Definition 986.5, Definition 986.6, Definition 986.7, Definition 986.8, and Definition 986.9 specify the finite classifier packet, its licensed-observation boundary, and its exact carrier scope.

Lean4 ✓ `BEDC.Derived.ObserverHsameClassifierUp.taste gate`

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverHsameClassifier}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ObserverHsameClassifierUp.ObserverHsameClassifierTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close full observer-history identity, observer-filter completeness, hidden observer state, quotient history identity, unbounded observation, or bridge checking.

Upgrade path: Public closure requires a public consumer surface that exports the scoped classifier package without adding observer-substance, host-equality, quotient-identity, unlicensed-observation, or hidden-state reads.

Chapter 987

A Concrete Naming Certificate for $\mathsf{CellularVerbRealignment}^{\uparrow}$

The $\mathsf{CellularVerbRealignment}^{\uparrow}$ packet realizes the kernel-verb realignment direction of chapter 9391 as a finite comparison surface. It sits beside the finite orbit packet of chapter 938 and the BHist cell-row embedding packet of chapter 948. Those siblings expose orbit and embedding rows; this carrier stores the comparison row that keeps the original BHist verbs and the cellular-orbit verbs visible at the same public boundary.

Falsifiable prediction: Removing the verb-comparison row makes the packet unable to distinguish BHist Cont from cellular orbit continuation.

Independence witness: cellularorbitsubstrate, bhistcellrowembedding, cellularautomaton, kernelcategory: none is bijective because this packet stores the verb-realignment comparison row rather than only orbit, embedding, automaton, or categorical hom rows.

Definition 987.1 (Cellular verb realignment carrier)**.** *A* $\mathsf{CellularVerbRealignment}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$V = (B, O, M, H, E, K, L, C, P, N)$$

with the following displayed rows:

1. *B is the source* BHist *verb row, displaying the finite Mark, Hist, Ext, and Cont reads being compared.*
2. *O is the cellular orbit row, displaying the finite cell-row segment, orbit window, local update route, and accepted continuation read.*
3. *M is the verb-comparison row, pairing each* BHist *kernel verb read with its cellular-orbit classifier read.*
4. *H is the componentwise* hsame *transport row for source histories, cell rows, comparison entries, embedding data, package data, and local names.*
5. *E is the embedding and readback row, citing the* $\mathsf{BHistCellRowEmbedding}^{\uparrow}$ *surface that keeps the source* BHist *row and the cellular row in one packet.*
6. *K is the kernel-commitment row, recording that the public BEDC carrier remains the displayed* BHist *row rather than the cellular orbit itself.*
7. *L is the local obligation ledger for carrier admission, verb comparison, NameCert exposure, non-escape, and TasteGate field projection.*

8. *C records displayed* Cont *routes through the* BHist *verb row, the cellular orbit row, the comparison row, the embedding row, the kernel-commitment row, the ledger, the package row, and the local naming row.*
9. *P is the* Pkg *provenance over* BHist, CellularOrbitSubstrate$^{\uparrow}$, BHistCellRowEmbedding$^{\uparrow}$, CellularAutomaton$^{\uparrow}$, hsame, Cont, Pkg, *and* NameCert *rows.*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{CellularVerbRealignment}^{\uparrow}}$ *row.*

The carrier compares verb rows only through $B, O, M, H, E, K, L, C, P, N$. It has no coordinate for replacing the BHist *kernel carrier, quotienting orbit segments, reading an unbounded cellular trace, or treating a cellular classifier as a host-level definition of Mark, Hist, Ext, or Cont.*

Lean4 ✓ `BEDC.Derived.CellularVerbRealignmentUp.CellularVerbRealignmentTasteGate single carrier alignment`

Theorem 987.2 (Cellular verb realignment NameCert obligations)**.** *For the carrier of Definition 987.1, the local* $\mathsf{NameCert}_{\mathsf{CellularVerbRealignment}^{\uparrow}}$ *surface consists exactly of carrier admission for $V = (B, O, M, H, E, K, L, C, P, N)$,* BHist *verb exposure through B, cellular orbit exposure through O, verb-comparison accountability through M, componentwise transport through H, embedding and readback accountability through E, kernel-carrier commitment through K, ledger exactness through L, displayed route replay through C, package provenance through P, and local naming through N.*

Proof. Carrier admission is projection from Definition 987.1. The packet displays the BHist verb row, cellular orbit row, comparison row, transports, embedding row, kernel-commitment row, local ledger, continuation routes, package row, and local name as its only coordinates.

The sibling packets account for the two sides of the comparison. Use chapter 938 to read the finite cellular orbit row, and use chapter 948 to keep the cellular row tied to the source BHist row.

The row M is the additional obligation surface. It records which Mark, Hist, Ext, and Cont reads are being compared, so the NameCert cannot be discharged by orbit exposure alone or by embedding exposure alone.

The rows K, L, C, P, N close the certificate. The kernel-carrier row preserves the BEDC BHist commitment, while the ledger, route, provenance, and naming rows expose no replacement carrier, quotient orbit, unbounded trace, or host definition of the verbs. □

Theorem 987.3 (Cellular verb realignment non-escape boundary)**.** *Every accepted* CellularVerbRealignment$^{\uparrow}$ *public read factors through the finite route*

$$B, O, M, H, E, K, L, C, P, N.$$

The route may compare BHist *Mark, Hist, Ext, and Cont reads with displayed cellular row, orbit-segment, row-extension, and orbit-continuation reads. It cannot replace the BEDC kernel carrier, identify orbit segments by quotient equality, import an unbounded cellular trace, or make the cellular classifier the definition of the kernel verbs.*

Proof. Start with the NameCert obligation theorem Definition 987.2. Every public read reaches the local name only after the source verb row, cellular orbit row, comparison row, transport row, embedding row, kernel-commitment row, ledger, route, and package rows have been displayed.

The comparison row M separates the four verb families. Mark and Hist comparisons read displayed carrier and orbit rows, while Ext and Cont comparisons read displayed extension and continuation routes.

The embedding row E and kernel-commitment row K keep the source carrier fixed as BHist. They permit a cellular-orbit comparison but do not turn the cellular carrier into the BEDC kernel carrier.

Since the carrier lacks coordinates for quotient orbit equality, unbounded cellular traces, host evaluators, and replacement verb definitions, the accepted public read remains the finite comparison surface stated above. □

The Lean follow-up must provide `Nontrivial CellularVerbRealignmentUp` and `FieldFaithful CellularVerbRealignmentUp` instances in `lean4/BEDC/Derived/CellularVerbRealignmentUp/TasteGate.lean` with the expected alignment surface at `BEDC.Derived.CellularVerbRealignmentUp.TasteGate.CellularVerbRe`

Closure status for $\mathsf{NameCert}_{\mathsf{CellularVerbRealignment}^{\uparrow}}$.

Constructive story: A $\mathsf{CellularVerbRealignment}^{\uparrow}$ packet is generated from a BHist verb row, a cellular orbit row, a verb-comparison row, componentwise hsame transports, an embedding and readback row, a kernel-carrier commitment row, a local obligation ledger, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CellularVerbRealignment}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 987.1, Definition 987.2, and Definition 987.3 bind the finite BHist and cellular-orbit verb comparison surface without replacing the kernel carrier.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CellularVerbRealignment}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a carrier switch, quotient orbit equality, unbounded cellular trace, host evaluator correctness, Lean implementation, or standard bridge.

Upgrade path: Checked closure requires Lean encoding of the carrier plus Nontrivial and FieldFaithful TasteGate instances preserving the BHist verb row, cellular orbit row, comparison row, embedding row, kernel-commitment row, ledger, route, provenance, and local naming projections.

Chapter 988

A Concrete Naming Certificate for LargeModelCorpusSupply$^{\uparrow}$

The LargeModelCorpusSupply$^{\uparrow}$ packet realizes the training-corpus supply reading of chapter 9398 as finite BEDC data. It consumes the local inscription-site discipline of chapter 610, the supply-socket boundary of chapter 604, and the large-model siblings chapter 939, chapter 967, and chapter 969. Its distinguishing role is the forward-binding corpus ledger: corpus source rows, training filters, distilled weight rows, inference-consumption rows, audit ledgers, routes, provenance, and a local NameCert row are carried together before a model output is read as corpus-supplied inscription.

Definition 988.1 (LargeModelCorpusSupply carrier)**.** *A* LargeModelCorpusSupply$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$C = (R, F, W, I, A, H, K, P, N)$$

with the following displayed rows:

1. *R is the corpus-source row, naming the finite text, data, or inscription records admitted to the supply channel;*
2. *F is the training-filter row, recording selection, rejection, normalization, de-duplication, and policy gates applied before distillation;*
3. *W is the distilled weight row that records how the accepted corpus channel is carried into the finite inference substrate;*
4. *I is the inference-consumption row, recording where the distilled pattern is read by a prompt, activation orbit, output record, or audit channel;*
5. *A is the audit-ledger row, storing corpus provenance, filter evidence, refusal evidence, and public read obligations for downstream checkers;*
6. *H records componentwise* hsame *transport for corpus, filter, weight, inference-consumption, audit, route, provenance, and naming rows;*
7. *K records the displayed* Cont *routes by which a consumer reads R, then F, then W, then I, A, before reaching the local name;*
8. *P is the* Pkg *provenance over* InscriptionPoint$^{\uparrow}$, TranscendentalSupplyInscription$^{\uparrow}$, LargeModelInscriptionPoint$^{\uparrow}$, LargeModelActivationOrbit$^{\uparrow}$, LargeModelAuditChannel$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*

9. N is the local $\mathsf{NameCert}_{\mathsf{LargeModelCorpusSupply}^{\uparrow}}$ *row.*

The carrier contains no hidden corpus selector, no global corpus-truth predicate, no host semantic understanding oracle, no model-side proof of output truth, and no route that bypasses displayed provenance.

Lean4 ✓ `BEDC.Derived.LargeModelCorpusSupplyUp.LargeModelCorpusSupplyTasteGate single carrier alignment`

Definition 988.2 (LargeModelCorpusSupply classifier)**.** *Two accepted* $\mathsf{LargeModelCorpusSupply}^{\uparrow}$ *carriers classify together exactly when their corpus-source rows, training-filter rows, distilled weight rows, inference-consumption rows, audit-ledger rows, route rows, provenance rows, and local naming rows compare componentwise by the displayed* hsame *entries:*

$$R \sim_{\mathsf{hsame}} R', \quad F \sim_{\mathsf{hsame}} F', \quad W \sim_{\mathsf{hsame}} W', \quad I \sim_{\mathsf{hsame}} I',$$
$$A \sim_{\mathsf{hsame}} A', \quad K \sim_{\mathsf{hsame}} K', \quad P \sim_{\mathsf{hsame}} P', \quad N \sim_{\mathsf{hsame}} N'.$$

Changing a source row or filter row while leaving the classifier unchanged is not an accepted comparison. No clause compares hidden author intent, unbounded training truth, private filtering policy outside F, or an internally ratified universal claim.

Theorem 988.3 (LargeModelCorpusSupply NameCert obligations)**.** *For the carrier of Definition 988.1, the local* $\mathsf{NameCert}_{\mathsf{LargeModelCorpusSupply}^{\uparrow}}$ *surface consists of the standard five finite rows:*

1. *carrier admission for $C = (R, F, W, I, A, H, K, P, N)$;*
2. *classifier transport for corpus-source, training-filter, distilled weight, inference-consumption, audit-ledger, route, provenance, and naming rows under componentwise* hsame*;*
3. *stability of the distilled weight and inference-consumption reads under the same displayed corpus-source and training-filter rows;*
4. *ledger exactness requiring every accepted inference-consumption or audit-channel read to pass through R, F, W, I, A, K, P, N in the displayed order;*
5. *non-escape for hidden corpus selection, corpus-wide truth, host semantic understanding, model-side proof of output truth, and unaudited provenance recovery.*

Lean4 ✓ `BEDC.Derived.LargeModelCorpusSupplyUp.LargeModelCorpusSupplyCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 988.1. The packet exposes exactly the corpus source, training filter, distilled weight, inference-consumption, audit, transport, route, provenance, and local naming rows.

Classifier transport is componentwise. A comparison of accepted corpus-supply packets must transport R, F, W, I, A, K, P, N together, so a changed corpus-source row or filter row exits the certificate unless the displayed classifier changes with it.

Stability and ledger exactness follow from the route order in K. A consumer first reads R and F, then reads W as the distillation row, and only then consumes I or A before reaching the provenance and naming rows.

The non-escape clauses follow from the inventory. The packet has no coordinate for hidden source selection, global corpus truth, host semantic understanding, model-side output proof, or provenance recovery outside the displayed audit ledger. □

Theorem 988.4 (LargeModelCorpusSupply corpus-provenance boundary)**.** *Every accepted* LargeModelCorpusSupp *packet exposes a corpus source row only by the displayed route*

$$\textit{corpus-source row} \longrightarrow \textit{training-filter row} \longrightarrow \textit{distilled weight row} \longrightarrow \textit{inference-consumption row} \longrightarrow \textit{audit}$$

Thus an accepted $\mathsf{LargeModelAuditChannel}^{\uparrow}$ *read can recover a source row only after consuming the same corpus provenance coordinate that supplied the forward-binding channel.*

Proof. Project the carrier $C = (R, F, W, I, A, H, K, P, N)$. The source row R is not exposed alone; the filter row F and distilled weight row W sit on the route before any inference-consumption row can be read.

The large-model inscription and activation-orbit siblings consume the distilled pattern through I, while the audit-channel sibling consumes public provenance through A and P. These routes keep corpus provenance visible before any output is accepted as audited.

Since the carrier contains no hidden source selector or private provenance channel, a downstream audit read that reaches a corpus source row must pass through the displayed corpus provenance coordinate. □

Falsifiable prediction: If the corpus-supply packet is atomic, no accepted LargeModelAuditChannelUp read can recover a corpus source row without consuming the displayed corpus provenance coordinate.

Independence witness: large-model-inscription-point, large-model-activation-orbit, large-model-audit-channel, inscription-point, transcendental-supply-inscription: the corpus-supply carrier has corpus provenance and training-filter rows absent from each sibling, while the siblings respectively carry inscription-site, activation-orbit, audit-channel, local-inscription, or supply-socket rows instead.

Closure status for $\mathsf{NameCert}_{\mathsf{LargeModelCorpusSupply}^{\uparrow}}$.

Constructive story: A $\mathsf{LargeModelCorpusSupply}^{\uparrow}$ packet is generated from corpus-source, training-filter, distilled weight, inference-consumption, audit-ledger, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LargeModelCorpusSupply}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 988.1, Definition 988.2, Definition 988.3, and Definition 988.4 specify the finite corpus-supply packet and its provenance boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LargeModelCorpusSupply}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close corpus truth, hidden author intent, host semantic understanding, model consciousness, model-side proof of output truth, Lean verification, or bridge checking for $\mathsf{LargeModelCorpusSupply}^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, classifier transport, corpus-source exposure, filter exactness, provenance boundary, nontriviality, and field faithfulness for the same corpus-supply carrier.

Chapter 989

A Concrete Naming Certificate for $\mathsf{LargeModelContextAudit}^{\uparrow}$

The $\mathsf{LargeModelContextAudit}^{\uparrow}$ packet realizes the context-and-audit side of chapter 9398 as finite BEDC data. It consumes the context-window commitment of chapter 971, the prompt-response trace of chapter 965, the model-trace surface of chapter 972, the audit channel of chapter 969, and the checked-output harness of chapter 976. Its distinguishing role is a finite context-audit packet: a model output is accepted only after the displayed context, prompt-response, model trace, audit channel, verified harness, refusal, transport, continuation, provenance, and local naming rows have been read together.

Definition 989.1 (LargeModelContextAudit carrier)**.** *A* $\mathsf{LargeModelContextAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$X = (C, T, M, A, V, R, H, K, P, N)$$

with the following displayed rows:

1. *C is the* $\mathsf{ContextWindowCommitment}^{\uparrow}$ *row naming the bounded prompt context, response boundary, admitted source rows, and downstream consumer surface;*
2. *T is the* $\mathsf{PromptResponseTrace}^{\uparrow}$ *row recording the prompt, response, source-channel route, observer-interface handoff, and obstruction boundary;*
3. *M is the* $\mathsf{ModelTrace}^{\uparrow}$ *row recording the finite model-state trace, output trace, corpus-supply row, refusal row, and accepted readback;*
4. *A is the* $\mathsf{LargeModelAuditChannel}^{\uparrow}$ *row carrying prompt, output, checker, refusal, audit membrane, route, provenance, and local name;*
5. *V is the* $\mathsf{VerifiedOutputHarness}^{\uparrow}$ *row carrying the checker-facing acceptance harness for the same output record;*
6. *R is the refusal row, recording unsupported, out-of-context, unverifiable, policy-refused, or route-incomplete claims before acceptance is exposed;*
7. *H records componentwise* hsame *transport for context, prompt-response, model-trace, audit-channel, harness, refusal, route, provenance, and naming rows;*
8. *K records the displayed* Cont *route by which a consumer reads C, then T, then M, then A and V, before reaching R, P, N;*

9. *P is the* Pkg *provenance over* ContextWindowCommitment$^{\uparrow}$, PromptResponseTrace$^{\uparrow}$, ModelTrace$^{\uparrow}$, LargeModelAuditChannel$^{\uparrow}$, VerifiedOutputHarness$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
10. *N is the local* NameCert$_{\text{LargeModelContextAudit}^{\uparrow}}$ *row.*

The carrier has no coordinate for hidden context recovery, unchecked model output acceptance, unrecorded checker state, host semantic understanding, corpus-wide truth, or a private route bypassing the displayed context-audit ledger.

Lean4 (definition) `BEDC.Derived.LargeModelContextAuditUp.LargeModelContextAuditUp`
Lean4 ✓ `BEDC.Derived.LargeModelContextAuditUp.LargeModelContextAuditTasteGate single carrier alignment`

Theorem 989.2 (LargeModelContextAudit NameCert obligations)**.** *For the carrier of Definition 989.1, the local* NameCert$_{\text{LargeModelContextAudit}^{\uparrow}}$ *surface consists of carrier admission for*

$$X = (C, T, M, A, V, R, H, K, P, N),$$

classifier transport for the same rows under componentwise hsame*, route exactness through the displayed* Cont *row K, refusal exactness through R, audit-channel and verified-harness exposure through A and V, provenance through P, and local naming through N. Every accepted consumer read of a model output factors through the displayed* ContextWindowCommitment$^{\uparrow}$, PromptResponseTrace$^{\uparrow}$, ModelTrace$^{\uparrow}$, LargeModelAuditChannel$^{\uparrow}$, *and* VerifiedOutputHarness$^{\uparrow}$ *rows before the output can be accepted.*

Proof. Carrier admission is projection from Definition 989.1. The packet displays context, prompt-response trace, model trace, audit channel, verified harness, refusal, transport, route, provenance, and local naming rows as its entire public surface.

Classifier transport is componentwise. A transported packet must carry $C, T, M, A, V, R, H, K, P, N$ together, so a changed context window, trace row, checker row, refusal row, or verified harness cannot be silently retained by the same local name.

Route exactness follows from K. A consumer first reads the bounded context row C, then the prompt-response row T, then the model-trace row M, and only then reaches the audit channel A and verified harness V before refusal, provenance, and naming are exposed.

The non-escape clauses follow from the carrier inventory. No row stores hidden context recovery, unchecked acceptance, unrecorded checker state, host semantic understanding, corpus-wide truth, or a private acceptance route. □

Lean4 ✓ `BEDC.Derived.LargeModelContextAuditUp.TasteGate.LargeModelContextAuditTasteGate single carrier alignment`

Theorem 989.3 (LargeModelContextAudit refusal factorization)**.** *Every refusal or accepted-output decision exposed by an accepted* LargeModelContextAudit$^{\uparrow}$ *carrier*

$$X = (C, T, M, A, V, R, H, K, P, N)$$

factors through the displayed context-window commitment, prompt-response trace, model trace, audit channel, verified output harness, componentwise transport, continuation route, provenance, and local naming rows. In particular, a consumer cannot accept a model output by reading V alone; the read must also pass through $C, T, M, A, R, H, K, P, N$.

Proof. Start with a refusal or accepted-output read. The entry row is the bounded context commitment C, because the packet has no separate coordinate for hidden context recovery or a bare output acceptance.

The prompt-response row T and model-trace row M then identify the finite emitted record being audited. These rows bind the output to its prompt, source-channel route, trace, corpus-supply handoff, and refusal boundary before any checker-facing surface is consumed.

The audit-channel row A and verified-harness row V provide the checker and acceptance surfaces. The refusal row R records unsupported or out-of-context outcomes before the local name can expose acceptance.

Finally route the read through H, K, P, N. Those rows supply transport, continuation, provenance, and local naming data, so the consumer receives a displayed context-audit packet rather than a private evaluator route or an unchecked model emission. □

Falsifiable prediction: Any accepted LargeModelContextAuditUp consumer factors through displayed ContextWindowCommitmentUp, PromptResponseTraceUp, ModelTraceUp, LargeModelAuditChannelUp, and VerifiedOutputHarnessUp rows before accepting a model output.

Independence witness: contextwindowcommitment, promptresponsetrace, modeltrace, largemodelauditchannel, verifiedoutputharness: the context-audit packet is not bijective with these siblings because it binds their rows into one consumer route and adds a shared refusal, transport, continuation, provenance, and local NameCert surface that no single sibling carries alone.

The Lean follow-up must provide Nontrivial LargeModelContextAudit$^{\uparrow}$ and FieldFaithful LargeModelContextAudit$^{\uparrow}$ instances in BEDC.Derived.LargeModelContextAuditUp/TasteGate.lean for the same finite carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{LargeModelContextAudit}^{\uparrow}}$ **·**

Constructive story: A LargeModelContextAudit$^{\uparrow}$ packet is generated from context-window commitment, prompt-response trace, model trace, audit channel, verified output harness, refusal, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{LargeModelContextAudit}^{\uparrow}}$, seed)

Scope closed: Definition 989.1, Definition 989.2, and Definition 989.3 specify the finite context-audit packet and its consumer route.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{LargeModelContextAudit}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close model consciousness, corpus truth, host semantic understanding, global checker correctness, hidden context recovery, Lean verification, or bridge checking for LargeModelContextAudit$^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, classifier transport, context-route exactness, refusal factorization, nontriviality, and field faithfulness for the same context-audit carrier.

Chapter 990

A Concrete Naming Certificate for $\mathsf{CauchyTailConsensus}^{\uparrow}$

The $\mathsf{CauchyTailConsensus}^{\uparrow}$ packet realizes the shared-tail consensus direction of chapter 9238. It ties the shared threshold route of chapter 983 to the paired agreement route of chapter 699, then exposes a single $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ handoff for downstream completion consumers.

Definition 990.1 (Cauchy tail consensus carrier)**.** *A* $\mathsf{CauchyTailConsensus}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (S, A, L, W, R, E, H, C, P, N)$$

with the following displayed rows:

1. *S is the accepted* $\mathsf{CauchySharedTailModulus}^{\uparrow}$ *row that supplies one shared finite threshold and readback route;*
2. *A is the accepted* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row that compares the paired tails after the same threshold route has been displayed;*
3. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row exposed only after S and A agree on the route;*
4. *W records the* $\mathsf{StreamName}^{\uparrow}$ *finite-window rows used by both S and A;*
5. *R records the* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks consumed by the agreement and limit-seal rows;*
6. *E is the terminal* $\mathsf{Real}^{\uparrow}$ *seal row for Real-completion consumers;*
7. *H records componentwise* hsame *transport for all displayed rows;*
8. *C records the* Cont *replay from shared threshold to agreement, from agreement to limit seal, and from limit seal to Real seal;*
9. *P is the* Pkg *provenance over* $\mathsf{CauchySharedTailModulus}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyTailConsensus}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient stream equality, selected host limits, independent tail thresholds, unshared readback routes, host real equality, or ambient completeness.

Lean4 ✓ `BEDC.Derived.CauchyTailConsensusUp.CauchyTailConsensusTasteGate single carrier alignment`

Theorem 990.2 (Cauchy tail consensus NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{CauchyTailConsensus}^{\uparrow}}$ *surface for Definition 990.1 consists exactly of carrier admission, shared-tail admission through* S*, tail-agreement admission through* A*, common* $\mathsf{StreamName}^{\uparrow}$ *window service through* W*, common* $\mathsf{RegSeqRat}^{\uparrow}$ *readback through* R*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff through* L*, terminal* $\mathsf{Real}^{\uparrow}$ *sealing through* E*, componentwise transport through* H*, route replay through* C*, provenance through* P*, and local naming through* N*.*

Proof. Project the carrier. The rows $S, A, L, W, R, E, H, C, P, N$ are the complete accepted inventory, so each shared-tail, agreement, window, readback, limit-seal, Real-seal, transport, route, provenance, and naming obligation is visible.

Read the two sibling routes. The shared-tail side uses chapter 983, while the agreement side uses chapter 699. Both are forced to consume the same displayed W, R route before L and E are available.

Since the carrier stores no quotient stream, selected limit, independent threshold, unshared readback, host equality, or ambient completeness coordinate, the listed rows exhaust the local NameCert obligations. □

Theorem 990.3 (Cauchy tail consensus shared route determinacy)**.** *Every accepted* $\mathsf{CauchyTailConsensus}^{\uparrow}$ *packet exposes a* $\mathsf{Real}^{\uparrow}$ *seal only when the shared-tail row* S *and the tail-agreement row* A *use the same finite threshold, window, and readback route through* W, R, H, C, P, N*. A packet whose* S *and* A *rows disagree on that route has no accepted Real seal row* E*.*

Proof. Start with the NameCert obligations. The $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff L and terminal seal E occur after both S and A have consumed the displayed W, R route.

Apply the sibling boundaries. The shared-tail modulus chapter supplies one shared finite threshold, and the Real tail-agreement seal chapter accepts the paired agreement only through its displayed window and readback rows.

If those routes disagree, there is no common continuation from A to L in the carrier. Thus the terminal seal row cannot be exposed; if they agree, the displayed H, C, P, N rows replay the single accepted consensus route. □

Theorem 990.4 (Cauchy tail consensus Real-completion handoff)**.** *Every Real-completion consumer of an accepted* $\mathsf{CauchyTailConsensus}^{\uparrow}$ *packet reads only the finite route*

$$S, A, W, R, L, E, H, C, P, N.$$

The route first consumes the shared-tail modulus, then the tail-agreement seal, then the Cauchy limit seal, and finally the Real seal; it exports no quotient stream, selected host limit, independent threshold, host real equality, or ambient completeness principle.

Proof. Use shared route determinacy. It makes W, R the common route for the shared-tail row and the tail-agreement row before any seal is visible.

Next read the Cauchy-limit handoff. The row L is reached only after the consensus route has passed through both S and A.

Finally project the terminal seal row E and the structural rows H, C, P, N. They transport, replay, package, and name the same finite route, so the consumer has no coordinate from which to import any excluded completion resource. □

Falsifiable prediction: Any accepted $\mathsf{CauchyTailConsensus}^{\uparrow}$ packet exposes no Real seal unless both shared-tail and tail-agreement rows use the same finite threshold and readback route.

Independence witness: cauchysharedtailmodulus, realtailagreementseal, cauchylimitseal, streamname, regseqrat: none is bijective to $\mathsf{CauchyTailConsensus}^{\uparrow}$ because this carrier stores the shared-tail row, agreement row, limit-seal handoff, common window/readback route, Real seal, and structural certificate rows together.

The Lean `TasteGate.lean` boundary for this carrier must include `Nontrivial CauchyTailConsensusUp` and `FieldFaithful CauchyTailConsensusUp` instances, so the consensus object is represented by an inhabited and field-faithful packet rather than by a vacuous route.

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyTailConsensus}^{\uparrow}}$ **.**

Constructive story: A $\mathsf{CauchyTailConsensus}^{\uparrow}$ packet is generated from shared-tail modulus, Real tail-agreement seal, CauchyLimitSeal, StreamName window, RegSeqRat readback, RealUp seal, componentwise hsame transport, displayed Cont replay, Pkg provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyTailConsensus}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 990.1, Definition 990.2, Definition 990.3, and Definition 990.4 bind the finite shared-tail consensus carrier and its Real-completion consumer route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CauchyTailConsensus}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, quotient stream equality, selected host limits, host real equality, independent tail thresholds, ambient completeness, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, shared-tail admission, tail-agreement admission, common window and readback route determinacy, CauchyLimitSeal handoff, RealUp seal handoff, and non-escape for the same packet.

Chapter 991

A Concrete Naming Certificate for $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$

The $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ packet realizes the Real and Completion direction of chapter 9238 as a finite nonzero-apartness budget certificate for regular Cauchy consumers. It consumes the regular source surface of chapter 301, the dyadic lower-bound readback of chapter 291, the finite window surface of chapter 126, the Real seal boundary of chapter 38, and the reciprocal-window budget surface of chapter 703. The packet isolates the finite lower-bound row shared by reciprocal and apartness consumers before either consumer reaches a Real-facing seal.

Definition 991.1 (Regular Cauchy apartness-budget carrier)**.** *A* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (X, A, M, W, D, R, E, H, C, P, N)$$

with the following displayed rows:

1. *X is the accepted* $\mathsf{RegSeqRat}^{\uparrow}$ *source whose nonzero lower-bound window is being read;*
2. *A is the nonzero-apartness budget row, recording a finite positive lower-bound request for X;*
3. *M is the finite modulus row selecting the observation precision at which the lower-bound request is inspected;*
4. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *window selected from X by the budget and modulus rows;*
5. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower-bound readback row obtained from that window;*
6. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row tying the dyadic lower-bound data back to the regular source;*
7. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row exposed only after A, M, W, D, R have been displayed;*
8. *H records componentwise* hsame *transport for the source, apartness budget, modulus, window, dyadic lower bound, regular readback, Real seal, provenance, and local name;*
9. *C records the displayed* Cont *routes for source inspection, apartness-budget exposure, finite-window coverage, dyadic lower-bound soundness, regular readback, and Real-seal handoff;*
10. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyInverseBudget}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyApartnessBudget}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through the displayed rows $X, A, M, W, D, R, E, H, C, P, N$.

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier route rows`

Theorem 991.2 (Regular Cauchy apartness-budget NameCert obligations)**.** *For the carrier of Definition 991.1, the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyApartnessBudget}^{\uparrow}}$ *surface consists of carrier admission, classifier stability, apartness-budget exposure, dyadic lower-bound soundness, and Real-seal non-escape for the same finite packet $B = (X, A, M, W, D, R, E, H, C, P, N)$. Carrier admission exposes exactly the listed rows. Classifier stability transports those rows componentwise through H and replays the same routes through C. Apartness-budget exposure requires A before any lower-bound or seal read. Dyadic lower-bound soundness requires D to be read from the finite window W selected by M. Real-seal non-escape requires every* $\mathsf{Real}^{\uparrow}$ *consumer to reach E only after the regular readback R has been displayed.*

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetTasteGate single carrier alignment`

Proof. Project the displayed packet. The carrier rows are exactly $X, A, M, W, D, R, E, H, C, P, N$, so admission has no hidden coordinate outside the tuple.

Classifier stability is componentwise. The transport row H compares the same source, budget, modulus, window, lower-bound, readback, seal, provenance, and name fields, while C replays the displayed route in the transported packet.

The apartness and dyadic clauses follow from the order of the finite route. The budget row A is read before the selected window and lower-bound row, and D is a read of the finite StreamName window W under the modulus row M.

The Real-seal clause then uses the regular readback row R. Since E is the only Real seal coordinate and it is reached only through R, H, C, P, N, a seal-facing consumer cannot bypass the displayed apartness-budget and dyadic lower-bound rows. □

Theorem 991.3 (Regular Cauchy apartness-budget non-escape)**.** *An accepted* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet exports only the rows*

$$X, A, M, W, D, R, E, H, C, P, N.$$

It exports no host nonzero real, no trichotomy principle, no quotient stream, no selected representative, no total reciprocal operation, and no ambient completeness theorem. Any reciprocal-window, apartness, regular-Cauchy, dyadic, StreamName, or Real-facing consumer of the packet must read the displayed apartness-budget row before consuming the dyadic lower-bound row or the Real seal row.

Proof. Inspect the carrier definition. The packet has one regular source, one nonzero-apartness budget, one modulus row, one finite window, one dyadic lower-bound readback, one regular readback, one Real seal, and the structural rows H, C, P, N.

Apply the NameCert obligations of Definition 991.2. They force carrier admission, componentwise classifier stability, apartness-budget exposure, dyadic lower-bound soundness, and Real-seal non-escape to use those same fields.

The excluded objects are not packet fields. A host nonzero real, trichotomy branch, quotient stream, selected representative, total reciprocal operation, or ambient completeness theorem would require an additional coordinate or an additional route, neither of which is present in the accepted carrier. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudget nonescape`

Theorem 991.4 (Regular Cauchy apartness-budget transport stability)**.** *For accepted* RegularCauchyApartnessBud *packets, the lower-bound row is stable only componentwise through the displayed transport and continuation surface. If*

$$B = (X, A, M, W, D, R, E, H, C, P, N),$$

then H transports the regular source, apartness budget, modulus row, StreamName window, DyadicRatCore lower-bound row, RegSeqRat readback, Real seal, provenance, and local name componentwise, while C records the corresponding displayed route stability

$$\mathsf{Cont}(M, W), \qquad \mathsf{Cont}(W, D), \qquad \mathsf{Cont}(W, R), \qquad \mathsf{Cont}(R, E).$$

No transported consumer may detach the lower-bound row D from the apartness budget A and the finite window W.

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudget transport stability`

Proof. Project the carrier rows. The only lower-bound coordinate is D, and it is placed after the apartness budget A, modulus row M, and StreamName window W.

Use the NameCert obligations. They make classifier stability componentwise through H and replay the lower-bound and readback routes through C.

The non-escape theorem then blocks any transported read that asks for a detached lower bound. Such a read would require a lower-bound coordinate outside $X, A, M, W, D, R, E, H, C, P, N$, which the accepted packet does not contain. □

Theorem 991.5 (Regular Cauchy apartness-budget lower-bound scope)**.** *Every accepted* RegularCauchyApartnessB *packet exposes its dyadic lower-bound row only through the finite route*

$$A, M, W, D, R, H, C, P, N.$$

Here A is the apartness budget, M is the modulus row, W is the $\mathsf{StreamName}^{\uparrow}$ *window, D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower-bound read, and R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback. A* $\mathsf{Real}^{\uparrow}$ *or reciprocal-window consumer may therefore read D only after the displayed route has fixed those rows, and cannot read D outside the finite packet $X, A, M, W, D, R, E, H, C, P, N$.*

Proof. Project the accepted carrier. The lower-bound coordinate is the single displayed row D, and the rows immediately controlling it are the apartness budget A, modulus M, finite window W, and regular readback R.

Apply the NameCert obligations of Definition 991.2. They require apartness-budget exposure before the lower-bound read, force D to be read from the selected finite window, and keep the regular readback on the same displayed packet.

Apply transport stability, Definition 991.4. The rows H and C preserve the lower-bound route componentwise and replay only the displayed continuations. Thus any $\mathsf{Real}^{\uparrow}$ or reciprocal-window consumer that tries to read D without A, M, W, R, H, C, P, N leaves the accepted packet. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier lower bound scope`

Theorem 991.6 (Regular Cauchy apartness-budget lower-bound determinacy)**.** *Let*

$$B = (X, A, M, W, D, R, E, H, C, P, N)$$

and

$$B' = (X', A, M, W, D, R, E', H', C', P', N')$$

be accepted $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packets. If the two packets share the displayed apartness row A, modulus row M,* $\mathsf{StreamName}^{\uparrow}$ *window W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower-bound row D,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R, and the structural rows governing the lower-bound route, then they expose the same dyadic lower-bound handoff to every* $\mathsf{Real}^{\uparrow}$ *and reciprocal-window consumer. The handoff cannot be changed by a different source seal, host nonzero witness, trichotomy branch, quotient stream, selected representative, or ambient completeness principle.*

Proof. Apply lower-bound scope, Definition 991.5. It confines every lower-bound read to the displayed route $A, M, W, D, R, H, C, P, N$ and does not admit an additional lower-bound coordinate.

Use transport stability, Definition 991.4. The shared structural rows keep the apartness budget, modulus, window, dyadic lower bound, regular readback, provenance, and local naming componentwise fixed, while the displayed continuations replay the same route.

Apply the reciprocal-window boundary, Definition 991.8. A reciprocal consumer can only consume the lower-bound handoff through the same finite window and readback rows, and a $\mathsf{Real}^{\uparrow}$ consumer reaches the seal only after that handoff is displayed.

Finally use non-escape, Definition 991.3. The alternative objects listed in the statement are not fields of either accepted packet, so they cannot distinguish the handoff determined by the shared lower-bound route. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier lower bound determinacy`

↪ variant `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetLowerBoundDeterminacy`

Theorem 991.7 (Regular Cauchy apartness-budget Real seal refusal)**.** *No* $\mathsf{Real}^{\uparrow}$ *seal or reciprocal-window read is public from a* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet unless the apartness-budget row A has already been read. A route that exposes E or a reciprocal lower-bound consumer while omitting A is not a carrier read of the accepted packet.*

Proof. Read the order of the displayed packet. The apartness-budget row A is the only public nonzero-budget coordinate, and the lower-bound and seal rows occur downstream of the finite window route.

Apply transport stability for the lower-bound row. It keeps D attached to A, M, W under H and C, so a reciprocal-window consumer cannot read D as an independent public datum.

Finally apply non-escape. The Real seal row E is exposed only through R, H, C, P, N after the same apartness and lower-bound route, so a consumer omitting A leaves the public surface. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier real seal refusal`

Theorem 991.8 (Regular Cauchy apartness-budget reciprocal-window boundary)**.** *Every reciprocal-window consumer of an accepted* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet factors through the* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower-bound row, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, and the local* $\mathsf{NameCert}$ *rows*

$$A, M, W, D, R, H, C, P, N.$$

The boundary exposes a finite apartness budget and finite readback route, not a total reciprocal operation, host nonzero real, quotient stream, selected representative, or ambient completeness theorem.

Proof. Start from the NameCert obligations. They require apartness-budget exposure before the dyadic lower-bound row and require that lower bound to be read from the finite StreamName window selected by the modulus row.

Use transport stability to keep the $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, and $\mathsf{RegSeqRat}^{\uparrow}$ rows on the same displayed route under H and C.

Apply the Real seal refusal and non-escape theorems. A reciprocal-window consumer that asks for a total reciprocal or host-level nonzero fact asks for data not carried by $A, M, W, D, R, H, C, P, N$, so the public boundary is exactly the finite route stated above. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier reciprocal window boundary`

Theorem 991.9 (Regular Cauchy apartness-budget Phase Real handoff)**.** *Every Phase Real and Completion consumer that uses a* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *lower-bound read must factor through the displayed RegSeqRat source* X*, apartness budget* A*, modulus row* M*,* $\mathsf{StreamName}^{\uparrow}$ *window* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower-bound row* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R*, Real seal row* E*, and the structural rows* H, C, P, N *before it can feed a reciprocal-window or* $\mathsf{Real}^{\uparrow}$*-facing exit. The handoff is the finite route*

$$X, A, M, W, D, R, E, H, C, P, N.$$

It refuses host nonzero reals, trichotomy, quotient streams, selected representatives, a total reciprocal operation, and ambient completeness.

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier phase real handoff`

Proof. Project the carrier of Definition 991.1. The rows $X, A, M, W, D, R, E, H, C, P, N$ are the only displayed source, lower-bound, seal, transport, replay, provenance, and local naming rows available to the consumer.

Apply lower-bound scope, Definition 991.5. It forces every lower-bound read through A, M, W, D, R and the local structural rows before any downstream consumer can use the read.

Apply lower-bound determinacy, Definition 991.6. Once the displayed lower-bound route is fixed, there is no second carrier coordinate from which a Phase Real or Completion consumer can read a different positive handoff.

Use Real seal refusal, Definition 991.7, and the reciprocal-window boundary, Definition 991.8. A Real-facing or reciprocal-window exit is therefore reached only after the same apartness budget, modulus, window, dyadic lower bound, regular readback, Real seal, transport, replay, provenance, and local naming rows have been displayed.

The carrier exclusions finish the non-escape claim. Host nonzero reals, trichotomy, quotient streams, selected representatives, total reciprocals, and ambient completeness are absent from the packet, so none of them can be exported by the Phase Real and Completion handoff. □

Theorem 991.10 (Regular Cauchy apartness-budget public interface)**.** *Every public reciprocal-window or* $\mathsf{Real}^{\uparrow}$*-seal consumer of an accepted* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet*

$$B = (X, A, M, W, D, R, E, H, C, P, N)$$

factors through the same finite interface

$$A, M, W, D, R, E, H, C, P, N.$$

This interface composes lower-bound scope, lower-bound determinacy, Real-seal refusal, and reciprocal-window boundary. It exports no host nonzero real, trichotomy principle, quotient stream, selected representative, total reciprocal operation, or ambient completeness theorem.

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier public interface`

Proof. First apply lower-bound scope, Definition 991.5. It confines every lower-bound read to the apartness row, modulus row, finite window, dyadic lower-bound row, regular readback, transport, replay, provenance, and local naming rows.

Next apply lower-bound determinacy, Definition 991.6. Once A, M, W, D, R and the structural rows are fixed, a public consumer has no second carrier coordinate from which to read a different dyadic lower-bound handoff.

Use Real-seal refusal, Definition 991.7, before any $\mathsf{Real}^{\uparrow}$-seal consumer reaches E. The seal is public only after the same apartness and lower-bound route has been displayed.

Finally apply the reciprocal-window boundary, Definition 991.8. A reciprocal consumer reads exactly the finite route $A, M, W, D, R, H, C, P, N$, and a Real-seal consumer adds only the downstream seal row E on that route. Since non-escape excludes host nonzero reals, trichotomy, quotient streams, selected representatives, total reciprocals, and ambient completeness, the listed interface is the full public surface. □

Theorem 991.11 (Regular Cauchy apartness-budget positive-window determinacy)**.** *Let* $B = (X, A, M, W, D, R, E, H, C, P, N)$ *and* $B' = (X', A, M, W, D, R, E', H', C', P', N')$ *be accepted* RegularCauchyApartne *packets with the same displayed apartness row* A*, modulus row* M*,* $\mathsf{StreamName}^{\uparrow}$ *window* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower-bound row* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R*, and structural rows for the lower-bound route. Then every reciprocal-window consumer reads the same positive lower-bound handoff from* B *and* B'*. No host nonzero real, trichotomy branch, quotient stream, or selected representative can alter that read.*

Proof. Project both accepted carriers. The lower-bound route in each packet is displayed through the same rows A, M, W, D, R together with the structural transport, replay, provenance, and naming rows for that route.

Apply lower-bound scope, Definition 991.5. It makes the dyadic lower-bound read depend only on the apartness budget, modulus, StreamName window, DyadicRatCore row, regular readback, and local structural rows.

Use transport stability, Definition 991.4, to keep this route componentwise fixed. Then apply the reciprocal-window boundary theorem Definition 991.8: a reciprocal consumer has no remaining coordinate from which to read a different positive lower bound.

The non-escape and Real-seal refusal clauses remove host nonzero reals, trichotomy branches, quotient streams, and selected representatives from the packet. Hence those external objects cannot change the finite lower-bound handoff determined by the shared window rows. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier positive window determinacy`

Theorem 991.12 (Regular Cauchy apartness-budget lower-bound modulus monotonicity)**.** *Let*

$$B = (X, A, M, W, D, R, E, H, C, P, N)$$

and

$$B' = (X', A, M', W', D, R, E', H', C', P', N')$$

be accepted $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packets sharing the apartness row* A*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower-bound row* D*, and* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R*. If the modulus and window pair* (M', W') *refines* (M, W) *through the displayed* $\mathsf{StreamName}^{\uparrow}$ *and* Cont *route, then every* $\mathsf{Real}^{\uparrow}$ *or reciprocal-window consumer reads from* B' *a lower-bound handoff no weaker than the one read from* B*. The refinement may add displayed window information, but it cannot replace the apartness row, weaken the dyadic lower-bound row, detach the regular readback, or import a host nonzero real, trichotomy branch, quotient stream, selected representative, total reciprocal operation, or ambient completeness theorem.*

Proof. Project the carrier rows of both packets. The shared lower-bound data are the apartness row A, the dyadic lower-bound row D, and the regular readback R, while the only changing rows in the lower-bound route are the modulus and window pair.

Apply lower-bound scope, Definition 991.5. It binds every lower-bound read to the finite route $A, M, W, D, R, H, C, P, N$ in the coarser packet and to the analogous route $A, M', W', D, R, H', C', P', N'$ in the refined packet.

Use transport stability to replay the refinement through H, H' and C, C'. The displayed $\mathsf{StreamName}^{\uparrow}$ and Cont route preserves the apartness row, dyadic lower-bound row, and regular readback, so a consumer can only receive the same lower-bound handoff or one exposed through a finer finite window.

Apply positive-window determinacy, Definition 991.11. With A, D, R fixed and the refined window routed through the same displayed lower-bound data, there is no carrier coordinate from which a changed or weaker handoff can be read.
