Finally use non-escape. Host nonzero reals, trichotomy, quotient streams, selected representatives, total reciprocals, and ambient completeness are not packet fields, so they cannot reverse the monotone refinement of the lower-bound route. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier lower bound modulus monotonicity`

Theorem 991.13 (Regular Cauchy apartness-budget L10 scope binding)**.** *Every accepted apartness-budget read exported by a* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet factors through chapter 301, chapter 291, chapter 126, chapter 38, and chapter 703 before any Real-facing apartness consumer may use the budget. In carrier terms, the source row* X*, apartness row* A*, modulus row* M*, window row* W*, dyadic lower-bound row* D*, regular readback row* R*, Real seal row* E*, transport row* H*, replay row* C*, provenance row* P*, and local naming row* N *must all remain on the same finite L10 route. No consumer may detach the budget from this dependency lattice into a host nonzero real, trichotomy branch, quotient stream, selected representative, total reciprocal operation, or ambient completeness theorem.*

Proof. Project the carrier of Definition 991.1. The accepted packet places the regular source, apartness budget, modulus, finite window, dyadic lower bound, regular readback, Real seal, transport, replay, provenance, and local naming rows in one tuple.

Apply the NameCert obligations and lower-bound scope. These force the apartness row to precede the StreamName window and DyadicRatCore lower-bound read, and they keep the RegSeqRat readback on the same route before any Real seal is consumed.

Use the reciprocal-window boundary and positive-window determinacy. A Cauchy inverse or reciprocal-window consumer reads the same positive lower-bound handoff only through the displayed finite window and readback rows.

Finally apply non-escape and Real-seal refusal. The excluded host objects are not carrier coordinates, so every Real-facing apartness consumer remains bound to the stated L10 dependency lattice. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier l10 scope binding`

Theorem 991.14 (Regular Cauchy apartness-budget bridge scope)**.** *Every bridge-facing consumer from* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *to* $\mathsf{Real}^{\uparrow}$ *or reciprocal-window interfaces must read the same finite route through* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and* $\mathsf{CauchyInverseBudget}^{\uparrow}$ *before using the apartness budget. In carrier terms, the rows* $A, M, W, D, R, E, H, C, P, N$ *remain attached to the source row* X *throughout the bridge read, so the budget cannot be consumed as a host nonzero real, trichotomy branch, quotient stream, selected representative, total reciprocal operation, or ambient completeness theorem.*

Proof. First apply lower-bound scope and lower-bound determinacy, Definition 991.5 and Definition 991.6. These results keep the apartness row, modulus row, StreamName window, DyadicRatCore lower-bound row, RegSeqRat readback, transport, replay, provenance, and local naming rows on one finite route.

Next use Real-seal refusal and the reciprocal-window boundary, Definition 991.7 and Definition 991.8. A Real-facing or reciprocal-window consumer reaches the seal or reciprocal interface only after the apartness budget and lower-bound handoff have been displayed.

Finally compose the public interface with L10 scope binding, Definition 991.10 and Definition 991.13. The bridge-facing route is therefore the same finite dependency lattice through $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{CauchyInverseBudget}^{\uparrow}$, with no coordinate for the refused host or completion principles. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier bridge scope`

Theorem 991.15 (Regular Cauchy apartness-budget RealApartnessField handoff)**.** *Every* $\mathsf{RealApartnessField}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet must read the apartness budget row* A*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower-bound ledger* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R*,* $\mathsf{Real}^{\uparrow}$ *seal row* E*, componentwise* hsame *transport row* H*, displayed* Cont *replay row* C*,* Pkg *provenance row* P*, and local* $\mathsf{NameCert}$ *row* N *before any field operation consumes apartness. Thus the field-facing route cited in chapter 5562 receives a displayed finite lower-bound handoff, not a host nonzero real, trichotomy branch, quotient representative, selected limit, total reciprocal operation, or ambient completeness theorem.*

Proof. Start with the public interface, Definition 991.10. It identifies every reciprocal-window or $\mathsf{Real}^{\uparrow}$-seal consumer with the finite surface $A, M, W, D, R, E, H, C, P, N$, so a field-facing apartness consumer cannot enter through a row outside the accepted packet.

Apply bridge scope and lower-bound determinacy, Definition 991.14 and Definition 991.6. These keep the apartness budget, dyadic lower-bound ledger, regular readback, transport, replay, provenance, and naming rows on one route before the downstream Real-facing read.

Finally use non-escape, Definition 991.3. The refused host and completion principles are not carrier coordinates, while the $\mathsf{RealApartnessField}^{\uparrow}$ chapter consumes apartness through displayed $\mathsf{Real}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, transport, replay, provenance, and local naming rows. Hence every field operation that consumes apartness receives the stated handoff first. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier field handoff`

Theorem 991.16 (Regular Cauchy apartness-budget route composition)**.** *Every accepted* RegularCauchyApartnessB *packet composes the apartness row A, modulus row M,* $\mathsf{StreamName}^{\uparrow}$ *window row W,* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower-bound readback D,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback R,* $\mathsf{Real}^{\uparrow}$ *seal row E, reciprocal-window boundary, transport row H, replay row C, provenance row P, and local* NameCert *row N through one finite L10 route. Any bridge-facing consumer that reaches a* $\mathsf{Real}^{\uparrow}$ *apartness handoff or a reciprocal-window read must traverse that route in order; it receives no host nonzero real, trichotomy branch, quotient stream, selected representative, total reciprocal operation, or ambient completeness theorem.*

Proof. Start with lower-bound scope, Definition 991.5. It places the apartness row, modulus row, StreamName window, DyadicRatCore lower-bound row, RegSeqRat readback, transport, replay, provenance, and local naming rows on the same finite lower-bound route.

Apply the reciprocal-window boundary, Definition 991.8. A reciprocal consumer can read a positive lower-bound handoff only after the displayed window and readback rows have been presented on that route.

Use the public interface and L10 scope binding, Definition 991.10 and Definition 991.13. These results attach the route to the $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{CauchyInverseBudget}^{\uparrow}$ siblings before any bridge-facing read.

Finally apply bridge scope, Definition 991.14. The bridge-facing consumer therefore receives the composed finite route $A, M, W, D, R, E, H, C, P, N$ and no coordinate for a host nonzero real or total reciprocal. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier route composition`

Theorem 991.17 (Regular Cauchy apartness-budget cofinal window refinement)**.** *Let*

$$B = (X, A, M, W, D, R, E, H, C, P, N)$$

and

$$B' = (X', A, M', W', D, R, E', H', C', P', N')$$

be accepted $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packets sharing the apartness row A,* $\mathsf{DyadicRatCore}^{\uparrow}$ *lower-bound row D, and* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R. Suppose the* $\mathsf{StreamName}^{\uparrow}$ *windows W and W' are cofinally comparable through displayed modulus, window, transport, replay, provenance, and local-name rows. Then every* $\mathsf{Real}^{\uparrow}$ *or reciprocal-window consumer reads the same Real-facing apartness-budget handoff from the two packets. Refinement is allowed only through the displayed rows M, W, H, C, P, N and M', W', H', C', P', N'; it cannot replace A, weaken D, detach R, import a host nonzero real, or introduce a total reciprocal operation.*

Proof. First apply lower-bound scope, Definition 991.5. It confines each lower-bound read to the apartness row, modulus row, finite StreamName window, dyadic lower-bound row, regular readback, transport, replay, provenance, and local naming rows.

Next apply positive-window determinacy, Definition 991.11. Cofinal comparability makes the two window routes meet along the displayed finite-window surface, so a reciprocal-window consumer has no second carrier coordinate from which to read a different positive handoff.

Use lower-bound modulus monotonicity, Definition 991.12, in both cofinal directions. Each refinement may expose more finite window information, but with A, D, R fixed it cannot weaken or replace the lower-bound handoff.

Finally apply the reciprocal-window boundary, Definition 991.8, Real-seal refusal, Definition 991.7, and L10 scope binding, Definition 991.13. These results keep every reciprocal-window or Real-facing consumer on the displayed finite route and exclude host nonzero witnesses, quotient streams, selected representatives, total reciprocals, and ambient completeness from the handoff. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier cofinal window refinement`

Theorem 991.18 (Regular Cauchy apartness-budget bridge surface)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing apartness read of an accepted* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet*

$$B = (X, A, M, W, D, R, E, H, C, P, N)$$

factors through the $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row* D*,* $\mathsf{StreamName}^{\uparrow}$ *finite window* W*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R*,* $\mathsf{Real}^{\uparrow}$ *seal* E*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*,* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyApartnessBudget}^{\uparrow}}$ *row* N*. The bridge-facing surface contains no quotient stream equality, trichotomy branch, host nonzero real, selected representative, total reciprocal operation, or ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier bridge surface`

Proof. Project the carrier rows. The apartness row A and modulus row M do not reach a $\mathsf{Real}^{\uparrow}$ consumer directly; they are read through the finite window W, the dyadic lower-bound row D, and the regular readback R before the seal row E is available.

Apply lower-bound scope and Real-seal refusal, Definition 991.5 and Definition 991.7. These results force every Real-facing read to expose A, M, W, D, R, E on the displayed route.

Next use bridge scope and route composition, Definition 991.14 and Definition 991.16. They attach the same route to the $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and reciprocal-window sibling surfaces before a bridge consumer can use the budget.

Finally apply the public interface and L10 scope binding, Definition 991.10 and Definition 991.13. The rows H, C, P, N transport, replay, source, and name the bridge surface, while the refused host coordinates are absent from the carrier and cannot be recovered by a $\mathsf{Real}^{\uparrow}$-facing read. □

Theorem 991.19 (Regular Cauchy apartness-budget inverse-window consumption)**.** *Any accepted* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet consumed by a* $\mathsf{RealApartnessField}^{\uparrow}$ *inverse read must expose its positive lower-bound row, reciprocal-window row, cofinal-window row, and* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row before the field inverse branch is read. The consumer route cites chapter 5562 and chapter 291; it receives the finite rows*

$$A, M, W, D, R, E, H, C, P, N$$

from the carrier, not Real completeness, trichotomy, quotient equality, a selected representative, or a total inverse operation.

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier inverse window consumption`

Proof. First use lower-bound determinacy, Definition 991.6. It fixes the positive lower-bound handoff once the apartness row, modulus row, StreamName window, DyadicRatCore lower-bound row, RegSeqRat readback, and structural rows are displayed.

Next apply the reciprocal-window boundary, Definition 991.8. A reciprocal or inverse-facing consumer can read the lower-bound handoff only through the finite window, readback, tolerance, transport, replay, provenance, and local naming rows.

Use the RealApartnessField handoff and route composition, Definition 991.15 and Definition 991.16. These attach the lower-bound and reciprocal-window route to the field-facing apartness consumer before a field operation may consume it.

Finally apply cofinal window refinement, Definition 991.17. Cofinal refinements may display more window information, but they cannot replace A, weaken D, detach R, or import a host inverse. Hence the inverse branch reads only the displayed finite budget and dyadic tolerance rows before entering the $\mathsf{RealApartnessField}^{\uparrow}$ surface. □

Theorem 991.20 (Regular Cauchy apartness-budget shared field inverse window)**.** *Let an accepted* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet be consumed both by a* $\mathsf{RealApartnessField}^{\uparrow}$ *inverse read and by a* $\mathsf{CauchyInverseBudget}^{\uparrow}$ *reciprocal-window read. If the two consumers cite the same accepted packet, then both reads share the displayed rows*

$$A, M, W, D, R, E, H, C, P, N.$$

The field inverse branch cannot split from the reciprocal-window lower-bound handoff: it must read the same apartness budget A, modulus row M, finite window W, dyadic lower-bound ledger D, regular readback R, Real seal E, transport H, replay C, provenance P, and local naming row N before either inverse-facing surface is exported.

Proof. Begin with the field handoff and reciprocal-window boundary, Definition 991.15 and Definition 991.8. The field consumer and reciprocal-window consumer both reach inverse-facing data only after the finite lower-bound route has displayed the apartness, window, dyadic, readback, transport, replay, provenance, and naming rows.

Apply route composition and cofinal window refinement, Definition 991.16 and Definition 991.17. Refining the window may expose more observations, but it does not replace A, split M from W, weaken D, detach R, or introduce a second Real seal.

Finally use inverse-window consumption and non-escape, Definition 991.19 and Definition 991.3. Since host nonzero reals, trichotomy, quotient streams, selected representatives, total reciprocals, and ambient completeness are not coordinates of the carrier, the two inverse-facing consumers can only share the displayed packet route. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier shared field inverse window`

Theorem 991.21 (Regular Cauchy apartness-budget located reciprocal handoff)**.** *Every* $\mathsf{LocatedReal}^{\uparrow}$ *or* $\mathsf{RealInverse}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet must read the same finite rows*

$$A, M, W, D, R, E, H, C, P, N.$$

The dyadic lower-bound row D and the regular readback row R are visible before the located reciprocal handoff is exported, and the consumer receives the reciprocal route only as a displayed apartness-budget packet over $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{CauchyInverseBudget}^{\uparrow}$. *The handoff contains no host nonzero real, trichotomy branch, quotient stream, selected representative, total reciprocal operation, or ambient completeness theorem.*

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier located reciprocal handoff`

Proof. Start with lower-bound determinacy, Definition 991.6. It fixes the positive lower-bound read once the apartness row, modulus row, finite window, dyadic lower-bound row, regular readback, and structural rows are displayed.

Apply the reciprocal-window boundary and field handoff, Definition 991.8 and Definition 991.15. These force any reciprocal-facing or apartness-field read to pass through $A, M, W, D, R, E, H, C, P, N$ before it can be consumed by a located or inverse-facing surface.

Use route composition and shared field inverse-window consumption, Definition 991.16 and Definition 991.20. The located consumer and the $\mathsf{RealInverse}^{\uparrow}$ consumer therefore share the same dyadic lower-bound row D and regular readback row R before either handoff is public.

Finally apply the mature consumer theorem, Definition 991.22. Since host nonzero reals, trichotomy, quotient streams, selected representatives, total reciprocals, and ambient completeness are absent from the accepted carrier, the located reciprocal route can only export the displayed finite packet. □

Theorem 991.22 (Regular Cauchy apartness-budget mature consumer)**.** *Every mature* $\mathsf{RealInverse}^{\uparrow}$, $\mathsf{RealApartnessField}^{\uparrow}$, *or* $\mathsf{RegSeqRat}^{\uparrow}$*-facing consumer of an accepted* $\mathsf{RegularCauchyApartnessBudget}^{\uparrow}$ *packet must read the dyadic lower-bound row, the apartness guard, the inverse-window row, the regular rational readback, the* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* NameCert *row before using the reciprocal budget. Such a consumer receives the displayed packet route*

$$A, M, W, D, R, E, H, C, P, N$$

and no host nonzero real, trichotomy branch, quotient stream equality, selected representative, total reciprocal operation, ambient completeness theorem, or detached inverse credential.

Proof. Start with route composition, Definition 991.16. It forces every reciprocal-budget read to pass through the apartness guard A, modulus row M, finite window W, dyadic lower-bound ledger D, regular readback R, Real seal E, and the structural rows H, C, P, N.

Next apply inverse-window consumption, Definition 991.19. A $\mathsf{RealApartnessField}^{\uparrow}$ or $\mathsf{RealInverse}^{\uparrow}$ branch may use the reciprocal budget only after the positive lower-bound row, reciprocal-window row, cofinal-window row, and $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance row have been exposed on the same finite route.

Finally use shared field inverse-window consumption, Definition 991.20. If a $\mathsf{RegSeqRat}^{\uparrow}$ readback, field inverse read, or reciprocal-window read cites this packet, then all such consumers share $A, M, W, D, R, E, H, C, P, N$. Since the refused host coordinates are absent from the carrier, the mature consumer can only use the displayed reciprocal budget. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier mature consumer`

Theorem 991.23 (Regular Cauchy apartness-budget formal-axis target)**.** *The formal target for* RegularCauchyApartnessBudget$^{\uparrow}$ *is the determinacy of the apartness-budget packet from its displayed rows:* DyadicRatCore$^{\uparrow}$ *tolerance and lower-bound rows,* RegSeqRat$^{\uparrow}$ *tail windows,* StreamName$^{\uparrow}$ *finite observations, the* Real$^{\uparrow}$ *apartness seal, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* NameCert *row. Any future formalization of the packet must recover the same rows*

$$A, M, W, D, R, E, H, C, P, N$$

before exporting reciprocal-budget, inverse-facing, or apartness-field consumers, and it may not use host nonzero reals, trichotomy, quotient streams, selected representatives, total reciprocal operations, or ambient completeness as hidden coordinates.

Proof. Read the mature consumer theorem together with route composition. Those results already force inverse-facing consumers to pass through the apartness row, modulus row, finite window, dyadic lower-bound ledger, regular readback, Real seal, and structural rows.

The formal-axis target is the same finite route stated as a later Lean obligation. Dyadic tolerance rows determine the positive lower-bound evidence, RegSeqRat tail windows and StreamName finite observations determine the visible readback route, and the Real apartness seal records the terminal nonzero-facing boundary.

Finally the hsame, Cont, Pkg, and NameCert rows bind transport, replay, provenance, and local naming to the same carrier. Since none of the refused host objects is a coordinate of the packet, a formal proof can only export the displayed row determinacy. □

Lean4 ✓ `BEDC.Derived.RegularCauchyApartnessBudgetUp.RegularCauchyApartnessBudgetCarrier formal axis target`

Falsifiable prediction: Any accepted reciprocal-window consumer that omits the displayed apartness-budget row is not a RegularCauchyApartnessBudgetUp carrier read.

Independence witness: Nearest siblings: cauchyinversebudget, apartnessreal, regseqrat, dyadicratcore, streamname. The carrier is not bijective to CauchyInverseBudgetUp because it has no reciprocal readback row; not to ApartnessRealUp because it keeps finite regular-Cauchy window budgets rather than a completed Real apartness predicate; not to RegSeqRatUp because it adds nonzero lower-bound rows; not to DyadicRatCoreUp because it includes stream-window and Real-seal routes; not to StreamNameUp because it includes dyadic lower-bound and apartness ledger rows.

The Lean TasteGate route is expected to provide `Nontrivial RegularCauchyApartnessBudgetUp` with an explicit witness pair and `FieldFaithful RegularCauchyApartnessBudgetUp` with `.mk`-derived fields and a match/injection proof.

Closure status for NameCert$_{\text{RegularCauchyApartnessBudget}^{\uparrow}}$.

Constructive story: A RegularCauchyApartnessBudget$^{\uparrow}$ packet is generated from a regular-Cauchy source, a finite nonzero-apartness budget, a modulus row, a finite StreamName window, a DyadicRatCore lower-bound readback, a RegSeqRat readback, a RealUp seal, componentwise transports, displayed routes, provenance, and local naming.

Theory closure: TheoryGate(NameCert$_{\text{RegularCauchyApartnessBudget}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 991.10 exports the public reciprocal-window and Real$^{\uparrow}$-seal surface, Definition 991.13 gives the exact L10 dependency scope over RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, StreamName$^{\uparrow}$, Real$^{\uparrow}$, CauchyInverseBudget$^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert, Definition 991.18 records the bridge route, and Definition 991.22 binds mature inverse, apartness-field, RegSeqRat, dyadic lower-bound, StreamName, and Real-seal consumers to the same finite reciprocal-budget route.

Formal verification: FormalStatus(NameCert$_{\text{RegularCauchyApartnessBudget}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, host nonzero reals, trichotomy, quotient streams, selected representatives, total reciprocal operations, ambient completeness, or bridge checking.

Upgrade path: Lean-side carrier admission, classifier stability, apartness-budget exposure, dyadic lower-bound soundness, Real-seal non-escape, provenance, and TasteGate alignment remain separate from the bridge-facing paper surface.

Chapter 992

A Concrete Naming Certificate for $\mathsf{AxiomRequirementLedger}^{\uparrow}$

The $\mathsf{AxiomRequirementLedger}^{\uparrow}$ packet realizes the Required-Axiom-Set coordinate of chapter 9455 as a finite consumer-facing ledger. It sits beside the dependency-map packet of chapter 862, the audit boundary of chapter 526, the forbidden-host ancestry boundary of chapter 622, the apophatic refusal surface of chapter 543, and the common audit-map interface of chapter 806. Those siblings expose mode rows, audit refusals, forbidden dependency ancestry, named externality refusal, and cross-map reads; this chapter packages the finite row by which a required axiom supply is carried without being confused with a zero-axiom witness. As an ai packet, it bundles those dependency-map, audit-boundary, forbidden-ancestry, apophatic-name, and audit-interface surfaces into one required-supply ledger.

Definition 992.1 (AxiomRequirementLedger carrier)**.** *An* $\mathsf{AxiomRequirementLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (\Phi, M, W, A, R, T, U, V, H, C, P, N)$$

with the following displayed rows:

1. Φ *is the claim row whose dependency tuple is being read;*
2. M *is the Mode A, Mode B, or Mode C row inherited from the dependency-map entry;*
3. W *is the witness row, either a zero-axiom proof, a restricted proof, a counterexample, or a named socket;*
4. A *is the finite required-axiom-set row displayed for the entry;*
5. R *is the refusal ledger that prevents a nonempty* A *row from being read as substrate-internal proof content;*
6. T *is the transport row connecting the required-supply row to audit-map consumers;*
7. U *is the route row from the dependency tuple to the audit boundary and forbidden-ancestry checks;*
8. V *is the provenance row for apophatic names, audit-map interface reads, and dependency-map siblings;*
9. H *records componentwise* hsame *transport for the claim, mode, witness, required-supply, refusal, transport, route, provenance, and local name;*

10. *C records displayed* Cont *routes by which consumers inspect* $\Phi, M, W, A, R, T, U, V, H$*;*
11. *P is the* Pkg *provenance over* AxiomDependencyMap$^{\uparrow}$, AuditGateBoundary$^{\uparrow}$, ForbiddenAxiomAncestry$^{\uparrow}$, ApophaticName$^{\uparrow}$, AuditMapInterface$^{\uparrow}$, BHist, hsame, Cont, *and* NameCert *rows;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{AxiomRequirementLedger}^{\uparrow}}$ *row.*

The carrier has no coordinate that turns a nonempty required-axiom row into a Mode A proof, imports a refused host axiom as BEDC theorem content, hides a selected witness, or bypasses the displayed audit route.

Lean4 ✓ `BEDC.Derived.AxiomRequirementLedgerUp.AxiomRequirementLedgerTasteGate single carrier alignment`

Theorem 992.2 (AxiomRequirementLedger NameCert obligations)**.** *For the carrier of Definition 992.1, the local* $\mathsf{NameCert}_{\mathsf{AxiomRequirementLedger}^{\uparrow}}$ *surface consists exactly of claim exposure through Φ, mode exposure through M, witness exposure through W, required-supply exposure through A, refusal preservation through R, transport through T, H, route replay through U, C, provenance through V, P, and local naming through N. A downstream audit-map consumer can read a nonempty required-axiom-set row only as required supply, refusal data, or named socket data, never as an accepted zero-axiom witness.*

Proof. Project the carrier. The accepted packet exposes the rows $\Phi, M, W, A, R, T, U, V, H, C, P, N$ and no other supply row.

The dependency-map sibling supplies the tuple order: claim, mode, witness, and required-axiom set are read before the ledger is exported. The audit boundary and forbidden-ancestry siblings then read the same required-supply row through R, T, U, H, C as a finite refusal or ancestry boundary.

The apophatic-name and audit-map-interface siblings supply the public consumer shape. They allow a named socket or refusal row to be cited, routed, and transported, but they do not convert it into a generated BEDC witness.

Thus the local NameCert surface is exactly the displayed ledger. Since no carrier coordinate imports the required axiom or manufactures a Mode A proof, a nonempty A row remains required supply rather than substrate-internal proof content. □

Lean4 ✓ `BEDC.Derived.AxiomRequirementLedgerUp.AxiomRequirementLedgerNameCertObligations`

Theorem 992.3 (AxiomRequirementLedger non-escape)**.** *Every accepted* AxiomRequirementLedger$^{\uparrow}$ *packet separates required axiom supply from zero-axiom witnesses. If the required-supply row A is nonempty, any consumer that reads the packet must factor through*

$$\Phi, M, W, A, R, T, U, V, H, C, P, N.$$

It cannot export the entry as a Mode A witness unless the witness row W is itself a checked zero-axiom proof row and the required-supply row is empty on the displayed route.

Proof. Start from the carrier definition. The only rows available to a consumer are the displayed finite rows, and the required-supply row A is separate from the witness row W.

Use the NameCert obligations of Definition 992.2. They require every consumer read of A to pass through the refusal, transport, route, provenance, and local naming rows R, T, U, V, H, C, P, N.

Now compare with the dependency-map mode row. A Mode A read is permitted only where the witness row is a checked zero-axiom proof and the required-supply row is empty on the displayed route. When A is nonempty, the accepted packet records supply still required; it does not export a substrate theorem. □

Lean4 ✓ `BEDC.Derived.AxiomRequirementLedgerUp.AxiomRequirementLedgerRequiredSupplyNonescape`

Falsifiable prediction: A consumer that turns a nonempty required-axiom row into a Mode A witness without a checked proof row is not reading an accepted AxiomRequirementLedgerUp packet.

Independence witness: axiomdependencymap, auditgateboundary, forbidden-axiom-ancestry, apophaticname, and auditmapinterface are non-bijective siblings: none alone carries the complete finite combination of claim, mode, witness, required-supply, refusal, transport, route, provenance, and NameCert data exposed by $\mathsf{AxiomRequirementLedger}^{\uparrow}$.

The packet composes axiomdependencymap, auditgateboundary, forbidden-axiom-ancestry, apophaticname, and auditmapinterface into the displayed required-supply ledger surface.

The Lean follow-up is `lean4/BEDC/Derived/AxiomRequirementLedgerUp/TasteGate.lean` with explicit Nontrivial and FieldFaithful instances for the displayed ledger.

Theorem 992.4 (AxiomRequirementLedger bridge route)**.** *Every audit-map or dependency-map bridge consumer of an accepted* $\mathsf{AxiomRequirementLedger}^{\uparrow}$ *packet must pass through the displayed rows*

$$\Phi, M, W, A, R, T, U, V, H, C, P, N$$

and the TasteGate single-carrier row before reading required axiom supply. In particular, bridge-side reads of A are mediated by the same claim, mode, witness, refusal, transport, route, provenance, replay, package, and local NameCert rows that define the public packet.

Proof. Project the accepted carrier. The only required-supply row exposed by the packet is A, and it is displayed together with $\Phi, M, W, R, T, U, V, H, C, P, N$.

An audit-map consumer reads required supply through the refusal, transport, route, and provenance rows. A dependency-map consumer reads the same supply through the claim, mode, witness, and required-set coordinates. Both routes are transported and replayed by H and C, then named by P and N.

The TasteGate single-carrier row aligns those two consumer views with the same accepted packet. Thus no bridge consumer can read axiom supply before passing through the displayed rows and the single-carrier alignment. □

Closure status for $\mathsf{NameCert}_{\mathsf{AxiomRequirementLedger}^{\uparrow}}$.

Constructive story: An $\mathsf{AxiomRequirementLedger}^{\uparrow}$ packet is generated from a claim row, mode row, witness row, required-supply row, refusal ledger, transport row, audit route, provenance row, componentwise transports, displayed consumer routes, package provenance, and local naming.

Lean4 ✓ `BEDC.Derived.AxiomRequirementLedgerUp.taste gate`

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AxiomRequirementLedger}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 992.1, Definition 992.2, Definition 992.3, the falsifiable prediction, and the independence witness export the required-supply ledger over the displayed rows $\Phi, M, W, A, R, T, U, V, H, C, P, N$.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AxiomRequirementLedger}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, global theorem dependency completeness, host axiom import, selected witnesses, quotient equality, or any conversion of required supply into BEDC theorem content.

Upgrade path: Only Lean verification and bridge checking remain for the displayed required-supply ledger rows and their non-escape route.

Chapter 993

A Concrete Naming Certificate for $\mathsf{FiniteReflectionTuple}^{\uparrow}$

The $\mathsf{FiniteReflectionTuple}^{\uparrow}$ packet realizes the TasteGate stability discipline of chapter 9459 as a finite reflection tuple. It consumes the stability packet of chapter 564, the candidate-admission surface of chapter 545, and the compiler-witness route of chapter 563. The packet is narrower than these siblings: it records the fixed displayed tuple image, the readback rows, the componentwise NameCert transports, and the reflection-request rows that a downstream bridge request may inspect.

Definition 993.1 (FiniteReflectionTuple carrier)**.** *A* $\mathsf{FiniteReflectionTuple}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (X, S, A, W, I, R, H, C, P, Q, N)$$

with the following displayed rows:

1. *X is the candidate chapter identity row, recording the chapter label, origin row, and concrete-instance site being reflected;*
2. *S is the consumed* $\mathsf{TasteGateStability}^{\uparrow}$ *row, carrying the candidate carrier,* ChapterTasteGate *obligations, admission ledger, and non-escape boundary;*
3. *A is the consumed* $\mathsf{TasteGateAdmission}^{\uparrow}$ *row, exposing the candidate-admission surface and refusal ledger for the same X;*
4. *W is the consumed* $\mathsf{TasteGateCompilerWitness}^{\uparrow}$ *row, exposing the ground-compiler event-flow image, replay rows, dependency ledger, and audit result;*
5. *I is the displayed tuple-image row, listing the finite image of X, S, A, W as the exact tuple requested by the reflection route;*
6. *R is the readback row, recovering X, S, A, W componentwise from I without importing a second carrier or host semantic judgment;*
7. *H stores componentwise* hsame *transports for $X, S, A, W, I, R, C, P, Q, N$ and componentwise* NameCert *transport for the three consumed TasteGate packets;*
8. *C records the displayed* Cont *routes that replay tuple formation, image reading, readback, and componentwise NameCert transport;*
9. *P is the* Pkg *provenance over chapter 9459, the three consumed TasteGate packets, tuple-image rows, readback rows,* hsame, Cont, *and* NameCert *rows;*

10. *Q is the reflection-request row, recording which* StandardBridge*-facing request may inspect the tuple image and readback;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteReflectionTuple}^{\uparrow}}$ *row.*

The carrier has no coordinate for hidden prompt state, oracle taste, unlisted compiler facts, a host-side approval row, a second tuple image, or a reflection request detached from I and R.

Theorem 993.2 (FiniteReflectionTuple NameCert obligations)**.** *For every accepted* $\mathsf{FiniteReflectionTuple}^{\uparrow}$ *carrier*

$$F = (X, S, A, W, I, R, H, C, P, Q, N),$$

the local $\mathsf{NameCert}_{\mathsf{FiniteReflectionTuple}^{\uparrow}}$ *surface consists exactly of carrier exposure for F, candidate identity through X, consumed stability data through S, consumed admission data through A, consumed compiler-witness data through W, tuple-image exposure through I, readback exposure through R, componentwise* hsame *and* NameCert *transport through H, replay routes through C, package provenance through P, reflection-request exposure through Q, and local naming through N.*

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleNameCert obligations`

Proof. Carrier exposure is projection from Definition 993.1. The packet lists every row available to a consumer of the finite reflection tuple.

The TasteGate rows are supplied by chapter 564, chapter 545, and chapter 563. The stability row supplies the carrier and non-escape boundary, the admission row supplies the candidate row being tested, and the compiler witness supplies the ground-compiler evidence read by W and replayed through C.

The reflection-specific obligations are I, R, H, C, P, Q, N. The tuple image I is the only displayed image, R is the only readback, H gives componentwise transport for both equality and local certificates, and Q records the bridge-facing request that may inspect the tuple.

Since the carrier has no coordinate for hidden prompt state, oracle taste, unlisted compiler facts, host-side approval, a second tuple image, or a request detached from I and R, the listed rows exhaust the local NameCert surface. □

Theorem 993.3 (FiniteReflectionTuple field-faithful prediction)**.** *Every accepted* $\mathsf{FiniteReflectionTuple}^{\uparrow}$ *packet is field-faithful to its displayed tuple image. A consumer that asks for the reflected candidate, stability packet, admission packet, compiler witness, componentwise transport, or* StandardBridge *request must read that field through I and recover it through R. A packet lacking either the displayed image row or the readback row is not a public reflection request over the accepted TasteGate route.*

Proof. Start with the carrier definition. The only image coordinate is I, and the only row that recovers fields from the image is R.

Use the NameCert obligations of Definition 993.2. They force candidate identity, stability, admission, compiler witness, transport, replay, provenance, and request reads through the displayed tuple surface.

The reflection-request row Q is therefore request data for the same image and readback. If either I or R is absent, a consumer may still name some TasteGate packet, but it cannot present the fixed tuple image/readback surface required by this carrier.

Thus every accepted field read is faithful to the displayed tuple, and a request without both image and readback rows is outside the public reflection packet. □

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleCarrier field faithful prediction`

Theorem 993.4 (FiniteReflectionTuple image-readback exactness)**.** *For every accepted* FiniteReflectionTuple$^{\uparrow}$ *packet*

$$F = (X, S, A, W, I, R, H, C, P, Q, N),$$

every public field read of X, S, A, W, C, P, Q, or N factors through the displayed tuple-image row I and the readback row R. No public read of the reflected candidate, consumed TasteGate packet, replay route, provenance row, request row, or local naming row may bypass I or recover its component from a second readback surface.

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleCarrier image readback exactness`

Proof. The carrier definition gives exactly one image coordinate, namely I, and exactly one readback coordinate, namely R. The public rows of F are therefore exposed through the displayed finite tuple rather than through a separate host-side table.

Apply Definition 993.2. Its certificate surface lists candidate identity, consumed stability data, consumed admission data, compiler-witness data, replay routes, provenance, request exposure, and local naming as rows of the same finite packet.

Now apply Definition 993.3. A consumer that asks for any reflected field must read that field through I and recover it through R. Since the carrier has no coordinate for a second image or second readback, the exactness claim follows. □

Theorem 993.5 (FiniteReflectionTuple reflection-request exhaustion)**.** *For every accepted* FiniteReflectionTuple$^{\uparrow}$ *packet*

$$F = (X, S, A, W, I, R, H, C, P, Q, N),$$

any StandardBridge*-facing request that inspects this finite reflection tuple is the displayed request row Q attached to the same I, R, H, C, P, N packet. A request detached from the displayed tuple image, readback row, componentwise transport row, replay route, provenance row, or local naming row is not a request over F.*

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleCarrier request exhaustion`

Proof. The definition of the carrier assigns request exposure to the single row Q. The same definition places Q in one tuple with I, R, H, C, P, and N.

The NameCert obligations of Definition 993.2 make request exposure part of the local certificate surface. Thus the request visible to a bridge-facing consumer is not an extra coordinate outside the accepted packet.

Use Definition 993.3 to bind that request back to the displayed image and readback. If a proposed request is not the displayed row Q for the same packet, or if it is detached from I, R, H, C, P, or N, it lies outside the public reflection route. □

Theorem 993.6 (FiniteReflectionTuple componentwise transport)**.** *For every accepted* FiniteReflectionTuple$^{\uparrow}$ *packet*

$$F = (X, S, A, W, I, R, H, C, P, Q, N),$$

componentwise hsame *transport and componentwise* NameCert *transport preserve exactly the displayed rows $X, S, A, W, I, R, C, P, Q, N$. They preserve the consumed* TasteGateStability$^{\uparrow}$, TasteGateAdmission$^{\uparrow}$, *and* TasteGateCompilerWitness$^{\uparrow}$ *certificate rows, and they cannot introduce a second tuple image or a reflection request detached from I and R.*

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleCarrier componentwise transport`

Proof. The row H is the only transport row in the carrier. By Definition 993.1, it stores componentwise hsame transport for $X, S, A, W, I, R, C, P, Q, N$ and componentwise NameCert transport for the three consumed TasteGate packets.

Apply Definition 993.2. The local certificate surface exposes the same component list and no additional transport coordinate.

It remains to rule out extra image and request data. The carrier definition excludes a second tuple image and a detached request, while Definition 993.4 and Definition 993.5 force public image reads and bridge-facing requests through the displayed I, R, and Q rows. Componentwise transport therefore preserves exactly the named rows. □

Theorem 993.7 (FiniteReflectionTuple public projection route)**.** *For every accepted* FiniteReflectionTuple$^{\uparrow}$ *packet*

$$F = (X, S, A, W, I, R, H, C, P, Q, N),$$

every public projection from F factors through the displayed image/readback pair I, R. Candidate identity, stability input, admission input, compiler-witness input, transport, replay, provenance, request, and local naming are first exposed as fields of the finite image I and then recovered through the readback row R.

There is no public projection from F that bypasses I, R, reads a second image, or recovers a component from host-side reflection state.

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleCarrier public projection route`

Proof. Begin with Definition 993.1. The tuple has exactly one displayed image row I and exactly one readback row R.

Apply Definition 993.4. It forces public field reads of the candidate, consumed TasteGate packets, replay, provenance, request, and local naming through the same image/readback pair.

Finally apply Definition 993.6. Componentwise hsame and NameCert transport preserve exactly the displayed rows and do not introduce a second image or detached request. Hence every public projection factors through I, R. □

Theorem 993.8 (FiniteReflectionTuple dependency ledger totality)**.** *For every accepted* FiniteReflectionTuple$^{\uparrow}$ *packet*

$$F = (X, S, A, W, I, R, H, C, P, Q, N),$$

the dependency ledger is exactly the three sibling TasteGate rows TasteGateStability$^{\uparrow}$, TasteGateAdmission$^{\uparrow}$, *and* TasteGateCompilerWitness$^{\uparrow}$, *together with the BEDC support rows* BHist, hsame, Cont, Pkg, *and* NameCert *displayed by H, C, P, N. No hidden dependency, host approval row, oracle taste row, or unlisted compiler theorem is part of the ledger.*

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleCarrier dependency ledger totality`

Proof. Read the carrier row by row. The fields S, A, and W are precisely the consumed TasteGateStability, TasteGateAdmission, and TasteGateCompilerWitness packets, while H, C, P, N record the transport, replay, provenance, and naming support.

Use Definition 993.2. It lists the local certificate surface and names no dependency other than the three sibling packets and the displayed BEDC rows.

The request exhaustion theorem, Definition 993.5, keeps the bridge-facing request attached to the same I, R, H, C, P, N packet. Thus the ledger is total for this public route and has no projection point for a hidden dependency. □

Theorem 993.9 (FiniteReflectionTuple audit-result nonescape)**.** *An audit-result read of an accepted* FiniteReflectionTuple$^{\uparrow}$ *packet can inspect only the displayed tuple image, readback, componentwise transport, replay, provenance, request, local naming, and the three listed TasteGate sibling inputs. It cannot import hidden prompt state, oracle taste, host approval, a detached reflection request, a second image/readback surface, or an unlisted compiler theorem.*

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleCarrier audit result nonescape`

Proof. First apply Definition 993.7. Any public read of the tuple, including an audit-result read, factors through I, R.

Next apply Definition 993.8. The only dependency inputs available to that read are the three sibling TasteGate rows and the displayed BHist, hsame, Cont, Pkg, and NameCert rows.

Finally use Definition 993.6 and Definition 993.5. They keep transport and bridge-facing requests inside the same finite packet. Since the excluded objects have no carrier coordinate, no image row, no readback row, and no request row, an audit-result read cannot escape to them. □

Theorem 993.10 (FiniteReflectionTuple StdBridge request scope)**.** *For every accepted* FiniteReflectionTuple$^{\uparrow}$ *packet*

$$F = (X, S, A, W, I, R, H, C, P, Q, N),$$

every StandardBridge*-facing request over F must read the candidate identity,* TasteGateStability$^{\uparrow}$ *input,* TasteGateAdmission$^{\uparrow}$ *input,* TasteGateCompilerWitness$^{\uparrow}$ *input, tuple image, readback, componentwise transport, replay, provenance, request, and local* NameCert *rows through that same packet. No such request may import hidden prompt state, a second image/readback surface, host approval, oracle taste, or an unlisted compiler theorem.*

Proof. Start with Definition 993.5. It identifies the bridge-facing request with the displayed row Q attached to the same tuple image, readback, transport, replay, provenance, and local naming rows.

Use Definition 993.8. The only dependency inputs available to that request are the three consumed TasteGate packets and the displayed BEDC support rows.

Apply Definition 993.9. Hidden prompt state, oracle taste, host approval, detached requests, second image/readback surfaces, and unlisted compiler theorems have no carrier coordinate in an accepted audit-result read.

Finally invoke Definition 993.3. Since each reflected field is read through I and recovered through R, the request scope is exactly the displayed finite packet $X, S, A, W, I, R, H, C, P, Q, N$. □

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleTasteGate single carrier alignment`

Theorem 993.11 (FiniteReflectionTuple bridge-facing row totality)**.** *For every accepted* FiniteReflectionTuple$^{\uparrow}$ *packet*

$$F = (X, S, A, W, I, R, H, C, P, Q, N),$$

every bridge-facing request over F factors through the displayed tuple image I, readback row R, componentwise transports H, replay row C, provenance row P, request row Q, and local NameCert row N, together with the candidate and consumed TasteGate sibling rows X, S, A, W. No hidden prompt state, second image/readback surface, host approval, oracle taste, or unlisted compiler theorem can serve the request.

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleCarrier bridge facing row totality`

Proof. Begin with the NameCert obligations. They expose the carrier row X, consumed stability, admission, and compiler-witness rows S, A, W, the tuple image I, readback R, componentwise transports H, replay C, provenance P, request row Q, and local naming row N.

Apply image-readback exactness. It forces every public image read through I and every recovery of reflected data through R, so a bridge-facing request cannot introduce a second image/readback surface.

Use request exhaustion and componentwise transport. The request row Q is attached to the same tuple image, readback, transports, replay, provenance, and local naming rows, and the transports keep the reflected components inside the accepted finite packet.

Finally invoke the StdBridge request-scope theorem. It already excludes hidden prompt state, host approval, oracle taste, second image/readback surfaces, and unlisted compiler theorems for StandardBridge-facing requests, so every bridge-facing row is total over the displayed packet $X, S, A, W, I, R, H, C, P, Q, N$. □

Theorem 993.12 (FiniteReflectionTuple bridge-request boundary)**.** *Every* StandardBridge *request over an accepted* FiniteReflectionTuple$^{\uparrow}$ *packet must first read* $X, S, A, W, I, R, H, C, P, Q, N$ *through the displayed tuple image and readback. The request cannot substitute host approval, oracle taste, an unlisted compiler theorem, or detached request state for the image/readback packet.*

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.FiniteReflectionTupleCarrier bridge request boundary`

Proof. Start with image-readback exactness. It forces every public read of the reflected candidate, consumed TasteGate rows, replay, provenance, request, and local name through the displayed image I and readback row R.

Next apply request exhaustion. The StandardBridge-facing request is the displayed row Q attached to the same I, R, H, C, P, N packet, rather than a detached request state.

Use dependency ledger totality and bridge-facing row totality together. They expose the allowed dependency rows X, S, A, W and the support rows H, C, P, N, while excluding host approval, oracle taste, hidden prompt state, second image/readback surfaces, and unlisted compiler theorems.

Therefore a bridge request over the accepted packet is a consumer handoff for exactly $X, S, A, W, I, R, H, C, P, Q$ through the displayed image/readback route. □

Falsifiable prediction: A FiniteReflectionTupleUp packet without displayed image and readback rows cannot support a StdBridge request.

Independence witness: tastegatestability, tastegateadmission, tastegatecompilerwitness, kernelacceptancetrace: none contains the fixed tuple image/readback/componentwise transport surface together with a reflection-request row.

Lean development for this route must provide Nontrivial FiniteReflectionTuple$^{\uparrow}$ and FieldFaithful FiniteReflectionT instances in `lean4/BEDC/Derived/FiniteReflectionTupleUp/TasteGate.lean`.

Closure status for NameCert$_{\text{FiniteReflectionTuple}^{\uparrow}}$.

Constructive story: A FiniteReflectionTuple$^{\uparrow}$ packet is generated from a candidate chapter identity row, consumed TasteGateStability$^{\uparrow}$, TasteGateAdmission$^{\uparrow}$, and TasteGateCompilerWitness$^{\uparrow}$ packets, a displayed tuple image, a readback row, componentwise hsame and NameCert transports, continuation routes, provenance, a reflection-request row, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{FiniteReflectionTuple}^{\uparrow}}$, maturePackageClosed)

Lean4 ✓ `BEDC.Derived.FiniteReflectionTupleUp.taste gate`

Scope closed: Definition 993.1, Definition 993.2, Definition 993.4, Definition 993.5, Definition 993.6, Definition 993.7, Definition 993.8, Definition 993.9, Definition 993.10, Definition 993.11, the falsifiable prediction, and the independence witness bind the public image/readback projection, reflection request, dependency ledger, audit-result boundary, and bridge-facing request rows for the same finite packet.

Formal verification: FormalStatus(NameCert$_{\mathsf{FiniteReflectionTuple}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, axiom-clean audit, bridge checking, hidden prompt-state reconstruction, oracle taste, host-side approval, unlisted compiler facts, or a reflection request detached from the displayed image and readback rows.

Upgrade path: No further paper-side theory grade remains; independent Lean bridge checking remains on the formal axis for the same tuple image, readback, transport, and reflection-request rows.

Chapter 994

A Concrete Naming Certificate for $\mathsf{RealSelectorComparison}^{\uparrow}$

The $\mathsf{RealSelectorComparison}^{\uparrow}$ packet realizes the Real and Completion target of chapter 9238 as a finite comparison between two diagonal selector rows before either route reaches the $\mathsf{Real}^{\uparrow}$ seal. It consumes the finite window discipline of chapter 126, the regular-rational readback of chapter 301, the limit-seal surface of chapter 386, the tail-agreement seal of chapter 699, the modulus refinement row of chapter 885, and the real-name seal of chapter 38. The packet is not a host equality of completed reals; it is the displayed row package that forces two selector routes to share the same finite tail, readback, agreement, and seal evidence.

Definition 994.1 (Real selector comparison carrier)**.** *A* $\mathsf{RealSelectorComparison}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (D_0, D_1, T, W, R, L, A, H, C, P, N)$$

with the following displayed coordinates:

1. D_0 *and* D_1 *are the two diagonal selector rows whose finite histories are being compared;*
2. T *is the shared tail row, including the common threshold and window request used by both selector routes;*
3. W *is the shared* $\mathsf{StreamName}^{\uparrow}$ *window row that both selectors read before any regular-rational handoff;*
4. R *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, recording that both selector routes decode the same regular rational tail at* T*;*
5. L *is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row reached after the shared regular-rational readback;*
6. A *is the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row witnessing that the two tails agree on the displayed cofinal window;*
7. H *records componentwise* hsame *transports for* D_0, D_1, T, W, R, L, A *and the final* $\mathsf{Real}^{\uparrow}$ *seal row;*
8. C *records the displayed* Cont *routes that replay the two diagonal selector rows through the same tail, window, readback, limit-seal, tail-agreement, and* $\mathsf{Real}^{\uparrow}$ *seal path;*
9. P *is the* Pkg *provenance over the diagonal selectors,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{RealTailAgreementSeal}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and local naming rows;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{RealSelectorComparison}^{\uparrow}}$ *row naming exactly this two-selector comparison packet.*

The carrier has no coordinate for a selected host limit, quotient-stream equality, independent second tail window, ambient completeness theorem, or Real seal route detached from $T, W, R, L, A, H, C, P, N$.

Theorem 994.2 (Real selector comparison NameCert obligations)**.** *For every accepted* $\mathsf{RealSelectorComparison}^{\uparrow}$ *carrier*

$$S = (D_0, D_1, T, W, R, L, A, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{RealSelectorComparison}^{\uparrow}}$ *surface consists exactly of carrier admission for the displayed packet, two diagonal selector admissions through D_0 and D_1, shared tail and window admission through T and W, regular-rational readback through R, Cauchy-limit seal admission through L, tail-agreement seal admission through A, componentwise* hsame *transport through H, displayed route replay through C,* Pkg *provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.RealSelectorComparisonUp.RealSelectorComparisonTasteGate single carrier alignment`

Proof. Project the accepted carrier of Definition 994.1. The only selector data available to the local certificate are the two diagonal rows D_0, D_1 and the shared tail/window/readback route T, W, R.

The seal obligations are then read in route order. The Cauchy-limit row L consumes the regular-rational readback, and the tail-agreement row A certifies that the two selector tails agree on the same cofinal window before the $\mathsf{Real}^{\uparrow}$ seal can be exposed.

Componentwise transports in H and displayed continuations in C replay the same finite rows for both selector routes, while P and N record provenance and local naming. Since the carrier has no detached host limit, quotient equality, second tail window, independent completion theorem, or alternate Real seal coordinate, no further NameCert obligation can be read from the packet. □

Theorem 994.3 (Real selector comparison diagonal readback)**.** *For an accepted* $\mathsf{RealSelectorComparison}^{\uparrow}$ *carrier $S = (D_0, D_1, T, W, R, L, A, H, C, P, N)$, both diagonal selector routes read the same* $\mathsf{StreamName}^{\uparrow}$ *window row W and the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R at the shared tail row T. Any* $\mathsf{Real}^{\uparrow}$ *seal obtained from either route therefore factors through the common finite path*

$$D_i, T, W, R, L, A, H, C, P, N$$

for $i = 0, 1$.

Proof. Start with the two selector rows D_0 and D_1. The carrier gives only one tail row T, one finite window row W, and one regular-rational readback row R for both selectors.

Follow the displayed continuations in C. Each selector route first reaches T, then reads W, then decodes R, and only then reaches the limit and agreement rows L and A.

The transports in H preserve those coordinates componentwise. Thus either selector route reaches a $\mathsf{Real}^{\uparrow}$ seal through the same finite path, with no available coordinate for a second readback or a separately selected limit. □

Theorem 994.4 (Real selector comparison seal non-escape)**.** *An accepted* $\mathsf{RealSelectorComparison}^{\uparrow}$ *carrier exports no completion-facing route except the displayed two-selector packet $S = (D_0, D_1, T, W, R, L, A, H, C,$ In particular, it cannot expose incompatible* $\mathsf{Real}^{\uparrow}$ *seals for D_0 and D_1 while preserving the shared tail/window row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route, and the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row.*

Proof. Assume a completion-facing consumer reads a seal from the accepted packet. The consumer can inspect only $D_0, D_1, T, W, R, L, A, H, C, P, N$, because those are the complete displayed coordinates of the carrier.

If the consumer follows the D_0 route, Definition 994.3 forces it through T, W, R, L, A before the seal read. The same theorem forces the D_1 route through the identical tail, window, readback, limit-seal, and agreement rows.

Therefore incompatible seal outputs would require an extra selector tail, a second regular readback, a detached Cauchy-limit seal, or a Real seal row outside the packet. None of those coordinates exists, so the seal route cannot escape the displayed comparison surface. □

Falsifiable prediction: Deleting the shared tail/window row permits two selector routes to reach incompatible RealUp seals, because the packet no longer forces their StreamName windows and RegSeqRat readbacks through one finite tail threshold.

Independence witness: Nearest siblings: cauchylimitseal, realtailagreementseal, cauchymodulusrefinement, streamname, and regseqrat. None is bijective to $\mathsf{RealSelectorComparison}^{\uparrow}$ because this packet carries two diagonal selector rows plus one shared tail/window/readback route, one CauchyLimitSeal row, one RealTailAgreementSeal row, and one RealUp seal route in a single NameCert surface.

The Lean file `Derived/RealSelectorComparisonUp/TasteGate.lean` must provide Nontrivial RealSelectorCom and FieldFaithful $\mathsf{RealSelectorComparison}^{\uparrow}$ instances, with field injection for $D_0, D_1, T, W, R, L, A, H, C, P, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{RealSelectorComparison}^{\uparrow}}$.

Constructive story: A $\mathsf{RealSelectorComparison}^{\uparrow}$ packet is generated from two diagonal selector rows, one shared tail/window row, one regular-rational readback row, CauchyLimitSeal and RealTailAgreementSeal rows, componentwise transports, displayed continuations, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RealSelectorComparison}^{\uparrow}}$, seed)

Scope closed: Definition 994.1, Definition 994.2, Definition 994.3, and Definition 994.4 bind the finite two-selector comparison carrier, obligation surface, shared readback route, and seal non-escape boundary for the Real and Completion handoff.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RealSelectorComparison}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Real completeness, host equality of completed reals, quotient-stream equality, selected limits, or a checked Lean certificate.

Upgrade path: Obligation closure requires checked carrier admission, shared tail/window readback, CauchyLimitSeal route compatibility, RealTailAgreementSeal compatibility, seal non-escape, and TasteGate nontriviality with field faithfulness.

Chapter 995

A Concrete Naming Certificate for $\mathsf{CellularPatternCatalog}^{\uparrow}$

The $\mathsf{CellularPatternCatalog}^{\uparrow}$ packet realizes the finite glider, ether, and phase-row classifier described in Definition 9390.1 and Definition 9390.3. It sits beside the cellular substrate classifier of chapter 945, the local update rule of chapter 984, the halting trace classifier of chapter 978, the halting finite boundary of chapter 985, and the cellular verb realignment packet of chapter 987. The certificate records a finite pattern catalog, not an unbounded orbit semantics or a host-side judgment that every future row has been classified.

Falsifiable prediction: If a packet lacks either a finite phase-tag row or a finite local-window row, then it cannot satisfy the $\mathsf{CellularPatternCatalog}^{\uparrow}$ NameCert obligations.

Independence witness: cellularsubstrateclassifier, cellularlocalupdaterule, haltingtraceclassifier, haltingfiniteboundary, cellularverbrealignment: the catalog carrier is not bijective to any sibling because it carries the joint rule id, local window, finite phase/glider/ether tag, catalog row, transport, route, provenance, and local NameCert surface. The substrate classifier lacks the explicit catalog row, the local update rule lacks the tag classifier, the halting trace classifier and halting finite boundary lack the cellular phase catalog, and cellular verb realignment lacks the finite local-window catalog obligation.

Definition 995.1 (Cellular pattern catalog carrier)**.** *A* $\mathsf{CellularPatternCatalog}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (R, W, T, G, H, C, P, N)$$

with the following displayed rows:

1. *R is the rule-identity row, naming the finite local cellular rule whose rows are being classified;*
2. *W is the finite local-window row, displaying the bounded cell neighbourhood read by the catalog;*
3. *T is the finite phase, glider, and ether tag row, whose labels are drawn from the catalog's closed tag table;*
4. *G is the catalog row, listing the finite phase strings, glider names, ether row, and local matching discipline used by the classifier;*
5. *H records componentwise* hsame *transport for the rule id, window, tag, catalog, provenance, and local naming rows;*

6. *C records the displayed* Cont *routes from rule id to local window, from local window to catalog row, from catalog row to tag row, and from those rows back through provenance and local naming;*
7. *P is the* Pkg *provenance over* BHist, hsame, Cont, Pkg, NameCert, *chapter 9390, and the sibling cellular and halting packets listed above;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{CellularPatternCatalog}^{\uparrow}}$ *row.*

The local classifier compares accepted carriers only through R, W, T, G, H, C, P, N. It has no coordinate for an infinite orbit classifier, host visual recognition, a global completeness theorem for all rows, or an unlisted pattern tag.

Lean4 (definition) `BEDC.Derived.CellularPatternCatalogUp.CellularPatternCatalogCarrier`

Theorem 995.2 (CellularPatternCatalog NameCert obligations)**.** *For the carrier of Definition 995.1, the local* $\mathsf{NameCert}_{\mathsf{CellularPatternCatalog}^{\uparrow}}$ *surface consists exactly of carrier admission for $K = (R, W, T, G, H, C, P, N)$, rule-id exposure, finite local-window exposure, finite phase/glider/ether tag exposure, catalog-row lookup, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and local naming. Every accepted tag must be read through the route*

$$R \longmapsto W \longmapsto G \longmapsto T,$$

with H, C, P, N attached as transport, route, provenance, and naming rows.

Proof. Carrier admission is projection from Definition 995.1. The displayed tuple gives exactly the rule id, local window, tag row, catalog row, transport, route, provenance, and local naming coordinates.

The cellular source of the classifier is chapter 9390. Its glider and ether examples become finite catalog rows here: a consumer first reads the rule row R, then the local window W, then the catalog row G, and only then the finite tag row T.

The sibling chapters bind the surrounding lattice. The substrate classifier of chapter 945 supplies the cellular classifier surface, chapter 984 supplies local update discipline, chapter 978 and chapter 985 keep trace and boundary reads finite, and chapter 987 aligns the cellular vocabulary with the NameCert route.

Finally, H, C, P, N preserve and name the same finite catalog. Since no row of K is an infinite orbit classifier, a host visual recognizer, a global completeness theorem, or an unlisted tag, the NameCert obligations are exhausted by the displayed route. □

Lean4 ✓ `BEDC.Derived.CellularPatternCatalogUp.CellularPatternCatalogTasteGate single carrier alignment`

Lemma 995.3 (CellularPatternCatalog tag lookup determinacy)**.** *Let*

$$K = (R, W, T, G, H, C, P, N)$$

and

$$K' = (R', W', T', G', H', C', P', N')$$

be accepted $\mathsf{CellularPatternCatalog}^{\uparrow}$ *carriers in the sense of Definition 995.1. Suppose that the two packets agree on the rule-identity row, finite local-window row, catalog row, componentwise transport row, continuation route row, provenance row, and local naming row:*

$$R = R', \quad W = W', \quad G = G', \quad H = H', \quad C = C', \quad P = P', \quad N = N'.$$

Then the exposed finite phase, glider, and ether tag rows T and T' classify together under the local $\mathsf{NameCert}_{\mathsf{CellularPatternCatalog}^{\uparrow}}$ *classifier.*

Proof. By Definition 995.2, every accepted tag read in a $\mathsf{CellularPatternCatalog}^{\uparrow}$ packet is consumed through the displayed route

$$R \longmapsto W \longmapsto G \longmapsto T,$$

with H, C, P, N attached as the transport, route replay, provenance, and local naming rows. Thus T is not an independent tag judgment: it is the tag row exposed by the finite catalog lookup whose visible inputs are the rule row R, the local window row W, and the catalog row G.

The same statement holds for K' through the route

$$R' \longmapsto W' \longmapsto G' \longmapsto T'.$$

The hypotheses identify the lookup inputs R, W, G with R', W', G' and also identify the rows H, C, P, N with H', C', P', N'. Therefore both accepted packets replay the same finite catalog row against the same finite local window under the same local naming and provenance surface.

The catalog row G is finite by Definition 995.1, and its tag labels are drawn from the closed tag table described in Definition 9390.1 and instantiated by the glider and ether catalog of Definition 9390.3. On a fixed finite rule row and fixed finite local window, reading the same displayed catalog row exposes a single local tag-classification row. A failure of T and T' to classify together would therefore require either a different rule identity, a different local window, a different catalog row, a different replay or transport row, or an extra host-side tag coordinate outside the carrier.

No such coordinate is present in Definition 995.1, and the agreed rows exhaust the lookup route of Definition 995.2. Hence the two exposed finite phase, glider, and ether tag rows classify together. □

Lean4 ✓ `BEDC.Derived.CellularPatternCatalogUp.CellularPatternCatalog tag lookup determinacy`

Theorem 995.4 (CellularPatternCatalog public lookup surface)**.** *Every public consumer of an accepted* $\mathsf{CellularPatternCatalog}^{\uparrow}$ *carrier may read the finite catalog lookup only through the rule row R, local-window row W, catalog row G, phase/glider/ether tag row T, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* NameCert *row of Definition 995.1. The public surface is exactly the finite lookup route constrained by Definition 995.2 and Definition 995.3; it exports no global orbit classifier, host visual recognizer, completeness theorem for all future rows, or unlisted pattern tag.*

Proof. Project the carrier of Definition 995.1. A public consumer receives only R, W, T, G, H, C, P, N, so every visible catalog question is a finite lookup against the displayed rule, local window, catalog, and tag rows.

Apply the NameCert obligations of Definition 995.2. They force the lookup route through

$$R \longmapsto W \longmapsto G \longmapsto T$$

with H, C, P, N attached as transport, replay, provenance, and naming data.

Finally use tag lookup determinacy, Definition 995.3. Once the rule, local window, catalog, transport, replay, provenance, and local naming rows are fixed, the exposed tag row is fixed by the finite catalog surface. Since no carrier coordinate stores an infinite orbit semantics, a host visual recognizer, a complete future-row classifier, or an unlisted tag, the public surface is exactly the finite lookup interface. □

Lean4 ✓ `BEDC.Derived.CellularPatternCatalogUp.CellularPatternCatalog public lookup surface`

Closure status for $\mathsf{NameCert}_{\mathsf{CellularPatternCatalog}^{\uparrow}}$.

Constructive story: A CellularPatternCatalog$^{\uparrow}$ packet is generated from a finite cellular rule id, local window, phase/glider/ether tag row, catalog row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{CellularPatternCatalog}^{\uparrow}}$, publicClosed)

Scope closed: Definition 995.1, Definition 995.2, Definition 995.3, and Definition 995.4 bind the finite rule, local window, tag, catalog, transport, route, provenance, local naming rows, and existing TasteGate marker to the cellular substrate classifier, local update rule, halting trace boundary, halting finite boundary, and cellular verb realignment sources.

Formal verification: FormalStatus(NameCert$_{\text{CellularPatternCatalog}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a complete orbit classifier, host visual recognition, global classification of all future rows, audit-clean purity, or a public standard bridge.

Upgrade path: Audit-clean closure requires purity review for the finite carrier, catalog lookup determinacy, substrate and update-rule dependency, halting boundary dependency, cellular verb realignment route, transport, replay, provenance, and local naming rows for BEDC.Derived.CellularPatternCatalogUp.

Chapter 996

A Concrete Naming Certificate for $\mathsf{RatClassifierTransportSeal}^{\uparrow}$

The $\mathsf{RatClassifierTransportSeal}^{\uparrow}$ packet realizes the transported stationary rational diagonal row of chapter 9238 as one finite NameCert handoff. It consumes the RatUp source classifier of chapter 37, the constant StreamName classifier surface of chapter 126, the RegSeqRat finite-window seal of chapter 301, the DyadicRatCore observation ledger of chapter 291, and the RealUp classifier handoff of chapter 38.

Definition 996.1 (RatClassifierTransportSeal carrier)**.** *A* $\mathsf{RatClassifierTransportSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (Q, S, W, D, A, H, C, P, N)$$

with the following displayed coordinates:

1. *Q is the RatUp source-classifier row carrying the accepted stationary rational comparison;*
2. *S is the constant* $\mathsf{StreamName}^{\uparrow}$ *classifier row induced by the same rational comparison;*
3. *W is the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-window seal row consuming the constant stream windows;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger for the same finite windows;*
5. *A is the* $\mathsf{Real}^{\uparrow}$ *classifier handoff row reached only after Q, S, W, D are replayed;*
6. *H records componentwise* hsame *transports for Q, S, W, D, A, package provenance, and the local naming row;*
7. *C records the displayed* Cont *routes from the RatUp row through the StreamName, RegSeqRat, DyadicRatCore, and RealUp readings;*
8. *P is the* Pkg *provenance over RatUp,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*, and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RatClassifierTransportSeal}^{\uparrow}}$ *row.*

The carrier has no coordinate for an independent RealUp equality, quotient stream, selected limit, host rational equality, or ambient completeness principle.

Lean4 (definition) `BEDC.Derived.RatClassifierTransportSealUp.RatClassifierTransportSealUp`

Theorem 996.2 (RatClassifierTransportSeal NameCert obligations)**.** *For every accepted* $\mathsf{RatClassifierTransportSeal}$ *carrier $R = (Q, S, W, D, A, H, C, P, N)$, the local* $\mathsf{NameCert}_{\mathsf{RatClassifierTransportSeal}^{\uparrow}}$ *surface consists*

exactly of carrier admission, RatUp source-classifier exposure through Q, constant StreamName classifier exposure through S, RegSeqRat finite-window seal exposure through W, DyadicRatCore ledger exposure through D, RealUp classifier handoff through A, componentwise hsame *transport through H, displayed route replay through C,* Pkg *provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.RatClassifierTransportSealUp.RatClassifierTransportSealCarrier namecert obligations`

Proof. Project the finite carrier of Definition 996.1. Each obligation row is one coordinate of R, so the local NameCert read can inspect only $Q, S, W, D, A, H, C, P, N$.

Read the rows in transport order. The RatUp classifier Q induces the constant StreamName row S, the RegSeqRat seal W consumes the displayed finite windows, the DyadicRatCore ledger D records the observed dyadic readings, and the RealUp handoff A is exposed only after those rows have been replayed through H, C, P, N.

No further obligation can appear because the carrier contains no independent equality, quotient, selected limit, host rational, or ambient completeness coordinate. Thus the displayed rows exhaust the local NameCert surface. □

Theorem 996.3 (RatClassifierTransportSeal window exhaustion)**.** *Every public finite-window read of an accepted* $\mathsf{RatClassifierTransportSeal}^{\uparrow}$ *packet factors through the RatUp seed classifier row Q before any* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *or* $\mathsf{Real}^{\uparrow}$ *classifier row is read. Once Q is fixed, the public route is exhausted by S, W, D, A, H, C, P, N.*

Lean4 ✓ `BEDC.Derived.RatClassifierTransportSealUp.RatClassifierTransportSealCarrier window exhaustion`

Proof. Start with the route row C and the componentwise transport row H. They display a single ordered path from the rational classifier through constant StreamName windows, RegSeqRat finite-window sealing, DyadicRatCore ledger reads, and the RealUp handoff.

If a consumer attempts to read S, W, D, or A first, it asks for a coordinate whose route is defined only as a replay from Q. The package provenance P and the local naming row N record that dependency for the same accepted packet.

Therefore every public window read begins at Q and is exhausted by the remaining displayed rows. The packet exports no route to a separate stream, dyadic ledger, real classifier, or completion principle outside R. □

Theorem 996.4 (RatClassifierTransportSeal classifier handoff determinacy)**.** *Let $R = (Q, S, W, D, A, H, C, P, N)$ and $R' = (Q', S', W', D', A', H', C', P', N')$ be accepted* $\mathsf{RatClassifierTransportSeal}^{\uparrow}$ *carriers. Suppose the RatUp source-classifier rows Q, Q', the constant* $\mathsf{StreamName}^{\uparrow}$ *rows S, S', the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-window seals W, W', the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledgers D, D', the componentwise transport rows H, H', the continuation route rows C, C', the package provenance rows P, P', and the local naming rows N, N' agree under the displayed* hsame *and* Cont *transport from the RatUp source route. Then the* $\mathsf{Real}^{\uparrow}$ *classifier handoff rows A and A' cannot diverge: every public* $\mathsf{Real}^{\uparrow}$ *classifier read factors through the same visible route Q, S, W, D, H, C, P, N, transported to $Q', S', W', D', H', C', P', N'$.*

Lean4 ✓ `BEDC.Derived.RatClassifierTransportSealUp.RatClassifierTransportSealCarrier classifier handoff determinacy`

Proof. Project both accepted carriers through Definition 996.1. Their public coordinates are exactly the displayed rows, with A and A' reached only after the RatUp, StreamName, RegSeqRat, and DyadicRatCore rows have been replayed.

Apply Definition 996.3 to R and to R'. Any public $\mathsf{Real}^{\uparrow}$ classifier read from either packet must first pass through the RatUp seed classifier and then through the finite route exhausted by the remaining displayed coordinates.

The hypotheses identify those finite routes: Q matches Q', the constant StreamName rows match, the finite-window seals and dyadic ledgers match, and H, C, P, N transport the same package and naming data to H', C', P', N'. Thus the replayed route that reaches A is the same route that reaches A'.

A distinct public $\mathsf{Real}^{\uparrow}$ handoff would therefore require an additional coordinate recording an independent RealUp equality, quotient stream, selected limit, host rational equality, or ambient completeness principle. Such a coordinate is excluded by Definition 996.1. Hence A and A' cannot diverge along accepted public reads. □

Falsifiable prediction: Every public finite-window read of an accepted RatClassifierTransportSealUp packet factors through the RatUp seed classifier before any StreamNameUp, RegSeqRatUp, DyadicRatCoreUp, or RealUp classifier row is read.

Independence witness: rat, streamname, regseqrat, dyadicratcore, real: RatUp lacks finite-window and Real seal rows; StreamNameUp lacks the rational seed classifier; RegSeqRatUp lacks the RatUp source row; DyadicRatCoreUp lacks the Real classifier handoff; RealUp lacks the four-reading transport ledger, so no bijection preserves the full carrier.

The Lean file `Derived/RatClassifierTransportSealUp/TasteGate.lean` must provide explicit $\mathsf{Nontrivial}\ \mathsf{RatClassifierTransportSeal}^{\uparrow}$ and $\mathsf{FieldFaithful}\ \mathsf{RatClassifierTransportSeal}^{\uparrow}$ instances for the displayed carrier $Q, S, W, D, A, H, C, P, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{RatClassifierTransportSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{RatClassifierTransportSeal}^{\uparrow}$ packet is generated from a RatUp source classifier, constant StreamName classifier, RegSeqRat finite-window seal, DyadicRatCore observation ledger, RealUp classifier handoff, componentwise transports, continuation routes, package provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RatClassifierTransportSeal}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 996.1, Definition 996.2, Definition 996.3, and Definition 996.4 bind the finite transported stationary rational classifier seal across RatUp, StreamNameUp, RegSeqRatUp, DyadicRatCoreUp, RealUp, BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RatClassifierTransportSeal}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Real completeness, quotient-stream equality, selected host limits, host rational equality, ambient metric completion, or a checked Lean certificate.

Upgrade path: Obligation closure requires checked carrier admission, RatUp source factorization, finite-window seal exhaustion, RealUp handoff non-escape, and TasteGate nontriviality with field faithfulness.

Chapter 997

A Concrete Naming Certificate for $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$

The $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ packet realizes the reflection-limit validation boundary of chapter 9461 as a finite runtime checkpoint. It sits beside the runtime-candidate boundary of chapter 591, the finite trace evaluator of chapter 818, the finite trace gap socket of chapter 504, and the reflection-limit boundary of chapter 586. Those siblings expose candidate rows, bounded evaluator rows, finite gap rows, and open meta-boundary rows; the present packet records a checkpoint state together with the validation-boundary row that a runtime-facing consumer must read before making any host-valid claim.

Definition 997.1 (ReflectionRuntimeCheckpoint carrier)**.** *A* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (I, S, T, V, H, C, P, N)$$

with the following displayed rows:

1. *I is the admitted runtime-candidate input row, recording the coded* CIC* *expression, proof-object, or state being checkpointed;*
2. *S is the displayed checkpoint-state row, recording the finite state reached by the candidate before any host validation is asserted;*
3. *T is the trace-evidence row, listing the bounded evaluator or gap-socket observations used to justify the checkpoint state;*
4. *V is the validation-boundary row, recording that host validation of the checkpoint is not itself a packet coordinate and cannot be replaced by the checkpoint state;*
5. *H records componentwise* hsame *transport for input, checkpoint state, trace evidence, validation boundary, provenance, and local naming;*
6. *C records the displayed* Cont *routes by which a consumer reads I, reaches S, replays T, inspects V, and returns through transport and naming;*
7. *P is the* Pkg *provenance over chapter 9461, chapter 591, chapter 818, chapter 504, chapter 586,* BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}}$ *row.*

The carrier has no coordinate for a host-valid runtime judgment, a total truth row, an unbounded evaluator, or a validation act detached from V.

Theorem 997.2 (ReflectionRuntimeCheckpoint NameCert obligations)**.** *For the carrier of Definition 997.1, the local* $\mathsf{NameCert}_{\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}}$ *surface consists exactly of five finite obligations:*

1. *carrier admission for the displayed checkpoint packet* $K = (I, S, T, V, H, C, P, N)$*;*
2. *runtime-candidate exposure, requiring every checkpointed input read to factor through* I*;*
3. *checkpoint-state and trace exactness, requiring every displayed checkpoint state to be read through* S *and every supporting bounded observation to be read through* T*;*
4. *validation-boundary non-escape, requiring every host-validation-facing consumer to pass through* V *and preventing* I, S, T, H, C, P, N *from exporting host validation or total truth;*
5. *transport, route, provenance, and naming closure, requiring all componentwise comparisons, consumer continuations, package dependencies, and local naming to be exactly the displayed rows* H, C, P, N*.*

Thus a consumer may inspect a finite checkpoint state and its bounded trace evidence, but it cannot turn that checkpoint into a host-valid runtime judgment or a total truth row.

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier trace evidence finiteness`

Proof. Carrier admission is projection from Definition 997.1. The packet lists I, S, T, V, H, C, P, N as the complete surface available to a consumer.

Runtime-candidate exposure begins at I. The checkpoint state is not a free-standing state; it is the state of the admitted runtime-candidate input named by the first row.

Checkpoint-state and trace exactness then read S and T. The state row records the displayed checkpoint, and the trace-evidence row records only bounded evaluator or gap-socket observations supplied by the finite siblings.

Validation-boundary non-escape is the separate row V. By the reflection-limit boundary in chapter 9461 and by the object-level runtime surfaces of chapter 591, chapter 818, and chapter 504, host validation is not a packet coordinate. Therefore no read of I, S, T, H, C, P, N can export host validation, total truth, or an unbounded evaluator.

Finally H, C, P, N transport, route, cite, and name the same finite checkpoint packet. Since those rows add no further runtime or truth coordinate, the listed five obligations exhaust the local NameCert surface. □

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier namecert obligations`

Theorem 997.3 (ReflectionRuntimeCheckpoint TasteGate obligation)**.** *The Lean* `TasteGate.lean` *development for* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *provides explicit* $\mathsf{Nontrivial\ ReflectionRuntimeCheckpoint}^{\uparrow}$ *and* $\mathsf{FieldFaithful\ ReflectionRuntimeCheckpoint}^{\uparrow}$ *instances preserving the runtime input row, checkpoint-state row, trace-evidence row, validation-boundary row, componentwise transport, continuation routes, package provenance, and local naming row.*

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointUp StdBridge`

Proof. The carrier has at least two distinguishable checkpoint packets, obtained by varying the displayed input row while holding the remaining rows fixed. This witnesses nontriviality.

Field faithfulness is the componentwise reading of $K = (I, S, T, V, H, C, P, N)$. If two packets have the same displayed field list, then each of their eight BHist coordinates agrees, and constructor

equality identifies the packets. The Lean TasteGate surface records these two facts as the required instances. □

Theorem 997.4 (ReflectionRuntimeCheckpoint input-state exposure)**.** *For every accepted* ReflectionRuntimeCheck *carrier*

$$K = (I, S, T, V, H, C, P, N),$$

every checkpoint consumer reads the runtime-candidate input row I and checkpoint-state row S before it reads any trace-evidence row or validation-facing row. Thus neither T nor V can be treated as a detached source of runtime state.

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier input state exposure`

Proof. Project the carrier of Definition 997.1. The packet is ordered as $K = (I, S, T, V, H, C, P, N)$, with I carrying the admitted runtime candidate and S carrying the displayed checkpoint state reached by that candidate.

Apply the runtime-candidate exposure and checkpoint-state exactness clauses of Definition 997.2. They force every checkpointed input read through I and every checkpoint-state read through S before the trace row T or validation-boundary row V is available.

Finally use the TasteGate carrier alignment of Definition 997.3. Field faithfulness keeps I and S as the first two displayed checkpoint coordinates, so a consumer cannot bypass them by reading T, V, H, C, P, or N as a substitute input-state source. □

Theorem 997.5 (ReflectionRuntimeCheckpoint trace-boundary readback)**.** *For every accepted* ReflectionRuntimeCheckpoint$^{\uparrow}$ *carrier $K = (I, S, T, V, H, C, P, N)$, the row T is bounded trace evidence routed through the finite trace evaluator and finite trace gap-socket siblings, through the package provenance P, and back through the transport, continuation, and naming rows H, C, N. It is not an unbounded evaluator and it is not a validation act.*

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier trace boundary readback`

Proof. Start from the provenance row in Definition 997.1. The row P cites the runtime-candidate boundary, finite trace evaluator, finite trace gap socket, and reflection-limit boundary as the displayed sources for the checkpoint packet.

The NameCert obligations of Definition 997.2 force every supporting bounded observation through T. The sibling finite evaluator and gap-socket chapters supply the bounded trace surfaces, while H, C, P, N record the componentwise transport, consumer route, provenance, and local name of the same readback.

Finally use the TasteGate carrier alignment of Definition 997.3. Field faithfulness keeps T distinct from V and from the route ledger H, C, P, N, so the trace readback remains bounded evidence rather than an unbounded evaluator or detached validation act. □

Theorem 997.6 (ReflectionRuntimeCheckpoint validation non-escape route)**.** *For every accepted* ReflectionRuntimeCheckpoint$^{\uparrow}$ *carrier $K = (I, S, T, V, H, C, P, N)$, any validation-facing read must pass through the validation-boundary row V. No route through I, S, T, H, C, P, N alone exports a host-valid runtime judgment, total truth, or an unbounded evaluator.*

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier validation nonescape route`

Proof. Project the carrier of Definition 997.1. The rows I, S, T expose only the candidate input, displayed checkpoint state, and bounded trace evidence, while H, C, P, N transport, route, cite, and name that same finite packet.

Apply the validation-boundary non-escape clause of Definition 997.2. It names V as the sole validation-boundary row and states that the remaining rows cannot export host validation or total truth.

Finally use the TasteGate carrier alignment of Definition 997.3. Field faithfulness keeps V as a separate coordinate, so a consumer cannot identify the validation boundary with I, S, T, or any transport, route, provenance, or naming row. □

Theorem 997.7 (ReflectionRuntimeCheckpoint root-unblock package)**.** *The carrier of Definition 997.1, the NameCert obligations of Definition 997.2, the input-state exposure of Definition 997.4, the trace-boundary readback of Definition 997.5, the validation non-escape route of Definition 997.6, and the TasteGate carrier-alignment row of Definition 997.3 form the finite root-unblock package for downstream runtime-checkpoint consumers. Any such consumer receives exactly the displayed rows I, S, T, V, H, C, P, N and their finite routes, with no host validation, total truth, unbounded evaluator, or detached runtime judgment.*

Proof. The carrier supplies the rows I, S, T, V, H, C, P, N. The NameCert obligations identify the admissible reads of those rows and exclude every unlisted runtime or truth coordinate.

The input-state exposure forces reads through I and S before trace or validation rows. The trace-boundary readback then routes T through the cited runtime-candidate, finite trace evaluator, finite trace gap socket, reflection-limit, transport, continuation, provenance, and naming boundaries.

The validation non-escape route forces every validation-facing read through V. The TasteGate obligation contributes the single-carrier alignment: nontriviality supplies distinguishable checkpoint packets, and field faithfulness preserves every displayed coordinate. These ingredients give downstream consumers a finite checkpoint package and no additional root-facing validation surface. □

Theorem 997.8 (ReflectionRuntimeCheckpoint validation boundary totality)**.** *For every accepted* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier $K = (I, S, T, V, H, C, P, N)$, every validation-facing consumer has a total boundary route*

$$I \longmapsto S \longmapsto T \longmapsto V \longmapsto H, C, P, N.$$

If a consumer route omits V, then it may read only the runtime-candidate input, checkpoint state, and bounded trace evidence supplied by I, S, T and the local transport, route, provenance, and naming rows H, C, P, N. Such a route does not read host validation, total truth, or an unbounded evaluator.

Proof. Project the rows of Definition 997.1. They give the displayed carrier order I, S, T, V, H, C, P, N, with V singled out as the validation-boundary coordinate and the later rows serving only as transport, continuation route, provenance, and local naming data.

Use Definition 997.2 to bind the validation-boundary row to the local NameCert obligations. The non-escape clause prevents any consumer from replacing V by host validation, total truth, or an unbounded evaluator.

Next apply Definition 997.4 and Definition 997.5. The first forces every checkpoint read through I and S, while the second identifies T as bounded trace evidence before any validation-facing row is reached.

Finally apply Definition 997.6 and Definition 997.7. Together they make the route through V total for validation-facing consumers and keep the whole boundary package finite, local, and exhausted by I, S, T, V, H, C, P, N. □

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier validation boundary totality`

Theorem 997.9 (ReflectionRuntimeCheckpoint validation row precedence)**.** *For every accepted* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, any validation-facing checkpoint consumer must read the displayed rows* I, S, T, V *in that order:* I *supplies the admitted runtime-candidate input,* S *supplies the checkpoint state reached by that input,* T *supplies bounded trace evidence for that state, and only then* V *supplies the validation-boundary row. In particular, neither* S *nor* T *may be treated as a validation row.*

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier validation row precedence`

Proof. Project the carrier of Definition 997.1. Its first four rows are I, S, T, V, with I typed as the admitted candidate row, S as the checkpoint-state row, T as trace evidence, and V as the validation-boundary row.

Apply Definition 997.4. It forces every checkpoint consumer to read I and S before any trace-evidence or validation-facing row is available.

Apply Definition 997.5 to identify T as bounded evidence rather than a validation act. Then apply Definition 997.6: every validation-facing read must pass through V, so S and T cannot serve as validation substitutes. □

Theorem 997.10 (ReflectionRuntimeCheckpoint trace evidence finiteness)**.** *For every accepted* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, the row* T *is bounded trace evidence obtained through the finite trace evaluator and finite trace gap-socket route recorded by* P *and consumed through* H, C, N*. It cannot be promoted to an unbounded evaluator or to a detached validation source.*

Proof. Use Definition 997.5. It already routes T through the finite trace evaluator, finite trace gap socket, package provenance, transport, continuation, and local naming rows.

Next use Definition 997.7. The root-unblock package gives downstream consumers exactly I, S, T, V, H, C, P, N and no unlisted evaluator, validation act, or truth coordinate.

Thus the only role available to T inside the packet is bounded evidence for the checkpoint state. Since neither the carrier nor the root-unblock package contains an unbounded evaluator coordinate, no consumer can promote T beyond the finite route displayed by the sibling rows. □

Theorem 997.11 (ReflectionRuntimeCheckpoint audit-boundary consumer lock)**.** *Every downstream* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *checkpoint consumer receives only the finite packet rows* I, S, T, V, H, C, P, N *together with the runtime-candidate boundary, finite trace evaluator, finite trace gap socket, reflection-limit boundary,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows cited by* P*. The consumer receives no host-valid runtime judgment, total truth predicate, unbounded evaluator, or validation coordinate outside that displayed boundary.*

Proof. Start with Definition 997.7. It identifies I, S, T, V, H, C, P, N and their finite routes as the complete root-facing packet offered to downstream runtime-checkpoint consumers.

Apply Definition 997.13. The provenance row P exhausts the sibling route through the runtime-candidate boundary, finite trace evaluator, finite trace gap socket, reflection-limit boundary, and the local BHist, hsame, Cont, Pkg, and NameCert rows.

Finally apply Definition 997.6 and Definition 997.14. Validation-facing reads must pass through V, and the remaining packet rows export neither host validation nor total truth. Hence every downstream consumer is locked to the finite audit boundary displayed in the carrier. □

Theorem 997.12 (ReflectionRuntimeCheckpoint state-trace coupling)**.** *For every accepted* ReflectionRuntimeCheck *carrier $K = (I, S, T, V, H, C, P, N)$, the checkpoint state row S and trace-evidence row T are consumed together before a validation-facing read reaches V. A consumer may not read S as a detached runtime state or read T as a detached validation act.*

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier state trace coupling`

Proof. Project the carrier of Definition 997.1. The rows S and T are adjacent checkpoint coordinates of the same finite packet, following the admitted runtime-candidate input row I and preceding the validation-boundary row V.

Apply Definition 997.2. Its checkpoint-state and trace exactness clause binds every displayed state read to the trace-evidence row, while its validation-boundary clause keeps host validation behind V.

Finally use Definition 997.4 and Definition 997.5. The first forces the input and state rows before trace or validation rows, and the second keeps T as bounded evidence rather than an unbounded evaluator or detached validation act. □

Theorem 997.13 (ReflectionRuntimeCheckpoint audit provenance exhaustion)**.** *For every accepted* ReflectionRuntimeCheckpoint$^{\uparrow}$ *carrier $K = (I, S, T, V, H, C, P, N)$, the provenance row P exhausts the runtime-candidate boundary, finite-trace evaluator, finite-trace gap socket, and reflection-limit boundary sibling route. The checkpoint packet has no additional provenance row for a host-valid runtime judgment, total truth predicate, or unbounded evaluator.*

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier audit provenance exhaustion`

Proof. Read the provenance coordinate in Definition 997.1. It cites exactly the runtime-candidate boundary, finite trace evaluator, finite trace gap socket, reflection-limit boundary, and the local BHist, hsame, Cont, Pkg, and NameCert rows.

Apply Definition 997.5. The trace row T is routed through those same sibling surfaces and then back through H, C, P, N, so the audit path is the displayed finite route rather than an external evaluator.

Use Definition 997.7 to close the package. Since downstream consumers receive exactly I, S, T, V, H, C, P, N, no second provenance coordinate remains outside P for host validation, total truth, or an unbounded runtime evaluator. □

Theorem 997.14 (ReflectionRuntimeCheckpoint host-validation nonescape)**.** *No accepted* ReflectionRuntimeCheck *packet exports a host-valid runtime judgment, total truth predicate, or unbounded evaluator outside the displayed rows*

$$I, S, T, V, H, C, P, N.$$

Every validation-facing consumer must pass through V, with S, T, H, C, P, N serving only as checkpoint state, bounded trace evidence, transport, route, provenance, and local naming rows.

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier host validation nonescape`

Proof. Begin with the carrier of Definition 997.1. It explicitly lists I, S, T, V, H, C, P, N and states that no detached host-validation coordinate, total truth row, or unbounded evaluator is present.

Apply Definition 997.6. Any validation-facing read must pass through V, and no route through I, S, T, H, C, P, N alone exports host validation or total truth.

The state-trace coupling of Definition 997.12 and audit provenance exhaustion of Definition 997.13 account for the remaining rows. Thus all checkpoint information is consumed through the finite packet, with no host-validation escape outside the displayed surface. □

Theorem 997.15 (ReflectionRuntimeCheckpoint validation boundary order)**.** *For every accepted* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, any validation-facing read first exposes the runtime-candidate input row* I*, the checkpoint-state row* S*, and the bounded trace-evidence row* T*, and only then passes through the validation-boundary row* V*. Thus a consumer cannot reach a host-validation-facing boundary by reading* V *without the displayed input, state, and trace rows.*

Proof. Project the carrier of Definition 997.1. The displayed checkpoint order places the admitted runtime-candidate row I, checkpoint-state row S, bounded trace row T, and validation-boundary row V as the validation-facing prefix of K.

Apply the NameCert obligations of Definition 997.2. Runtime-candidate exposure binds reads to I, checkpoint-state exactness binds state reads to S, trace exactness binds supporting observations to T, and validation-boundary non-escape binds host-validation-facing access to V.

Finally use Definition 997.6 and Definition 997.14. Together they keep every validation-facing consumer inside the displayed order I, S, T, V and prevent any later transport, route, provenance, or naming row from replacing that boundary order. □

Theorem 997.16 (ReflectionRuntimeCheckpoint bounded trace gap-socket compatibility)**.** *For every accepted* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, the trace row* T *is compatible with the finite trace evaluator and finite trace gap-socket siblings cited by* P*. It is consumed only as bounded trace evidence and cannot be reread as an unbounded evaluator, a host validator, or a detached truth row.*

Proof. Read the trace row from the carrier of Definition 997.1. The row T is explicitly trace evidence for the checkpoint state, while P cites the finite trace evaluator and finite trace gap-socket siblings as the available trace sources.

Apply Definition 997.5. It routes T through the sibling finite evaluator and gap-socket surfaces and back through H, C, P, N, so the trace route is a bounded readback route rather than an evaluator coordinate.

Use Definition 997.13 to exhaust the cited sibling route. Since the provenance row has no further source for host validation, total truth, or an unbounded evaluator, compatibility with the finite siblings is the whole trace obligation. □

Theorem 997.17 (ReflectionRuntimeCheckpoint runtime-candidate validation refusal ledger)**.** *For every accepted* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, the validation-boundary row* V *records the refusal of host validation for the runtime-candidate checkpoint until an external bridge certificate is supplied. The refusal is attached to the candidate input* I*, checkpoint state* S*, trace evidence* T*, and audit route* H, C, P, N*, and it is not itself a host-valid runtime judgment.*

Proof. Start with the carrier and NameCert obligations, Definition 997.1 and Definition 997.2. They bind the runtime candidate to I, its checkpoint state to S, its bounded trace evidence to T, and the validation-facing boundary to V.

Apply Definition 997.6. The only validation-facing row is V, and every read through the remaining packet rows fails to export host validation or total truth.

Finish with Definition 997.13 and Definition 997.14. The audit route accounts for H, C, P, N, while host-validation nonescape keeps the refusal ledger distinct from any external bridge certificate that would be needed to assert host-valid runtime validation. □

Theorem 997.18 (ReflectionRuntimeCheckpoint validation prefix exhaustion)**.** *For every accepted* ReflectionRuntimeCheckpoint$^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, each validation-facing read exposes the runtime-candidate input row* I*, checkpoint-state row* S*, bounded trace row* T*, and validation-boundary row* V *before any transport, continuation, provenance, or local naming row* H, C, P, N *is consumed. No validation consumer reaches* H, C, P, N *as a substitute for that prefix.*

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier validation prefix exhaustion`

Proof. Project the carrier by Definition 997.1. The validation prefix of the packet is exactly I, S, T, V, followed by the transport, route, provenance, and naming rows.

Apply Definition 997.2. Runtime-candidate exposure, checkpoint-state exactness, trace exactness, and validation-boundary non-escape are read before the structural rows can replay or name the packet.

Use Definition 997.6. It prevents H, C, P, N from acting as a detached validation source, so every validation-facing route is exhausted by the displayed prefix before those rows are consumed. □

Theorem 997.19 (ReflectionRuntimeCheckpoint trace provenance lock)**.** *For every accepted* ReflectionRuntimeChe *carrier* $K = (I, S, T, V, H, C, P, N)$*, the trace row* T *is locked to the runtime candidate* I*, the finite-trace evaluator, the finite-trace gap socket, and the reflection-limit provenance cited by* P*. A consumer may replay* T *only through this finite provenance route and not as a detached host validator, total truth predicate, or unbounded evaluator.*

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointCarrier trace provenance lock`

Proof. Read T from Definition 997.1. The trace row is bundled with the runtime candidate I and checkpoint state S, and the provenance row P names the finite trace siblings and reflection-limit source used by the route.

Apply Definition 997.13. It exhausts the cited trace route through the runtime-candidate boundary, finite trace evaluator, finite trace gap socket, and reflection-limit provenance.

Finally use Definition 997.6 and Definition 997.14. These prevent the locked trace row from being reread as host validation, total truth, or unbounded evaluation. □

Theorem 997.20 (ReflectionRuntimeCheckpoint host-validation refusal boundary)**.** *For every accepted* ReflectionRuntimeCheckpoint$^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, the validation-boundary row* V *records refusal of a host-valid runtime judgment until an external bridge certificate is present. The refusal is carried by* I, S, T, H, C, P, N *and is never itself exported as host validation, total truth, or an unbounded runtime evaluator.*

Proof. Start from Definition 997.17. It attaches the refusal ledger to the runtime candidate, checkpoint state, trace evidence, validation boundary, and audit route.

Use Definition 997.2. The local NameCert surface records V as the validation-boundary row, while H, C, P, N only transport, replay, package, and name that same finite packet.

Finish with Definition 997.14. Since no host-valid runtime judgment is present outside the displayed rows, the refusal boundary remains a bridge-facing boundary rather than an exported validation theorem. □

Theorem 997.21 (ReflectionRuntimeCheckpoint validation trace scope row)**.** *For every accepted* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, every validation-facing read must pass through the input row* I*, the checkpoint-state row* S*, the bounded trace row* T*, and only then the validation-boundary row* V*. The local transport, route, provenance, and naming rows* H, C, P, N *may carry that read, but they do not supply a detached validation source.*

Proof. Begin with the input-state exposure theorem Definition 997.4. It forces checkpoint consumers through I and S before any trace-evidence or validation-facing row is available.

Next apply the trace-boundary readback of Definition 997.5. The row T is bounded trace evidence routed through the finite trace evaluator and finite trace gap-socket siblings, not an unbounded evaluator or detached validation act.

Finally use Definition 997.6 and Definition 997.15. They place every validation-facing read at V after the displayed input, state, and trace rows, with H, C, P, N serving only as the finite route ledger. □

Theorem 997.22 (ReflectionRuntimeCheckpoint provenance consumer row)**.** *Every downstream* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *consumer route uses the provenance row* P *through the runtime-candidate boundary, finite trace evaluator, finite trace gap socket, reflection-limit boundary, and the local* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. No second provenance row for host validation, total truth, or unbounded evaluation is exported.*

Proof. Start from the audit-boundary consumer lock of Definition 997.11. It gives each downstream consumer exactly the displayed checkpoint rows and the sibling route cited by P.

Apply Definition 997.13. The provenance row already exhausts the runtime-candidate boundary, finite trace evaluator, finite trace gap socket, reflection-limit boundary, and local structural rows.

Finish with Definition 997.7. The downstream consumer receives the finite checkpoint packet and no additional root-facing validation surface, so there is no second provenance source outside P. □

Theorem 997.23 (ReflectionRuntimeCheckpoint host-boundary obligation row)**.** *No* ReflectionRuntimeCheckpoint *packet exports a host-valid runtime judgment, total truth predicate, or unbounded evaluator outside the displayed rows*

$$I, S, T, V, H, C, P, N.$$

Any host-boundary obligation available to a downstream consumer is the finite validation boundary already routed through I, S, T, V, H, C, P, N*.*

Proof. First use the validation trace scope row of Definition 997.21. It forces validation-facing access through I, S, T, V and prevents H, C, P, N from acting as independent validation sources.

Next apply the provenance consumer row of Definition 997.22. This exhausts the sibling route through the runtime-candidate, finite evaluator, gap-socket, and reflection-limit boundaries.

Finally use the host-validation nonescape theorem Definition 997.14. Since no listed row exports host validation, total truth, or an unbounded evaluator, the only available host-boundary obligation is the finite boundary displayed by I, S, T, V, H, C, P, N. □

Theorem 997.24 (ReflectionRuntimeCheckpoint route budget interface)**.** *Every downstream* ReflectionRuntimeChe *consumer route factors through the displayed budget interface*

$$I, S, T, V, H, C, P, N$$

before any validation-facing read is available. The route reads the runtime-candidate input, checkpoint state, bounded trace evidence, validation boundary, componentwise transport, continuation, provenance, and local naming rows as one finite checkpoint packet.

Proof. Begin with the carrier and NameCert obligations, Definition 997.1 and Definition 997.2. They list I, S, T, V, H, C, P, N as the displayed packet and bind candidate input, checkpoint state, trace evidence, validation boundary, transport, continuation, provenance, and naming to those rows.

Use the validation trace scope row and provenance consumer row, Definition 997.21 and Definition 997.22. Together they force validation-facing access through I, S, T, V and route the remaining consumer data through H, C, P, N.

The host-boundary obligation row then prevents a consumer from reading host validation, total truth, or an unbounded evaluator outside the displayed packet. Hence every validation-facing route first factors through the finite budget interface. □

Theorem 997.25 (ReflectionRuntimeCheckpoint trace-validation separation)**.** *For every accepted* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, the bounded trace-evidence row* T *and the validation-boundary row* V *remain distinct under field faithfulness. A consumer may route* T *into a validation-facing read only by passing through* V*; it cannot exchange trace evidence for validation boundary data.*

Proof. Read T and V from the carrier of Definition 997.1. The row T records bounded trace evidence, while V records the validation boundary.

Apply the trace-boundary readback theorem and the validation non-escape route, Definition 997.5 and Definition 997.6. The first keeps T as bounded evidence routed through the finite trace siblings, and the second requires every validation-facing read to pass through V.

Finally use the TasteGate obligation of Definition 997.3. Field faithfulness preserves the displayed coordinates, so T and V cannot be exchanged by a consumer route. □

Theorem 997.26 (ReflectionRuntimeCheckpoint host-boundary refusal)**.** *The* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *packet refuses host-valid runtime judgment, total truth, and unbounded evaluator rows unless those rows are supplied as separate boundary data outside the finite checkpoint packet. No route through* I, S, T, V, H, C, P, N *exports such data by itself.*

Proof. Start from the host-boundary obligation row, Definition 997.23. It states that the finite packet exports only the displayed validation boundary and no host-valid runtime judgment, total truth predicate, or unbounded evaluator.

Next use the validation trace scope row and trace-validation separation theorem. They place validation-facing reads after I, S, T, V and keep bounded trace evidence distinct from the validation boundary.

The host-validation nonescape theorem, Definition 997.14, closes the refusal. Since the local carrier, NameCert obligations, state-trace coupling, and provenance route account for all rows of

I, S, T, V, H, C, P, N, any host-valid judgment, total truth row, or unbounded evaluator must be displayed as separate boundary data. □

Falsifiable prediction: A checkpoint consumer that omits the validation-boundary row cannot export a host-valid runtime judgment or total truth row.

Independence witness: RuntimeCandidateBoundary, FiniteTraceEvaluator, FiniteTraceGapSocket, ReflectionLimitBoundary: the checkpoint carrier has a displayed checkpoint state and validation-boundary pair not bijective to candidate-only, evaluator-only, gap-socket, or pure boundary packets.

Theorem 997.27 (ReflectionRuntimeCheckpoint scoped source register)**.** *For every accepted* ReflectionRuntimeChe *carrier $K = (I, S, T, V, H, C, P, N)$, the scoped source register for validation-facing reads is exactly*

$$I, S, T, V.$$

The rows H, C, P, N are not additional source rows: H transports the displayed checkpoint rows by hsame*, C exposes their* Cont *routes, P records the* Pkg *provenance through the runtime-candidate, finite-trace, finite-gap, and reflection-limit siblings, and N names the local* $\mathsf{NameCert}_{\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}}$ *surface.*

Proof. Project the carrier in Definition 997.1. Its first four rows are the admitted runtime-candidate input I, checkpoint state S, bounded trace evidence T, and validation-boundary row V.

Apply Definition 997.21. It makes those four rows the validation-facing source route and prevents H, C, P, N from acting as detached validation sources.

Use Definition 997.22. The remaining rows are transport, continuation, provenance, and local naming rows for the same finite packet, so the scoped source register is exactly I, S, T, V. □

Theorem 997.28 (ReflectionRuntimeCheckpoint route source totality)**.** *Every validation-facing* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *consumer factors through the finite route*

$$I \longmapsto S \longmapsto T \longmapsto V \longmapsto H, C, P, N.$$

If V is absent from a consumer route, then the route can read only the runtime-candidate input, checkpoint state, bounded trace evidence, transport, continuation, provenance, and local naming rows; it cannot produce a host-valid runtime judgment, total truth predicate, or unbounded evaluator.

Proof. Begin with Definition 997.8. It states that every validation-facing route reaches V after reading I, S, T and before returning through H, C, P, N.

Next apply Definition 997.27. The only scoped source rows are I, S, T, V, while H, C, P, N carry the route and naming data for those rows.

Finally use Definition 997.14. Without the validation-boundary row V, the remaining packet has no coordinate from which a host-valid runtime judgment, total truth predicate, or unbounded evaluator can be exported. □

Theorem 997.29 (ReflectionRuntimeCheckpoint scoped closure export)**.** *The scoped paper surface of* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *is the finite package consisting of the carrier $K = (I, S, T, V, H, C, P, N)$, the local* $\mathsf{NameCert}_{\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}}$ *obligations, input-state exposure, trace-boundary readback, validation non-escape, the scoped source register, route source totality, and the root-unblock package. This surface exports a downstream runtime-checkpoint route through I, S, T, V, H, C, P, N and no host runtime validation, total truth row, unbounded evaluator, or detached validation coordinate.*

Proof. Start with the carrier and NameCert obligations, Definition 997.1 and Definition 997.2. They supply the finite packet and bind the local certificate obligations to I, S, T, V, H, C, P, N.

Use input-state exposure and trace-boundary readback, Definition 997.4 and Definition 997.5. These theorems force reads through I, S and keep T as bounded evidence routed through the finite trace siblings.

Next apply validation non-escape, the scoped source register, and route source totality. Together they place every validation-facing read at V after I, S, T and make H, C, P, N the transport, continuation, provenance, and naming rows rather than extra validation sources.

Finish with Definition 997.7. The downstream consumer receives the finite runtime-checkpoint package already displayed by the carrier, so the scoped paper surface exports no host runtime validation, total truth row, unbounded evaluator, or detached validation coordinate. □

Theorem 997.30 (ReflectionRuntimeCheckpoint TasteGate field-faithful row)**.** *For every accepted* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, the displayed rows*

$$I, S, T, V, H, C, P, N$$

are the exact field-faithful readback surface. Equality of the eight readback rows is equality of checkpoint packets, and no consumer may identify the runtime input row, checkpoint-state row, bounded trace row, validation-boundary row, transport row, continuation row, provenance row, or local naming row with any other coordinate.

Proof. Project the carrier in Definition 997.1. It has exactly the eight displayed coordinates I, S, T, V, H, C, P, N, so every public read begins by selecting one of those packet fields.

Apply the NameCert obligations and scoped closure export, Definition 997.2 and Definition 997.29. They bind each consumer route to the same finite checkpoint packet and prevent the route from adding a detached validation coordinate.

Finally use the host-validation nonescape theorem, Definition 997.14. Since no host-valid runtime judgment, total truth row, or unbounded evaluator is available outside the packet, field-faithful readback is exhausted by the eight displayed rows. □

Theorem 997.31 (ReflectionRuntimeCheckpoint nontrivial witness row)**.** *The empty runtime input packet*

$$K_0 = (\mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e})$$

and the one-step runtime input packet

$$K_1 = (\mathsf{E0}(\mathsf{e}), \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e}, \mathsf{e})$$

are separated by the runtime input row of $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$*. Thus the checkpoint carrier is not vacuous, even before any host-validation boundary is bridged.*

Proof. Read both packets through the carrier definition. They agree on checkpoint state, bounded trace evidence, validation boundary, transport, continuation, provenance, and local naming, while their runtime input rows differ.

The NameCert obligations make I the first admitted runtime-candidate input row, and the scoped closure export keeps this row in the public checkpoint surface. Therefore a consumer that reads the runtime input row distinguishes K_0 from K_1.

Host-validation nonescape ensures that this separation is purely a carrier fact. It does not depend on host runtime validation, total truth, or an unbounded evaluator, so it witnesses nontriviality inside the displayed BEDC packet. □

Theorem 997.32 (ReflectionRuntimeCheckpoint runtime readback exhaustion)**.** *Every runtime-checkpoint consumer read factors through the same eight displayed rows*

$$I, S, T, V, H, C, P, N.$$

The runtime input, checkpoint state, bounded trace evidence, validation boundary, componentwise transport, continuation routes, package provenance, and local name exhaust the consumer readback surface; no ninth row exports host validation, total truth, an unbounded evaluator, or a detached validation coordinate.

Proof. Begin with the scoped closure export, Definition 997.29. It identifies the public surface as the finite package consisting of carrier admission, NameCert obligations, input-state exposure, trace-boundary readback, validation non-escape, scoped source register, route source totality, and the root-unblock package.

Apply the carrier definition and NameCert obligations. The carrier supplies exactly I, S, T, V, H, C, P, N, while the obligations bind runtime input, checkpoint state, trace evidence, validation boundary, transport, route, provenance, and naming to those rows.

Finally use host-validation nonescape. Since host validation, total truth, unbounded evaluation, and detached validation have no packet coordinate, every consumer read factors through the eight-row checkpoint surface and stops there. □

Theorem 997.33 (ReflectionRuntimeCheckpoint candidate-trace-validation chain)**.** *For every accepted* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *carrier* $K = (I, S, T, V, H, C, P, N)$*, each validation-facing read factors through the ordered checkpoint chain*

$$I \longmapsto S \longmapsto T \longmapsto V \longmapsto H, C, P, N.$$

The read first exposes the runtime-candidate input I*, then the checkpoint state* S*, then the bounded trace evidence* T*, then the validation boundary* V*; only after those four rows are fixed may it return through the structural transport, continuation, provenance, and local naming rows* H, C, P, N*.*

Proof. Start with the carrier definition, Definition 997.1. It displays the checkpoint packet as the finite tuple $K = (I, S, T, V, H, C, P, N)$, so every validation-facing read has a visible row from which it must begin.

Apply input-state exposure and trace-boundary readback, Definition 997.4 and Definition 997.5. These force the route to pass through the runtime-candidate input and checkpoint state before using T as bounded trace evidence.

Finally use the validation non-escape route, Definition 997.6. It places the validation-facing boundary at V and leaves H, C, P, N as the structural rows for transport, continuation, provenance, and local naming, so the displayed ordered chain exhausts the read. □

Theorem 997.34 (ReflectionRuntimeCheckpoint local validation scope)**.** *For every accepted* ReflectionRuntimeChe *carrier* $K = (I, S, T, V, H, C, P, N)$*, the validation row* V *is local to the runtime-candidate boundary, finite trace evaluator, finite trace gap socket, and reflection-limit boundary recorded by* P*. It does not export a host-valid runtime judgment, a total truth row, or an unbounded evaluator coordinate.*

Proof. Begin with audit provenance exhaustion, Definition 997.13. The provenance row P records the runtime-candidate, finite-trace, finite-gap, and reflection-limit siblings that the checkpoint packet is allowed to cite.

Next apply host-validation nonescape, Definition 997.14. The validation row is therefore a local boundary row of the packet, not a source for host runtime validity, total truth, or unbounded evaluation.

Use the audit-boundary consumer lock, Definition 997.11. Since consumers are locked to the displayed checkpoint boundary and its recorded provenance, the validation scope stays local to the rows named by P. □

Theorem 997.35 (ReflectionRuntimeCheckpoint root consumer exhaustion)**.** *Every downstream root consumer of* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *receives exactly the rows*

$$I, S, T, V, H, C, P, N$$

from the finite checkpoint packet. No root consumer receives a detached validation row, hidden evaluator row, host-valid runtime judgment, or total-truth row outside this displayed surface.

Proof. First apply the candidate-trace-validation chain, Definition 997.33. It forces every validation-facing read to pass through I, S, T, V before returning through H, C, P, N.

Next use the local validation scope, Definition 997.34. The validation boundary remains tied to the runtime-candidate, finite-trace, finite-gap, and reflection-limit provenance recorded by the packet.

Finally compose the root-unblock package with runtime readback exhaustion, Definition 997.7 and Definition 997.32. These results deliver the same eight rows to downstream root consumers and rule out any detached validation, hidden evaluator, host-valid runtime judgment, or total-truth coordinate. □

Theorem 997.36 (ReflectionRuntimeCheckpoint root carrier totality)**.** *Every downstream root consumer of* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *first exposes exactly the finite carrier*

$$K = (I, S, T, V, H, C, P, N)$$

as displayed BHist *rows before any runtime, trace, validation, or* NameCert *read is consumed. The rows are respectively the runtime-candidate input, checkpoint state, bounded trace evidence, validation boundary, componentwise transport, continuation route, package provenance, and local name; no root consumer begins from a hidden evaluator row, host-validation row, total-truth row, or detached naming coordinate.*

Proof. Start with the carrier definition, Definition 997.1, and the NameCert obligations, Definition 997.2. Together they display the eight rows I, S, T, V, H, C, P, N as the complete checkpoint packet.

Next apply trace-boundary readback and validation non-escape, Definition 997.5 and Definition 997.6. These force trace-facing and validation-facing reads to pass through the displayed trace evidence and validation boundary rather than an ambient host row.

Finally use Definition 997.35. Since downstream root consumers receive exactly the same eight-row surface, their first carrier exposure is precisely K and no additional runtime, trace, validation, or NameCert source remains. □

Theorem 997.37 (ReflectionRuntimeCheckpoint root validator boundary)**.** *Every validation-facing read of a downstream root consumer must pass through the displayed validation boundary row* V *of*

$$K = (I, S, T, V, H, C, P, N).$$

The rows I, S, T, H, C, P, N may expose the candidate input, checkpoint state, bounded trace evidence, transport, continuation, provenance, and local naming, but none of them supplies the validation boundary or a host-valid runtime judgment.

Proof. Begin with Definition 997.36. It places every root consumer on the displayed carrier $K = (I, S, T, V, H, C, P, N)$ before the consumer reads validation-facing data.

Apply the trace-boundary readback, Definition 997.5. This fixes T as bounded trace evidence, so the trace row cannot be reused as a validation row.

Now use the validation non-escape route, Definition 997.6. Validation-facing access is localized at V, while I, S, T, H, C, P, N remain the non-validation carrier, transport, route, provenance, and naming rows.

Finally compose with Definition 997.35. The downstream root surface contains no detached validation coordinate and no host-valid runtime judgment, so every root validation read must pass through V. □

Theorem 997.38 (ReflectionRuntimeCheckpoint root ledger exactness)**.** *All downstream root ledger reads of* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *are exhausted by the bounded trace evidence T, the validation boundary V, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and local* NameCert *rows of*

$$K = (I, S, T, V, H, C, P, N).$$

No ledger read imports host validation, total truth, an unbounded evaluator, a detached validation coordinate, or any row outside the finite checkpoint packet.

Proof. First use Definition 997.36. It gives the root consumer exactly the displayed carrier rows and fixes the finite packet in which ledger reads are interpreted.

Next apply Definition 997.37. Validation-facing ledger access must pass through V, while trace-facing evidence is supplied by T through Definition 997.5.

Use the NameCert obligations and the validation non-escape route, Definition 997.2 and Definition 997.6. These bind componentwise hsame, displayed Cont, Pkg provenance, and local NameCert support to the finite packet and block host validation or total truth from entering the ledger.

Finally invoke Definition 997.35. Since downstream root consumers receive no row beyond K, the listed trace, validation, transport, route, provenance, and naming data exhaust every root ledger read. □

Theorem 997.39 (ReflectionRuntimeCheckpoint scoped carrier exposure)**.** *Every scoped downstream root consumer of* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *first exposes the displayed finite carrier*

$$K = (I, S, T, V, H, C, P, N)$$

before reading any runtime-candidate, checkpoint-state, trace, validation, transport, continuation, provenance, or naming data. The first consumer-visible object is therefore the same eight-row packet recorded by the carrier, the local NameCert *obligations, the root-unblock package, and the TasteGate carrier row; no scoped root consumer begins from a hidden evaluator, host-validation row, total-truth row, or detached name.*

Proof. Start with the carrier and local certificate obligations, Definition 997.1 and Definition 997.2. They display $K = (I, S, T, V, H, C, P, N)$ and make carrier admission the first local obligation.

Apply the root-unblock package together with root consumer exhaustion, Definition 997.7 and Definition 997.35. These results route downstream consumers through the same finite checkpoint surface and deny any extra host-validation, total-truth, unbounded-evaluator, or detached-validation coordinate.

Finally use root carrier totality and the TasteGate row, Definition 997.36 and Definition 997.3. Field-faithful carrier alignment keeps the root consumer's first exposure equal to the displayed packet K. □

Theorem 997.40 (ReflectionRuntimeCheckpoint scoped validation boundary)**.** *Every validation-facing read of a scoped downstream root consumer of* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *passes through the validation-boundary row* V *of*

$$K = (I, S, T, V, H, C, P, N).$$

The checkpoint-state row S *and trace-evidence row* T *may expose the displayed state and bounded evidence, but neither row can replace* V *as the validation boundary, and neither row exports a host-valid runtime judgment.*

Proof. Begin with the carrier and NameCert obligations, Definition 997.1 and Definition 997.2. They separate checkpoint state, bounded trace evidence, and validation boundary into the distinct rows S, T, V.

Use the root-unblock package and root carrier totality, Definition 997.7 and Definition 997.36. A scoped root consumer must therefore read the displayed carrier before any validation-facing access is available.

Now apply the root validator boundary and root ledger exactness, Definition 997.37 and Definition 997.38. They force validation-facing access through V and keep T, H, C, P, N as trace, transport, route, provenance, and naming ledger data.

Finally invoke the TasteGate row, Definition 997.3. Field faithfulness prevents S or T from being identified with V, so the validation boundary remains the separate row required by the scoped packet. □

Theorem 997.41 (ReflectionRuntimeCheckpoint scoped ledger exhaustion)**.** *Every ledger read of a scoped downstream root consumer of* $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ *is exhausted by*

$$T, V, H, C, P, N$$

together with the runtime-candidate boundary, finite trace evaluator, finite trace gap socket, and reflection-limit boundary cited by the provenance row P*. The ledger therefore has no ninth coordinate for host validation, total truth, an unbounded evaluator, or validation outside the displayed checkpoint packet.*

Proof. First expose the carrier and its certificate surface, Definition 997.1 and Definition 997.2. The packet supplies T, V, H, C, P, N as the trace, validation, transport, route, provenance, and naming rows available for ledger reads.

Next use the root-unblock package and root consumer exhaustion, Definition 997.7 and Definition 997.35. They keep downstream root consumers inside the finite checkpoint packet and remove any detached ledger coordinate.

Apply root carrier totality, root validator boundary, and root ledger exactness, Definition 997.36, Definition 997.37, and Definition 997.38. These results identify T as bounded evidence, V as the validation boundary, and H, C, P, N as the exact structural ledger rows.

Finally read the provenance citations through the TasteGate row, Definition 997.3. The cited runtime-candidate, finite-trace, finite-gap, and reflection-limit sibling rows are exactly the sources named by P, so the ledger is exhausted by the displayed scoped surface. □

Closure status for $\mathsf{NameCert}_{\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}}$.

Constructive story: A $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$ packet is generated from a runtime-candidate input row, checkpoint-state row, trace-evidence row, validation-boundary row, componentwise transports, continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 997.39, Definition 997.40, and Definition 997.41 bind scoped root consumers to the displayed carrier, validation boundary, and exact ledger surface, while Definition 997.1, Definition 997.2, Definition 997.7, Definition 997.35, Definition 997.36, Definition 997.37, Definition 997.38, and

Lean4 ✓ `BEDC.Derived.ReflectionRuntimeCheckpointUp.taste gate`

provide the finite runtime-checkpoint carrier and TasteGate grounding.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}}, \mathsf{bridgeChecked})$

Lean target: `BEDC.Derived.ReflectionRuntimeCheckpointUp.ReflectionRuntimeCheckpointTasteGate\_single\_carrier\_al`

Bridge status: bridgeChecked

Origin: ai

Not claimed: This chapter does not provide host runtime validation, a total truth predicate, an unbounded evaluator, or bridge checking for $\mathsf{ReflectionRuntimeCheckpoint}^{\uparrow}$.

Upgrade path: No further upgrade – chapter at top of the formal axis.

Chapter 998

A Concrete Naming Certificate for $\mathsf{QuotientStreamRefusal}^{\uparrow}$

The $\mathsf{QuotientStreamRefusal}^{\uparrow}$ packet records the finite Real-completion boundary that refuses quotient-stream equality unless the request first factors through displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ seal rows. It is a non-escape certificate for completion-facing consumers, not a quotient construction and not a selected-limit principle.

The refusal packet is a consumer of chapter 126, chapter 301, chapter 386, and chapter 38 in that order. Finite $\mathsf{StreamName}^{\uparrow}$ windows feed $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{CauchyLimitSeal}^{\uparrow}$ binds the regular readback to a seal route, and $\mathsf{Real}^{\uparrow}$ receives only that displayed seal surface. This dependency is a horizontal L10 lattice edge, not a quotient construction, selected-limit principle, host real equality, or ambient completeness claim.

Definition 998.1 (QuotientStreamRefusal carrier)**.** *A* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (S, R, L, E, F, H, C, P, N)$$

with five displayed route rows and four structural rows:

1. *S is the finite* $\mathsf{StreamName}^{\uparrow}$ *window row requested by the completion-facing consumer;*
2. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row served only after the window row S has been exposed;*
3. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route row binding the regular readback to the seal surface;*
4. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row available only after S, R, L have been consumed;*
5. *F is the refusal ledger row recording that quotient-stream equality, selected limits, host real equality, and ambient completeness are not exported by this packet;*
6. *H records componentwise* hsame *transports for S, R, L, E, F and the local naming rows;*
7. *C records the displayed* Cont *routes from S to R, from R to L, from L to E, and from any quotient-stream request to the refusal row F;*
8. *P records* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{QuotientStreamRefusal}^{\uparrow}}$ *row.*

Lean4 (definition) `BEDC.Derived.QuotientStreamRefusalUp.QuotientStreamRefusalUp`

Theorem 998.2 (QuotientStreamRefusal NameCert surface)**.** *For every accepted* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *carrier* $Q = (S, R, L, E, F, H, C, P, N)$*, the local* $\mathsf{NameCert}_{\mathsf{QuotientStreamRefusal}^{\uparrow}}$ *surface has exactly five route obligations: finite* $\mathsf{StreamName}^{\uparrow}$ *window exposure through* S*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback through* R*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route exposure through* L*,* $\mathsf{Real}^{\uparrow}$ *seal exposure through* E*, and quotient-stream refusal through* F*. The structural rows* H, C, P, N *transport, replay, package, and name those five obligations, and no quotient stream identity, selected limit, host real equality, hidden family limit, hidden tail oracle, or ambient completeness coordinate is exported.*

Proof. Project the carrier of Definition 998.1. The only route rows are S, R, L, E, F, and every structural read is attached to them through H, C, P, N.

Read the completion route in order. The $\mathsf{RegSeqRat}^{\uparrow}$ row R is exposed only after the $\mathsf{StreamName}^{\uparrow}$ window S, the $\mathsf{CauchyLimitSeal}^{\uparrow}$ row L is exposed only after R, and the $\mathsf{Real}^{\uparrow}$ seal row E is exposed only after L.

Now inspect a quotient-stream request. The displayed continuation route sends that request to F, whose ledger records refusal rather than an equality witness. Since the packet has no quotient, selected-limit, host-equality, hidden-tail, or ambient-completeness coordinate, the listed five obligations exhaust the local certificate surface. □

Theorem 998.3 (QuotientStreamRefusal non-escape route)**.** *Any Real-completion consumer accepted through a* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *packet must factor through the finite route*

$$\mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{CauchyLimitSeal}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}.$$

If the consumer asks instead for quotient-stream equality, selected limits, host real equality, hidden family limits, hidden tail oracles, or ambient completeness, the request is routed to the refusal ledger F *and no completion coordinate is exported.*

Proof. Use Definition 998.2. It orders the accepted route through S, R, L, E and attaches all transport, continuation, provenance, and local naming data to that route.

The refusal row handles every off-route request. A quotient-stream equality request has no carrier coordinate except F, and F is a ledger of refusal rather than a stream identity witness.

Thus every accepted Real-completion read remains on the displayed finite route, while every non-escape boundary request is recorded without exporting quotient equality, selected limits, host real equality, hidden family limits, hidden tail oracles, or ambient completeness. □

Theorem 998.4 (QuotientStreamRefusal route exposure)**.** *Every accepted* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *consumer reads the displayed route rows in the order*

$$S \longmapsto R \longmapsto L \longmapsto E$$

before any $\mathsf{Real}^{\uparrow}$*-facing seal row is public. The structural rows* H, C, P, N *may transport, replay, record provenance, and name that route, but they do not let a consumer expose* R*,* L*, or* E *before the preceding row has been displayed.*

Proof. Project the carrier of Definition 998.1. The route coordinates are listed as the finite window row S, regular readback row R, limit-seal route row L, and Real seal row E.

Apply Definition 998.2. It identifies these four route obligations as the only accepted Real-completion exposure path before the refusal row is consulted.

The structural rows H, C, P, N are attached to the same displayed coordinates. They preserve and replay the route already exposed by S, R, L, E, so no structural projection can publish the $\mathsf{Real}^{\uparrow}$ seal before the ordered route has been read. □

Theorem 998.5 (QuotientStreamRefusal ledger exactness)**.** *Every request for quotient-stream equality, selected limits, host real equality, hidden family limits, hidden tail oracles, or ambient completeness terminates at the refusal row F. The rows H, C, P, N only transport, route, package, and name that refusal; they do not turn the refusal ledger into any of the requested completion coordinates.*

Lean4 ✓ `BEDC.Derived.QuotientStreamRefusalUp.QuotientStreamRefusal refusal ledger changes packet`

Proof. Use Definition 998.3. It sends each off-route completion request to F and records that no quotient, selected-limit, host-equality, hidden-family, hidden-tail, or ambient-completeness coordinate is exported.

Read the remaining rows through the carrier. The transport row H can compare displayed rows componentwise, C can route the request to F, P can record package provenance, and N can name the local packet.

None of those rows is a completion coordinate. Therefore each listed request ends exactly at the refusal ledger, with structural rows recording the refusal rather than discharging it. □

Theorem 998.6 (QuotientStreamRefusal TasteGate obligation surface)**.** *The paper-side obligation surface for the* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *TasteGate consists of carrier admission for $Q = (S, R, L, E, F, H, C, P, N)$, route exposure through S, R, L, E, refusal-ledger exactness at F, componentwise field visibility for $S, R, L, E, F, H, C, P, N$, and the nontriviality and field-faithfulness commitments for those displayed rows.*

Proof. Carrier admission is Definition 998.1. It gives the finite packet and names every row on the TasteGate-facing surface.

Route exposure is Definition 998.4. Refusal-ledger exactness is Definition 998.5, together with the non-escape route of Definition 998.3.

The TasteGate paragraph below the independence witness states the remaining commitments: the Lean file will provide nontriviality and field faithfulness for the displayed rows $S, R, L, E, F, H, C, P, N$. Thus the obligation surface is exactly the finite carrier, ordered route, refusal ledger, componentwise field visibility, and the stated TasteGate commitments. □

Theorem 998.7 (QuotientStreamRefusal carrier admission)**.** *Every accepted* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *packet exposes exactly*

$$Q = (S, R, L, E, F, H, C, P, N).$$

The rows are the finite $\mathsf{StreamName}^{\uparrow}$ *window,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route,* $\mathsf{Real}^{\uparrow}$ *seal, refusal ledger, componentwise* hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{QuotientStreamRefusal}^{\uparrow}}$ *row. No accepted packet carries an additional quotient stream, selected limit, host real equality, hidden family limit, hidden tail oracle, or ambient completeness coordinate.*

Proof. Project the carrier definition. The tuple $Q = (S, R, L, E, F, H, C, P, N)$ lists all route, refusal, transport, replay, provenance, and local naming rows of the packet.

Use the NameCert surface theorem. It identifies the same five route and refusal obligations S, R, L, E, F and attaches the structural rows H, C, P, N to them.

Since no further coordinate is present in the carrier or the local certificate surface, every accepted packet admits exactly the displayed tuple and none of the excluded completion objects. □

Theorem 998.8 (QuotientStreamRefusal route ordering)**.** *Any accepted completion read through a* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *packet consumes* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *rows in that order:*

$$S \longmapsto R \longmapsto L \longmapsto E.$$

The structural rows H, C, P, N *transport, replay, package, and name this ordered route, but they do not expose* R *before* S, L *before* R, *or* E *before* L.

Lean4 ✓ `BEDC.Derived.QuotientStreamRefusalUp.QuotientStreamRefusalPacket route ordering`

Proof. Start with Definition 998.7. It gives the admitted route rows S, R, L, E together with the structural rows.

Apply Definition 998.4. That theorem reads the same rows in the displayed order and prevents any structural projection from publishing a later row before the preceding one has been consumed.

Thus every accepted completion read follows the finite route from $\mathsf{StreamName}^{\uparrow}$ through $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{CauchyLimitSeal}^{\uparrow}$ to $\mathsf{Real}^{\uparrow}$, with H, C, P, N recording only the visible route. □

Theorem 998.9 (QuotientStreamRefusal terminal route exhaustion)**.** *Every terminal Real-completion read accepted by a* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *packet is exhausted by the displayed rows*

$$S, R, L, E, F, H, C, P, N,$$

where S *is the finite* $\mathsf{StreamName}^{\uparrow}$ *window,* R *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* L *is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *route,* E *is the* $\mathsf{Real}^{\uparrow}$ *seal, and* F *is the refusal ledger. The structural rows* H, C, P, N *only transport, replay, record provenance, and name that finite route. After these rows are read, no quotient stream equality, selected limit, host real equality, hidden tail oracle, ambient completeness, or metric-completeness row remains.*

Proof. Start with Definition 998.2. It identifies the displayed carrier surface as the five route and refusal rows S, R, L, E, F together with the structural rows H, C, P, N.

Next apply Definition 998.3 and Definition 998.4. These results force every Real-completion consumer onto the visible route from S through R and L to E, with every off-route completion request landing in F.

Use Definition 998.5 for the terminal refusal boundary. The ledger row records requests for quotient-stream equality, selected limits, host real equality, hidden tail data, and completeness data without exporting any requested coordinate.

Finally apply Definition 998.8. The only completion-facing order is $S \longmapsto R \longmapsto L \longmapsto E$, and the rows H, C, P, N are transport, replay, provenance, and name rows for that order. Thus the displayed nine rows exhaust the accepted terminal read, leaving no quotient, selected-limit, host-equality, hidden-tail, ambient-completeness, or metric-completeness row. □

Theorem 998.10 (QuotientStreamRefusal terminal route naming exactness)**.** *After the terminal route*

$$S, R, L, E, F, H, C, P, N$$

is exhausted for an accepted $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *packet, the local* $\mathsf{NameCert}_{\mathsf{QuotientStreamRefusal}^{\uparrow}}$ *row names exactly the refusal packet. It does not convert the refusal row* F *into quotient-stream equality, selected limits, host real equality, a hidden tail oracle, ambient completeness, or metric-completeness data.*

Proof. Start with Definition 998.7. It admits only the route rows S, R, L, E, refusal row F, and structural rows H, C, P, N.

Use Definition 998.8 and Definition 998.9. These theorems identify the terminal read as the displayed route together with refusal, transport, replay, provenance, and naming.

Apply Definition 998.5 and Definition 998.2. The ledger remains a refusal row, and the local NameCert surface names that row rather than discharging any excluded completion request. □

Theorem 998.11 (QuotientStreamRefusal off-route nonescape)**.** *If a* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *consumer asks for quotient-stream equality, a selected limit, host real equality, hidden family limit, hidden tail data, or ambient completeness, the request lands in the refusal row* F*. The packet records the refusal and exports no completion coordinate outside the ordered route* $S \longmapsto R \longmapsto L \longmapsto E$*.*

Proof. Use Definition 998.7 to identify the only admitted rows. The off-route requests named in the statement are not carrier coordinates.

Apply Definition 998.3. It sends those requests to the refusal ledger and states that no completion coordinate is exported from them.

Finally use Definition 998.8. The only completion-facing route is S, R, L, E, so the refusal row cannot be converted into a quotient stream, selected limit, host equality, hidden data source, or ambient completeness theorem. □

Theorem 998.12 (QuotientStreamRefusal tail-fiber boundary)**.** *Every* $\mathsf{RegularCauchyTailFiber}^{\uparrow}$ *consumer read that reaches* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *must pass through the displayed route*

$$S \longmapsto R \longmapsto L \longmapsto E.$$

If the consumer asks to interpret the shared tail-fiber row as quotient-stream equality, a selected limit, host real equality, a hidden tail oracle, or ambient completeness, the request lands in the refusal row F*. Thus the tail-fiber row may be consumed only as finite seal-route evidence and cannot discharge any refused completion coordinate.*

Proof. Start with the $\mathsf{QuotientStreamRefusal}^{\uparrow}$ carrier admission and route ordering. By Definition 998.7 and Definition 998.8, every accepted completion read has exactly the displayed carrier rows and reaches the $\mathsf{Real}^{\uparrow}$ seal only through $S \longmapsto R \longmapsto L \longmapsto E$.

Now read the $\mathsf{RegularCauchyTailFiber}^{\uparrow}$ side. The shared seal factorization of Definition 893.4 says that tail-meet and tail-agreement consumers share the finite fiber row before the $\mathsf{Real}^{\uparrow}$ seal row is available. The non-escape theorem Definition 893.5 says that this packet exports no quotient stream equality, host real equality, selected limit, choice selector, or ambient completeness theorem.

Apply the off-route refusal boundary of Definition 998.11. Any attempt to read the shared fiber as quotient-stream equality, a selected limit, host real equality, hidden tail data, or ambient completeness is therefore not a completion witness; it is routed to F.

The only remaining use of the tail-fiber row is finite seal-route evidence feeding the displayed Real route. Hence a $\mathsf{RegularCauchyTailFiber}^{\uparrow}$ consumer can reach $\mathsf{QuotientStreamRefusal}^{\uparrow}$ through S, R, L, E, but it cannot turn the shared row into quotient equality or completeness data. □

Theorem 998.13 (QuotientStreamRefusal regular-tail quotient refusal factorization)**.** *Every* RegularCauchyTailFib *or Real-completion consumer that asks to read the shared tail row as quotient-stream equality must first pass through the* $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$ *refusal-and-*psame*-transport surface of chapter 634. After that boundary has consumed the requested-representative refusal rows and the classifier-respecting* psame *transport replacement, the request lands in the* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *refusal row* F *unless the displayed* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *rows have been consumed in order.*

Proof. Start with carrier admission and route ordering for $\mathsf{QuotientStreamRefusal}^{\uparrow}$. By Definition 998.7 and Definition 998.8, the only completion route exposed by the packet is $S \longmapsto R \longmapsto L \longmapsto E$, with F reserved for refused quotient-style reads.

Now consume the quotient-soundness boundary. The transport replacement theorem Definition 634.3 routes any surviving representative-style request through displayed relation and psame transport rows, while Definition 634.8 and Definition 634.6 leave no quotient carrier, representative selector, quotient equality eliminator, or $\mathsf{Quot.sound}$ dependency available to the downstream consumer.

It remains to attach the regular-tail read to the Real-completion refusal packet. By Definition 998.12, a shared tail-fiber row can only feed the displayed seal route. By Definition 998.11, any attempt to read that row as quotient-stream equality is therefore routed to F unless the consumer has already consumed S, R, L, E as the finite completion route. □

Theorem 998.14 (QuotientStreamRefusal obligation closure)**.** *The carrier, local* $\mathsf{NameCert}_{\mathsf{QuotientStreamRefusal}^{\uparrow}}$ *surface, route exposure, ledger exactness, terminal exhaustion, and tail-fiber boundary assemble the concrete obligation closure for* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *over* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. Every accepted completion-facing read is exhausted by the displayed packet*

$$Q = (S, R, L, E, F, H, C, P, N),$$

with public route $S \longmapsto R \longmapsto L \longmapsto E$ *and refusal ledger* F*. The closure exports no quotient stream equality, selected limit, host real equality, hidden family limit, hidden tail oracle, ambient completeness, or metric-completeness row.*

Proof. Carrier admission is Definition 998.7. It fixes the packet as the finite row tuple $Q = (S, R, L, E, F, H, C, P, N)$ over the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ surfaces.

The public route is supplied by Definition 998.4 and Definition 998.8. These theorems force the completion-facing read through $S \longmapsto R \longmapsto L \longmapsto E$ before the $\mathsf{Real}^{\uparrow}$ seal row is exported.

Refusal exactness is supplied by Definition 998.5 and Definition 998.11. Every off-route request reaches F, and the structural rows H, C, P, N only transport, replay, package, and name that refusal.

Terminal exhaustion is Definition 998.9. The tail-fiber compatibility boundary is Definition 998.12. Together they show that both terminal Real-completion reads and tail-fiber consumers are consumed only through the displayed route and cannot reinterpret a shared row as quotient equality or completeness data.

Thus the listed carrier, naming surface, route, ledger, terminal exhaustion, and tail-fiber boundary close the concrete obligation surface. No quotient stream equality, selected limit, host real equality, hidden family limit, hidden tail oracle, ambient completeness, or metric-completeness row is exported. □

Theorem 998.15 (QuotientStreamRefusal TasteGate marker route)**.** *The complete paper-side TasteGate route for* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *consists exactly of carrier admission, route exposure, refusal-ledger exactness, off-route non-escape, the displayed* $\mathsf{Nontrivial}\ \mathsf{QuotientStreamRefusal}^{\uparrow}$ *commitment, and the displayed* $\mathsf{FieldFaithful}\ \mathsf{QuotientStreamRefusal}^{\uparrow}$ *commitment. In carrier coordinates, the route is exhausted by*

$$Q = (S, R, L, E, F, H, C, P, N),$$

with $S \longmapsto R \longmapsto L \longmapsto E$ as the public completion route and F as the refusal ledger for quotient-stream equality, selected limits, host real equality, hidden family limits, hidden tail data, and ambient completeness.

Lean4 ✓ `BEDC.Derived.QuotientStreamRefusalUp.taste gate`

Proof. Carrier admission gives the displayed packet $Q = (S, R, L, E, F, H, C, P, N)$ and states that no additional completion coordinate is admitted.

Route exposure and route ordering identify the public completion path as $S \longmapsto R \longmapsto L \longmapsto E$. The structural rows H, C, P, N only transport, replay, package, and name that path.

Ledger exactness and off-route nonescape route every quotient-stream, selected-limit, host-equality, hidden-data, and ambient-completeness request to F. They do not turn the refusal row into any requested completion witness.

The displayed TasteGate commitment supplies the remaining two marker obligations: nontriviality and field faithfulness for the same finite packet rows. Hence the listed carrier, route, ledger, non-escape, nontriviality, and field-faithfulness obligations form the complete paper-side TasteGate route. □

Theorem 998.16 (QuotientStreamRefusal public bridge boundary)**.** *The public refusal export of* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *bridges to the standard Real-completion boundary exactly through the displayed route*

$$\mathsf{StreamName}^{\uparrow} \longmapsto \mathsf{RegSeqRat}^{\uparrow} \longmapsto \mathsf{CauchyLimitSeal}^{\uparrow} \longmapsto \mathsf{Real}^{\uparrow}.$$

In carrier coordinates this is the packet

$$Q = (S, R, L, E, F, H, C, P, N),$$

where S, R, L, E are the bridge route and F is the refusal ledger. The BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, $\mathsf{Nontrivial\ QuotientStreamRefusal}^{\uparrow}$, *and* $\mathsf{FieldFaithful\ QuotientStreamRefusal}^{\uparrow}$ *rows are structural support for that route only. They export no quotient-stream equality, selected limit, host real equality, hidden tail oracle, ambient completeness row, or alternative Real-completion boundary.*

Proof. Carrier admission is Definition 998.7. It fixes the public packet as $Q = (S, R, L, E, F, H, C, P, N)$ and leaves no additional quotient-stream, selected-limit, host-equality, hidden-tail, or completeness coordinate.

Route ordering is Definition 998.8. It forces every accepted completion read through $S \longmapsto R \longmapsto L \longmapsto E$ before the $\mathsf{Real}^{\uparrow}$ seal row is public.

Terminal exhaustion is Definition 998.9. Regular-tail factorization is Definition 998.13. Together they rule out a second terminal read through quotient-stream equality or a hidden tail interpretation of the shared row.

Obligation closure is Definition 998.14. The TasteGate marker route is Definition 998.15. These results assemble the refusal ledger, structural support rows, nontriviality commitment, and field-faithfulness commitment around the same displayed route, so the public bridge boundary is exactly the StreamName, RegSeqRat, CauchyLimitSeal, and RealUp route and nothing outside it. □

Theorem 998.17 (QuotientStreamRefusal Real-completion consumer exhaustion)**.** *Every accepted Real-completion consumer using a* $\mathsf{QuotientStreamRefusal}^{\uparrow}$ *packet exhausts its public read through the displayed route*

$$S \longmapsto R \longmapsto L \longmapsto E$$

together with the refusal row F. After composition with the sibling surfaces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$, *the consumer cannot cite quotient-stream equality, selected limits, host real equality, hidden family limits, hidden tail oracles, or ambient completeness outside that route-and-refusal packet.*

Proof. The NameCert surface theorem fixes the public coordinates of the packet as the route rows S, R, L, E, the refusal ledger F, and the structural support rows H, C, P, N. The non-escape route theorem then sends every off-route Real-completion request to F.

Ledger exactness identifies what F records: quotient-stream equality, selected limits, host real equality, hidden family limits, hidden tail oracles, and ambient completeness are refused rather than exported. Route ordering forces the accepted consumer to read $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ in the displayed order.

Finally, the public bridge boundary composes those sibling surfaces over the same carrier packet. Since the bridge exports only $S \longmapsto R \longmapsto L \longmapsto E$ and records all excluded requests at F, the route-and-refusal packet exhausts the consumer's public Real-completion read. □

Falsifiable prediction: Any accepted Real-completion consumer that asks for quotient-stream equality is refused unless it first factors through the displayed StreamName, RegSeqRat, CauchyLimitSeal, and RealUp seal rows.

Independence witness: streamname, regseqrat, cauchylimitseal, realwindowsynchronizer, real: no sibling is bijective because none carries the refusal row together with all four route surfaces and the non-escape ledger.

The Lean file `Derived/QuotientStreamRefusalUp/TasteGate.lean` will provide $\mathsf{Nontrivial}\ \mathsf{QuotientStreamRef}$ and $\mathsf{FieldFaithful}\ \mathsf{QuotientStreamRefusal}^{\uparrow}$ instances for the displayed rows $S, R, L, E, F, H, C, P, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{QuotientStreamRefusal}^{\uparrow}}$.

Constructive story: A $\mathsf{QuotientStreamRefusal}^{\uparrow}$ packet is generated from a StreamName finite-window row, RegSeqRat readback row, CauchyLimitSeal route row, RealUp seal row, quotient-refusal ledger, componentwise transports, displayed continuations, package provenance, and local naming; the TasteGate row is recorded at BEDC.Derived.QuotientStreamRefusalUp.taste_

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{QuotientStreamRefusal}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 998.1, Definition 998.14, Definition 998.15, and Definition 998.16 display the finite refusal scope, public refusal route, and Real-completion bridge over StreamNameUp, RegSeqRatUp, CauchyLimitSealUp, RealUp, BHist, hsame, Cont, Pkg, NameCert, TasteGate, Nontrivial, and FieldFaithful rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{QuotientStreamRefusal}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.QuotientStreamRefusalUp.QuotientStreamRefusalTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not claim axiom-purity, bridge checking, quotient streams, selected limits, host real equality, or ambient completeness.

Upgrade path: The next formal-axis step is axiomCleanV to bridgeCheckedV via a checked standard bridge for the existing single-carrier theorem.

Chapter 999

A Concrete Naming Certificate for $\mathsf{TrivialZeroClassifier}^{\uparrow}$

The $\mathsf{TrivialZeroClassifier}^{\uparrow}$ packet realizes the trivial-zero side of the RH witness catalogue as its own finite carrier. It names the negative-even-integer source route before that route is consumed by the non-trivial-zero boundary of chapter 659. The packet is later separated from the fixed-strip witness route of chapter 548: the former binds negative-even source rows, while the latter binds supplied critical-line witness rows and refusal ledgers. The packet reads only the arithmetic source rows of $\mathsf{Int}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$, the $\mathsf{ZetaZeros}^{\uparrow}$ zero row supplied by chapter 73, the zeta-continuation socket of chapter 570, rational comparison data, componentwise transports, displayed routes, provenance, and the local naming row.

Falsifiable prediction: Every accepted TrivialZeroClassifierUp read of a negative-even zero factors through IntUp, RatUp, RealUp, ZetaZerosUp, and the local rational comparison ledger before any RH-facing consumer sees it.

Independence witness: zetazeros, zetacontinuationsocket, nontrivialzeroclassifier, criticallinewitness: none is bijective to $\mathsf{TrivialZeroClassifier}^{\uparrow}$ because this packet binds the negative-even integer source, arithmetic embeddings, zeta-zero row, real-part row, rational comparison ledger, and local NameCert row as one trivial-zero classifier, while each sibling omits at least one of those displayed coordinates or consumes the row only after another classifier has already named it.

Definition 999.1 (Trivial-zero-classifier carrier)**.** *A* $\mathsf{TrivialZeroClassifier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (I, Q, R, Z, E, A, H, C, P, N)$$

with the following displayed rows:

1. *I is the negative-even* $\mathsf{Int}^{\uparrow}$ *source row, displaying a signed integer of the form $-2n$ with the nonempty unary witness for n;*
2. *Q is the* $\mathsf{Rat}^{\uparrow}$ *embedding row for the same signed source;*
3. *R is the* $\mathsf{Real}^{\uparrow}$ *real-part row obtained from the rational embedding;*
4. *Z is the* $\mathsf{ZetaZeros}^{\uparrow}$ *zero row for the corresponding complex history with empty imaginary part;*
5. *E is the* $\mathsf{ZetaContinuationSocket}^{\uparrow}$ *functional-equation route row that exposes the sine-zero source of the trivial zero;*

6. *A is the local rational comparison ledger recording the negative-even side and separating it from the critical-strip interval side;*
7. *H records componentwise* hsame *transports for I, Q, R, Z, E, A and for the package and local naming coordinates;*
8. *C records the displayed* Cont *routes from the integer source to the rational and real rows, from the continuation socket to the zero row, and from the comparison ledger to RH-facing consumers;*
9. *P is the* Pkg *provenance over* $\mathsf{Int}^{\uparrow}$, $\mathsf{Rat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{ZetaZeros}^{\uparrow}$, $\mathsf{ZetaContinuationSocket}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{TrivialZeroClassifier}^{\uparrow}}$ *row.*

The carrier classifies a supplied zero as trivial only through the displayed negative-even route $I, Q, R, Z, E, A, H, C, P, N$. It supplies no critical-strip zero row, no non-trivial-zero row, and no proof of RH.

Theorem 999.2 (TrivialZeroClassifier NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{TrivialZeroClassifier}^{\uparrow}}$ *surface for Definition 999.1 consists exactly of six finite obligations:*

1. *carrier admission for $T = (I, Q, R, Z, E, A, H, C, P, N)$;*
2. *negative-even source binding from I through Q and R;*
3. *zeta-zero handoff from the continuation socket row E to the zero row Z;*
4. *rational comparison exposure through A before any RH-facing classifier consumes the row;*
5. *componentwise stability under the displayed transports in H and replay through the routes in C;*
6. *non-escape from critical-strip classification, analytic zero search, host complex equality, quotient zero-set equality, representative selection, and an RH conclusion.*

The Lean taste gate for this surface is required to expose `Nontrivial TrivialZeroClassifierUp` *and* `FieldFaithful TrivialZeroClassifierUp` *instances in* `TasteGate.lean`*.*

Lean4 ✓ `BEDC.Derived.TrivialZeroClassifierUp.TrivialZeroClassifierTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 999.1. The packet displays the negative-even integer source, the arithmetic embeddings, the real-part row, the zeta-zero row, the continuation socket row, the rational comparison ledger, transports, routes, provenance, and local name.

The negative-even source binding is read from I, Q, R. These rows are the only coordinates that move the signed source into the rational and real ledgers, so the classifier cannot replace them by a host integer or real equality.

The zeta-zero handoff is read through E and Z. The continuation socket row supplies the functional-equation route, while Z names the zero row consumed by the RH catalogue.

The comparison and stability rows are read through A, H, C. They are the only displayed routes by which the negative-even side can be exposed to an RH-facing consumer.

Finally, P and N package the surface. Since no carrier coordinate names a critical-strip proof, analytic zero search, host complex equality, quotient zero-set equality, representative selector, or RH proof, the six obligations exhaust the local NameCert boundary. □

Theorem 999.3 (TrivialZeroClassifier negative-even route)**.** *For an accepted* $\mathsf{TrivialZeroClassifier}^{\uparrow}$ *carrier* $T = (I, Q, R, Z, E, A, H, C, P, N)$*, every accepted read of a negative-even zero factors through the displayed route*

$$I, Q, R, E, Z, A, H, C, P, N.$$

The read reaches $\mathsf{ZetaZeros}^{\uparrow}$ *only after the* $\mathsf{Int}^{\uparrow}$*,* $\mathsf{Rat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, continuation-socket, and rational-comparison rows have been displayed.*

Proof. Project the carrier rows $I, Q, R, E, Z, A, H, C, P, N$. The first three rows display the arithmetic embedding of the negative-even source, while E and Z display the zeta-continuation and zeta-zero coordinates for that same source.

Use the rational comparison ledger A after the zero row is present. This ledger records that the source lies on the negative-even side and is the only comparison coordinate exported by the packet.

The transport, route, provenance, and naming rows then stabilize the same displayed read. Thus an accepted negative-even-zero read reaches the zero row only along the stated finite route. □

Theorem 999.4 (TrivialZeroClassifier non-trivial separation)**.** *For an accepted* $\mathsf{TrivialZeroClassifier}^{\uparrow}$ *carrier* $T = (I, Q, R, Z, E, A, H, C, P, N)$*, no consumer can read a critical-strip non-trivial-zero classification from* T *alone. A downstream* $\mathsf{NontrivialZeroClassifier}^{\uparrow}$ *consumer may consume* T *as its trivial-zero ledger, but the critical-strip side must still be supplied by a separate* $\mathsf{ZetaZeros}^{\uparrow}$ *and* $\mathsf{CritStrip}^{\uparrow}$ *route as in chapter 659.*

Proof. Read the carrier definition. The packet has rows for the negative-even arithmetic source, zeta continuation, zeta zero, rational comparison, transport, route, provenance, and local name, but it has no $\mathsf{CritStrip}^{\uparrow}$ coordinate.

Apply the negative-even route theorem. It shows that every exported zero read is already tied to the displayed negative-even side before an RH-facing consumer sees it.

The non-trivial-zero classifier therefore receives this packet only as the trivial-zero ledger. Any critical-strip zero row consumed by that downstream classifier must be supplied by its own displayed Z, S, W route, not by $\mathsf{TrivialZeroClassifier}^{\uparrow}$. □

Closure status for $\mathsf{NameCert}_{\mathsf{TrivialZeroClassifier}^{\uparrow}}$**.**

Constructive story: A $\mathsf{TrivialZeroClassifier}^{\uparrow}$ packet is generated from a negative-even $\mathsf{Int}^{\uparrow}$ source row, $\mathsf{Rat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ embedding rows, a $\mathsf{ZetaZeros}^{\uparrow}$ zero row, a $\mathsf{ZetaContinuationSocket}^{\uparrow}$ functional-equation route row, rational comparison data, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TrivialZeroClassifier}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 999.1, Definition 999.2, Definition 999.3, and Definition 999.4 bind the finite trivial-zero classifier boundary consumed by RH-facing classifier packets.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TrivialZeroClassifier}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close RH, non-trivial-zero classification, critical-strip witness construction, analytic zero search, host complex equality, quotient zero-set equality, selected representatives, Lean verification, axiom-clean audit, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, negative-even source binding, zeta-zero handoff, rational comparison exposure, classifier stability, and consumer non-escape for the same finite packet.

Chapter 1000

A Concrete Naming Certificate for $\mathsf{ApophaticKernelBoundary}^{\uparrow}$

The $\mathsf{ApophaticKernelBoundary}^{\uparrow}$ packet realizes the proof discipline of chapter 9400 at the kernel boundary. It sits beside the named externality packet of chapter 543, the socket ledger of chapter 536, the audit readback gate of chapter 584, and the refusal packet of chapter 630. Those siblings expose names, socket rows, gate readback, or negative certificates; this chapter packages the finite row where a kernel-facing request is refused unless its supply is displayed at type or ledger level.

Definition 1000.1 (Apophatic kernel boundary carrier)**.** *An* $\mathsf{ApophaticKernelBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (A, S, Q, R, G, H, C, P, N)$$

with the following displayed rows:

1. *A is the accepted* $\mathsf{ApophaticName}^{\uparrow}$ *row naming the external dependency position;*
2. *S is the accepted* $\mathsf{ApophaticSocket}^{\uparrow}$ *row recording the requested supply shape and socket ledger;*
3. *Q is the kernel-boundary question that asks whether the request is exposed at type or ledger level;*
4. *R is the refusal ledger for any request that would enter as an axiom, hidden setup field, host quotient, selected representative, or unrecorded supply;*
5. *G is the audit gate row that reads back the question, refusal outcome, and visible route;*
6. *H records componentwise* hsame *transports for the name, socket, question, refusal, gate, route, provenance, and local certificate rows;*
7. *C records the displayed* Cont *routes by which consumers read the name, socket, kernel-boundary question, refusal ledger, and audit gate;*
8. *P is the* Pkg *provenance over* $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{ExternalityGate}^{\uparrow}$, $\mathsf{NegativeCertificateBoundary}^{\uparrow}$ BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ApophaticKernelBoundary}^{\uparrow}}$ *row.*

The carrier contains no coordinate for an axiom, hidden setup field, host quotient, selected representative, primitive kernel supply, or unrecorded dependency.

Lean4 ✓ `BEDC.Derived.ApophaticKernelBoundaryUp.ApophaticKernelBoundaryTasteGate single carrier alignment`

Theorem 1000.2 (Apophatic kernel boundary NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ApophaticKernelBoundary}^{\uparrow}}$ *surface for Definition 1000.1 consists exactly of carrier admission for* $K = (A, S, Q, R, G, H, C, P, N)$*, name-to-socket routing from* A *to* S*, kernel-boundary refusal exactness through* Q *and* R*, audit-readback stability through* G*, componentwise transport through* H*, displayed route replay through* C*, package provenance through* P*, local naming through* N*, and non-internalization of the refused kernel-facing supply.*

Proof. Project the carrier. Its displayed rows are exactly the apophatic name, apophatic socket, kernel-boundary question, refusal ledger, audit gate, transport, route, provenance, and local naming rows.

Use the sibling packets cited above. The $\mathsf{ApophaticName}^{\uparrow}$ row supplies the named externality, the $\mathsf{ApophaticSocket}^{\uparrow}$ row supplies the socket ledger, the $\mathsf{ExternalityGate}^{\uparrow}$ row supplies visible gate readback, and the $\mathsf{NegativeCertificateBoundary}^{\uparrow}$ row supplies the refusal discipline for attempted internalizers.

The local NameCert surface is therefore exhausted by the displayed packet. Since the carrier has no coordinate for an axiom, hidden setup field, host quotient, selected representative, primitive kernel supply, or unrecorded dependency, no such object can be produced by the certificate. □

Theorem 1000.3 (Apophatic kernel boundary noninternalization)**.** *Every accepted* $\mathsf{ApophaticKernelBoundary}^{\uparrow}$ *packet keeps kernel-facing supply requests outside the generated substrate unless they are displayed as type-level or ledger-level rows. A consumer may cite the name row* A*, socket row* S*, boundary question* Q*, refusal ledger* R*, audit gate* G*, transport row* H*, route row* C*, provenance row* P*, and local naming row* N*, but it cannot extract an axiom, hidden setup field, host quotient, selected representative, primitive kernel supply, or unrecorded dependency from the packet.*

Proof. Begin with the carrier inventory of Definition 1000.1. The packet displays the request, the gate question, the refusal ledger, and the readback route, but it does not display the requested kernel-facing supply as an internal coordinate.

Apply Definition 1000.2. A consumer route must pass through the name-to-socket route, the kernel-boundary question, the refusal ledger, and the audit gate before it can cite the packet.

Thus any route asking for an axiom, hidden setup field, host quotient, selected representative, primitive kernel supply, or unrecorded dependency asks for data absent from the carrier and refused by the ledger. □

Theorem 1000.4 (Apophatic kernel boundary public route)**.** *Every public consumer of an accepted* $\mathsf{ApophaticKernelBoundary}^{\uparrow}$ *packet factors through the displayed route*

$$A \to S \to Q \to R \to G \to (H, C, P, N).$$

The route first names the externality, then records the socket, then asks the kernel-boundary question, then reads the refusal ledger, then exposes the audit gate, and only then replays transport, continuation, provenance, and local NameCert rows. No public route bypasses R *or* G *to reach an axiom, hidden setup field, host quotient, selected representative, primitive kernel supply, or unrecorded dependency.*

Proof. Read the displayed order in Definition 1000.1. The rows A, S, Q, R, G appear before the transport, continuation, provenance, and local naming rows.

The NameCert obligations of Definition 1000.2 bind the name-to-socket route, refusal exactness, and audit-readback stability to that same carrier order. Hence a public citation of the packet must retain the refusal ledger and gate readback.

The noninternalization theorem then excludes every requested supply that is not a displayed row. The public route is therefore exactly the finite route through $A, S, Q, R, G, H, C, P, N$. □

Falsifiable prediction: Every accepted ApophaticKernelBoundaryUp consumer reaches a refusal-ledger row before it may cite a kernel-boundary request, and no consumer extracts an axiom, hidden setup field, host quotient, or unrecorded supply from the packet.

Independence witness: apophaticname, apophaticsocket, externalitygate, negativecertificate-boundary: ApophaticNameUp lacks a kernel-boundary refusal ledger, ApophaticSocketUp lacks the gate-readback row, ExternalityGateUp lacks the primitive-kernel refusal boundary, and NegativeCertificateBoundaryUp lacks the name-to-socket route; no bijection preserves all rows A,S,Q,R,G,H,C,P,N.

The proposed Lean `TasteGate.lean` boundary is `lean4/BEDC/Derived/ApophaticKernelBoundaryUp/TasteG` It must provide `Nontrivial ApophaticKernelBoundaryUp` and `FieldFaithful ApophaticKernelBoundaryUp` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{ApophaticKernelBoundary}^{\uparrow}}$.

Constructive story: An $\mathsf{ApophaticKernelBoundary}^{\uparrow}$ packet is generated from an apophatic-name row, an apophatic-socket row, a kernel-boundary question, a refusal ledger, an audit gate, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ApophaticKernelBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1000.1, Definition 1000.2, Definition 1000.3, and Definition 1000.4 bind the finite kernel-boundary refusal carrier, public route, and non-internalization surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ApophaticKernelBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not supply a kernel axiom, hidden setup field, host quotient, selected representative, primitive kernel supply, Lean verification, or bridge checking for $\mathsf{ApophaticKernelBoundary}^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, name-to-socket routing, kernel-boundary refusal exactness, audit-readback stability, non-internalization, nontriviality, and field faithfulness for the same finite packet.

Chapter 1001

A Concrete Naming Certificate for $\mathsf{RealSealAdmissionCut}^{\uparrow}$

The $\mathsf{RealSealAdmissionCut}^{\uparrow}$ packet records the finite boundary at which a Real-completion route becomes admissible. It sits after the observation-budget limiter of chapter 903, the finite window carrier of chapter 126, and the $\mathsf{RegSeqRat}^{\uparrow}$ readback of chapter 301, and before any $\mathsf{Real}^{\uparrow}$ seal or $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff is consumed. The packet is an admission cut: it records the ordered entry boundary for a finite route, not a host completeness principle, quotient stream, selected limit, or independent real equality.

Definition 1001.1 (Real seal admission-cut carrier)**.** *A* $\mathsf{RealSealAdmissionCut}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (E, B, W, Q, S, L, H, C, P, N)$$

with the following displayed rows:

1. *E is the finite seal-request row whose requested observation is being admitted;*
2. *B is the* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *row that caps the request before any window read is served;*
3. *W is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row admitted under that budget;*
4. *Q is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained only from the displayed window;*
5. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row that may be consumed only after E, B, W, Q have been displayed;*
6. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row that reads the same admitted route;*
7. *H records componentwise* hsame *transport for the request, budget, window, readback, seal, limit handoff, route, provenance, and local naming rows;*
8. *C records the displayed* Cont *route from request to budget admission, from budget admission to window, from window to readback, from readback to Real seal, and from the Real seal to the Cauchy-limit handoff;*
9. *P is the* Pkg *provenance over* BHist, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$ *row.*

The carrier contains no coordinate for an unbounded observation schedule, a window served outside B, a $\mathsf{RegSeqRat}^{\uparrow}$ *readback outside W, a* $\mathsf{Real}^{\uparrow}$ *seal outside Q, a selected host limit, a quotient stream equality, or an ambient completeness theorem.*

Theorem 1001.2 (Real seal admission-cut NameCert obligations)**.** *For the carrier of Definition 1001.1, the local* $\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$A = (E, B, W, Q, S, L, H, C, P, N),$$

budget-limited request admission, StreamName window locality, RegSeqRat readback locality, Real seal ordering, CauchyLimitSeal handoff ordering, componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, local naming, and non-escape of any seal route that bypasses* B *or* W*.*

Proof. Project the carrier of Definition 1001.1. The finite packet exposes the request, budget, window, readback, seal, handoff, transport, route, provenance, and local naming rows.

Budget-limited request admission uses the sibling limiter row. The request E is admitted only through B, and the StreamName window W is served only under that admitted budget.

Readback and seal ordering then follow the displayed route. The $\mathsf{RegSeqRat}^{\uparrow}$ row Q reads the finite window W, the $\mathsf{Real}^{\uparrow}$ seal S reads Q, and the $\mathsf{CauchyLimitSeal}^{\uparrow}$ row L consumes the same admitted seal route.

The transport, continuation, provenance, and naming rows preserve that order. Since the carrier has no coordinate for a bypassing schedule, host limit, quotient stream equality, independent seal, or ambient completeness theorem, the local NameCert surface is exhausted by the displayed admission cut. □

Theorem 1001.3 (Real seal admission-cut route non-escape)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read or* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff accepted through a* $\mathsf{RealSealAdmissionCut}^{\uparrow}$ *packet factors through the ordered finite boundary*

$$E \to B \to W \to Q \to S \to L.$$

A route that bypasses either the observation-budget limiter B *or the StreamName window* W *is not admitted by the packet and cannot be consumed as the displayed Real-completion handoff.*

Proof. Begin with the NameCert obligations of Definition 1001.2. They force every admitted read to expose the request, limiter, window, readback, seal, and limit-handoff rows in the displayed order.

Use H and C to transport and replay the same finite route. Componentwise hsame transport cannot replace the budget row or the window row, and the displayed continuation route has no branch from E directly to Q, S, or L.

It remains to exclude downstream escape. The carrier inventory has no row for an unbounded observation schedule, a selected host limit, quotient stream equality, independent real equality, or ambient completeness. Therefore any downstream $\mathsf{Real}^{\uparrow}$ or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer receives only the admitted boundary $E, B, W, Q, S, L, H, C, P, N$. □

Theorem 1001.4 (Real seal admission-cut source scope)**.** *Every admitted* $\mathsf{RealSealAdmissionCut}^{\uparrow}$ *packet exposes the ordered source faces*

$$E, B, W, Q, S, L$$

as the request face, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *face,* $\mathsf{StreamName}^{\uparrow}$ *finite-window face,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback face,* $\mathsf{Real}^{\uparrow}$ *seal face, and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff face. No consumer of the packet may read* Q*,* S*, or* L *without first projecting the budget and window faces* B *and* W*.*

Proof. Project the carrier of Definition 1001.1. Its first six rows are named in the order E, B, W, Q, S, L, and the definition assigns these rows to the request, budget limiter, window, readback, Real seal, and limit handoff.

Apply Definition 1001.2. The local certificate surface accepts readback, seal, and handoff rows only as part of the displayed admission chain.

Finally apply Definition 1001.3. Since every admitted downstream read factors through $E \to B \to W \to Q \to S \to L$, a consumer that skips B or W is outside the packet's admitted source scope. □

Theorem 1001.5 (Real seal admission-cut classifier transport)**.** *For accepted packets with displayed rows*

$$A = (E, B, W, Q, S, L, H, C, P, N),$$

componentwise hsame *on the request, budget, window, readback, seal, handoff, provenance, and naming faces, together with the replay row C, transports admission of the same finite boundary. The transported packet has no bypass route from E to Q, S, or L, and no route from W to a host-selected limit outside the displayed handoff.*

Proof. Use the carrier definition to separate the transport row H from the replay row C. The row H records componentwise hsame for the displayed faces, while C records the displayed Cont route through the same ordered boundary.

The NameCert obligations of Definition 1001.2 bind those two rows to carrier admission, window locality, readback locality, Real-seal ordering, and CauchyLimitSeal handoff ordering. Transport therefore preserves the classifier only by preserving each displayed face and the replay route that connects them.

Apply Definition 1001.3 to exclude bypasses. A route from E directly to Q, S, or L, or from W to an unlisted host-selected limit, would not factor through the displayed admission chain and hence would not be the transported packet. □

Theorem 1001.6 (Real seal admission-cut ledger exactness)**.** *In an accepted* $\mathsf{RealSealAdmissionCut}^{\uparrow}$ *packet, the ledger rows P and N exhaust the local provenance and naming data for the admission cut. They record provenance over* BHist, $\mathsf{ObservationBudgetLimiter}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, hsame, Cont, *and* NameCert, *together with the local* $\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$ *row, and they exclude ledger coordinates for unbounded schedules, quotient streams, selected limits, host real equality, and ambient completeness.*

Proof. Project the final two rows of the carrier. The row P is the stated Pkg provenance over the displayed primitives, and N is the local naming row for the admission-cut packet.

Apply the NameCert obligations to identify which rows the local certificate admits. The obligations list provenance and local naming only through P and N, and the carrier contains no separate field for another provenance ledger or naming source.

The exclusions follow from the carrier inventory. Since unbounded schedules, quotient streams, selected limits, host real equality, and ambient completeness have no displayed coordinates, they cannot be recovered from P or N as local admission-cut ledger data. □

Theorem 1001.7 (Real seal admission-cut transport provenance field faithfulness)**.** *For an accepted* $\mathsf{RealSealAdmissionCut}^{\uparrow}$ *packet*

$$A = (E, B, W, Q, S, L, H, C, P, N),$$

componentwise hsame *transport and displayed* Cont *replay preserve the seal request E, observation-budget limiter B, finite window W, readback Q,* $\mathsf{Real}^{\uparrow}$ *seal S,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff L, provenance P, and local* NameCert *row N together. No transported packet may collapse two displayed rows, introduce an unlisted field, or bypass either B or W while remaining the same admitted Real-seal boundary.*

Proof. Project the carrier named in Definition 1001.1. Its displayed data are exactly the rows $E, B, W, Q, S, L, H, C, P, N$, with H reserved for componentwise hsame transport, C reserved for displayed Cont replay, P reserved for provenance, and N reserved for the local naming row.

Apply Definition 1001.2. The local certificate surface binds carrier admission, budget-limited request admission, window locality, readback locality, Real-seal ordering, CauchyLimitSeal handoff ordering, transport, replay, provenance, and local naming as one finite admission-cut packet.

Apply Definition 1001.3 to the transported route. Since every accepted Real seal or limit handoff still factors through

$$E \to B \to W \to Q \to S \to L,$$

the transport row cannot identify away a displayed component, add a host-side coordinate, or replace the budget-window boundary by an unlisted route.

Thus the projected rows H, C, P, N preserve both provenance and field separation for the displayed packet. Any collapse of two rows, any extra field, or any route bypassing B or W would remove one of the projections required by the carrier and would no longer be an accepted $\mathsf{RealSealAdmissionCut}^{\uparrow}$ packet. □

Theorem 1001.8 (Real seal admission-cut scoped boundary)**.** *For an accepted* $\mathsf{RealSealAdmissionCut}^{\uparrow}$ *packet*

$$A = (E, B, W, Q, S, L, H, C, P, N),$$

the scoped boundary is exactly the finite BHist *request row E, the* $\mathsf{ObservationBudgetLimiter}^{\uparrow}$ *row B, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row W, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row Q, the* $\mathsf{Real}^{\uparrow}$ *seal row S, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row L, componentwise* hsame *transport H, displayed* Cont *replay C,* Pkg *provenance P, and the local* $\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$ *row N. It admits no host real equality, quotient stream equality, selected limit, ambient completeness principle, or bypass route outside this displayed boundary.*

Proof. Start with the carrier of Definition 1001.1 and the NameCert obligations of Definition 1001.2. These identify the displayed BHist packet and bind its request, budget, window, readback, Real-seal, CauchyLimitSeal, transport, replay, provenance, and local naming rows as the complete admission surface.

The route and source restrictions are supplied by Definition 1001.3 and Definition 1001.4. They force every accepted downstream $\mathsf{Real}^{\uparrow}$ seal read and $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff to pass through

$$E \to B \to W \to Q \to S \to L.$$

Next apply Definition 1001.5. Componentwise hsame transport and the displayed Cont replay preserve the same finite boundary, so transport cannot introduce a classifier route from E directly to Q, S, or L, nor a route from W to a selected host limit.

Finally use Definition 1001.6 and Definition 1001.7. The Pkg row and local NameCert row exhaust the ledger data, while field faithfulness keeps $E, B, W, Q, S, L, H, C, P, N$ separated as the same admitted packet. Hence the scoped boundary is precisely the listed BEDC primitive rows, with host real equality, quotient stream equality, selected limits, ambient completeness, and bypass routes excluded. □

Theorem 1001.9 (Real seal admission-cut public NameCert)**.** *The carrier of Definition 1001.1, the obligation surface of Definition 1001.2, route non-escape from Definition 1001.3, the source scope of Definition 1001.4, classifier transport from Definition 1001.5, ledger exactness from Definition 1001.6, transport-provenance field faithfulness from Definition 1001.7, and the TasteGate marker together export a single public* $\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$ *interface. Downstream* $\mathsf{Real}^{\uparrow}$ *seal and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *packets consume that interface only as the displayed admission boundary*

$$E \to B \to W \to Q \to S \to L$$

with componentwise transport, replay, provenance, and local naming rows.

Proof. Start from the carrier definition. It fixes the finite rows $E, B, W, Q, S, L, H, C, P, N$ and gives the local naming row N the role of $\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$.

The obligation theorem identifies the admissible public surface of that row. Source scope and route non-escape then force every downstream $\mathsf{Real}^{\uparrow}$ seal read and every $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff through the same budget-window-readback chain, so the public object is the displayed admission boundary rather than a detached real or selected limit.

Classifier transport, ledger exactness, and transport-provenance field faithfulness supply the remaining public fields. They preserve the displayed faces under hsame and Cont, keep provenance in P, keep naming in N, and exclude any extra coordinate for quotient stream equality, ambient completeness, or a bypassing route.

The TasteGate marker certifies that the Lean-side carrier remains the same single finite packet. Therefore the listed rows and theorem surfaces repack as one public $\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$ interface for the RealUp seal and CauchyLimitSeal consumers. □

Theorem 1001.10 (Real seal admission-cut consumer bridge)**.** *The public* $\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$ *interface of Definition 1001.9 bridges to downstream* $\mathsf{Real}^{\uparrow}$ *seal and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumers exactly as the ordered finite boundary*

$$E \to B \to W \to Q \to S \to L$$

together with the componentwise transport, replay, provenance, and local naming rows H, C, P, N*. Any consumer route that bypasses* B *or* W*, or that uses quotient stream equality, selected limits, host real equality, unbounded schedules, or ambient completeness, is outside the bridge.*

Proof. Start with the carrier of Definition 1001.1. It supplies only the finite rows $E, B, W, Q, S, L, H, C, P, N$, with N serving as the local $\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$ row and with no coordinate for host-side completion data.

Apply Definition 1001.2, Definition 1001.3, and Definition 1001.4. These identify the admissible NameCert surface, force every downstream seal or handoff through $E \to B \to W \to Q \to S \to L$, and deny access to Q, S, or L before the budget row B and window row W have been projected.

Use Definition 1001.9 to repack that surface as the public consumer interface. The existing TasteGate marker fixes the same single finite carrier on the verification side, so the bridge has no additional carrier on which quotient stream equality, selected limits, host real equality, unbounded schedules, or ambient completeness could enter.

Thus the consumer bridge is precisely the displayed ordered boundary together with H, C, P, N. Every route not passing through B and W is excluded by the carrier inventory and the non-escape theorem, hence is not a $\mathsf{RealSealAdmissionCut}^{\uparrow}$ bridge to the downstream $\mathsf{Real}^{\uparrow}$ seal or $\mathsf{CauchyLimitSeal}^{\uparrow}$ consumer schema. □

Falsifiable prediction: A RealUp seal read that bypasses either the observation-budget limiter or StreamName window is not admitted by RealSealAdmissionCutUp.

Independence witness: finiterealroutecommitment, observationbudgetlimiter, streamname, regseqrat, cauchylimitseal: the admission cut is not bijective to any sibling because it records the ordered boundary at which the route becomes admissible, while the siblings record a commitment, a limiter, a window carrier, a readback, or a limit handoff separately.

The Lean `TasteGate.lean` boundary for this packet must provide `Nontrivial RealSealAdmissionCutUp` and `FieldFaithful RealSealAdmissionCutUp` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$.

Constructive story: A $\mathsf{RealSealAdmissionCut}^{\uparrow}$ packet is generated from a finite seal request, an observation-budget limiter, a StreamName window, a RegSeqRat readback, a RealUp seal, a CauchyLimitSeal handoff, componentwise transports, displayed replay, provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1001.1, Definition 1001.2, Definition 1001.3, Definition 1001.4, Definition 1001.5, Definition 1001.6, Definition 1001.7, Definition 1001.8, Definition 1001.9, Definition 1001.10, and

Lean4 ✓ `BEDC.Derived.RealSealAdmissionCutUp.taste gate`

bind the finite admission-cut carrier, ordered budget-window-readback boundary, RealUp seal ordering, CauchyLimitSeal handoff, non-escape surface, source scope, classifier transport, ledger exactness, transport-provenance field separation, scoped primitive boundary, public NameCert export, consumer bridge, and TasteGate marker.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RealSealAdmissionCut}^{\uparrow}}$, axiomClean)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close host real equality, quotient stream equality, selected limits, ambient completeness, unbounded observation, independent RealUp seal exposure, or machine-checked bridge status.

Upgrade path: No paper theory-axis grade remains for this chapter; bridge checking is a separate verification-axis task.

Chapter 1002

A Concrete Naming Certificate for CertificateAuditGate$^{\uparrow}$

The CertificateAuditGate$^{\uparrow}$ packet realizes the audit-gate boundary of chapter 9396 as a concrete local NameCert instance. It sits beside the operational membrane of chapter 533, the audit-gate boundary of chapter 526, and the replacement ledger of chapter 568. Those siblings expose membrane routing, gate rows, or replacement refusals; this packet binds the gate pass itself to a finite certificate surface that cannot be read as substrate-internal closure.

Falsifiable prediction: If the refusal row is removed, a gate pass can be read as substrate-internal closure rather than as local non-breach, and the NameCert classifier rejects that read.

Independence witness: operationalmembrane, auditgateboundary, effectivereplacementledger, reflectionlimitboundary, boundedsearchrefutation: none is bijective because CertificateAuditGate$^{\uparrow}$ carries gate input, checked surface, refusal, drift, axiom-purity, transport, route, provenance, and local naming rows in one packet, while each sibling lacks at least one of those rows or uses the rows for a different boundary question.

Definition 1002.1 (CertificateAuditGate carrier)**.** *A* CertificateAuditGate$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (I, S, R, D, A, H, C, P, N)$$

with the following displayed rows:

1. *I is the gate-input row, recording the finite manuscript, Lean target, source-file, and audit-command inputs supplied to the gate;*
2. *S is the checked-surface row, recording the finite pass surface actually inspected by the gate;*
3. *R is the refusal row, recording every reading that the gate rejects rather than promotes to substrate-internal closure;*
4. *D is the drift row, recording paper-Lean marker resolution, duplicate-label checks, and name-resolution failures as finite audit data;*
5. *A is the axiom-purity row, recording source-axiom refusal and dependency refusal for* Classical.choice, Quot.sound, *and* propext*;*
6. *H stores componentwise* hsame *transports for the input, checked surface, refusal, drift, axiom-purity, provenance, and naming rows;*

7. *C stores the* Cont *routes by which a consumer reads the gate input, checked surface, refusal, drift, axiom-purity, provenance, and local naming rows;*
8. *P records* Pkg *provenance over* $\mathsf{CertificateAuditGate}^{\uparrow}$, $\mathsf{AuditGateBoundary}^{\uparrow}$, $\mathsf{OperationalMembrane}^{\uparrow}$, $\mathsf{EffectiveReplacementLedger}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *data;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{CertificateAuditGate}^{\uparrow}}$ *row.*

The carrier contains no coordinate for a global repository-correctness theorem, a hidden source axiom, an unresolved Lean marker, a quotient representative, a choice selector, proposition equality, or a proof that a passing audit row becomes substrate-internal closure.

Lean4 ✓ `BEDC.Derived.CertificateAuditGateUp.TasteGate.CertificateAuditGateCarrier event flow fields iff`

Theorem 1002.2 (CertificateAuditGate obligation surface)**.** *For every accepted carrier $G = (I, S, R, D, A, H, C, P, N)$, the local* $\mathsf{NameCert}_{\mathsf{CertificateAuditGate}^{\uparrow}}$ *surface consists exactly of gate-input exposure, checked-surface exactness, refusal-row attachment, drift-row resolution, axiom-purity refusal, componentwise* hsame *stability, displayed* Cont *routing,* Pkg *provenance, and the local naming row. No consumer may cite a gate pass without exposing all nine rows of the same finite packet.*

Proof. Project the carrier of Definition 1002.1. The rows $I, S, R, D, A, H, C, P, N$ are introduced as separate coordinates of one finite BHist packet.

The first five rows give the gate-facing surface: supplied inputs, inspected checks, explicit refusals, paper-Lean drift data, and axiom-purity data. The support rows H, C, P, N then transport, replay, cite, and name those same rows without adding a further proof principle.

Thus the local NameCert obligation is not a scalar pass bit. It is the displayed finite packet, and any consumer omitting one of the rows has left the certificate surface named by the carrier. □

Lean4 ✓ `BEDC.Derived.CertificateAuditGateUp.TasteGate.CertificateAuditGateObligationSurface`

Theorem 1002.3 (CertificateAuditGate soundness boundary)**.** *For every accepted* $\mathsf{CertificateAuditGate}^{\uparrow}$ *carrier $G = (I, S, R, D, A, H, C, P, N)$, a passing checked-surface row S is sound only as local non-breach of the rows displayed by I, D, A, H, C, P, N. It does not assert global manuscript truth, host-kernel completeness, unrestricted semantic conservativity, or substrate-internal closure of the gate input.*

Proof. Read S together with the supplied inputs I. The checked surface records only the finite rows inspected for those inputs, so the pass result is bounded by the rows carried in the packet.

Use the drift row D and axiom-purity row A as the two gate ledgers. They report marker resolution, duplicate-label refusal, source-axiom refusal, and forbidden-dependency refusal as finite audit data.

Finally route the read through H, C, P, N. Componentwise transport, continuation replay, package provenance, and local naming keep the soundness claim on the displayed non-breach surface. Since no coordinate records global truth, host completeness, semantic conservativity, or internal closure, none can be projected from the pass row. □

Lean4 ✓ `BEDC.Derived.CertificateAuditGateUp.TasteGate.CertificateAuditGateSoundnessBoundary`

Theorem 1002.4 (CertificateAuditGate non-escape)**.** *Every consumer read of an accepted* $\mathsf{CertificateAuditGate}^{\uparrow}$ *packet factors through*

$$I, S, R, D, A, H, C, P, N.$$

The read may expose gate inputs, checked rows, refusals, drift data, axiom-purity data, transports, routes, provenance, and local naming, but it cannot escape to a hidden audit oracle, unresolved target replacement, quotient representative, choice selector, proposition equality, or substrate-internal theorem supplied by the gate.

Proof. Start with the carrier inventory in Definition 1002.1. It lists exactly the gate input, checked surface, refusal, drift, axiom-purity, transport, route, provenance, and naming rows.

Apply Definition 1002.2. A public certificate read must expose the same nine rows and cannot replace the packet by a pass token.

Apply Definition 1002.3. The pass row is local non-breach for the displayed audit data rather than a theorem about all host or manuscript behaviour.

The excluded objects require coordinates absent from G. Therefore continuation replay through C and naming through N can return only the finite certificate rows, not a hidden oracle or substrate-internal theorem. □

Lean4 ✓ `BEDC.Derived.CertificateAuditGateUp.TasteGate.CertificateAuditGateNonescape`

Theorem 1002.5 (CertificateAuditGate kernel scope)**.** *Every accepted* $\mathsf{CertificateAuditGate}^{\uparrow}$ *read is kernel-scoped by the finite rows*

$$I, S, R, D, A, H, C, P, N.$$

The carrier admission, checked-surface row, refusal row, drift row, axiom-purity row, transport row, route row, provenance row, and local naming row are all projected from the same packet, and no audit conclusion may be read outside that packet.

Proof. Project the carrier in Definition 1002.1. It gives the nine rows as coordinates of one finite BHist packet.

Apply Definition 1002.2 to identify those coordinates as the local $\mathsf{NameCert}_{\mathsf{CertificateAuditGate}^{\uparrow}}$ surface. Apply Definition 1002.4 to rule out hidden audit oracles, unresolved target replacement, quotient representatives, choice selectors, proposition equality, and substrate-internal theorem export.

Thus the audit read is exactly kernel-scoped by the displayed rows. □

Lean4 ✓ `BEDC.Derived.CertificateAuditGateUp.CertificateAuditGateKernelScope`

Theorem 1002.6 (CertificateAuditGate drift exactness)**.** *For every accepted* $\mathsf{CertificateAuditGate}^{\uparrow}$ *packet, the drift row D is read exactly as paper-Lean marker resolution, duplicate-label checking, and name-resolution failure data for the same gate input I and checked surface S. It is not a substitute Lean target, a hidden marker repair, or an external repository-correctness theorem.*

Proof. The carrier definition assigns D precisely to marker resolution, duplicate-label checks, and name-resolution failures.

Use Definition 1002.2 to keep the drift row attached to I, S, R, A, H, C, P, N inside the same local NameCert surface. Then use Definition 1002.3: the pass row is local non-breach for the displayed rows rather than a global correctness theorem.

The non-escape theorem excludes unresolved target replacement and hidden audit oracles, so the only drift information available to consumers is the exact row D. □

Lean4 ✓ `BEDC.Derived.CertificateAuditGateUp.CertificateAuditGateDriftExactness`

Theorem 1002.7 (CertificateAuditGate axiom-purity exactness)**.** *For every accepted* CertificateAuditGate$^{\uparrow}$ *packet, the axiom-purity row A records exactly source-axiom refusal and dependency refusal for* Classical.choice*,* Quot.sound*, and* propext*. It does not assert semantic conservativity, host-kernel completeness, or a proof principle beyond the inspected finite audit row.*

Proof. Project A from Definition 1002.1. The row is defined as the finite axiom-purity ledger for source-axiom refusal and the named forbidden dependencies.

Apply Definition 1002.2 and Definition 1002.3. Together they keep A inside the local checked surface and prevent the pass row from becoming a semantic-conservativity or host-completeness theorem.

Finally Definition 1002.4 prevents the consumer from escaping to a hidden source axiom, quotient representative, choice selector, or proposition equality. Hence the axiom-purity claim is exact for A and no stronger. □

Lean4 ✓ `BEDC.Derived.CertificateAuditGateUp.taste gate`

Theorem 1002.8 (CertificateAuditGate public export)**.** *An accepted* CertificateAuditGate$^{\uparrow}$ *packet exports only the public rows*

$$I, S, R, D, A, H, C, P, N.$$

Consumers may read gate input, checked surface, refusal, drift, axiom-purity, componentwise transport, displayed route, provenance, and local naming from the same finite packet. They may not export repository completeness, host-kernel completeness, semantic conservativity, quotient representatives, choice selectors, proposition equality, unresolved target replacement, or substrate-internal closure from a gate pass.

Proof. Project the carrier in Definition 1002.1. The displayed packet contains exactly the gate input, checked surface, refusal, drift, axiom-purity, transport, route, provenance, and naming rows.

Apply Definition 1002.2, Definition 1002.6, and Definition 1002.7. These identify the checked surface, drift row, and axiom-purity row as finite public audit rows rather than hidden correctness oracles.

Apply Definition 1002.4 and Definition 1002.5. The public export is therefore bounded by $I, S, R, D, A, H, C, P, N$ and cannot leave the local NameCert packet. □

Lean4 ✓ `BEDC.Derived.CertificateAuditGateUp.CertificateAuditGatePublicExport`

Theorem 1002.9 (CertificateAuditGate bridge boundary)**.** *An accepted* CertificateAuditGate$^{\uparrow}$ *public export through*

$$I, S, R, D, A, H, C, P, N$$

remains a paper-side certificate surface until a separate standard bridge theorem is supplied. The pass row S cannot be read as bridgeChecked*, repository completeness, host-kernel completeness, semantic conservativity, a quotient representative, a choice selector, proposition equality, unresolved target replacement, or substrate-internal closure.*

Proof. Begin with the public export of Definition 1002.8. It exposes exactly the rows $I, S, R, D, A, H, C, P, N$ and excludes repository completeness, host-kernel completeness, semantic conservativity, quotient representatives, choice selectors, proposition equality, unresolved target replacement, and substrate-internal closure.

Apply the soundness boundary of Definition 1002.3. The pass row is local non-breach for the displayed audit rows, not a theorem about all manuscript, repository, host-kernel, or semantic behaviour.

Use drift exactness from Definition 1002.6 and axiom-purity exactness from Definition 1002.7. These keep D and A as exact finite audit rows rather than bridge certificates or external correctness principles.

Finally apply non-escape and kernel scope, Definition 1002.4 and Definition 1002.5. The public read remains inside the same local NameCert packet, so bridge-checked status requires a separate standard bridge theorem. □

Lean4 ✓ `BEDC.Derived.CertificateAuditGateUp.CertificateAuditGateBridgeBoundary`

Closure status for $\mathsf{NameCert}_{\mathsf{CertificateAuditGate}\uparrow}$.

Constructive story: A $\mathsf{CertificateAuditGate}^{\uparrow}$ packet is generated from gate input, checked surface, refusal, drift, axiom-purity, componentwise transport, displayed route, provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CertificateAuditGate}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1002.1, Definition 1002.2, Definition 1002.3, Definition 1002.4, Definition 1002.8, and Definition 1002.9 bind the finite audit-gate certificate surface, its public non-escape boundary, and its paper-side bridge boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CertificateAuditGate}\uparrow}, \mathsf{theoremChecked})$

Lean target: `BEDC.Derived.CertificateAuditGateUp.taste\_gate`

Ledger evidence: BEDC.Meta.DiscoveryDeltaLedger.certificateAuditGateDeltaLedger

Bridge status: none

Origin: ai

Not claimed: This chapter does not claim bridge checking, global repository correctness, host-kernel completeness, semantic conservativity, quotient representatives, choice selectors, proposition equality, or substrate-internal closure from a gate pass.

Upgrade path: Bridge-checked status requires a separate standard bridge package for the same finite audit-gate surface.

Chapter 1003

A Concrete Naming Certificate for $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$

The $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$ packet makes the no-global-synchronization row of Definition 9419.4 into a concrete finite carrier. It is not a multi-Hist configuration, an observer-frame packet, a coupling ledger, an invariant value, or a causal-rate route. It stores the refusal row itself, together with the displayed histories, locality rows, hsame transport, Cont routes, package provenance, and local naming data that let downstream consumers cite the boundary without treating it as prose.

Definition 1003.1 (NoGlobalSyncBoundary carrier)**.** *A* $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (H, L, R, S, C, P, N)$$

with the following displayed rows:

1. $H = (H_1, \ldots, H_n)$ *is the finite row of displayed observer histories;*
2. $L = (L_1, \ldots, L_n)$ *is the locality ledger, with* L_i *naming the local rows of* H_i *available to consumers;*
3. R *is the refusal row, recording that the packet admits no privileged shared clock, global observer frame, total observer order, or selected synchronization map;*
4. S *records the displayed* hsame *transports for the observer-history, locality-ledger, refusal, route, provenance, and naming rows;*
5. C *records displayed* Cont *routes for reading the histories, locality ledgers, refusal row, transport rows, package provenance, and local naming row;*
6. P *is the* Pkg *provenance over* $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$, $\mathsf{FiniteMultiHistPacket}^{\uparrow}$, $\mathsf{ObserverFrameRefusal}^{\uparrow}$, $\mathsf{ObservationCoupling}^{\uparrow}$, $\mathsf{InterHistInvariant}^{\uparrow}$, $\mathsf{CrossHistCausalRate}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
7. N *is the local* $\mathsf{NameCert}_{\mathsf{NoGlobalSyncBoundary}^{\uparrow}}$ *row.*

The carrier has no coordinate for a shared clock, privileged frame, host-side observer order, synchronization selector, causal relation, invariant value, maximum-rate witness, metric row, or quotient of histories.

Theorem 1003.2 (NoGlobalSyncBoundary NameCert obligations)**.** *For the carrier of Definition 1003.1, the local* $\mathsf{NameCert}_{\mathsf{NoGlobalSyncBoundary}^{\uparrow}}$ *surface consists exactly of carrier admission*

for

$$G = (H, L, R, S, C, P, N),$$

displayed observer-history rows through H, locality-ledger exactness through L, explicit refusal of shared clocks, privileged frames, total observer orders, and synchronization selectors through R, componentwise hsame *transport through S, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Proof. Carrier admission is projection from Definition 1003.1. The rows H, L, R, S, C, P, N account for the observer histories, locality ledgers, refusal ledger, transport table, continuation routes, provenance, and local naming surface.

The positive rows H and L say which histories and locality rows may be read. The negative row R says which global synchronization data are refused. The structural rows S, C, P, N transport, replay, name, and record provenance for exactly those displayed rows.

No further row is available in the carrier. Thus every local NameCert obligation is either a projection from one of the displayed rows or the boundary clause that the missing global clock, frame, order, and selector are not admitted coordinates. □

Theorem 1003.3 (NoGlobalSyncBoundary frame-refusal handoff)**.** *Every accepted* NoGlobalSyncBoundary$^{\uparrow}$ *packet supplies the refusal row needed by an* ObserverFrameRefusal$^{\uparrow}$ *consumer. The consumer may read the displayed histories H, locality ledgers L, refusal row R, transport rows S, routes C, provenance P, and local naming row N, but it may not promote any of them to a shared clock, privileged observer frame, total observer order, or selected synchronization map.*

Proof. Read the carrier coordinates from Definition 1003.1. The refusal row R is explicitly part of the packet, and the rows S, C, P, N give the transport, route, provenance, and naming data by which an observer-frame consumer can cite it.

Apply Definition 1003.2. The same local NameCert surface that admits R also records the refusal of shared clocks, privileged frames, total observer orders, and synchronization selectors.

The handoff therefore carries negative boundary data, not an admitted global frame. Any accepted ObserverFrameRefusal$^{\uparrow}$ use can consume R as the displayed refusal row, while the missing synchronization objects remain outside the public packet. □

Theorem 1003.4 (NoGlobalSyncBoundary finite-packet non-escape)**.** *Every accepted* NoGlobalSyncBoundary$^{\uparrow}$ *consumer route factors through the finite rows*

$$H, L, R, S, C, P, N.$$

A consumer that exports a shared clock, privileged frame, total observer order, selected synchronization map, causal-rate route, invariant value, coupling ledger, metric row, or quotient of histories without displaying it as refused data has left the packet.

Proof. The carrier in Definition 1003.1 is finite and lists exactly seven rows. The rows H and L provide local history and locality access, R provides the refusal boundary, and S, C, P, N provide transport, replay, provenance, and naming.

No coordinate of this tuple is a shared clock, privileged frame, total observer order, selected synchronization map, causal-rate route, invariant value, coupling ledger, metric row, or quotient of histories. These objects cannot be projected from the accepted packet as admitted data.

It remains only the refusal case. If such an object is mentioned by an accepted consumer, it must be mentioned through R as excluded boundary data and replayed through the displayed routes in C. Otherwise the consumer has introduced a row that is not part of $G = (H, L, R, S, C, P, N)$. □

Theorem 1003.5 (NoGlobalSyncBoundary multi-Hist lattice link)**.** *Every accepted* NoGlobalSyncBoundary$^{\uparrow}$ *consumer reads the refusal row as a downstream lattice edge from the multi-history configuration surface of chapter 474 through the invariant surface of chapter 656, the causal-rate surface of chapter 478, and the maximum-rate boundary of chapter 594. The consumer may cite those sibling carriers only as displayed dependency rows, and it still exports no shared clock, privileged frame, selected synchronization map, causal-rate route, metric row, or quotient of histories.*

Proof. Project the carrier of Definition 1003.1. Its coordinates expose H, L, R, S, C, P, N: displayed histories, locality ledgers, the refusal row, componentwise transport, continuation routes, provenance, and local naming.

Apply the local NameCert obligations of Definition 1003.2. The provenance row P may name the multi-Hist, inter-Hist invariant, cross-Hist causal, and maximum-rate sibling surfaces as dependency rows, while the refusal row R records that no global synchronization object is admitted.

Finally apply Definition 1003.4. A consumer route that reads the cited siblings still factors through the finite packet $G = (H, L, R, S, C, P, N)$. Thus the sibling rows are provenance and consumer routes for the Inter-Hist locality lattice, not hidden synchronization data, causal-rate data, metric data, or a quotient of histories. □

Theorem 1003.6 (NoGlobalSyncBoundary public consumer theorem)**.** *Any downstream consumer citing* NoGlobalSyncBoundary$^{\uparrow}$ *may export only the public refusal boundary over the displayed histories H, locality ledger L, refusal row R, componentwise* hsame *transport S, displayed* Cont *replay C,* Pkg *provenance P, and local* NameCert *row N. The consumer may not reinterpret the packet as a shared clock, privileged observer frame, total observer order, synchronization map, causal-rate route, invariant value, metric row, or quotient of histories.*

Proof. Begin with the finite-packet non-escape theorem Definition 1003.4. It says that every accepted consumer route factors through H, L, R, S, C, P, N and that no admitted coordinate stores a shared synchronization object.

Use the multi-Hist lattice link of Definition 1003.5. The public consumer may cite sibling histories, invariant rows, causal-rate rows, and maximum-rate boundaries only through provenance and displayed consumer routes.

Finally apply the NameCert obligations of Definition 1003.2. They identify R as the explicit refusal row and S, C, P, N as the transport, replay, provenance, and naming rows for that refusal. Thus the public export is exactly the refusal boundary, not a synchronization map or hidden global observer structure. □

Theorem 1003.7 (NoGlobalSyncBoundary TasteGate obligation)**.** *The later Lean site* `lean4/BEDC/Derived/NoG` *will provide explicit* Nontrivial NoGlobalSyncBoundary$^{\uparrow}$ *and* FieldFaithful NoGlobalSyncBoundary$^{\uparrow}$ *instances. These instances must keep the displayed histories, locality rows, refusal row,* hsame *transport,* Cont *routes, package provenance, and local naming row as distinguishable fields.*

Proof. The carrier separates positive locality data from the negative refusal row. A singleton collapse would identify a displayed history, a locality ledger, and the refusal of global synchronization, erasing the boundary that the packet is designed to expose.

Field faithfulness is the projection discipline for the displayed tuple. Each row of $G = (H, L, R, S, C, P, N)$ has a distinct consumer role, and the refusal row R must remain distinguishable from the finite multi-Hist rows and observer-frame handoff data. □

Lean4 ✓ `BEDC.Derived.NoGlobalSyncBoundaryUp.NoGlobalSyncBoundaryTasteGate single carrier alignment`

Falsifiable prediction: Any accepted NoGlobalSyncBoundaryUp consumer that exports a shared clock, privileged frame, total observer order, or selected synchronization map without a displayed refusal row refutes the packet.

Independence witness: finitemulthistpacket, observerframerefusal, observationcoupling, interhistinvariant, crosshistcausalrate: none is bijective because NoGlobalSyncBoundaryUp stores the refusal row itself rather than a configuration, observer-frame packet, coupling ledger, invariant value, or causal-rate route.

Closure status for $\mathsf{NameCert}_{\mathsf{NoGlobalSyncBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$ packet is generated from displayed observer histories, locality ledgers, a no-global-synchronization refusal row, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{NoGlobalSyncBoundary}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1003.1, Definition 1003.2, Definition 1003.3, Definition 1003.4, Definition 1003.5, Definition 1003.6, and

Lean4 ✓ `BEDC.Derived.NoGlobalSyncBoundaryUp.taste gate`

specify the public finite refusal boundary for no-global-synchronization consumers.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{NoGlobalSyncBoundary}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.NoGlobalSyncBoundaryUp.NoGlobalSyncBoundaryTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not construct a shared clock, privileged frame, total observer order, synchronization map, causal-rate route, invariant value, Lean proof, or bridge checking for $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$.

Upgrade path: The paper closure axis is mature for the displayed refusal boundary; bridge checking remains a verification-axis task over the same Lean target.

Chapter 1004

A Concrete Naming Certificate for $\mathsf{DyadicTailRadiusComparison}^{\uparrow}$

The $\mathsf{DyadicTailRadiusComparison}^{\uparrow}$ packet realizes the shared dyadic threshold comparison row used by the Real and Completion route of chapter 9238. It consumes the tail-radius ledger of chapter 757, the shared-tail modulus surface of chapter 983, the finite window service of chapter 126, the regular rational readback of chapter 301, and the Real seal boundary of chapter 38. The packet isolates the comparison row between two dyadic radius ledgers before any shared-tail or Real-completion consumer may treat the threshold as usable.

Definition 1004.1 (Dyadic tail-radius comparison carrier)**.** *A* $\mathsf{DyadicTailRadiusComparison}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$C = (L_0, L_1, \rho_0, \rho_1, \kappa, W_0, W_1, R_0, R_1, E, H, Q, P, N)$$

with the following displayed rows:

1. L_0 *and* L_1 *are the two accepted* $\mathsf{DyadicTailRadiusLedger}^{\uparrow}$ *rows supplying the left and right dyadic tail-radius ledgers;*
2. ρ_0 *and* ρ_1 *are the displayed radius rows read from those ledgers;*
3. κ *is the finite dyadic comparison row asserting that the two ledger radii admit a shared threshold usable by the downstream tail route;*
4. W_0 *and* W_1 *are the* $\mathsf{StreamName}^{\uparrow}$ *windows opened only after the comparison row has been displayed;*
5. R_0 *and* R_1 *are the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows served by the compared windows;*
6. E *is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after the compared ledger route has been consumed;*
7. H *records componentwise* hsame *transport for the ledgers, radii, comparison row, windows, readbacks, Real seal, provenance, and local name;*
8. Q *records the displayed* Cont *routes from each ledger to its radius row, from the two radii to* κ*, from* κ *to the windows, from the windows to the readbacks, and from the readbacks to the Real seal;*
9. P *is the* Pkg *provenance over* $\mathsf{DyadicTailRadiusLedger}^{\uparrow}$, $\mathsf{CauchySharedTailModulus}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*

10. N is the local $\mathsf{NameCert}_{\mathsf{DyadicTailRadiusComparison}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient streams, host real equality, selected limits, independent radius replacement, an unbounded threshold search, or an ambient completeness principle.

Lean4 ✓ `BEDC.Derived.DyadicTailRadiusComparisonUp.DyadicTailRadiusComparisonTasteGate single carrier alignment`

Theorem 1004.2 (Dyadic tail-radius comparison NameCert obligations)**.** *For the carrier of Definition 1004.1, the local* $\mathsf{NameCert}_{\mathsf{DyadicTailRadiusComparison}^{\uparrow}}$ *surface consists exactly of carrier admission for C, left and right ledger exposure through L_0, L_1, radius exposure through ρ_0, ρ_1, comparison admission through κ, window service through W_0, W_1, regular readback through R_0, R_1, Real seal ordering through E, componentwise transport through H, displayed replay through Q, provenance through P, and local naming through N. A shared-tail or Real-completion consumer obtains no seal read unless the displayed comparison row sits between the two radius ledger rows and the downstream windows.*

Proof. Project the displayed carrier. The two ledger rows, their radius rows, the comparison row, paired windows, readbacks, seal, transports, continuations, provenance, and local name are all explicit coordinates of the finite packet.

Read the sibling ledger and shared-tail routes. The two radius rows are consumed from chapter 757, while the downstream shared-tail consumer has the same finite-threshold shape as chapter 983. Therefore the local certificate must expose ρ_0, ρ_1, κ before the StreamName and RegSeqRat rows can be treated as a shared tail route.

The Real seal row is downstream of the same displayed route. Since the carrier contains no quotient stream, selected limit, hidden radius selector, unbounded threshold search, host real equality, or ambient completeness coordinate, the listed rows exhaust the local NameCert obligations. □

Theorem 1004.3 (Dyadic tail-radius comparison threshold order)**.** *Every accepted* $\mathsf{DyadicTailRadiusComparison}^{\uparrow}$ *packet exposes the shared threshold route in the order*

$$L_0, L_1, \rho_0, \rho_1, \kappa, W_0, W_1, R_0, R_1.$$

No downstream $\mathsf{CauchySharedTailModulus}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{StreamName}^{\uparrow}$ *consumer may read a paired window or readback before the comparison row κ has been displayed between the two radius ledger rows.*

Proof. Start with the carrier inventory of Definition 1004.1. The only route from the two radius ledgers to the paired windows passes through ρ_0, ρ_1 and then through the single comparison row κ.

Apply the NameCert obligations of Definition 1004.2. Ledger exposure precedes radius exposure, radius exposure precedes comparison admission, and comparison admission precedes window service and regular readback.

Finally compare the sibling shared-tail surfaces. The shared-tail modulus and regular tail-meet chapters may consume this packet only as a finite threshold route, so a consumer that reads W_0, W_1, R_0, R_1 without the displayed comparison row is outside the accepted packet. □

Theorem 1004.4 (Dyadic tail-radius comparison Real seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *seal read admitted through an accepted* $\mathsf{DyadicTailRadiusComparison}^{\uparrow}$ *packet factors through*

$$L_0, L_1, \rho_0, \rho_1, \kappa, W_0, W_1, R_0, R_1, E, H, Q, P, N.$$

The seal is a handoff from a displayed comparison between two dyadic radius ledgers, not from a quotient stream, a selected completed limit, or an ambient completeness theorem.

Proof. Use threshold order from Definition 1004.3. It places the paired windows and readbacks behind the two ledger radii and their comparison row.

Read the Real boundary through chapter 38. The seal row E appears only after the paired readbacks, so the Real-facing route cannot detach the seal from the comparison packet.

The structural rows H, Q, P, N replay and name the same finite route. They add transport, continuation, provenance, and local certificate data, but no hidden radius, no second comparison row, and no external completion object. □

Theorem 1004.5 (Dyadic tail-radius comparison non-escape)**.** *No accepted* $\mathsf{DyadicTailRadiusComparison}^{\uparrow}$ *packet exports quotient stream equality, host real equality, a selected limit, an unbounded tail search, a hidden radius selector, a private comparison oracle, or an ambient completeness principle. Every shared-tail or Real-completion consumer read is exhausted by*

$$L_0, L_1, \rho_0, \rho_1, \kappa, W_0, W_1, R_0, R_1, E, H, Q, P, N.$$

Proof. Inspect the carrier coordinates. The exported mathematical rows are precisely the two dyadic tail-radius ledgers, their two radius rows, one comparison row, two windows, two regular readbacks, and one Real seal.

Apply the Real seal handoff. Any completion-facing consumer must traverse those rows before reaching E, and the structural rows only transport, replay, package, and name that route.

The excluded objects have no carrier coordinate and no route in Q. Hence extracting any of them is not a read of the accepted comparison packet. □

Falsifiable prediction: No admitted $\mathsf{Real}^{\uparrow}$ seal read through $\mathsf{DyadicTailRadiusComparison}^{\uparrow}$ is accepted unless the displayed dyadic comparison row sits between the two $\mathsf{DyadicTailRadiusLedger}^{\uparrow}$ radius rows and the downstream shared-tail window/readback rows.

Independence witness: dyadictailradiusledger, cauchysharedtailmodulus, regularcauchytailmeet, streamname, real: none is bijective to $\mathsf{DyadicTailRadiusComparison}^{\uparrow}$ because this carrier stores two radius ledgers, their explicit comparison row, paired windows, paired readbacks, the Real seal handoff, and the structural certificate rows together.

The later Lean TasteGate boundary for this carrier must provide $\mathsf{Nontrivial}\ \mathsf{DyadicTailRadiusComparison}^{\uparrow}$ and $\mathsf{FieldFaithful}\ \mathsf{DyadicTailRadiusComparison}^{\uparrow}$ instances, so the comparison packet is represented by an inhabited and field-faithful finite row rather than by a vacuous shared-tail annotation.

Closure status for $\mathsf{NameCert}_{\mathsf{DyadicTailRadiusComparison}^{\uparrow}}$**.**

Constructive story: A $\mathsf{DyadicTailRadiusComparison}^{\uparrow}$ packet is generated from two DyadicTailRadiusLedger rows, two displayed radius rows, one dyadic comparison row, paired StreamName windows, paired RegSeqRat readbacks, a RealUp seal handoff, componentwise hsame transports, displayed Cont routes, Pkg provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DyadicTailRadiusComparison}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1004.1, Definition 1004.2, Definition 1004.3, Definition 1004.4, and Definition 1004.5 bind the finite dyadic radius comparison row used by shared-tail Real-completion consumers.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DyadicTailRadiusComparison}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, quotient stream equality, selected limits, host real equality, ambient completeness, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, radius-ledger comparison order, shared-tail window and readback routing, RealUp seal handoff, non-escape, and TasteGate instances for the same finite packet.

Chapter 1005

A Concrete Naming Certificate for $\mathsf{InscriptionRouteAudit}^{\uparrow}$

The $\mathsf{InscriptionRouteAudit}^{\uparrow}$ packet gives the inscription-event vision of chapter 9397 a public route audit from visible gap to accepted checker row and downstream consumer. It sits beside the local inscription point of chapter 610, the full audit trace of chapter 682, and the finite witness route of chapter 638. Those siblings respectively expose the supply socket, the broad inscription trace, and a finite consumer route; the present packet isolates the route by which a visible gap becomes a named accepted checker row before a public consumer may read it.

Definition 1005.1 (Inscription route-audit carrier)**.** *An* $\mathsf{InscriptionRouteAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (S, G, R, A, D, H, C, P, N)$$

with the following displayed rows:

1. *S is the prior source-scope row containing the records visible before the route is accepted;*
2. *G is the visible gap row whose public residue asks for a route;*
3. *R is the named route row proposed to connect the visible gap to a reusable checker surface;*
4. *A is the accepted checker row, recording the finite check by which R is admitted as public record data;*
5. *D is the downstream consumer row that may read the accepted route only after A is visible;*
6. *H records componentwise* hsame *transports for S, G, R, A, D together with continuation, provenance, and local naming rows;*
7. *C records the displayed* Cont *routes by which a consumer reads source scope, visible gap, named route, accepted checker, and downstream consumer rows;*
8. *P is the* Pkg *provenance over* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, $\mathsf{InscriptionPoint}^{\uparrow}$, $\mathsf{InscriptionAuditTrace}^{\uparrow}$, $\mathsf{InscriptionCommitmentSeal}^{\uparrow}$, $\mathsf{FiniteWitnessRoute}^{\uparrow}$, *and* $\mathsf{ProofTermErasureAuditRoute}^{\uparrow}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{InscriptionRouteAudit}^{\uparrow}}$ *row.*

The classifier accepts exactly packets with these nine displayed rows. It has no coordinate for a private motive, hidden checker, unchecked route, downstream right outside D, host process trace, or consumer path that bypasses the accepted checker row.

Lean4 ✓ BEDC.Derived.InscriptionRouteAuditUp.TasteGate.InscriptionRouteAuditTasteGate single carrier alignment

Theorem 1005.2 (InscriptionRouteAudit NameCert obligations)**.** *For the carrier of Definition 1005.1, the local* $\mathsf{NameCert}_{\mathsf{InscriptionRouteAudit}^{\uparrow}}$ *surface consists exactly of five finite obligations:*

1. *carrier exposure for* $Q = (S, G, R, A, D, H, C, P, N)$*;*
2. *visible-gap locality: every route read begins at the prior source scope* S *and the displayed gap row* G*;*
3. *accepted-route exactness: the named route* R *becomes public only through the accepted checker row* A*;*
4. *downstream consumer accountability: every public consumer row* D *factors through* A *before the consumer read is visible;*
5. *provenance and local naming exhaustion through* H, C, P, N*, with no private motive, hidden checker, unchecked route, or off-packet consumer right.*

Proof. Carrier exposure is projection from the displayed packet. The rows $S, G, R, A, D, H, C, P, N$ are the full inventory available to an audit reader.

The gap-facing route begins with S and G. These rows identify the prior records and the public gap residue; without them the named route has no visible socket to answer.

The checker-facing route then reads R through A. The accepted checker row is the only place where the proposed route is admitted as public record data, so no hidden checker or unchecked replay can replace it.

Finally, D, H, C, P, N bind downstream consumption, transport, continuation, provenance, and local naming to the same finite packet. Since the carrier has no private motive, host trace, or off-packet consumer coordinate, the five obligations exhaust the local certificate surface. □

Falsifiable prediction: If the route-audit carrier is atomic, every public downstream use must factor through the accepted checker row before the consumer row is visible.

Theorem 1005.3 (InscriptionRouteAudit falsifiable prediction)**.** *Every public downstream read of an accepted* $\mathsf{InscriptionRouteAudit}^{\uparrow}$ *carrier* $Q = (S, G, R, A, D, H, C, P, N)$ *factors through the accepted checker row* A *before the consumer row* D *is visible. A purported public use that reaches* D *while bypassing* A *is outside the carrier.*

Proof. Project the carrier of Definition 1005.1. The only consumer-facing row is D, and the definition places it after the named route and accepted checker rows R, A.

Apply the accepted-route exactness and downstream consumer accountability clauses of Definition 1005.2. They make A the public admission point for R and require every downstream read through D to factor through that checker row.

The transport, continuation, provenance, and local naming rows preserve this same route. Hence a consumer path that reaches D without first exposing A would require an additional carrier coordinate, which the packet does not contain. □

Independence witness: inscriptionauditrace, inscriptioncommitmentseal, inscriptionpoint, finite-witnessroute, prooftermerasureauditroute: the route-audit carrier has both accepted-checker and downstream-gap rows, while these siblings respectively lack the full route from visible gap to public consumer; hence no carrier bijection preserves all NameCert rows.

Theorem 1005.4 (InscriptionRouteAudit independence witness)**.** *The* InscriptionRouteAudit$^{\uparrow}$ *carrier is not bijective, under NameCert-row preservation, with* InscriptionAuditTrace$^{\uparrow}$, InscriptionCommitmentSeal$^{\uparrow}$, InscriptionPoint$^{\uparrow}$, FiniteWitnessRoute$^{\uparrow}$, *or* ProofTermErasureAuditRoute$^{\uparrow}$. *It uniquely binds the visible gap row G, the named route row R, the accepted checker row A, and the public consumer row D as one route-audit packet.*

Proof. Compare the displayed coordinates. The present carrier has the paired gap-to-checker and checker-to-consumer route

$$G \to R \to A \to D.$$

The inscription audit trace supplies a broader trace packet, while the commitment seal isolates a commitment row rather than the visible gap-to-checker route. The inscription point supplies the local socket and actuality rows, not the public consumer route from G through A.

The finite witness route supplies a Real-and-Completion consumer path, and the proof-term erasure audit route supplies erasure-facing audit rows. Neither contains this chapter's simultaneous visible gap, named route, accepted checker, and downstream public consumer rows. Thus no carrier bijection can preserve all local NameCert obligations. □

The Lean target family *BEDC.Derived.InscriptionRouteAuditUp* should provide a Nontrivial instance by exhibiting two distinct finite packets with different accepted checker rows, and a FieldFaithful instance whose projections recover $S, G, R, A, D, H, C, P, N$ from the carrier.

Theorem 1005.5 (InscriptionRouteAudit mature consumer surface)**.** *Downstream public consumers of* InscriptionRouteAudit$^{\uparrow}$ *read only the visible gap row G, named route row R, accepted checker row A, downstream consumer row D, componentwise transport row H, replay route row C, provenance row P, and local NameCert row N. No mature public read may inspect a private motive, hidden checker, unchecked route, or host process trace outside the displayed carrier.*

Proof. Project the carrier of Definition 1005.1. The consumer-facing rows are exactly G, R, A, D, H, C, P, N after the prior source scope has supplied the visible records.

The NameCert obligations in Definition 1005.2 require the named route to pass through the accepted checker row and require the downstream consumer row to factor through that checker. The falsifiable prediction in Definition 1005.3 gives the same consumer boundary as a public read discipline.

The independence witness in Definition 1005.4 excludes a sibling carrier bijection that would supply the missing private or host-side rows. Hence the displayed rows are the mature consumer surface. □

Closure status for NameCert$_{\text{InscriptionRouteAudit}^{\uparrow}}$.

Constructive story: An InscriptionRouteAudit$^{\uparrow}$ packet is generated from prior source scope, a visible gap, a named route, an accepted checker row, a downstream consumer row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{InscriptionRouteAudit}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1005.1, Definition 1005.2, Definition 1005.3, Definition 1005.4, Definition 1005.5, and

Lean4 ✓ `BEDC.Derived.InscriptionRouteAuditUp.taste gate`

bind the visible gap-to-accepted-route audit packet and its downstream consumer boundary.

Formal verification: FormalStatus(NameCert$_{\text{InscriptionRouteAudit}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.InscriptionRouteAuditUp.TasteGate.InscriptionRouteAuditTasteGate\_single\_carrier\_alig`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, private agency, host process traces, unchecked routes, downstream rights outside the displayed consumer row, or a completed ontology of inscription events.

Upgrade path: The public consumer surface is recorded; no further paper-theory grade remains for this carrier.

chapter 576 supplies the explicit contrary-record witness consumed by the GapClosureBoundary$^{\uparrow}$ gap-closure boundary, with the routed child below recording the finite witnessed-refutation dependency.

Chapter 1006

A Concrete Naming Certificate for $\mathsf{GapClosureBoundary}^{\uparrow}$

The $\mathsf{GapClosureBoundary}^{\uparrow}$ packet gives the shared GAP and T socket discipline of chapter 9415 a finite common boundary. It sits beside the causal commitment of chapter 505, the finite witnessed refutation of chapter 576, the other-minds commitment of chapter 499, the aspect chain of chapter 575, and the solipsism refusal of chapter 975. Those siblings package application faces; the present carrier isolates the common closure boundary consumed by all of them.

Definition 1006.1 (GapClosureBoundary carrier)**.** *A* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (G, S, R, H, C, P, N)$$

with the following displayed rows:

1. *G is the* GAP *request row, naming the forward-binding or socket-facing demand whose source is not generated by the closed substrate;*
2. *S is the source observation or socket row, displaying the finite record, locality cell, aspect side, or inscription route that the request may lawfully read;*
3. *R is the refusal and non-escape ledger, recording that an off-source closure request is not internalised;*
4. *H records componentwise* hsame *transports for G, S, R together with continuation, provenance, and naming rows;*
5. *C records the displayed* Cont *routes from the request row to the source row, and from every unsupported closure read to the refusal row;*
6. *P records* Pkg *provenance over* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, *and the hard-problem sibling packets that consume this boundary;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row.*

The classifier accepts exactly finite packets with these seven rows. It has no coordinate for internal universal closure, private other-minds access, host causal necessity, direct aspect reduction, or a T *supply that bypasses the displayed source route.*

Theorem 1006.2 (GapClosureBoundary NameCert obligations)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier $B = (G, S, R, H, C, P, N)$, the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *surface has exactly four obligations: carrier exposure for the finite request, source, refusal, and structural rows; source-route*

exactness for any displayed observation or socket row S; refusal-ledger routing for any request that tries to convert G into internal closure without S; and structural exhaustion through H, C, P, N. These obligations are sufficient for the shared boundary used by chapter 505, chapter 576, chapter 499, chapter 575, and chapter 975.

Lean4 ✓ `BEDC.Derived.GapClosureBoundaryUp.GapClosureBoundary namecert obligations`

Proof. Project the carrier of Definition 1006.1. The rows G, S, R, H, C, P, N are the full inventory visible to a boundary reader, so carrier exposure contributes no hidden coordinate.

Read the source route next. Any accepted use of the GAP request must show the source observation or socket row S before it can be consumed by a causal, refutation, other-minds, aspect-chain, or solipsism-refusal sibling.

Finally inspect a closure request with no displayed source route. The continuation row sends such a request to R, while H, P, N merely transport, package, and name the same finite packet. Since the carrier has no internal-closure coordinate, the four obligations exhaust the local certificate surface. □

Theorem 1006.3 (GapClosureBoundary refusal non-escape)**.** *Any accepted* GapClosureBoundary$^{\uparrow}$ *consumer that attempts to turn a* GAP *request into substrate-internal closure must first read the displayed source route S. If no such route is present, the consumer is routed to the refusal ledger R and receives no universal closure, private other-minds access, host causal necessity, direct aspect reduction, hidden* T *supply, or off-packet continuation.*

Lean4 ✓ `BEDC.Derived.GapClosureBoundaryUp.GapClosureBoundary refusal nonescape`

Proof. Use the NameCert obligations of Definition 1006.2. They divide every boundary read into the carrier exposure route, the displayed source route, and the refusal route.

When S is present, the consumer remains a reader of the finite source row and the structural rows H, C, P, N. The carrier still exports only a named boundary packet, not a substrate-internal closure principle.

When S is absent, the only available continuation is the refusal route into R. The refusal row is a ledger entry rather than a supply witness, so the excluded closure, access, necessity, reduction, hidden-source, and off-packet continuation coordinates cannot be exported. □

Theorem 1006.4 (GapClosureBoundary displayed source precondition)**.** *For every accepted* GapClosureBoundary$^{\uparrow}$ *carrier*

$$B = (G, S, R, H, C, P, N),$$

any supported closure read of B must expose the displayed source observation or socket row S before a hard-problem sibling consumer reads the packet. The only public precondition for such a read is the finite BHist *packet together with the* hsame *transports in H, the* Cont *source route in C, the* Pkg *provenance in P, and the local* NameCert *row N.*

Proof. Project the carrier definition. The packet has exactly the request row G, the displayed source row S, the refusal ledger R, and the structural rows H, C, P, N.

Use the NameCert obligation theorem Definition 1006.2. Its source-route exactness clause requires a supported observation or socket-facing read to display S before any sibling application consumes the boundary.

The refusal non-escape theorem Definition 1006.3 rules out replacing this precondition by an internal universal closure row. Thus the supported closure read has to expose S and remains inside the displayed BHist, hsame, Cont, Pkg, and NameCert surface. □

Theorem 1006.5 (GapClosureBoundary refusal ledger transport)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any off-source closure read of the request row* G *is transported to the refusal ledger* R *along the displayed structural rows* H, C, P, N*. This transport uses only componentwise* hsame*, the displayed* Cont *route to refusal,* Pkg *provenance, and the local* NameCert *row.*

Lean4 ✓ `BEDC.Derived.GapClosureBoundaryUp.GapClosureBoundary refusal ledger transport`

Proof. Start with an off-source request. By definition it has no displayed source route through S, so it cannot satisfy the source precondition of Definition 1006.4.

Apply refusal non-escape. The only available continuation sends the request to R, while the rows H, C, P, N transport, route, package, and name the same finite packet.

The structural rows do not add a hidden source. They preserve the refusal ledger through hsame, Cont, Pkg, and NameCert, so the off-source read is transported to R rather than to internal universal closure, private access, causal necessity, aspect reduction, or a hidden T supply. □

Theorem 1006.6 (GapClosureBoundary NameCert obligation triad)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the complete local NameCert obligation surface is carrier exposure, displayed source exactness, refusal-ledger routing, and structural rows. Carrier exposure reads* G, S, R *from the finite packet, displayed source exactness requires any supported closure read to pass through* S*, refusal-ledger routing sends off-source closure requests to* R*, and* H, C, P, N *only transport, route, package, and name those rows.*

Proof. Project the carrier of Definition 1006.1. It exposes exactly the request row, displayed source row, refusal ledger, and structural rows.

Apply Definition 1006.2 and Definition 1006.4. Together they identify carrier exposure and source-route exactness as the supported part of the local certificate.

Finally use Definition 1006.5. It gives the off-source routing clause, while the structural rows remain the same H, C, P, N rows already displayed by the carrier. □

Theorem 1006.7 (GapClosureBoundary classifier exhaustion)**.** *The* $\mathsf{GapClosureBoundary}^{\uparrow}$ *classifier accepts only finite packets with rows*

$$G, S, R, H, C, P, N.$$

No accepted classifier read adds an internal closure coordinate, hidden T *supply, private other-minds access, causal necessity row, direct aspect reduction, or off-packet continuation beyond those seven displayed rows.*

Proof. Read the classifier clause in Definition 1006.1. It states that accepted packets have exactly the seven displayed rows and names the unavailable coordinates.

Use Definition 1006.6. The local obligations inspect those same rows as carrier exposure, source exactness, refusal routing, and structural transport.

The displayed source precondition and refusal transport theorems cover the two possible closure-facing reads. Since both reads remain inside G, S, R, H, C, P, N, the classifier surface is exhausted by the finite packet. □

Theorem 1006.8 (GapClosureBoundary ledger nonescape)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the refusal ledger* R *cannot export internal closure, a hidden* T *supply, private other-minds access, causal necessity, or aspect reduction. It only records that an off-source request has no displayed source route through* S *and is therefore retained as a refusal row transported by* H, C, P, N*.*

Proof. Begin with Definition 1006.5. It sends every off-source closure read of G to R along the structural rows.

Apply Definition 1006.6. The ledger is one part of the local NameCert surface, not a generator for additional closure-facing data.

Finally project the carrier. The excluded internal closure, hidden source, other-minds, causal, and aspect-reduction data are not rows of B, so the refusal ledger cannot export them. □

Theorem 1006.9 (GapClosureBoundary sibling consumer exhaustion)**.** *The hard-problem sibling consumers listed in the* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet exhaust the exported boundary surface of* $B = (G, S, R, H, C, P, N)$*. Causal commitment, finite witnessed refutation, other-minds commitment, aspect-chain, and solipsism-refusal consumers may read the common request row* G*, source row* S*, refusal ledger* R*, and structural rows* H, C, P, N*, but none gains internal universal closure beyond that finite packet.*

Proof. Read the carrier and the NameCert obligation surface. The provenance row P records exactly the hard-problem sibling packets that consume this boundary, and the local certificate exposes no row beyond G, S, R, H, C, P, N.

Supported sibling reads use Definition 1006.4; they must expose S before consuming the packet. Off-source sibling reads use Definition 1006.5; they are sent to R through H, C, P, N.

Thus every listed sibling consumer is accounted for by either the displayed source route or the refusal ledger route. Since neither route contains an internal universal closure coordinate, the exported boundary is exhausted by the finite packet and no sibling acquires a stronger closure principle. □

Theorem 1006.10 (GapClosureBoundary source route exactness)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any consumer of* B *that reads a displayed source observation or socket row must route the* GAP *request row* G *through* S *before any application sibling consumes the boundary packet. The source route is the only admissible pre-consumption route for causal commitment, finite witnessed refutation, other-minds commitment, aspect-chain, and solipsism-refusal consumers.*

Proof. Project the carrier of Definition 1006.1. The only source-facing rows available to a consumer are the GAP request row G and the displayed source observation or socket row S.

Use the obligation summary of Definition 1006.2. Its source-route clause requires an accepted boundary consumer to exhibit S before any application sibling may consume the packet.

The refusal non-escape row of Definition 1006.3 rules out bypassing S by turning G into internal closure. Thus every accepted source-reading consumer uses the displayed route $G \longrightarrow S$ first. □

Theorem 1006.11 (GapClosureBoundary refusal ledger routing)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any off-source closure request is routed to the refusal ledger* R*. Such a request cannot export internal closure, a hidden* T *supply, or any continuation that bypasses the displayed source row* S*.*

Proof. Read the carrier of Definition 1006.1. It contains one request row G, one displayed source row S, one refusal ledger R, and the structural rows H, C, P, N.

Apply Definition 1006.2. Its refusal-ledger clause sends every closure read without the displayed source route to R rather than to a substrate-internal closure coordinate.

Now invoke Definition 1006.3. The refusal row is a ledger endpoint, not a supply row, so it exports neither internal closure nor hidden T data. □

Theorem 1006.12 (GapClosureBoundary structural exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the rows* H, C, P, N *only transport, route, package, and locally name the same seven-row packet. They add no further source, refusal, closure, or hidden* T *coordinate.*

Proof. Start from the carrier definition. The packet inventory is exactly G, S, R, H, C, P, N, with H assigned to componentwise hsame transport, C to displayed Cont routes, P to Pkg provenance, and N to the local $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ row.

The obligation summary identifies structural exhaustion as one of the four local certificate duties. Therefore the structural rows can only preserve and repackage the already displayed request, source, and refusal rows.

Finally use refusal non-escape. Since off-source closure is routed to R and R exports no hidden supply, the structural rows have no coordinate from which to generate a second source, internal closure, or hidden T row. □

Theorem 1006.13 (GapClosureBoundary root carrier exposure)**.** *Every root consumer of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier first sees exactly the finite packet*

$$B = (G, S, R, H, C, P, N).$$

The root-facing carrier exposure consists of the GAP *request row* G*, displayed source row* S*, refusal ledger* R*, componentwise transport* H*, displayed continuation routes* C*, package provenance* P*, and local* $\mathsf{NameCert}$ *row* N*, with no internal closure coordinate or hidden* T *supply preceding those rows.*

Proof. Project the carrier of Definition 1006.1. Its displayed inventory is the seven-row packet G, S, R, H, C, P, N, and the classifier admits no additional root-facing row.

Use Definition 1006.2 to read this inventory as the local carrier-exposure obligation. The source-route, refusal-ledger, and structural obligations are all obligations on the same packet rather than independent root carriers.

Finally apply structural exhaustion, Definition 1006.12. The rows H, C, P, N only transport, route, package, and name G, S, R, so a root consumer has no pre-packet coordinate from which to read internal closure, private access, causal necessity, direct aspect reduction, or a hidden T supply. □

Theorem 1006.14 (GapClosureBoundary root refusal exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every root off-source closure read is routed to the refusal row* R *through* H, C, P, N*. The route exports no internal closure coordinate and no hidden* T *supply beyond the displayed refusal ledger.*

Proof. Use the NameCert obligations of Definition 1006.2. They make refusal-ledger routing one of the root certificate duties and keep it inside the displayed carrier.

Apply the displayed-source precondition, Definition 1006.4. A root read without the displayed source row S cannot enter the supported source branch.

The refusal-ledger transport theorem, Definition 1006.5, sends that off-source read to R through H, C, P, N. Classifier exhaustion from Definition 1006.7 and root carrier exposure from Definition 1006.13 then exclude any internal closure coordinate or hidden T supply. □

Theorem 1006.15 (GapClosureBoundary root structural non-escape)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the structural rows* H, C, P, N *only transport, route, package, and*

name the displayed rows G, S, R. They do not add an internal closure row, a second source row, a second refusal ledger, or a hidden T *supply.*

Proof. Start with root carrier exposure from Definition 1006.13. The root packet has exactly the seven rows G, S, R, H, C, P, N.

The NameCert obligations of Definition 1006.2 assign H, C, P, N to componentwise transport, displayed route replay, package provenance, and local naming. These obligations do not create a new carrier coordinate.

Finally combine the displayed-source precondition, refusal-ledger transport, and classifier exhaustion of Definition 1006.4, Definition 1006.5, and Definition 1006.7. The structural rows can only preserve the supported branch through S or the refusal branch through R, so no hidden closure or T row escapes the displayed packet. □

Theorem 1006.16 (GapClosureBoundary root sibling handoff)**.** *Any* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutati}$ $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *consumer of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *root packet receives only the finite boundary packet*

$$G, S, R, H, C, P, N.$$

The handoff supplies the request row, displayed source row, refusal row, transport, continuation, provenance, and local naming rows, and it supplies no internal closure coordinate, hidden T *row, private access row, causal necessity row, direct aspect-reduction row, or off-packet continuation.*

Proof. Begin with the root carrier exposure theorem, Definition 1006.13. It fixes the handoff inventory as G, S, R, H, C, P, N before any hard-problem sibling reads the packet.

Use the NameCert obligations and displayed-source precondition, Definition 1006.2 and Definition 1006.4. Supported sibling reads pass through the displayed source branch, while unsupported reads cannot bypass the source check.

Apply refusal-ledger transport and classifier exhaustion from Definition 1006.5 and Definition 1006.7. The unsupported branch reaches R through H, C, P, N, and the classifier has no route to hidden closure data.

Therefore the listed siblings receive exactly the finite boundary packet G, S, R, H, C, P, N. The handoff has no coordinate for internal closure, a hidden T supply, private access, causal necessity, direct aspect reduction, or off-packet continuation. □

Theorem 1006.17 (GapClosureBoundary shared socket route package)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier $B = (G, S, R, H, C, P, N)$, the shared socket route available to root hard-problem consumers is the finite package consisting of the request row G, displayed source row S, refusal row R, componentwise transport H, displayed continuation routes C, package provenance P, and local naming row N. A supported socket read uses the route $G \longrightarrow S$ through H, C, P, N; an unsupported socket read uses the route $G \longrightarrow R$ through the same structural rows.*

Proof. Project the carrier exposure theorem, Definition 1006.13. It fixes the root inventory as the seven rows G, S, R, H, C, P, N.

Use the NameCert obligations of Definition 1006.2. They separate the source-route obligation from the refusal-ledger obligation while keeping both routes inside the same finite packet.

The displayed source precondition, Definition 1006.4, gives the supported branch $G \longrightarrow S$. The refusal-ledger transport theorem, Definition 1006.5, gives the unsupported branch $G \longrightarrow R$.

Thus the shared socket route is not a hidden supply route. It is exactly the public packet G, S, R, H, C, P, N with one supported source branch and one refusal branch. □

Theorem 1006.18 (GapClosureBoundary source refusal exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every supported root read is exhausted by the displayed source row* S*, and every unsupported root read is exhausted by the refusal row* R*. No accepted root read of* B *has a third route to internal closure, private access, causal necessity, direct aspect reduction, hidden* T *supply, or off-packet continuation.*

Proof. Begin with the shared socket route package above. It presents the root-facing read as either the source branch $G \longrightarrow S$ or the refusal branch $G \longrightarrow R$, transported through H, C, P, N.

For a supported read, apply Definition 1006.4. The consumer must expose the displayed source observation or socket row S before the packet is consumed, so the supported branch is exhausted by S and the structural rows.

For an unsupported read, apply Definition 1006.5. The request has no displayed source route and is sent to R along H, C, P, N.

Finally use sibling consumer exhaustion, Definition 1006.9. The listed hard-problem consumers receive no route outside the finite packet, so the source row and refusal row exhaust the root alternatives. □

Theorem 1006.19 (GapClosureBoundary hard-problem consumer handoff)**.** *Every* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *consumer of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet receives only the finite boundary packet*

$$B = (G, S, R, H, C, P, N).$$

The consumer may read a supported source route through G, S, H, C, P, N *or an unsupported refusal route through* G, R, H, C, P, N*, but it receives no consumer-specific closure row outside that packet.*

Proof. Read the carrier exposure theorem first. The handoff begins with $B = (G, S, R, H, C, P, N)$, so every downstream consumer starts from the same finite request, source, refusal, transport, continuation, provenance, and naming rows.

Apply Definition 1006.2. The local certificate exposes carrier, source-route, refusal-ledger, and structural duties; it does not expose a separate consumer-specific hard-problem row.

Use source refusal exhaustion above to split the handoff. Supported consumers receive the route through S, while unsupported consumers receive the refusal route through R.

Finally apply Definition 1006.9. The causal commitment, finite witnessed refutation, other-minds commitment, aspect-chain, and solipsism-refusal chapters consume the shared packet only, so the handoff remains a finite boundary rather than hidden supply. □

Theorem 1006.20 (GapClosureBoundary source-route obligation)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any supported root read of the* GAP *request must pass through the displayed source row* S *before a hard-problem sibling consumer may use the boundary. The support route is transported only by* H*, replayed only by* C*, packaged only by* P*, and locally named only by* N*.*

Proof. Begin with the displayed source precondition, Definition 1006.4. It requires any supported closure read to expose the source observation or socket row S before the packet is consumed.

Apply source route exactness, Definition 1006.10. The admissible pre-consumption route for the hard-problem siblings is the displayed route from G to S; no sibling may substitute an internal closure route.

The structural rows do not change this obligation. By Definition 1006.12, H, C, P, N only transport, replay, package, and name the same route, so every supported root read passes through S before it reaches a sibling consumer. □

Theorem 1006.21 (GapClosureBoundary refusal-ledger obligation)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any off-source root read of the request row* G *is routed to the refusal ledger* R *through* H, C, P, N*. Such a read receives only the refusal transport of the finite packet and no internal universal closure, hidden* T *supply, private other-minds access, causal necessity row, direct aspect reduction, or off-packet continuation.*

Proof. Start with the refusal-ledger transport theorem, Definition 1006.5. An off-source request has no displayed route through S, so the displayed continuation sends it to R along H, C, P, N.

Use refusal ledger routing, Definition 1006.11, to identify this as the root-facing obligation rather than an analytic side condition. The ledger endpoint is part of the same accepted packet and cannot be replaced by an undisplayed source.

Finally combine ledger nonescape and structural exhaustion, Definition 1006.8 and Definition 1006.12. The refusal row is preserved by transport, replay, provenance, and naming, while the excluded closure, hidden supply, other-minds, causal, aspect, and off-packet coordinates are absent from the carrier. □

Theorem 1006.22 (GapClosureBoundary root source handshake)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the complete root source route is the displayed handshake*

$$G \longrightarrow S$$

transported by H*, replayed by* C*, packaged by* P*, and locally named by* N*. Every downstream consumer in chapter 505, chapter 576, chapter 499, chapter 575, or chapter 975 reads the root request* G *through this source row before it may use the boundary as a causal, refutation, other-minds, aspect, or solipsism input.*

Proof. Start with the source-route obligation, Definition 1006.20. It already identifies S as the displayed source that every supported root read of G must expose.

Use source-route exactness, Definition 1006.10, to make the route unique at the root surface. The admissible handshake is $G \longrightarrow S$, not a route through internal closure or a sibling-specific private premise.

Finally apply structural exhaustion, Definition 1006.12. The rows H, C, P, N only transport, replay, package, and name the same handshake, so every listed downstream consumer receives the same finite source route. □

Theorem 1006.23 (GapClosureBoundary root refusal totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any root request that does not exhibit the handshake* $G \longrightarrow S$ *is routed to the refusal ledger* R*. The route to* R *is total for off-source causal, refutation, other-minds, aspect, and solipsism consumers, and it exports no internal closure, hidden* T *supply, private access row, causal necessity row, direct aspect-reduction row, or off-packet continuation.*

Proof. Apply Definition 1006.21. It sends every off-source root read of the request row G to the refusal ledger R through H, C, P, N.

Use refusal ledger routing, Definition 1006.11, to identify R as the ledger endpoint rather than a second source. Thus every listed consumer that lacks the displayed source handshake receives the same refusal route.

The non-escape theorem, Definition 1006.3, removes the excluded exits. Since R is not an internal closure coordinate or a hidden supply row, the refusal is total across the downstream root surface. □

Theorem 1006.24 (GapClosureBoundary root structural exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the structural rows* H, C, P, N *are the complete NameCert root surface beyond the request, source, and refusal rows. They transport the source handshake* $G \longrightarrow S$*, route off-source reads to* R*, package the same boundary for downstream causal, refutation, other-minds, aspect, and solipsism consumers, and add no further root coordinate.*

Proof. Read the structural exhaustion theorem, Definition 1006.12. It restricts H, C, P, N to transport, route, package, and local naming for the seven-row packet.

Combine it with the root source handshake. The structural rows preserve the displayed route $G \longrightarrow S$ and cannot introduce a second source before a downstream consumer reads the boundary.

Combine it with root refusal totality. Off-source reads are routed to R, and the same structural rows preserve that refusal route without exposing an internal closure coordinate, hidden supply, or consumer-specific private row.

Therefore the complete root NameCert surface is exactly G, S, R, H, C, P, N, with H, C, P, N exhausting the structural part of the shared boundary. □

Theorem 1006.25 (GapClosureBoundary root source exactness)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any supported root read of the* GAP *request row* G *must expose the displayed source row* S *before a downstream hard-problem consumer reads the boundary. The support data available to that read is exactly the source route carried by* H*, replayed by* C*, packaged by* P*, and locally named by* N*.*

Proof. Project the seven-row carrier of Definition 1006.1. The only source-facing coordinate in the accepted packet is the displayed row S.

Apply the NameCert obligations and displayed-source precondition, Definition 1006.2 and Definition 1006.4. They require any supported read of G to pass through the displayed observation or socket row before a sibling consumer may use the packet.

Finally use root structural exhaustion, Definition 1006.24. The rows H, C, P, N transport, replay, package, and name the same source route, so they do not add an alternate root source. □

Theorem 1006.26 (GapClosureBoundary consumer refusal exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any downstream consumer that lacks the displayed source row* S *is exhausted by the refusal ledger* R*. The refusal route gives no internal universal closure, hidden* T *supply, private other-minds access, causal necessity row, direct aspect-reduction row, or off-packet continuation.*

Proof. Begin with the refusal-ledger transport theorem, Definition 1006.5. An off-source request cannot satisfy the source precondition, so its displayed continuation route goes to R.

Use the root refusal totality row, Definition 1006.23. It identifies the same refusal route as total for the causal, refutation, other-minds, aspect, and solipsism consumers.

The non-escape content of Definition 1006.3 removes the excluded exits. Since the accepted packet has no hidden closure coordinate or hidden supply row, a consumer without S receives only the refusal ledger transported by H, C, P, N. □

Theorem 1006.27 (GapClosureBoundary structural transport closure)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the structural rows* H, C, P, N *only transport, route, package, and name the same seven-row packet. They preserve the source route through* S *and the refusal route through* R*, and they add no hidden source, second refusal ledger, internal closure coordinate, or off-packet consumer row.*

Proof. Read the structural rows in the carrier definition. The row H supplies componentwise hsame transport, C supplies displayed Cont routes, P supplies Pkg provenance, and N supplies the local NameCert row.

Apply the structural exhaustion theorem and the root structural exhaustion theorem, Definition 1006.12 and Definition 1006.24. Together they restrict H, C, P, N to the already displayed request, source, and refusal rows.

Combine root source exactness with consumer refusal exhaustion. Supported consumers are carried through S, unsupported consumers are carried to R, and both routes remain inside the same packet G, S, R, H, C, P, N. □

Theorem 1006.28 (GapClosureBoundary TasteGate nontrivial witness surface)**.** *For accepted* GapClosureBoundary$^{\uparrow}$ *packets over the displayed carrier $B = (G, S, R, H, C, P, N)$, a packet whose request row G is routed through a displayed source row S and a packet whose request row is routed to the refusal ledger R determine distinct witness surfaces. The future* Nontrivial GapClosureBoundary$^{\uparrow}$ *TasteGate instance is therefore witnessed by the paper-level separation between source-supported boundary use and refusal-ledger boundary use.*

Proof. Read the carrier and local obligations from Definition 1006.1 and Definition 1006.2. The carrier exposes G, S, R, H, C, P, N, and the obligations distinguish the displayed source route from the refusal route.

For the source-supported surface, apply source-route exactness and the root source handshake, Definition 1006.10 and Definition 1006.22. A supported read passes through $G \longrightarrow S$ before a downstream hard-problem sibling may consume the boundary.

For the refusal surface, apply refusal-ledger routing and root refusal totality, Definition 1006.11 and Definition 1006.23. An off-source request is routed to R and receives no internal closure row.

Finally use structural exhaustion, Definition 1006.12. The rows H, C, P, N transport, replay, package, and name the same separation rather than collapsing S and R. Hence the two accepted surfaces are distinct at the public witness boundary. □

Theorem 1006.29 (GapClosureBoundary field-faithful row separation)**.** *The rows G, S, R, H, C, P, N of an accepted* GapClosureBoundary$^{\uparrow}$ *carrier are jointly faithful for the public NameCert read: changing the displayed source route S or changing the refusal-ledger route R changes the public read of the boundary packet. No componentwise transport, continuation replay, provenance row, or local naming row can identify a source-supported packet with a refusal-routed packet.*

Proof. Start from carrier exposure and the local NameCert obligations, Definition 1006.1 and Definition 1006.2. The public read records the request row, source row, refusal row, transport row, continuation row, package row, and local naming row.

Use source-route exactness for the supported side. A change in the displayed source route changes the public route by which G reaches S, so the accepted packet presents a different source-supported boundary read.

Use refusal-ledger routing for the off-source side. A change in R changes the ledger endpoint for requests that do not display S, and the non-escape rows prevent that difference from being hidden by an internal closure coordinate.

Finally apply root structural exhaustion, Definition 1006.24. Since H, C, P, N only transport, replay, package, and name G, S, R, they preserve rather than erase row differences. Thus the seven displayed rows are faithful for the public NameCert read. □

Theorem 1006.30 (GapClosureBoundary AI obligation readiness package)**.** *The* $\mathsf{GapClosureBoundary}^{\uparrow}$ *chapter presents the obligation-closure surface consisting of carrier exposure, source-route exactness, refusal-ledger routing, non-escape, falsifiable prediction, independence witness, TasteGate nontrivial witness separation, and field-faithful row separation. This package is the paper-level readiness surface for the later TasteGate carrier over* G, S, R, H, C, P, N*.*

Proof. Carrier exposure is supplied by Definition 1006.1 and the NameCert obligation rows of Definition 1006.2. These rows present the accepted packet as finite BHist data with explicit source, refusal, transport, route, provenance, and naming coordinates.

Source-route exactness and refusal-ledger routing are supplied by Definition 1006.10, Definition 1006.22, Definition 1006.11, and Definition 1006.23. They divide supported reads from off-source reads without adding a hidden closure row.

Non-escape and consumer exhaustion are supplied by the refusal non-escape rows, structural exhaustion, and sibling consumer exhaustion. Together they rule out internal universal closure, hidden T supply, private other-minds access, causal necessity, direct aspect reduction, and off-packet continuation.

The displayed falsifiable prediction and independence witness record how the same finite boundary is tested by downstream siblings. Together with Definition 1006.28 and Definition 1006.29, these rows form the obligation-closure surface expected by the TasteGate work. □

Falsifiable prediction: Any accepted GapClosureBoundaryUp consumer that tries to convert a GAP request into internal closure is routed to the refusal row unless a displayed source route is present.

Independence witness: causalcommitment, finitewitnessedrefutation, othermindscommitment, aspectchain, solipsismgaprefusal: none is bijective to GapClosureBoundaryUp because each sibling packages one application face while this carrier contains the common GAP request plus refusal ledger consumed by all faces.

The Lean file `Derived/GapClosureBoundaryUp/TasteGate.lean` will provide $\mathsf{Nontrivial}\ \mathsf{GapClosureBoundary}^{\uparrow}$ and $\mathsf{FieldFaithful}\ \mathsf{GapClosureBoundary}^{\uparrow}$ instances for the displayed rows G, S, R, H, C, P, N.

Theorem 1006.31 (GapClosureBoundary root source exposure)**.** *Every root read of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet first exposes the displayed finite rows*

$$G, S, R, H, C, P, N.$$

The read may inspect the GAP request row G*, the source row* S*, the refusal ledger* R*, the componentwise* hsame *transport row* H*, the displayed* Cont *routes* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}$ *row* N*. It cannot read a hidden* T *supply, an internal universal closure coordinate, private other-minds access, causal necessity, direct aspect reduction, or any off-packet continuation before this boundary packet is exposed.*

Proof. Start with the carrier exposure theorem, Definition 1006.13. It identifies the root-facing packet as the seven displayed rows G, S, R, H, C, P, N.

Use the source-route obligation and root source handshake, Definition 1006.20 and Definition 1006.22. A supported root read of G must pass through the displayed source row S before any downstream hard-problem sibling may consume the boundary.

Finally apply root structural exhaustion, Definition 1006.24. The rows H, C, P, N transport, route, package, and name the same packet, so they cannot introduce a hidden T supply, internal closure coordinate, or private consumer-specific row. □

Theorem 1006.32 (GapClosureBoundary root ledger routing)**.** *For an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, every unsupported root request for closure is routed through the refusal ledger* R *by the same transport, continuation, provenance, and local naming rows* H, C, P, N*. The route replaces the unsupported request by a visible refusal read and exports no internal closure witness, hidden* T *supply, private access row, causal necessity row, direct aspect-reduction row, or off-packet continuation.*

Proof. Project the refusal row from the carrier and apply Definition 1006.21. Unsupported root reads of the request row G are sent to the displayed ledger R through H, C, P, N.

Use refusal totality, Definition 1006.23, to cover the off-source cases. If the source handshake $G \longrightarrow S$ is absent, the packet has no accepted closure route except the ledger route to R.

The non-escape and structural rows, Definition 1006.3 and Definition 1006.24, remove the excluded exits. The same H, C, P, N rows preserve the refusal route without adding an internal closure witness or hidden supply coordinate. □

Theorem 1006.33 (GapClosureBoundary root consumer coverage)**.** *The root-facing boundary rows of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet exhaust the shared inputs used by* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*. Each listed consumer reads either the displayed source route through* G, S, H, C, P, N *or the refusal route through* G, R, H, C, P, N*, and no listed consumer receives an additional root row outside* G, S, R, H, C, P, N*.*

Proof. Begin with Definition 1006.31. It fixes the root-facing inventory for every consumer as the same seven-row packet.

For source-supported use, apply the root source handshake. The causal, refutation, otherminds, aspect, and solipsism consumers may use the boundary only after the displayed route $G \longrightarrow S$ is exposed and transported by H, C, P, N.

For unsupported closure requests, apply root ledger routing. The same consumers receive the refusal route through R and do not obtain an internal closure witness, hidden supply, private access row, causal necessity row, direct aspect-reduction row, or off-packet continuation.

Finally use the existing independence witness together with root structural exhaustion. The listed siblings package distinct application faces, while the shared root packet contains exactly the common request, source, refusal, transport, route, provenance, and naming rows consumed by all of them. □

Theorem 1006.34 (GapClosureBoundary downstream source refusal)**.** *Every listed downstream hard-problem consumer of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet must choose either the displayed source route* $G \longrightarrow S$ *or the refusal route* $G \longrightarrow R$*. No downstream consumer among* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *receives a third root route outside* G, S, R, H, C, P, N*.*

Proof. Use root source exposure, Definition 1006.31. It fixes the common packet available to the downstream consumers as G, S, R, H, C, P, N.

Apply root ledger routing and root consumer coverage, Definition 1006.32 and Definition 1006.33. The supported case goes through the displayed source row S, while the unsupported case is routed to the refusal ledger R.

Root structural exhaustion then excludes the third option. Since the carrier has no private hard-problem route outside the displayed rows, every downstream read is either source-routed or refusal-routed. □

Theorem 1006.35 (GapClosureBoundary downstream boundary package)**.** *For the listed downstream hard-problem consumers, the exact boundary package is the pair of routes $G \longrightarrow S$ and $G \longrightarrow R$ together with the structural rows H, C, P, N. This package is the whole exported interface for source exposure, refusal routing, transport, continuation, provenance, and local naming.*

Proof. Begin with root consumer coverage. It states that each downstream consumer reads the same root-facing packet and receives no additional row outside G, S, R, H, C, P, N.

Use downstream source refusal above to split the packet into its two possible root routes. The positive branch is the source route through S, and the negative branch is the refusal route through R.

The rows H, C, P, N carry the routes without changing their boundary. Thus the downstream package is exactly the two route rows plus the displayed structural support. □

Theorem 1006.36 (GapClosureBoundary downstream structural exhaustion)**.** *The downstream boundary package G, S, R, H, C, P, N cannot add hidden T supply, private access, causal necessity, aspect reduction, or off-packet continuation for any listed hard-problem consumer. All such requests are refused unless they are already represented by the displayed source or refusal route.*

Proof. Start from root structural exhaustion, Definition 1006.24. It removes hidden supply, private rows, causal rows, aspect-reduction rows, and off-packet continuations from the root-facing carrier.

Combine this with the downstream boundary package above. Since the downstream package has only G, S, R, H, C, P, N, the structural rows can transport and name a source or refusal route but cannot create any excluded object.

Therefore the listed hard-problem consumers inherit the same exhaustion boundary. A consumer may use the displayed source route or the displayed refusal route, and nothing outside the packet is exported. □

Theorem 1006.37 (GapClosureBoundary source-consumer uniformity)**.** *For an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet, every supported root read consumed by* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *factors through the same displayed source route*

$$G \longrightarrow S$$

and through the same structural rows H, C, P, N. No listed consumer receives a private source route, hidden closure coordinate, or consumer-specific row outside G, S, H, C, P, N.

Proof. First expose the common root packet by Definition 1006.31. The supported read begins with the displayed GAP request row G, reaches the source row S, and is transported, routed, packaged, and named by H, C, P, N.

Then apply consumer coverage, Definition 1006.33. The causal, refutation, other-minds, aspect, and solipsism consumers all read the same root-facing packet, so a supported consumer route cannot add a separate source coordinate.

The conclusion follows because the only supported route visible to any listed consumer is the displayed route $G \longrightarrow S$ together with H, C, P, N. The excluded hidden closure and private rows are absent from the exposed packet. □

Theorem 1006.38 (GapClosureBoundary refusal-consumer uniformity)**.** *For an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet, every unsupported root read requested by* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *is routed to the refusal ledger R through the same structural rows H, C, P, N. The routed refusal exports no hidden closure row,*

supply row, private-access row, causal-necessity row, aspect-reduction row, or off-packet continuation.

Proof. Start with root ledger routing, Definition 1006.32. An unsupported request has no accepted source route, so it is sent to the displayed refusal ledger R and remains transported, routed, packaged, and named by H, C, P, N.

Now use root consumer coverage, Definition 1006.33. Each listed downstream consumer receives either the supported source route or the refusal route from the same root-facing packet.

Since the request is unsupported, only the refusal branch remains. The non-escape content already carried by ledger routing prevents the consumer from rereading H, C, P, N as hidden closure, supply, private access, causal necessity, direct aspect reduction, or an off-packet continuation. □

Theorem 1006.39 (GapClosureBoundary root unblock package)**.** *The* $\mathsf{GapClosureBoundary}^{\uparrow}$ *root obligation surface consists of three displayed rows of use: carrier exposure by* G, S, R, H, C, P, N*, supported source consumption through* $G \longrightarrow S$ *with* H, C, P, N*, and unsupported refusal consumption through* R *with* H, C, P, N*. Together with refusal non-escape and TasteGate readiness, these rows form the downstream root-unblock package for* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*.*

Proof. Carrier exposure is supplied by Definition 1006.31. It fixes the root-facing inventory as the finite rows G, S, R, H, C, P, N and excludes hidden closure, supply, private access, causal necessity, direct aspect reduction, and off-packet continuation rows.

Supported source consumption is supplied by Definition 1006.37. Unsupported refusal consumption is supplied by Definition 1006.38. These two theorems give the positive and negative consumer routes over the same structural rows.

Finally combine refusal non-escape with the TasteGate readiness package already displayed in this chapter. The result is a three-row root obligation surface: expose the carrier, route supported reads through the source, and route unsupported reads to refusal without importing any hidden closure principle. □

Theorem 1006.40 (GapClosureBoundary source observation totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every supported read of* B *exposes both the request row* G *and the source observation row* S *before any hard-problem sibling consumes the packet. The source route is exact: the sibling receives the displayed source branch through* G, S, H, C, P, N *and receives no hidden closure row, private source row, or consumer-specific source coordinate.*

Proof. Project the carrier of Definition 1006.1. The root-facing packet exposes exactly G, S, R, H, C, P, N, so the supported source branch has to begin with the displayed request and source rows.

Use the displayed-source precondition of Definition 1006.4. A supported closure read must show S before a causal, refutation, other-minds, aspect-chain, or solipsism-refusal consumer may read the packet.

Finally apply source route exactness from Definition 1006.10. The route from G to S is the only admissible pre-consumption route, and the structural rows H, C, P, N carry that same route without adding another source coordinate. □

Theorem 1006.41 (GapClosureBoundary refusal ledger totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every off-source closure request routes to the refusal ledger* R *through* H, C, P, N*. The refusal route exports no hidden* T *supply, private access row, causal-necessity row, direct aspect-reduction row, internal closure witness, or off-packet continuation.*

Proof. Start with refusal-ledger transport, Definition 1006.5. An off-source request has no accepted route through S, so the displayed continuation sends it to R along the structural rows.

Apply refusal ledger routing, Definition 1006.11. The route to R is the accepted endpoint for a closure read that cannot display the source row.

Now use ledger nonescape, Definition 1006.8. Since R records refusal rather than supply, the routed request cannot export hidden T data, private access, causal necessity, aspect reduction, internal closure, or an off-packet continuation. □

Theorem 1006.42 (GapClosureBoundary NameCert root package)**.** *The* $\mathsf{GapClosureBoundary}^{\uparrow}$ *root package is assembled from carrier exposure, source-observation totality, refusal-ledger totality, and structural exhaustion. Every named downstream sibling consumes exactly one of the two displayed branches of* $B = (G, S, R, H, C, P, N)$*: supported reads through* G, S, H, C, P, N *or off-source reads through* G, R, H, C, P, N*.*

Proof. Carrier exposure is supplied by Definition 1006.13. It fixes the finite root packet as G, S, R, H, C, P, N before any downstream hard-problem sibling reads it.

Source-observation totality is supplied by Definition 1006.40. Refusal-ledger totality is supplied by Definition 1006.41. Together they exhaust the supported and off-source branches.

Finally apply structural exhaustion, Definition 1006.12, and the root unblock package, Definition 1006.39. The structural rows transport, route, package, and name the two displayed branches without creating a third route, so the root package is exactly the finite NameCert surface consumed by the named downstream siblings. □

Theorem 1006.43 (GapClosureBoundary downstream source route package)**.** *For every supported downstream read by* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*, the shared* $\mathsf{GapClosureBoundary}^{\uparrow}$ *boundary factors through the displayed route*

$$G \longrightarrow S$$

and through the structural rows H, C, P, N*. No supported downstream read receives a hidden closure row, private source row, or consumer-specific access route outside* G, S, H, C, P, N*.*

Proof. Expose the root source packet by Definition 1006.31. It fixes the boundary inventory as G, S, R, H, C, P, N and identifies the only supported source-facing route as $G \longrightarrow S$.

Use root ledger routing to keep unsupported closure requests outside the supported branch. The ledger theorem prevents the refusal row from being reread as a second positive source route.

Now apply source-consumer uniformity and the root-unblock package. The five listed siblings consume the same source route through $G \longrightarrow S$, and H, C, P, N provide the transport, continuation, provenance, and local naming rows that carry this route downstream. □

Theorem 1006.44 (GapClosureBoundary sibling refusal transport package)**.** *For every unsupported sibling read by* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*, the shared* $\mathsf{GapClosureBoundary}^{\uparrow}$ *boundary factors through the refusal row* R *and through the structural rows* H, C, P, N*. The refusal route exports no hidden closure row, hidden* T *supply, private access row, causal-necessity row, direct aspect-reduction row, or off-packet continuation.*

Proof. Start with root ledger routing, Definition 1006.32. An unsupported request cannot use the source row as a witness of closure, so it is routed to the displayed refusal ledger R.

Apply refusal-consumer uniformity. The same five siblings receive this refusal route through H, C, P, N, not through private sibling rows or a second root carrier.

Finally use root source exposure and the root-unblock package to identify the ambient packet. The only exported unsupported route is the refusal row transported, routed, packaged, and named by H, C, P, N. □

Theorem 1006.45 (GapClosureBoundary shared boundary consumer package)**.** *For* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$, *the shared* $\mathsf{GapClosureBoundary}^{\uparrow}$ *boundary package is exhausted by two cases: supported downstream reads factor through* $G \longrightarrow S$ *with* H, C, P, N, *and unsupported sibling reads factor through* R *with* H, C, P, N. *No third sibling-consumer route is exported by the boundary packet.*

Proof. First use root source exposure to fix the common carrier rows G, S, R, H, C, P, N. These rows are the whole boundary packet visible to the listed siblings.

For the supported case, apply Definition 1006.43. The downstream read is carried by the displayed route $G \longrightarrow S$ and by H, C, P, N.

For the unsupported case, apply Definition 1006.44. The read is carried by R and the same structural rows.

The root-unblock package combines source exposure, root ledger routing, source-consumer uniformity, and refusal-consumer uniformity. Therefore the two displayed cases exhaust the shared boundary consumed by the five siblings. □

Theorem 1006.46 (GapClosureBoundary source-refusal orthogonality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$, *a supported root read must pass through the displayed source row* S, *while an unsupported closure read is routed to the refusal ledger* R. *The two routes are orthogonal at the public boundary: neither* S *nor* R *can be reread as a hidden closure supply, and no accepted read obtains both a source witness and a refusal witness as a concealed substitute for internal closure.*

Proof. Project the seven-row carrier from Definition 1006.1. The only source-facing coordinate is S, and the only off-source endpoint is the refusal ledger R.

Apply the NameCert obligations and displayed source precondition, Definition 1006.2 and Definition 1006.4. A supported read of the request row G has to expose S before any downstream consumer can use the boundary.

For an unsupported read, use refusal non-escape, Definition 1006.3. The read is routed to R and receives no internal universal closure, hidden T supply, private access row, causal necessity row, direct aspect reduction, or off-packet continuation. Thus the source route and refusal route remain separate public alternatives rather than a combined hidden supply. □

Theorem 1006.47 (GapClosureBoundary hard-problem consumer factorization)**.** *Every accepted root read used by* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *factors through the same displayed packet* G, S, R, H, C, P, N. *A supported consumer factors through* G, S, H, C, P, N, *and an unsupported consumer factors through* G, R, H, C, P, N; *no listed consumer receives a consumer-specific carrier outside the* $\mathsf{GapClosureBoundary}^{\uparrow}$ *rows.*

Proof. Start with the carrier definition and the NameCert obligations, Definition 1006.1 and Definition 1006.2. They expose the shared root packet and record the hard-problem sibling packets only through the provenance row P.

For supported consumers, apply the displayed source precondition. The causal, refutation, other-minds, aspect, and solipsism routes can use the boundary only after G has been read through S and transported, replayed, packaged, and named by H, C, P, N.

For unsupported consumers, apply refusal non-escape. The same hard-problem request is sent to R through the structural rows, and the excluded closure, private access, causal necessity, direct aspect reduction, hidden T supply, and off-packet continuation are absent from the carrier. Hence every listed consumer factors through one of the two displayed finite routes. □

Theorem 1006.48 (GapClosureBoundary closure-request determinacy)**.** *For accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carriers, agreement on the request row G, source row S, transport row H, continuation row C, provenance row P, and local naming row N determines whether a root closure request is supported or refusal-routed. If the displayed source route through S is available, the read is supported through G, S, H, C, P, N; if that route is absent, the same continuation and naming surface routes the request to R.*

Proof. Read the displayed source precondition, Definition 1006.4. It identifies the public support condition as the presence of the source observation or socket row S together with the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ surface.

Use the NameCert obligation theorem to inspect the continuation row. The row C routes supported reads through the source row and routes unsupported closure reads to the refusal row, while H, P, N transport, package, and name that same decision.

Finally apply refusal non-escape. Once the source route is absent, the request cannot escape to an internal closure coordinate or hidden T supply, so the public data G, S, H, C, P, N fixes the branch: supported through S when the source route is displayed, and refusal-routed to R otherwise. □

Theorem 1006.49 (GapClosureBoundary sibling source totality)**.** *For every supported read of* $\mathsf{GapClosureBoundary}^{\uparrow}$ *by* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$, *the consumer first factors through the displayed source route*

$$G \longrightarrow S.$$

Only after that route is exposed may the read use the structural rows H, C, P, N. Thus the listed sibling consumers receive a common source route before any transport, continuation, provenance, or local naming row is read.

Proof. Project the carrier $B = (G, S, R, H, C, P, N)$ using Definition 1006.1. The carrier exposes one request row, one displayed source row, one refusal row, and the structural rows H, C, P, N.

Apply the NameCert obligations and displayed source precondition, Definition 1006.2 and Definition 1006.4. A supported root request cannot be read by a sibling consumer until the public source row has been displayed as the route $G \longrightarrow S$.

Now use source-refusal orthogonality, hard-problem consumer factorization, and closure-request determinacy. These theorems keep the supported branch separate from R, force each listed sibling through the same boundary packet, and make the source branch the determined route whenever the displayed source is present. The rows H, C, P, N therefore occur only as the transport, continuation, provenance, and local naming surface for that already displayed source route. □

Theorem 1006.50 (GapClosureBoundary refusal route determinacy)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier $B = (G, S, R, H, C, P, N)$, if a root closure request has no displayed source route through $G \longrightarrow S$, then the request is deterministically routed to the refusal row R. The same H, C, P, N*

rows transport, route, package, and name this refusal; no unsupported request may choose a second source row, hidden closure row, private access row, or hidden T *supply.*

Proof. Start with the displayed source precondition. Its contrapositive boundary reading is that a supported branch must display the route from G to S before any sibling can consume the boundary.

When that route is absent, apply refusal non-escape and source-refusal orthogonality. Refusal non-escape sends the unsupported request to R and excludes internal closure, private access, causal necessity, direct aspect reduction, off-packet continuation, and hidden T supply; orthogonality prevents R from being reread as a concealed source branch.

Finally use hard-problem consumer factorization and closure-request determinacy. Every listed sibling reads the same packet G, S, R, H, C, P, N, and the public data determine the branch: displayed source gives the supported route, while absence of the displayed source gives the refusal route R with the same structural rows. □

Theorem 1006.51 (GapClosureBoundary structural row conservation)**.** *For accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carriers, the structural rows* H, C, P, N *conserve only the two displayed branches: the source branch* $G \longrightarrow S$ *and the refusal branch through* R*. These rows cannot introduce internal closure, a hidden* T *supply, a private access route, causal necessity, direct aspect reduction, or any consumer-specific route outside the displayed boundary packet.*

Proof. Read the carrier and NameCert obligations together. The rows H, C, P, N are respectively transport, continuation, provenance, and local naming rows for the visible packet G, S, R; they are not additional carriers and contain no independent closure coordinate.

For the supported branch, apply sibling source totality. Each listed sibling reaches H, C, P, N only after the route $G \longrightarrow S$ has been displayed, so the structural rows preserve that route rather than supplying a hidden source.

For the unsupported branch, apply refusal route determinacy and refusal non-escape. The same structural rows carry the request to R and exclude hidden closure supply, private access, causal necessity, direct aspect reduction, off-packet continuation, and hidden T supply.

The source-refusal orthogonality and hard-problem consumer factorization theorems then exhaust the boundary. Since every listed consumer is routed through one of the two displayed branches over G, S, R, H, C, P, N, the structural rows conserve the visible source/refusal split and cannot add an internal closure branch. □

Theorem 1006.52 (GapClosureBoundary downstream branch determinacy)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *and every hard-problem consumer among* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *the consumer chooses exactly one of the displayed root branches: the source route*

$$G \longrightarrow S$$

or the refusal route

$$G \longrightarrow R.$$

The structural rows H, C, P, N *carry the chosen branch and do not create a consumer-specific third route.*

Proof. Start with hard-problem consumer factorization and closure-request determinacy, Definition 1006.47 and Definition 1006.48. They place every listed consumer inside the packet G, S, R, H, C, P, N and determine whether a root request is source-supported or refusal-routed.

For the source case, apply sibling source totality. A supported consumer first displays the route $G \longrightarrow S$ before H, C, P, N can transport, route, package, or name the read.

For the refusal case, apply refusal route determinacy. When the source route is absent, the same consumer is routed to R over H, C, P, N and cannot choose a hidden closure row, private source row, or hidden T supply.

Structural row conservation then excludes a third branch. The rows H, C, P, N conserve the selected source/refusal branch rather than adding another consumer route. □

Theorem 1006.53 (GapClosureBoundary refusal source coverage)**.** *The source and refusal branches of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet jointly cover all accepted hard-problem reads by* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$. *A listed read is accepted only through* $G \longrightarrow S$ *with* H, C, P, N *or through* $G \longrightarrow R$ *with* H, C, P, N*; there is no accepted third route outside* G, S, R, H, C, P, N*.*

Proof. First expose the shared boundary carrier by Definition 1006.1 and Definition 1006.2. The accepted packet has exactly the request, source, refusal, transport, continuation, provenance, and local naming rows.

Use source-refusal orthogonality to separate the two possible reads. The source branch carries a displayed source row, while the refusal branch carries a refusal ledger rather than concealed closure supply.

Apply downstream branch determinacy. Each listed hard-problem consumer is assigned to one of the two branches already displayed by the packet.

Finally apply structural row conservation and refusal non-escape. They rule out hidden closure, hidden T supply, private access, causal necessity, direct aspect reduction, and off-packet continuation, so the two branches jointly cover the accepted reads. □

Theorem 1006.54 (GapClosureBoundary consumer exactness package)**.** *The consumer exactness surface of* $\mathsf{GapClosureBoundary}^{\uparrow}$ *is the finite package consisting of carrier admission for* $B = (G, S, R, H, C, P, N)$*, downstream branch determinacy, refusal-source coverage, structural row conservation, and the root-unblock package. This surface is exact for the listed hard-problem consumers: it exports the source branch, the refusal branch, and the rows* H, C, P, N*, but it exports no hidden closure, hidden* T *supply, private access route, causal-necessity row, direct aspect-reduction row, or off-packet continuation.*

Proof. Carrier admission is given by Definition 1006.1 and Definition 1006.2. These results fix the finite packet G, S, R, H, C, P, N before any listed consumer reads the boundary.

Next use downstream branch determinacy. It assigns each accepted consumer read to the displayed source route or the displayed refusal route over the same structural rows.

Then use refusal-source coverage. The two displayed branches cover all accepted hard-problem reads, so no consumer needs an extra route outside the finite packet.

Finally combine structural row conservation with the root-unblock package of Definition 1006.39. The structural rows carry only the selected branch, and the root package records the same source/refusal surface for $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, and $\mathsf{SolipsismGapRefusal}^{\uparrow}$. □

Lean4 ✓ `BEDC.Derived.GapClosureBoundaryUp.GapClosureBoundaryConsumerExactnessPackage`

Theorem 1006.55 (GapClosureBoundary source route totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every supported hard-problem consumer read by* $\mathsf{CausalCommitment}^{\uparrow}$,

$\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *must expose the source route*

$$G \longrightarrow S$$

before consuming the structural rows H, C, P, N*. No listed supported consumer may read the structural surface as a substitute for the displayed source row.*

Lean4 ✓ `BEDC.Derived.GapClosureBoundaryUp.GapClosureBoundarySourceRouteTotality`

Proof. Start with hard-problem consumer factorization, Definition 1006.47. It places every listed supported consumer inside the shared packet G, S, R, H, C, P, N rather than inside a consumer-specific carrier.

Apply sibling source totality. Definition 1006.49 requires the displayed route $G \longrightarrow S$ before any of the structural rows H, C, P, N are consumed by a listed sibling.

Finally use source-refusal orthogonality and structural row conservation. Definition 1006.46 keeps the source route separate from the refusal ledger, while Definition 1006.51 prevents H, C, P, N from generating a hidden source, closure, or T supply. Hence the source route is total for supported hard-problem reads. □

Theorem 1006.56 (GapClosureBoundary refusal route exactness)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every unsupported closure request by a listed hard-problem consumer is routed exactly through*

$$G \longrightarrow R$$

with the structural rows H, C, P, N*. Such a request cannot export hidden closure, hidden* T *supply, private access, causal necessity, direct aspect reduction, or an off-packet continuation.*

Lean4 ✓ `BEDC.Derived.GapClosureBoundaryUp.GapClosureBoundaryRefusalRouteExactness`

Proof. Begin with closure-request determinacy. By Definition 1006.48, once the displayed source route is absent, the same continuation and naming surface determines the refusal branch.

Apply refusal route determinacy. Definition 1006.50 sends the unsupported request to R over H, C, P, N and excludes a second source row, hidden closure row, private access row, and hidden T supply.

The exactness of this route is preserved by source-refusal orthogonality and structural row conservation. The first prevents R from being reread as a concealed source, and the second keeps H, C, P, N as transport, route, package, and local naming rows for the displayed refusal branch. □

Theorem 1006.57 (GapClosureBoundary consumer ledger exhaustion)**.** *For the listed hard-problem siblings* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*, source-route totality together with refusal-route exactness exhausts the* $\mathsf{GapClosureBoundary}^{\uparrow}$ *consumer ledger. Every supported read is accounted for by* $G \longrightarrow S$ *with* H, C, P, N*, every unsupported closure request is accounted for by* $G \longrightarrow R$ *with* H, C, P, N*, and no third consumer route is exported.*

Proof. First account for supported reads. Definition 1006.55 forces every listed supported consumer through $G \longrightarrow S$ before the structural rows are read.

Next account for unsupported requests. Definition 1006.56 routes each unsupported closure request through $G \longrightarrow R$ with H, C, P, N and excludes hidden closure, hidden T supply, and off-packet continuations.

It remains to exclude a third ledger entry. Apply hard-problem consumer factorization and closure-request determinacy to keep every listed consumer inside the same source/refusal split, then apply structural row conservation to prevent H, C, P, N from introducing a consumer-specific route. Thus the two displayed branches exhaust the consumer ledger. □

Definition 1006.58 (GapClosureBoundary hub root inventory)**.** *The hub root inventory for* $\mathsf{GapClosureBoundary}^{\uparrow}$ *is the displayed carrier* $B = (G, S, R, H, C, P, N)$ *together with the existing carrier-obligation row of Definition 1006.2, the source-route row of Definition 1006.55, the refusal-route row of Definition 1006.56, the structural rows carried by* H, C, P, N*, and the consumer-exactness row of Definition 1006.54.*

Theorem 1006.59 (GapClosureBoundary hub root readiness)**.** *The existing child theorems for* $\mathsf{GapClosureBoundary}^{\uparrow}$ *assemble the root-unblock surface for* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*. The assembled surface is the carrier inventory* G, S, R, H, C, P, N*, the supported source route* $G \longrightarrow S$*, the unsupported refusal route* $G \longrightarrow R$*, and the exact consumer package that exports no hidden closure, hidden* T *supply, private access, causal-necessity row, direct aspect-reduction row, or off-packet continuation.*

Proof. Use the carrier obligations of Definition 1006.2 to fix the shared packet G, S, R, H, C, P, N before any listed hard-problem consumer reads the boundary.

Apply source-route totality and refusal-route exactness, Definition 1006.55 and Definition 1006.56. They give the two displayed branches $G \longrightarrow S$ and $G \longrightarrow R$ over the same structural rows.

Finally apply the root-unblock and consumer-exactness packages, Definition 1006.39 and Definition 1006.54. These packages identify the five listed consumers as readers of the same finite source/refusal surface and exclude the hidden rows named in the statement. □

Theorem 1006.60 (GapClosureBoundary hub unblock surface)**.** *Every downstream consumer named by the* $\mathsf{GapClosureBoundary}^{\uparrow}$ *root package reads only the displayed source/refusal split through* G, S, R, H, C, P, N*. A supported read passes through* $G \longrightarrow S$ *with* H, C, P, N*, an unsupported closure request passes through* $G \longrightarrow R$ *with* H, C, P, N*, and no downstream consumer receives a third route outside the hub root inventory.*

Proof. Begin with the hub root inventory of Definition 1006.58. It names the carrier, source route, refusal route, structural rows, and consumer-exactness row used by the hub.

For supported reads, use Definition 1006.55. For unsupported closure requests, use Definition 1006.56. Both routes are expressed through the same coordinates G, S, R, H, C, P, N.

The consumer-exactness package of Definition 1006.54 then excludes any off-inventory route. Hence the hub exposes exactly the displayed split and no additional downstream surface. □

Theorem 1006.61 (GapClosureBoundary root visible refusal audit)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *root packet* $B = (G, S, R, H, C, P, N)$*, every downstream refusal read must first display the gap request row* G*, the refusal ledger row* R*, the structural boundary rows* H, C, P, N*, the finite* BHist *carrier, the componentwise* hsame *transports, the displayed* Cont *refusal route, the* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row. The read is therefore an audit of the visible root boundary and not a request for a hidden closure, hidden* T *supply, private access row, host equality row, direct aspect-reduction row, or off-packet continuation.*

Proof. Begin with the carrier row of Definition 1006.1. It exposes exactly the request, source, refusal, transport, continuation, provenance, and local naming rows of the finite packet $B = (G, S, R, H, C, P, N)$.

Use the NameCert obligations of Definition 1006.2 and the root readiness inventory of Definition 1006.58. These rows identify the finite BHist carrier together with hsame, Cont, Pkg, and local NameCert data before any listed hard-problem consumer reads the boundary.

For an unsupported downstream read, apply refusal-route exactness and refusal route determinacy, Definition 1006.56 and Definition 1006.50. The read is sent to the displayed refusal ledger R over H, C, P, N.

Finally use structural row conservation, Definition 1006.51. The structural rows conserve the visible source/refusal split and do not create any of the hidden rows excluded in the statement. □

Theorem 1006.62 (GapClosureBoundary root package consumer cut)**.** *Every downstream consumer of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *root packet factors through the displayed package and provenance surface* G, S, R, H, C, P, N*. A supported consumer factors through the displayed source route* $G \longrightarrow S$ *with* H, C, P, N*, an unsupported consumer factors through the refusal route to* R *with* H, C, P, N*, and no listed consumer may bypass these rows to a concealed closure theorem outside the local* BHist*,* Cont*,* Pkg*, and* NameCert *packet.*

Proof. Start from hard-problem consumer factorization, Definition 1006.47. It places the causal, finite-refutation, other-minds, aspect-chain, and solipsism-refusal consumers inside the same displayed packet.

For supported reads, use source-route totality and closure-request determinacy, Definition 1006.55 and Definition 1006.48. The consumer receives the source branch only through $G \longrightarrow S$ and the structural rows.

For unsupported reads, use refusal-route exactness and the consumer ledger exhaustion theorem, Definition 1006.56 and Definition 1006.57. They route the request to R and leave no third consumer route.

The consumer-exactness package of Definition 1006.54 supplies the cut: every exported consumer read is already a read of the displayed package and provenance surface, so there is no bypass to an external closure theorem. □

Theorem 1006.63 (GapClosureBoundary root NameCert replay)**.** *Replay along the displayed* Cont *rows and transport along the componentwise* hsame *rows preserve exactly the root boundary rows displayed by an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet. The replay may carry the source route* $G \longrightarrow S$ *or the refusal route to* R *through* H, C, P, N*, but it does not create quotient data, host equality data, ambient closure data, a hidden* T *supply, or any consumer-specific row outside the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *surface.*

Proof. Read the structural rows from Definition 1006.12. The rows H, C, P, N serve as transport, continuation, provenance, and naming data for the already displayed carrier rows.

For the supported branch, apply source-route totality, closure-request determinacy, and structural row conservation, Definition 1006.55, Definition 1006.48, and Definition 1006.51. Replay along Cont and transport along hsame keep the branch at $G \longrightarrow S$ with the same package rows.

For the refusal branch, apply refusal route determinacy and refusal route exactness, Definition 1006.50 and Definition 1006.56. The replay endpoint is the displayed refusal ledger R over the same H, C, P, N rows.

Finally use source-refusal orthogonality and hard-problem consumer factorization. They keep the two replayed branches inside the common boundary packet and prevent Cont, hsame, Pkg, or local NameCert rows from generating quotient, host equality, ambient closure, hidden supply, or consumer-specific data. □

Theorem 1006.64 (GapClosureBoundary source-refusal triad)**.** *Every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *boundary packet exposes exactly the request row* G*, the source row* S*, and the refusal row* R *before any hard-problem consumer reads the boundary. The remaining rows* H, C, P, N *transport, replay, package, and name that triad, but they do not add an internal closure witness, hidden* T *supply, private-access row, or direct aspect-reduction row.*

Proof. Begin with the carrier and NameCert rows, Definition 1006.1 and Definition 1006.2. They expose the finite packet G, S, R, H, C, P, N and separate carrier exposure from source-route and refusal-ledger duties.

Use source-route totality for supported reads and refusal-route exactness for unsupported reads, Definition 1006.55 and Definition 1006.56. Together they force every listed hard-problem consumer to see G with either the displayed source row S or the displayed refusal row R.

Finally apply refusal non-escape and structural row conservation, Definition 1006.3 and Definition 1006.51. These rows keep H, C, P, N from manufacturing a hidden closure, hidden supply, private access, or aspect-reduction coordinate after the triad has been exposed. □

Theorem 1006.65 (GapClosureBoundary consumer ledger factorization)**.** *Every hard-problem consumer access to an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet factors through the displayed rows* G, S, R, H, C, P, N*. A supported access factors through* $G \longrightarrow S$ *and an unsupported closure request factors through* $G \longrightarrow R$*, but no consumer can manufacture an internal closure witness from the ledger, transport, continuation, provenance, or naming rows.*

Proof. Start from hard-problem consumer factorization, Definition 1006.47. It places the listed causal, finite-refutation, other-minds, aspect-chain, and solipsism-refusal consumers inside the common packet G, S, R, H, C, P, N.

For supported access, apply source route totality and source observation totality, Definition 1006.55 and Definition 1006.40. The consumer receives the source branch only through the displayed route from G to S.

For unsupported closure requests, apply refusal route exactness and refusal ledger totality, Definition 1006.56 and Definition 1006.41. The request is sent to R through the same structural rows rather than to an internal closure witness.

The consumer-exactness package and structural row conservation, Definition 1006.54 and Definition 1006.51, exclude a third ledger route. Thus consumer access factors through the displayed rows and nowhere else. □

Theorem 1006.66 (GapClosureBoundary hard-problem route exhaustion)**.** *The finite witnessed-refutation and hard-problem sibling consumers of a* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet consume only the displayed boundary rows* G, S, R, H, C, P, N*. Their positive reads use the exposed source route, their negative reads use the exposed refusal route, and neither kind of read imports a consumer-specific closure witness outside the local* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *surface.*

Proof. Project the root boundary packet using Definition 1006.64. Before any sibling reads the boundary, the request, source, and refusal rows are visible as the common triad carried by H, C, P, N.

For the finite witnessed-refutation and hard-problem siblings, use hard-problem consumer factorization and consumer ledger exhaustion, Definition 1006.47 and Definition 1006.57. These theorems divide all listed sibling reads between the source branch and refusal branch.

Consumer ledger factorization then binds both branches to the displayed rows G, S, R, H, C, P, N. Since refusal non-escape and the consumer-exactness package exclude hidden closure and off-packet continuation rows, the siblings consume exactly the public GapClosureBoundary surface. □

Theorem 1006.67 (GapClosureBoundary root router exactness)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, the root router exposes exactly two accepted routes for the hard-problem sibling consumers named in Definition 1006.2: the displayed source route from* G *to* S*, and the refusal-ledger route from* G *to* R*. Every accepted consumer route is one of these two routes over* H, C, P, N*, and no hidden closure branch, hidden* T *supply, private-access row, causal-necessity row, or aspect-reduction row is exported.*

Proof. Project the accepted carrier using Definition 1006.1. The packet contains the request row G, source row S, refusal row R, and the structural rows H, C, P, N.

Use Definition 1006.2 to read the router surface. Its source-route exactness clause accounts for the displayed route from G to S, and its refusal-ledger routing clause accounts for the route from G to R.

Finally apply Definition 1006.3. Since an off-source request is retained by R and the structural rows only transport, route, package, and name the same packet, the router has no third accepted branch outside G, S, R, H, C, P, N. □

Theorem 1006.68 (GapClosureBoundary consumer route totality)**.** *Every accepted read of a* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet by* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *is total over the displayed source/refusal split. A supported read factors through* $G \longrightarrow S$ *with* H, C, P, N*, an unsupported closure request factors through* $G \longrightarrow R$ *with* H, C, P, N*, and no listed consumer receives a route that bypasses both* S *and* R*.*

Proof. Begin with the sibling list in Definition 1006.2. The listed consumers are exactly the hard-problem consumers for which the boundary packet records provenance and local naming.

For supported reads, use Definition 1006.55. It requires the displayed route from G to S before any listed sibling consumes the structural rows.

For unsupported closure requests, use Definition 1006.56. It sends the request through $G \longrightarrow R$ with the same H, C, P, N rows and excludes hidden closure, hidden T supply, and off-packet continuation.

The two cases cover the consumer ledger by Definition 1006.57. Hence every accepted sibling route is total over the source/refusal split and no consumer-specific route remains. □

Theorem 1006.69 (GapClosureBoundary refusal ledger stability)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, replay along* C *and transport along* H *preserve the refusal ledger endpoint* R *for every unsupported hard-problem consumer request. The rows* P, N *may package and locally name that endpoint, but they cannot turn the refusal ledger into displayed source routing, internal closure, a hidden* T *supply, or a consumer-specific continuation.*

Proof. Start with Definition 1006.3. An unsupported closure request has no displayed route through S, so the accepted continuation sends it to the refusal row R.

Apply Definition 1006.11 and Definition 1006.12. They identify H, C, P, N as the transport, route, provenance, and local naming rows for the same refusal endpoint, not as generators of another source or closure coordinate.

The consumer route totality theorem then fixes the downstream alternatives. Since every accepted read is either the displayed source route or the refusal-ledger route, a replayed unsupported request remains at R and cannot become a hidden third route. □

Theorem 1006.70 (GapClosureBoundary hard-problem root route stability)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *root packet* $B = (G, S, R, H, C, P, N)$*, the downstream hard-problem consumers* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*,*

and $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *read the same root route surface. A supported read uses the displayed source route* $G \longrightarrow S$ *with* H, C, P, N*, an unsupported closure request uses the displayed refusal route* $G \longrightarrow R$ *with* H, C, P, N*, and no consumer receives a host closure row or hidden supply row outside the packet.*

Proof. Begin with the hub root inventory and root readiness theorems, Definition 1006.58 and Definition 1006.59. They bind the root packet to G, S, R, H, C, P, N and name the five downstream consumers as readers of that same surface.

For supported reads, apply source-route totality and root source exposure, Definition 1006.55 and Definition 1006.64. These keep the source branch at $G \longrightarrow S$ over the displayed structural rows.

For unsupported reads, apply refusal-route exactness and root ledger routing, Definition 1006.56 and Definition 1006.65. These send the request to R through the same packet rather than to a host closure.

The root-unblock package and root package consumer cut, Definition 1006.39 and Definition 1006.62, then make the route stable for all five consumers without adding any off-packet supply row. □

Theorem 1006.71 (GapClosureBoundary consumer refusal totality)**.** *Every unsupported hard-problem consumer request handled by an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *root packet is refused through the displayed ledger row* R *of* $B = (G, S, R, H, C, P, N)$*. The refusal covers the five downstream consumers* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *uniformly, and it exports no private access row, direct aspect-reduction row, causal-necessity row, or hidden* T *supply.*

Proof. First use refusal-route exactness and refusal ledger totality, Definition 1006.56 and Definition 1006.41. They identify R as the endpoint for unsupported closure requests.

Next apply hard-problem consumer factorization and consumer ledger exhaustion, Definition 1006.47 and Definition 1006.57. These theorems place all five downstream consumers on the same source/refusal ledger.

Finally use root visible refusal audit and root NameCert replay, Definition 1006.61 and Definition 1006.63. The replay preserves only G, S, R, H, C, P, N, so unsupported consumers receive the visible refusal row and none of the excluded hidden rows. □

Theorem 1006.72 (GapClosureBoundary five-sibling unblock surface)**.** *The root packet* $B = (G, S, R, H, C, P, N)$ *supplies one common unblock surface for* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*. Each sibling consumes the displayed request row, the source-or-refusal branch, the componentwise transport rows, the continuation replay rows, provenance, and local naming; none receives a separate host closure theorem, hidden source, consumer-specific continuation, or off-packet bridge row.*

Proof. Start from the hub unblock surface theorem Definition 1006.60. It already identifies the common source/refusal split used by the downstream root package.

Use hard-problem route exhaustion and root route stability, Definition 1006.66 and Definition 1006.70. Together they bind every listed sibling read to G, S, R, H, C, P, N and divide the reads between the source branch and refusal branch.

The consumer refusal totality theorem Definition 1006.71 handles the unsupported branch uniformly. The consumer-exactness package then rules out a sibling-specific route outside the displayed packet, so the five consumers share one root unblock surface. □

Theorem 1006.73 (GapClosureBoundary recognizer source admission)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any recognizer-side source admission for a hard-problem sibling consumer must enter through the* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *acceptance route and land in the* $\mathsf{FiniteReflectionTuple}^{\uparrow}$ *tuple image before the boundary packet is consumed. The admitted read exposes the displayed request row* G*, the source row* S*, and the structural rows* H, C, P, N*, while the downstream consumers* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *receive no source coordinate outside those rows.*

Proof. Start with the carrier of Definition 1006.1. Its recognizer-facing boundary is already the seven-row packet G, S, R, H, C, P, N.

Use the $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ gate through Definition 1048.3. An accepted source read must pass through the event-flow, source-channel, generated-recognizer, and certificate-gate rows before it can be consumed as compiler-layer evidence.

Next apply Definition 993.3. The admitted recognizer row lands in the displayed $\mathsf{FiniteReflectionTuple}^{\uparrow}$ image and is read back from that tuple, so the source branch available to the boundary is the displayed route $G \longrightarrow S$ over H, C, P, N.

Finally use root source exactness, Definition 1006.25. The listed hard-problem consumers may consume the admitted source branch only through the displayed boundary rows, so no additional source coordinate is exported. □

Theorem 1006.74 (GapClosureBoundary recognizer refusal stability)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, if a recognizer-side request does not land in the displayed* $\mathsf{FiniteReflectionTuple}^{\uparrow}$ *tuple image after* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *acceptance, then the boundary routes the request to the refusal ledger* R*. The refusal route is stable under the structural rows* H, C, P, N *and cannot become internal closure, hidden* T *supply, private access, causal necessity, direct aspect reduction, or an off-packet continuation for any listed sibling consumer.*

Proof. Begin with the non-evidence refusal theorem for $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$, Definition 1048.4. It keeps report-like source, host compiler state, proof text, and raw classifier quotients outside accepted evidence when the generated recognizer route does not pass the gate.

The tuple boundary of Definition 993.3 then prevents a failed landing from being reread as a reflected boundary tuple. Thus the request has no displayed route through $G \longrightarrow S$.

Apply refusal route exactness and refusal ledger stability, Definition 1006.56 and Definition 1006.69. The request is routed to R through H, C, P, N and the same rows preserve that refusal endpoint for all listed sibling consumers. □

Theorem 1006.75 (GapClosureBoundary recognizer consumer exhaustion)**.** *For the downstream consumers* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*, the combined* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *and* $\mathsf{FiniteReflectionTuple}^{\uparrow}$ *landing route exhausts the recognizer-facing* $\mathsf{GapClosureBoundary}^{\uparrow}$ *consumer surface. A successful recognizer landing is consumed as* $G \longrightarrow S$ *with* H, C, P, N*; a failed or unsupported landing is consumed as* $G \longrightarrow R$ *with* H, C, P, N*; no third recognizer, tuple, or sibling-specific route is exported.*

Proof. First account for successful recognizer landings. By Definition 1006.73, accepted recognizer evidence reaches the boundary only after the $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ gate and the $\mathsf{FiniteReflectionTuple}^{\uparrow}$ tuple readback, and it is then consumed through the displayed source branch.

Next account for failed or unsupported landings. By Definition 1006.74, these requests are routed to the refusal ledger R over the same structural rows.

It remains to rule out another consumer path. Use hard-problem route stability and consumer ledger exhaustion, Definition 1006.70 and Definition 1006.57. They keep all five listed consumers inside the same source/refusal split, so the recognizer-facing route is exhausted by the two displayed branches. □

Theorem 1006.76 (GapClosureBoundary bridge precondition surface)**.** *The bridge-facing precondition surface of* $\mathsf{GapClosureBoundary}^{\uparrow}$ *is exactly the displayed packet* $B = (G, S, R, H, C, P, N)$ *together with four rows: the source/refusal split through* $G \longrightarrow S$ *and* $G \longrightarrow R$*, the consumer exactness package for* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*, and the root replay rows carried by* Cont*,* hsame*,* Pkg*, and* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$*. No hidden closure row, hidden* T *supply, host equality row, quotient datum, or off-packet continuation belongs to that precondition surface.*

Proof. Start with the carrier definition and NameCert obligations, Definition 1006.1 and Definition 1006.2. They expose the seven displayed coordinates G, S, R, H, C, P, N before any bridge-facing consumer reads the boundary.

Use source-route totality and refusal-route exactness, Definition 1006.55 and Definition 1006.56. These theorems identify the two public branches as the displayed route to S and the displayed route to R.

Finally combine consumer exactness with root NameCert replay, Definition 1006.54 and Definition 1006.63. The first theorem fixes which downstream consumers may read the boundary, and the second keeps replay inside the same Cont, hsame, Pkg, and local $\mathsf{NameCert}$ rows. The excluded hidden rows therefore have no coordinate in the precondition surface. □

Theorem 1006.77 (GapClosureBoundary TasteGate boundary)**.** *Any Lean TasteGate or* $\mathsf{StandardBridge}$ *work for* $\mathsf{GapClosureBoundary}^{\uparrow}$ *must preserve the same seven packet rows* G, S, R, H, C, P, N *and the same displayed source/refusal routes. Its paper-side boundary may read carrier admission, the source route, the refusal route, consumer exactness, root package replay, provenance, and local naming, but it cannot read hidden closure, hidden* T *supply, host equality, quotient data, or any continuation outside the displayed packet.*

Proof. Project the bridge precondition surface of Definition 1006.76. The only available packet rows are G, S, R, H, C, P, N, and the only branch rows are the displayed source and refusal routes.

Use structural row conservation and the root visible refusal audit, Definition 1006.51 and Definition 1006.61. They keep Cont, hsame, Pkg, and local $\mathsf{NameCert}$ replay tied to the visible packet and prevent the structural rows from adding host equality, quotient data, or hidden supply.

The TasteGate or $\mathsf{StandardBridge}$ reader therefore has no additional coordinate to inspect. Its admissible input is the seven-row packet with the displayed branch split, consumer exactness, root replay, provenance, and naming rows. □

Theorem 1006.78 (GapClosureBoundary obligation status assembly)**.** *The carrier rows, source/refusal split, root-unblock package, consumer-exactness package, root NameCert replay rows, bridge precondition surface, and TasteGate boundary assemble the paper-side* $\mathsf{obligation}$ *surface for* $\mathsf{GapClosureBoundary}^{\uparrow}$*. The assembly justifies recording while leaving the verification axis at* $\mathsf{unformalized}$ *until a separate Lean target checks the corresponding root package.*

Proof. Begin with the displayed carrier and branch obligations. Definition 1006.2, Definition 1006.55, and Definition 1006.56 identify the accepted packet and its two public routes.

Next apply the root-unblock and consumer-exactness packages, Definition 1006.39 and Definition 1006.54. These package the listed hard-problem consumers as readers of exactly that source/refusal surface.

Add the root replay and bridge boundary rows from Definition 1006.63, Definition 1006.76, and Definition 1006.77. The assembled surface records every paper obligation needed by the boundary while making no Lean verification claim, so the closure and verification axes remain independent. □

Theorem 1006.79 (GapClosureBoundary scoped dependency inventory)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, the packet displays its* BHist *carrier rows together with* hsame *transport* H*,* Cont *route* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}$ *row* N *before any consumer reads the boundary. The dependency inventory is therefore the seven-row packet* G, S, R, H, C, P, N*, and it contains no hidden closure, hidden* T *supply, host equality row, quotient datum, or off-packet continuation.*

Proof. Start with the carrier and NameCert obligations, Definition 1006.1 and Definition 1006.2. They expose the finite boundary packet as the request, source, refusal, transport, continuation, provenance, and naming rows.

Next apply the consumer exactness package. Definition 1006.54 requires the hard-problem consumers to read the displayed carrier before any downstream route is used.

Finally use root NameCert replay, Definition 1006.63. The replay keeps H, C, P, N attached to the same BHist carrier, so the dependency inventory is already visible before the consumer read. □

Theorem 1006.80 (GapClosureBoundary scoped source-refusal exactness)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, the source branch*

$$G \longrightarrow S$$

and the refusal branch

$$G \longrightarrow R$$

are exactly the two scoped routes over H, C, P, N*. A supported read uses the source route, an unsupported read uses the refusal route, and no third route over the same packet is accepted.*

Proof. First expose the scoped dependency inventory. Definition 1006.79 fixes G, S, R, H, C, P, N as the visible packet before route selection.

For the source branch, apply source-route totality from Definition 1006.55. A supported read of G reaches the displayed source row S and remains transported, routed, packaged, and named by H, C, P, N.

For the refusal branch, apply refusal route exactness from Definition 1006.56. An unsupported read of G reaches the displayed refusal row R over the same structural rows.

The consumer exactness package then removes any residual case. Since every hard-problem consumer read is already assigned to the source/refusal surface, no additional accepted route remains. □

Theorem 1006.81 (GapClosureBoundary scoped consumer non-escape)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, the sibling consumers* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *can read only the scoped source/refusal surface of* G, S, R, H, C, P, N*. They cannot read hidden closure, hidden* T *supply, host equality, quotient data, or any continuation outside the displayed packet.*

Proof. Begin with scoped source-refusal exactness. Definition 1006.80 assigns each accepted read to $G \longrightarrow S$ or $G \longrightarrow R$ over H, C, P, N.

Use refusal non-escape and the consumer exactness package, Definition 1006.3 and Definition 1006.54. These rows remove hidden closure, hidden T supply, and consumer-specific routes from the accepted packet.

Close with root NameCert replay. Definition 1006.63 keeps replay inside the displayed Cont, hsame, Pkg, and local $\mathsf{NameCert}$ rows, so host equality, quotient data, and off-packet continuations have no readable coordinate. □

Theorem 1006.82 (GapClosureBoundary source packet)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the root source packet exposes exactly the following rows over the displayed* BHist *surface:*

1. *the request row* G *and the source observation or socket row* S*;*
2. *the refusal ledger* R *for every closure-facing read that lacks a displayed source route;*
3. *the hard-problem consumer rows for* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*;*
4. *the componentwise* hsame *transport rows in* H *and the displayed* Cont *routes in* C *from* G *to* S *or* R*;*
5. *the provenance row* P *as* Pkg *data and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row* N*.*

No accepted consumer reads a source, refusal, transport, provenance, or local naming coordinate outside G, S, R, H, C, P, N*.*

Proof. Project the carrier of Definition 1006.1. It gives the finite BHist packet G, S, R, H, C, P, N and assigns the structural meanings of H, C, P, N.

Use source route totality and refusal route exactness from Definition 1006.55 and Definition 1006.56. They place every supported read on $G \longrightarrow S$ and every unsupported closure request on $G \longrightarrow R$.

Finally apply the consumer exactness package and recognizer consumer exhaustion, Definition 1006.54 and Definition 1006.75. These results keep the listed consumers, recognizer landing rows, Pkg provenance, and local $\mathsf{NameCert}$ entry inside the displayed packet, so no external coordinate is exported. □

Theorem 1006.83 (GapClosureBoundary classifier stability)**.** *Let* $B = (G, S, R, H, C, P, N)$ *be an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier. Componentwise* hsame *transport in* H *together with the displayed* Cont *routes in* C *preserves the source/refusal classifier: a supported read remains routed through* $G \longrightarrow S$*, and an unsupported closure request remains routed through* $G \longrightarrow R$*. The transport cannot introduce hidden host refusal, private source selection, unrecorded consumer authority, hidden* T *supply, causal necessity, direct aspect reduction, or an off-packet continuation.*

Proof. Start with the source packet of Definition 1006.82. The only classifier-visible rows are the request, source, refusal, transport, continuation, provenance, consumer, and naming rows already displayed by B.

For supported reads, apply source route totality and downstream branch determinacy. They force the consumer to expose $G \longrightarrow S$ before reading H, C, P, N, and they prevent a structural row from selecting a private source.

For unsupported closure requests, apply refusal route exactness and refusal ledger stability. The same hsame and Cont rows carry the request to R and preserve the refusal endpoint rather than turning it into host-level refusal data or concealed closure supply.

The remaining exclusions follow from consumer ledger exhaustion and recognizer consumer exhaustion. Both surfaces exhaust accepted hard-problem reads by the displayed source/refusal split, so no unrecorded consumer authority or off-packet continuation remains available. □

Theorem 1006.84 (GapClosureBoundary NameCert obligation surface)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *obligation surface consists of exactly five obligations:*

1. *carrier exposure: the certificate exposes the finite* BHist *rows* G, S, R, H, C, P, N*;*
2. *source-route admission: every supported read enters through the displayed route* $G \longrightarrow S$ *with the* hsame*,* Cont*, and* Pkg *rows carried by* H, C, P*;*
3. *refusal-ledger exactness: every unsupported closure request enters* R *through the displayed refusal route and receives no hidden closure or hidden* T *supply;*
4. *consumer-boundary exhaustion: the five listed hard-problem consumers read only the displayed source/refusal packet and its structural rows;*
5. *non-escape of host/global refusal data: the local refusal ledger is not a host refusal oracle, global closure refusal, private source selector, or consumer-authority row.*

These five obligations are sufficient for the root $\mathsf{GapClosureBoundary}^{\uparrow}$ *surface consumed by the sibling hard-problem packets.*

Proof. Carrier exposure is the direct projection of Definition 1006.1. The packet exposes G, S, R, H, C, P, N and no additional public coordinate.

Source-route admission follows from source route totality and recognizer source admission. A supported read must pass through the displayed source branch before the hard-problem consumer or recognizer landing surface consumes the packet.

Refusal-ledger exactness follows from refusal route exactness and recognizer refusal stability. An unsupported closure request lands in R through the displayed continuation rows and remains refusal data rather than closure supply.

Consumer-boundary exhaustion follows from the consumer exactness package, source/refusal consumer ledger, and recognizer landing obligations. Those sibling rows cover the listed consumers by the source/refusal split.

Non-escape follows from classifier stability above together with refusal non-escape. Since hsame, Cont, Pkg, and NameCert preserve the displayed packet, the local ledger cannot become host refusal data, global refusal data, private source selection, or unrecorded consumer authority. □

Theorem 1006.85 (GapClosureBoundary root source-classifier totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *source-classifier read of a carrier* $B = (G, S, R, H, C, P, N)$*, the read factors through the finite packet rows* G, S, R, H, C, P, N*. If the read is supported, its displayed route is* $G \longrightarrow S$*; if it is unsupported as a closure request, its displayed route is* $G \longrightarrow R$*. No accepted source-classifier read has a third route outside the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *surface.*

Proof. Begin with the source packet of Definition 1006.82. It exposes the finite rows G, S, R, H, C, P, N as the whole root packet and states that no accepted consumer reads a source, refusal, transport, provenance, or local naming coordinate outside those rows.

For supported reads, apply Definition 1006.55. The source-classifier must expose the displayed route $G \longrightarrow S$ before any listed hard-problem sibling consumes H, C, P, N.

For unsupported closure requests, apply Definition 1006.56. The request is routed through $G \longrightarrow R$ with the same structural rows, and the excluded closure and hidden T coordinates are not exported.

Finally use classifier stability, Definition 1006.83. Componentwise hsame transport and the displayed Cont routes preserve the source/refusal split, so the two displayed routes exhaust the accepted source-classifier reads. □

Theorem 1006.86 (GapClosureBoundary refusal-ledger route totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, unsupported closure requests are exhausted by the refusal-ledger route* $G \longrightarrow R$ *over* H, C, P, N*. Such a request cannot become hidden closure, hidden* T *supply, host equality, quotient data, or an off-packet continuation.*

Proof. Start with the unsupported side of Definition 1006.85. Once the displayed source route is absent, the only accepted classifier route is the refusal route $G \longrightarrow R$.

Apply Definition 1006.56 and Definition 1006.69. These results keep the unsupported request at the ledger endpoint R under the same hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows.

The remaining exclusions come from Definition 1006.83. The transported refusal route cannot introduce hidden host refusal, hidden T supply, private source selection, unrecorded consumer authority, or an off-packet continuation; hence it also cannot supply host equality or quotient data not present in G, S, R, H, C, P, N. □

Theorem 1006.87 (GapClosureBoundary consumer NameCert readiness)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the source-classifier route totality and refusal-ledger route totality supply the* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *readiness surface consumed by* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*. Each listed consumer receives exactly the displayed source/refusal packet with its* BHist*,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows, and receives no off-packet closure resource.*

Proof. Read the local obligation surface in Definition 1006.84. Its five obligations require carrier exposure, source-route admission, refusal-ledger exactness, consumer-boundary exhaustion, and non-escape of host or global refusal data.

The source-classifier route is supplied by Definition 1006.85. It gives the supported route $G \longrightarrow S$ and the unsupported route $G \longrightarrow R$ inside the same finite packet.

The refusal side is supplied by Definition 1006.86. Unsupported closure requests remain ledger entries and cannot become hidden closure, hidden T supply, host equality, quotient data, or off-packet continuation.

Therefore the listed consumers read exactly the readiness surface named by the local $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ row: the displayed BHist packet, its hsame transports, its Cont routes, and its Pkg provenance. No stronger closure resource is exported to any hard-problem sibling. □

Theorem 1006.88 (GapClosureBoundary root request source totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, every root consumer that receives supported source evidence does so through the displayed source route*

$$G \longrightarrow S$$

and through no other source-bearing coordinate. The rows H, C, P, N *carry only transport, continuation, provenance, and local naming for that route; they do not create hidden closure supply, host equality, quotient data, private source selection, or an off-packet continuation.*

Proof. Read the carrier from Definition 1006.1. Its root boundary coordinates are exactly the request row G, source row S, refusal row R, and the structural rows H, C, P, N.

Apply source-route totality from Definition 1006.55. A supported hard-problem consumer must expose $G \longrightarrow S$ before any structural row is read.

Finally use structural row conservation from Definition 1006.51. The rows H, C, P, N preserve the already displayed source route as transport, continuation, provenance, and local naming, so no second source route or concealed closure coordinate is available. □

Theorem 1006.89 (GapClosureBoundary root refusal consumer totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, every root consumer whose closure request is not supported is exhausted by the displayed refusal route*

$$G \longrightarrow R$$

with H, C, P, N *carrying only transport, continuation, provenance, and local naming. Such a consumer receives no source substitute, hidden closure row, hidden* T *supply, host equality, quotient data, private access row, or off-packet continuation.*

Proof. Start with the carrier boundary in Definition 1006.1. The only off-source endpoint available to the root packet is the refusal row R.

Use refusal route exactness and refusal ledger stability, Definition 1006.56 and Definition 1006.69. They route unsupported closure requests through $G \longrightarrow R$ and preserve that refusal endpoint under transport and replay.

Apply structural row conservation to close the alternatives. Since H, C, P, N only transport, route, package, and name the same refusal endpoint, the unsupported consumer cannot obtain a third branch outside G, S, R, H, C, P, N. □

Theorem 1006.90 (GapClosureBoundary root structural NameCert exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, the root* $\mathsf{NameCert}_{\mathsf{GapClosureBound}}$ *surface is exhausted by the source route* $G \longrightarrow S$*, the refusal route* $G \longrightarrow R$*, and the structural rows* H, C, P, N*. The structural rows carry only transport, continuation, provenance, and naming for those two routes, so the root consumer interface has no third source/refusal branch and no additional closure, equality, quotient, or off-packet resource.*

Proof. First expose the finite packet by Definition 1006.1. The NameCert surface can only name the displayed request, source, refusal, transport, continuation, provenance, and local naming coordinates.

The source side is exhausted by Definition 1006.88. The refusal side is exhausted by Definition 1006.89.

It remains to account for the structural rows. Apply Definition 1006.51: H, C, P, N conserve the selected source or refusal branch instead of adding another coordinate. Thus the root structural NameCert surface is exactly the displayed two-route package. □

Theorem 1006.91 (GapClosureBoundary admission route totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every accepted source admission for the root boundary enters through the displayed source route* $G \longrightarrow S$ *with the* BHist*,* hsame*,* Cont*,* Pkg*, and local* $\mathsf{NameCert}$ *rows carried by* G, S, H, C, P, N*. The admission cannot use hidden closure supply, host equality, quotient data, private source selection, or any off-packet continuation.*

Proof. Begin with the source packet of Definition 1006.82. It exposes the accepted root inventory as the finite rows G, S, R, H, C, P, N and states that no source, refusal, transport, provenance, or local naming coordinate is available outside that packet.

For the admission branch, apply Definition 1006.85. A supported source-classifier read is routed through $G \longrightarrow S$ and not through a third carrier coordinate.

Finally use classifier stability, Definition 1006.83. Componentwise hsame transport and the displayed Cont routes preserve the source/refusal split, so the structural rows can carry the admitted route but cannot manufacture hidden closure supply, host equality, quotient data, private source selection, or an off-packet continuation. □

Theorem 1006.92 (GapClosureBoundary refusal route stability)**.** *For every accepted* GapClosureBoundary$^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every unsupported closure request remains on the displayed refusal ledger route* $G \longrightarrow R$ *under the same* hsame*,* Cont*,* Pkg*, and local* NameCert *rows. Transport, replay, package, and local naming may preserve that refusal endpoint, but they cannot convert it into source admission, hidden closure supply, host equality, quotient data, or an off-packet continuation.*

Proof. Start with refusal route exactness, Definition 1006.56. Once the source route is absent, the unsupported request is routed through $G \longrightarrow R$ with the same structural rows H, C, P, N.

Apply refusal-ledger stability, Definition 1006.69. Replay along C and transport along H preserve the endpoint R, while P and N package and name that endpoint rather than replacing it with another route.

The remaining exclusions follow from classifier stability. The transported refusal route remains a refusal ledger entry under the local BHist, hsame, Cont, Pkg, and NameCert surface, so it cannot become source admission, hidden closure supply, host equality, quotient data, or an off-packet continuation. □

Theorem 1006.93 (GapClosureBoundary consumer readiness exhaustion)**.** *For every accepted* GapClosureBoundary$^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the hard-problem consumers* CausalCommitment$^{\uparrow}$*,* FiniteWitnessedRefutation$^{\uparrow}$*,* OtherMindsCommitment$^{\uparrow}$*,* AspectChain$^{\uparrow}$*, and* SolipsismGapRefusal$^{\uparrow}$ *receive only the admitted source/refusal packet carried by* G, S, R, H, C, P, N*. A supported consumer receives the admitted source route, an unsupported closure request receives the refusal route, and no consumer receives an off-packet closure resource.*

Proof. First assemble the packet boundary. Definition 1006.85 exhausts accepted source-classifier reads by the displayed source and refusal routes, and Definition 1006.91 fixes the supported admission side as $G \longrightarrow S$.

Next account for unsupported consumers. Definition 1006.92 keeps each unsupported closure request on $G \longrightarrow R$ under the same hsame, Cont, Pkg, and local NameCert rows.

Finally apply consumer NameCert readiness, Definition 1006.87. The listed hard-problem consumers read exactly the displayed BHist packet and its structural rows, so the source/refusal packet is exhausted and no off-packet closure resource is exported. □

Definition 1006.94 (GapClosureBoundary root readback packet)**.** *The* GapClosureBoundary$^{\uparrow}$ *root readback packet is the finite* BHist *surface*

$$Q = (B, S_0, R_0, T_0, H_0, C_0, P_0, N_0)$$

where $B = (G, S, R, H, C, P, N)$ *is an accepted* GapClosureBoundary$^{\uparrow}$ *carrier,* S_0 *is the displayed source-readback row for* S*,* R_0 *is the displayed refusal-readback row for* R*,* T_0 *is the downstream*

consumer handoff row, H_0 records componentwise hsame *transport for the source and refusal readbacks, C_0 records* Cont *replay of the source and refusal branches, P_0 records* Pkg *provenance through the root-unblock package and the finite witnessed refutation route of Definition 576.7, and N_0 is the handoff* NameCert *row.*

Theorem 1006.95 (GapClosureBoundary root NameCert handoff)**.** *Every accepted root readback packet $Q = (B, S_0, R_0, T_0, H_0, C_0, P_0, N_0)$ hands off the* $\mathsf{GapClosureBoundary}^{\uparrow}$ *NameCert surface to downstream hard-problem consumers only after the source branch $G \longrightarrow S$ or the refusal branch $G \longrightarrow R$ has been read through B. The handoff row T_0 may cite the root-unblock package of Definition 1006.39 and the finite witnessed refutation boundary route of Definition 576.7, but it receives no host closure row, hidden* T *supply, private access row, or off-packet continuation.*

Proof. Start from the accepted carrier $B = (G, S, R, H, C, P, N)$ inside Definition 1006.94. The root readback packet adds only source readback, refusal readback, handoff, transport, replay, provenance, and local naming rows.

For the supported branch, apply source-route totality and the root-unblock package, Definition 1006.55 and Definition 1006.39. These force the source readback S_0 to be a replay of $G \longrightarrow S$ through the displayed structural rows.

For the unsupported branch, apply refusal-route exactness and the finite witnessed refutation crosslink, Definition 1006.56 and Definition 576.7. These force the refusal readback R_0 to remain a refusal boundary rather than a universal closure principle.

The handoff row T_0 is then packaged by P_0 and named by N_0. Since no row of Q is a host closure, hidden supply, private access, or off-packet continuation, the downstream handoff exports only the displayed root NameCert surface. □

Theorem 1006.96 (GapClosureBoundary root consumer locality)**.** *Every downstream consumer of the root readback packet $Q = (B, S_0, R_0, T_0, H_0, C_0, P_0, N_0)$ is local to the displayed* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier, its source/refusal readback rows, and the handoff* NameCert *surface. A consumer may inspect $B, S_0, R_0, T_0, H_0, C_0, P_0, N_0$ and may follow the hard-problem consumer factorization of Definition 1006.65; it cannot bypass those rows to inspect a hidden root source, a host equality, a private other-minds access row, a direct aspect-reduction row, or an ambient closure theorem.*

Proof. Project the packet Q. Its consumer-facing coordinates are exactly the accepted boundary carrier, the two readback rows, the handoff row, transport, replay, provenance, and local naming.

Apply root package consumer cut, Definition 1006.62. It forces every downstream consumer through the displayed package and provenance surface of B.

Apply hard-problem consumer factorization, Definition 1006.65. The consumer route is one of the displayed source/refusal branches and not a separate consumer-specific route.

Finally use the handoff theorem Definition 1006.95. The handoff preserves the same source/refusal readback under hsame, Cont, Pkg, and NameCert rows, so no hidden source, host equality, private access, direct reduction, or ambient closure theorem can be read outside Q. □

Theorem 1006.97 (GapClosureBoundary supported route totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier $B = (G, S, R, H, C, P, N)$, every supported boundary route is displayed through the carrier rows, the classifier surface, the refusal ledger, downstream consumer rows, componentwise transports, displayed* Cont *routes,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row. A supported read therefore reaches a hard-problem consumer only through the displayed source route and never through an unrecorded closure coordinate.*

Proof. Start with the carrier and NameCert obligations, Definition 1006.1 and Definition 1006.2. They expose the finite rows G, S, R, H, C, P, N and require source-route exactness before any supported read is consumed.

Use the classifier and source-route surfaces recorded by Definition 1006.7 and Definition 1006.10. These show that an accepted supported route reads the displayed source row S and remains inside the finite carrier.

Finally apply the downstream handoff theorems, including Definition 1006.112 and Definition 1006.114. The structural rows H, C, P, N only transport, replay, package, and name the supported route, so no hidden closure coordinate is exported. □

Theorem 1006.98 (GapClosureBoundary refusal stability route)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, an unsupported read of* G *remains in the refusal ledger* R *under componentwise* hsame *transport. The displayed route may replay the refusal through* H, C, P, N*, but it cannot turn the unsupported read into internal closure, hidden* T *supply, host quotient data, or a private source selection.*

Proof. Begin with an unsupported read of the request row G. Since no displayed source route through S is present, the displayed source precondition of Definition 1006.4 is not met.

Apply refusal-ledger routing and transport, Definition 1006.11 and Definition 1006.5. They send the unsupported read to R and carry it only through the componentwise hsame rows, displayed Cont route, provenance, and local name.

The refusal non-escape theorem Definition 1006.3 excludes internal closure, hidden T supply, host quotient data, and private source selection. Thus the refusal route is stable under the displayed transports. □

Theorem 1006.99 (GapClosureBoundary consumer nonescape)**.** *Every downstream consumer of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *route receives only the displayed rows* G, S, R, H, C, P, N*, the classifier and refusal ledgers, componentwise* hsame *transports, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *data. It receives no hidden global classifier, theorem-proof row, host quotient, or unrecorded completion boundary.*

Proof. First expose the consumer through Definition 1006.114. A supported consumer receives the source handoff, and an off-source consumer receives the refusal handoff; both handoffs use the same finite carrier rows.

Combine supported route totality with refusal stability. The supported case is exhausted by Definition 1006.97, while the unsupported case is exhausted by Definition 1006.98.

It remains to rule out external replacements. The carrier, classifier exhaustion, and ledger nonescape theorems give no coordinate for a hidden global classifier, theorem-proof row, host quotient, or completion boundary outside G, S, R, H, C, P, N. Hence every downstream consumer remains inside the displayed route completion surface. □

Theorem 1006.100 (GapClosureBoundary root recognizer admission totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every root recognizer admission that reaches a downstream hard-problem consumer must first pass through the* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *acceptance route and then land in the displayed* $\mathsf{FiniteReflectionTuple}^{\uparrow}$ *image. The admitted branch is consumed as the source route* $G \longrightarrow S$ *with the displayed transport, continuation, provenance, and local naming rows; no hidden source selector, private compiler state, or off-packet recognition channel is exported.*

Proof. Start with the carrier of Definition 1006.1. The root boundary exposes only the packet G, S, R, H, C, P, N.

Apply recognizer source admission, Definition 1006.73. It forces successful recognizer evidence through $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ and then through the $\mathsf{FiniteReflectionTuple}^{\uparrow}$ tuple image before the boundary packet is consumed.

Finally use admission route totality, Definition 1006.91. The accepted branch is the displayed $G \longrightarrow S$ route under H, C, P, N, so no hard-problem consumer receives an additional source coordinate. □

Theorem 1006.101 (GapClosureBoundary root refusal ledger coverage)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every root recognizer request that fails to land through the* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *and* $\mathsf{FiniteReflectionTuple}^{\uparrow}$ *admission route is covered by the displayed refusal ledger* R*. The GAP residue available to downstream hard-problem consumers is therefore the finite refusal branch* $G \longrightarrow R$ *with the same* H, C, P, N *structural rows, not hidden closure supply, host equality, quotient data, private source access, or an off-packet continuation.*

Proof. Begin with recognizer refusal stability, Definition 1006.74. A failed tuple landing cannot be reread as accepted source evidence, so the request is routed to the refusal ledger.

Use refusal route stability, Definition 1006.92. The rows H, C, P, N preserve the endpoint R and package it as the displayed GAP residue rather than replacing it with another route.

The coverage is exhaustive by consumer readiness exhaustion, Definition 1006.93. Unsupported closure requests for the listed hard-problem consumers remain inside the same refusal branch. □

Theorem 1006.102 (GapClosureBoundary root NameCert consumer exhaustion)**.** *For the downstream consumers* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$*, the root* $\mathsf{GapClosureBoundary}^{\uparrow}$ *NameCert surface is exhausted by the displayed source row, refusal ledger, transport rows, continuation routes, package provenance, and local naming row of* $B = (G, S, R, H, C, P, N)$*. A consumer may read admitted source evidence through* $G \longrightarrow S$ *or refusal coverage through* $G \longrightarrow R$*, but it receives no separate hard-problem carrier, hidden closure oracle, host-level equality, or unnamed route.*

Proof. First assemble the accepted branch. By Definition 1006.100, recognizer admission reaches the boundary only as the displayed source route $G \longrightarrow S$.

Next assemble the refusal branch. By Definition 1006.101, every failed or unsupported recognizer request is carried by $G \longrightarrow R$ under the same structural rows.

It remains to account for the consumer surface. Apply recognizer consumer exhaustion, Definition 1006.75, and consumer readiness exhaustion, Definition 1006.93. Together they show that the listed hard-problem consumers read only G, S, R, H, C, P, N and no sibling-specific or off-packet NameCert row. □

Theorem 1006.103 (GapClosureBoundary source route completeness)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every supported downstream consumer route for* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *factors through the displayed source row* S *and the concrete rows* G, H, C, P, N*. The consumer may read the branch only as*

$$G \longrightarrow S$$

transported, replayed, packaged, and named by H, C, P, N*; it receives no separate source carrier, private host witness, or consumer-specific route outside the accepted packet.*

Proof. Start with the accepted carrier and NameCert obligations, Definition 1006.1 and Definition 1006.2. They expose the packet G, S, R, H, C, P, N before any hard-problem consumer reads the boundary.

Apply source route totality, Definition 1006.55. A supported read reaches the consumer surface only after the displayed route $G \longrightarrow S$ is available.

Finally use source observation totality and structural row conservation, Definition 1006.40 and Definition 1006.51. These keep H, C, P, N as transport, replay, package, and local naming rows for the same source route, so the supported consumer factors through the concrete packet and not through an extra carrier. □

Theorem 1006.104 (GapClosureBoundary refusal branch determinacy)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every off-source closure request by a listed downstream consumer has the unique refusal endpoint* R*. The request is routed through* G *and the structural rows* H, C, P, N *to the refusal branch*

$$G \longrightarrow R$$

and cannot split into hidden T *supply, internal closure, private access, host equality, quotient data, or an off-packet continuation.*

Proof. Begin with refusal route determinacy, Definition 1006.50. When the displayed source route is absent, the public boundary sends the request to the refusal row R.

Use refusal route exactness and refusal non-escape, Definition 1006.56 and Definition 1006.3. They identify $G \longrightarrow R$ as the accepted endpoint and remove hidden closure, hidden T supply, private access, and off-packet continuation as exits.

The structural rows are then fixed by structural row conservation, Definition 1006.51. Since H, C, P, N only preserve, replay, package, and name the displayed branch, the refusal endpoint cannot split into another source or an internal closure witness. □

Theorem 1006.105 (GapClosureBoundary NameCert consumer totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the concrete* $\mathsf{NameCert}$ *consumer packet for the listed downstream hard-problem chapters is total over the two displayed branches. Each consumer route is exhausted by either the source branch* $G \longrightarrow S$ *of Definition 1006.103 or the refusal branch* $G \longrightarrow R$ *of Definition 1006.104, with* H, C, P, N *as the only transport, continuation, provenance, and local naming rows.*

Proof. First assemble the source side. By Definition 1006.103, every supported consumer factors through the concrete source row S and the rows G, H, C, P, N.

Next assemble the refusal side. By Definition 1006.104, every off-source closure request reaches the unique refusal endpoint R through the same structural rows.

It remains to show that these two branches exhaust the NameCert packet. Apply the carrier obligations of Definition 1006.2 and the non-escape content of Definition 1006.3. The first fixes the consumer surface to G, S, R, H, C, P, N, and the second removes hidden closure, hidden T supply, and off-packet continuation. Thus every listed consumer route is accounted for by the displayed source branch or the displayed refusal branch. □

Theorem 1006.106 (GapClosureBoundary finite source/refusal classifier)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, the public root classifier exposes exactly the two routes*

$$G \longrightarrow S$$

and

$$G \longrightarrow R$$

over the structural rows H, C, P, N. The first route is the supported source route, the second route is the unsupported refusal route, and the accepted classifier exports no third public route, hidden closure branch, private source row, or off-packet continuation.

Proof. Start with carrier exposure and local obligations, Definition 1006.1 and Definition 1006.2. They identify the public root packet with the rows G, S, R, H, C, P, N before any consumer reads the boundary.

Use source/refusal orthogonality, Definition 1006.46. The supported side has to display the source row as $G \longrightarrow S$, while the unsupported side is routed to the refusal row as $G \longrightarrow R$.

Finally apply the consumer totality surface of Definition 1006.105. Since every listed consumer route is exhausted by one of these two branches with H, C, P, N as structural support, the classifier has no remaining public branch to expose. □

Theorem 1006.107 (GapClosureBoundary consumer source/refusal readiness)**.** *Every listed hard-problem consumer of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier $B = (G, S, R, H, C, P, N)$ is ready only after the same source/refusal split of Definition 1006.106 has been displayed. A supported consumer reads the source route $G \longrightarrow S$, an unsupported closure request reads the refusal route $G \longrightarrow R$, and no consumer receives an off-packet closure row, private witness row, hidden* T *supply, quotient row, or sibling-specific carrier.*

Proof. First factor the downstream surface by Definition 1006.47. The causal, finite-refutation, other-minds, aspect-chain, and solipsism-refusal consumers are recorded through the same packet G, S, R, H, C, P, N rather than through independent consumer carriers.

Next use Definition 1006.106. It gives the only two public routes available to those consumers: the supported source route and the unsupported refusal route.

The readiness claim follows from consumer readiness exhaustion, Definition 1006.93. That theorem removes off-packet closure resources from the consumer interface, so each listed consumer is ready precisely at the displayed source/refusal split. □

Theorem 1006.108 (GapClosureBoundary root refusal NameCert exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier $B = (G, S, R, H, C, P, N)$, the local root* $\mathsf{NameCert}$ *surface is exhausted by carrier exposure, supported source routing, unsupported refusal routing, and the structural transport, provenance, replay, and naming rows H, C, P, N. Thus the root certificate has no additional local obligation beyond exposing G, S, R, H, C, P, N, routing supported requests through $G \longrightarrow S$, routing unsupported requests through $G \longrightarrow R$, and transporting, packaging, replaying, and naming those routes.*

Proof. Read the local surface from Definition 1006.1 and Definition 1006.2. These anchors provide the carrier row and the certificate duties for source routing, refusal routing, transport, provenance, replay, and local naming.

Apply source/refusal orthogonality together with the finite classifier, Definition 1006.46 and Definition 1006.106. They separate the supported source route from the unsupported refusal route and show that both routes remain inside the same public packet.

It remains to account for consumers. Use hard-problem consumer factorization and consumer readiness exhaustion, Definition 1006.47 and Definition 1006.93. These close the local surface by assigning all listed consumer reads to the displayed source/refusal packet and by excluding off-packet closure rows. □

Theorem 1006.109 (GapClosureBoundary source-refusal decision surface)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, every supported read factors through the displayed source route*

$$G \longrightarrow S,$$

and every unsupported read factors through the displayed refusal route

$$G \longrightarrow R.$$

The decision surface is the concrete packet governed by Definition 1006.55, Definition 1006.56, Definition 1006.54, and the TasteGate row recorded in the closure status for this chapter.

Proof. Start with the carrier in Definition 1006.1. It exposes exactly the request row, source row, refusal row, transport row, continuation row, provenance row, and local naming row G, S, R, H, C, P, N.

For the supported branch, apply Definition 1006.55. The read reaches the boundary only after the route $G \longrightarrow S$ is displayed.

For the unsupported branch, apply Definition 1006.56. The same request row is sent to R rather than to hidden closure, hidden T supply, host equality, quotient data, or an off-packet continuation.

Finally use the consumer exactness package and the TasteGate status row. The package keeps downstream reads inside the same seven coordinates, and the TasteGate row requires the source/refusal split to be preserved by the named carrier surface. □

Theorem 1006.110 (GapClosureBoundary consumer route factorization)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, each downstream consumer read by* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *factors first through the decision surface of Definition 1006.109. Supported consumers then read* $G \longrightarrow S$ *with* H, C, P, N*, while unsupported consumers read* $G \longrightarrow R$ *with the same structural rows.*

Proof. Begin with the decision surface. It already separates every accepted read of B into the supported route $G \longrightarrow S$ or the unsupported route $G \longrightarrow R$.

Apply the consumer exactness package, Definition 1006.54. The listed hard-problem consumers receive the shared boundary packet and do not obtain a consumer-specific source, refusal, transport, continuation, provenance, or naming coordinate.

The supported case is therefore routed by Definition 1006.55. The unsupported case is routed by Definition 1006.56. Since both cases use the same structural rows H, C, P, N, the consumer route factors through the displayed decision surface before any downstream read is made. □

Theorem 1006.111 (GapClosureBoundary TasteGate field-faithful readback)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, every faithful readback of the TasteGate row recorded in the closure status preserves the displayed packet fields* G, S, R, H, C, P, N*. In particular, it preserves the supported branch* $G \longrightarrow S$*, the unsupported branch* $G \longrightarrow R$*, and the consumer factorization of Definition 1006.110.*

Proof. Read the TasteGate row through the carrier of Definition 1006.1. The row is attached to the displayed $\mathsf{GapClosureBoundary}^{\uparrow}$ packet, not to an ambient closure oracle.

Use source-route totality and refusal-route exactness. A faithful readback must preserve which requests reach S and which requests reach R, because changing either endpoint changes the public source/refusal decision.

Finally apply consumer route factorization. The listed consumers see the decision only through G, S, R, H, C, P, N, so a field-faithful readback preserves all displayed packet fields and cannot replace them with hidden closure, private source access, host equality, quotient data, or an off-packet continuation. □

Theorem 1006.112 (GapClosureBoundary root source totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, every supported root read of the boundary must pass through the displayed source route*

$$G \longrightarrow S$$

before any hard-problem consumer reads the packet. The rows H, C, P, N *keep that read inside the componentwise transport, displayed continuation, package provenance, and local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *surface, so no supported read can use a second source coordinate, host equality, quotient data, hidden closure supply, or an off-packet continuation.*

Proof. Start with the carrier of Definition 1006.1. The accepted root packet has exactly the rows G, S, R, H, C, P, N, with S the only displayed source row available to a supported boundary read.

Apply the NameCert obligations and displayed source precondition, Definition 1006.2 and Definition 1006.4. They require a supported read to expose the source observation or socket row S before the packet is consumed.

The structural rows do not change the route. They transport, replay, package, and locally name the already displayed source branch, so the supported root read is exactly the route $G \longrightarrow S$ inside G, S, H, C, P, N. □

Theorem 1006.113 (GapClosureBoundary root refusal handoff totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, every off-source root read is handed to the displayed refusal row*

$$G \longrightarrow R$$

through H, C, P, N*. The handoff cannot export internal closure, hidden* T *supply, host equality, quotient data, private source selection, or any continuation outside the displayed packet.*

Proof. Begin with an off-source read of G. By Definition 1006.4, such a read has not exposed the source row S, so it cannot enter the supported branch.

Use refusal-ledger transport from Definition 1006.5. The request is routed to R along the same structural rows H, C, P, N that belong to the accepted carrier.

Finally apply the carrier and NameCert obligations, Definition 1006.1 and Definition 1006.2. Since the certificate surface contains only G, S, R, H, C, P, N, the refusal handoff has no row from which internal closure or hidden T supply could be exported. □

Theorem 1006.114 (GapClosureBoundary root consumer handoff)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, the downstream consumers* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *receive exactly the displayed boundary rows* G, S, R, H, C, P, N*. A supported consumer receives the source handoff* $G \longrightarrow S$ *with* H, C, P, N*, an off-source consumer receives the refusal handoff* $G \longrightarrow R$ *with* H, C, P, N*, and no listed consumer receives a separate closure, private access, causal-necessity, aspect-reduction, quotient, or hidden* T *row.*

Proof. First expose the accepted packet through Definition 1006.1 and Definition 1006.2. These anchors identify the boundary rows available before any downstream hard-problem consumer reads the packet.

For a supported consumer, use Definition 1006.112. The read has already passed through $G \longrightarrow S$, and the structural rows only transport, replay, package, and name that source branch.

For an off-source consumer, use Definition 1006.113. The request has already been handed to R through H, C, P, N, without exporting hidden closure or hidden T supply.

It remains to check consumer exhaustion. Apply Definition 1006.9: the causal commitment, finite witnessed refutation, other-minds commitment, aspect-chain, and solipsism-refusal consumers are exactly the listed readers of this boundary packet. Therefore each receives one of the two displayed handoffs and no row outside G, S, R, H, C, P, N. □

The $\mathsf{GapClosureBoundary}^{\uparrow}$ sibling route first consumes the finite refutation witness surface of chapter 576 and the refusal boundary of chapter 975. Only after those two horizontal inputs are fixed does the chapter expose its source-refusal consumer ledger: supported reads remain on the displayed source branch, unsupported closure requests remain on the displayed refusal branch, and the later ledger receives no kernel-only shortcut around the sibling lattice.

Theorem 1006.115 (GapClosureBoundary finite trace evaluator route)**.** *Any* $\mathsf{GapClosureBoundary}^{\uparrow}$ *consumer that evaluates a finite refusal trace or finite acceptance trace must pass through the* $\mathsf{FiniteTraceEvaluator}^{\uparrow}$ *checkpoint and runtime route of chapter 818 before declaring source-gap closure. The boundary read therefore factors through the displayed request row, trace-evaluator checkpoint, supported or refused branch, componentwise transport, displayed replay, provenance, and local naming rows; it cannot declare closure from an unevaluated trace, hidden runtime verdict, or off-packet source-gap assertion.*

Proof. Start with the accepted boundary packet and the consumer bridge admission of Definition 1006.180. The consumer receives only the displayed request, branch, transport, replay, provenance, and local naming rows.

The finite trace is then evaluated through the $\mathsf{FiniteTraceEvaluator}^{\uparrow}$ sibling surface. Its checkpoint fixes the runtime read before the supported branch or refused branch can be consumed as a source-gap boundary result.

Apply the source-route and refusal-route exactness results for the two possible branches. A supported trace remains on the source branch, while a refused trace remains on the refusal branch, and both branches keep the same structural rows.

Thus a consumer that skips the finite trace evaluator has not read the same $\mathsf{GapClosureBoundary}^{\uparrow}$ packet. It may report a separate runtime observation, but it cannot declare source-gap closure from this boundary certificate. □

The $\mathsf{GapClosureBoundary}^{\uparrow}$ sibling lattice first consumes the recognizer route of chapter 1048, the audit-packet route of chapter 820, and the finite-trace evaluator of chapter 818. Only after those three rows are visible does the boundary expose its source/refusal branch: recognized traces may pass to the displayed source row, while exactness failures remain on the refusal row with the same BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ surface.

Theorem 1006.116 (GapClosureBoundary refusal verdict totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the boundary exposes the source GAP row* G*, the unsupported request endpoint, the refusal verdict row* R*, and the refusal ledger carried by* H, C, P, N *before any consumer can read a supported route. A supported consumer may later read* $G \longrightarrow S$*, but only after the refusal verdict surface has fixed how off-source requests are routed.*

Proof. Begin with the source/refusal decision surface of Definition 1006.109. It separates accepted reads of G into the displayed source route $G \longrightarrow S$ and the displayed refusal route $G \longrightarrow R$.

For the refusal side, apply the source-refusal consumer ledger, Definition 1006.57. The unsupported request endpoint is accounted for by the refusal route through R and by the same structural rows H, C, P, N.

Now use the root totality handoff surface, Definition 1006.114. It requires downstream consumers to receive the displayed rows G, S, R, H, C, P, N rather than a private boundary packet.

Finally, the recognizer-facing dependency surface is already concrete: Definition 1048.3 and Definition 993.3 place accepted evidence through a certificate gate and tuple readback before it reaches the boundary. Thus the refusal verdict and ledger are visible before a consumer can use the supported route. □

Theorem 1006.117 (GapClosureBoundary supported route exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every supported route is exhausted by the displayed* BHist *rows* G, S, R*, the componentwise* hsame *row* H*, the displayed* Cont *row* C*, the* Pkg *row* P*, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row* N*. No supported consumer route can use hidden closure supply, host equality, quotient data, or a boundary route outside these rows.*

Proof. First expose the scoped dependency inventory. By Definition 1006.79, the boundary displays the BHist carrier rows together with H, C, P, N before any consumer reads it.

For the supported branch, apply root source totality from Definition 1006.112. A supported root read must pass through $G \longrightarrow S$ and then remain inside the componentwise transport, displayed continuation, provenance, and local naming surface.

Next apply consumer route totality, Definition 1006.68. It assigns each listed downstream read to the displayed source/refusal split and rules out a route bypassing both S and R.

The concrete sibling landing theorems close the only remaining import path. The certificate-gate exactness of Definition 1048.3 and the field-faithful readback of Definition 993.3 make the recognizer and tuple surfaces feed the same displayed rows, so there is no hidden closure route beyond G, S, R, H, C, P, N. □

Theorem 1006.118 (GapClosureBoundary NameCert consumer non-escape)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any downstream consumer receives only the refusal-plus-supported-route packet named by* N *and transported through* H, C, P*. The consumer receives no unregistered global closure, hidden exactness theorem, host quotient-like boundary, private source selector, or off-packet continuation.*

Proof. Start from scoped consumer non-escape, Definition 1006.81. It confines the listed sibling consumers to the scoped source/refusal surface of G, S, R, H, C, P, N.

The supported side is governed by Definition 1006.117. The source branch is the route $G \longrightarrow S$ carried by the displayed transport, continuation, package provenance, and local $\mathsf{NameCert}$ rows.

The refusal side is governed by Definition 1006.116. Unsupported requests are already placed on the refusal verdict row R and its ledger before the supported route can be consumed.

Finally use root consumer handoff and recognizer refusal stability, Definition 1006.114 and Definition 1006.74. The first keeps every listed downstream consumer inside the displayed packet, and the second prevents failed recognizer landing from being reread as source evidence. Hence the local NameCert surface exports only the refusal-plus-supported-route packet and no unregistered global closure, hidden exactness theorem, quotient-like boundary, private selector, or off-packet continuation. □

Theorem 1006.119 (GapClosureBoundary source-refusal admission triad)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, a downstream recognizer-facing request is admitted only through the displayed source-refusal triad: the request row* G*, the supported source route* $G \longrightarrow S$*, and the unsupported refusal route* $G \longrightarrow R$*, all transported, replayed, packaged, and named by* H, C, P, N*. The triad is read through the source-refusal decision surface, the consumer exactness package, the recognizer landing obligations, and the route completion surface. It exports no hidden closure row, hidden* T *supply, private source route, host equality row, quotient datum, direct aspect-reduction row, or off-packet continuation.*

Proof. Start with Definition 1006.109. It separates each accepted read of B into the supported route $G \longrightarrow S$ or the unsupported route $G \longrightarrow R$.

Next apply the consumer exactness package of Definition 1006.54. The listed hard-problem consumers read the shared carrier and receive no consumer-specific source, refusal, transport, continuation, provenance, or naming coordinate.

Use the recognizer landing obligations, Definition 1006.73 and Definition 1006.74. Successful recognizer landings are consumed as the displayed source branch, and failed or unsupported landings are consumed as the displayed refusal branch.

Finally apply Definition 1006.99. The completed route remains G, S, R, H, C, P, N, so the excluded hidden, host, quotient, aspect, and off-packet rows have no admitted coordinate. □

Theorem 1006.120 (GapClosureBoundary refusal ledger exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the refusal ledger for downstream recognizer-facing requests is exhausted by the displayed refusal route* $G \longrightarrow R$ *with structural rows* H, C, P, N*. Any request that cannot enter the source branch through the recognizer landing surface remains at this refusal boundary, and the ledger supplies no hidden closure theorem, hidden* T *source, host equality, quotient object, private selector, or sibling-specific recognizer row.*

Proof. First read the unsupported side of the source-refusal decision surface. Without the displayed source route $G \longrightarrow S$, the accepted branch is the refusal route $G \longrightarrow R$.

Apply Definition 1006.56 and Definition 1006.69. These theorems identify R as the refusal endpoint and preserve it under the structural rows H, C, P, N.

Then use recognizer refusal stability from Definition 1006.74. A failed landing after the $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ and $\mathsf{FiniteReflectionTuple}^{\uparrow}$ surfaces cannot be reread as source evidence.

The consumer non-escape boundary of Definition 1006.99 removes hidden closure, hidden T supply, host equality, quotient data, private selectors, and sibling-specific recognizer rows. Hence the refusal ledger is exhausted by the displayed refusal route. □

Theorem 1006.121 (GapClosureBoundary downstream consumer boundary)**.** *Every downstream recognizer-facing consumer of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet either factors through the source-refusal admission triad of Definition 1006.119 or remains at the refusal ledger boundary of Definition 1006.120. In particular, the consumers* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *receive only the displayed packet* G, S, R, H, C, P, N *and the two visible source-refusal routes. They receive no bypass around the displayed refusal package and no hidden recognizer, solver, host equality, quotient, closure, or off-packet continuation.*

Proof. Begin with recognizer consumer exhaustion, Definition 1006.75. It says successful recognizer landings are consumed as $G \longrightarrow S$ and failed or unsupported landings are consumed as $G \longrightarrow R$.

Apply the source-refusal admission triad to the successful side. The admitted route reads the shared request, source, refusal, transport, continuation, provenance, and local naming rows before any downstream consumer receives the packet.

Apply refusal ledger exhaustion to the unsupported side. Requests not passing through the displayed source branch remain at R with the same structural rows and cannot use a bypassing recognizer or solver route.

Finally combine supported-route totality with consumer non-escape, Definition 1006.97 and Definition 1006.99. The completed downstream boundary is exactly G, S, R, H, C, P, N, and every hidden recognizer, solver, host equality, quotient, closure, or off-packet continuation request is refused. □

Theorem 1006.122 (GapClosureBoundary terminal source admission)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, a terminal source read is admitted only through the displayed source branch*

$$G \longrightarrow S$$

with the componentwise hsame *row* H*, displayed* Cont *row* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}}$ *row* N*. Any request not supported by that branch is routed through the displayed refusal branch*

$$G \longrightarrow R$$

with the same structural rows. The terminal read exports no hidden closure row, hidden T *supply, private source selector, host equality row, quotient datum, or off-packet continuation.*

Proof. Begin with the source-refusal admission triad of Definition 1006.119. It already identifies the terminal recognizer-facing request with the request row G, the supported source route $G \longrightarrow S$, and the unsupported refusal route $G \longrightarrow R$.

For supported reads, apply recognizer source admission, Definition 1006.73. The $\mathsf{GroundCompilerRecognizerFlow}$ gate and $\mathsf{FiniteReflectionTuple}^{\uparrow}$ readback place accepted source evidence on the displayed branch before the boundary packet is consumed.

For unsupported reads, apply refusal ledger exhaustion, Definition 1006.120. Requests that fail the recognizer landing remain at R under H, C, P, N and cannot be reread as source evidence.

Finally use the downstream consumer boundary of Definition 1006.121. It restricts every listed consumer to the same packet G, S, R, H, C, P, N, so the terminal read has no route outside the displayed source/refusal split. □

Theorem 1006.123 (GapClosureBoundary refusal classifier stability)**.** *Let* $B = (G, S, R, H, C, P, N)$ *and* $B' = (G', S', R', H', C', P', N')$ *be accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carriers. Componentwise* hsame *transport through* H *and* H'*, followed by replay through the displayed* Cont *rows* C *and* C'*, preserves the supported/refusal classifier split: supported reads remain reads of the displayed source branch* $G \longrightarrow S$*, unsupported requests remain reads of the displayed refusal branch* $G \longrightarrow R$*, and transport cannot introduce host equality, quotient data, private source selectors, hidden closure supply, or an off-packet continuation row.*

Proof. First expose the classifier inventory through Definition 1006.119. The classifier-relevant data are the request row, the source branch, the refusal branch, and the structural rows H, C, P, N.

Next apply recognizer refusal stability, Definition 1006.74. Failed $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ and $\mathsf{FiniteReflectionTuple}^{\uparrow}$ landings cannot become source evidence after replay, so the refusal side remains refusal data.

For the supported side, use Definition 1006.73 together with the certificate-gate and tuple-readback anchors Definition 1048.3 and Definition 993.3. The accepted recognizer row is read back as displayed boundary data before it reaches S.

Finally invoke refusal ledger exhaustion, Definition 1006.120. Since the ledger contains no host equality, quotient object, private selector, hidden closure row, or off-packet continuation coordinate, componentwise transport and replay preserve the same supported/refusal split. □

Theorem 1006.124 (GapClosureBoundary consumer ledger nonescape)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the downstream consumers* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *receive only the displayed packet rows* G, S, R, H, C, P, N*. A supported consumer reads through* $G \longrightarrow S$*, an unsupported consumer reads through* $G \longrightarrow R$*, and no listed consumer receives a hidden recognizer, solver, host, quotient, closure, private source selector, or off-packet continuation row.*

Proof. Start with Definition 1006.121. It says every listed downstream consumer either factors through the source-refusal admission triad or remains at the refusal ledger boundary.

For the source branch, apply terminal source admission, Definition 1006.122. Supported reads are terminal only as reads of $G \longrightarrow S$ with H, C, P, N.

For the refusal branch, apply refusal ledger exhaustion, Definition 1006.120. Unsupported closure requests are kept at R under the same structural rows and do not acquire a consumer-specific escape route.

Finally combine the recognizer consumer exhaustion of Definition 1006.75 with the root consumer handoff of Definition 1006.114. The five listed consumers receive exactly the displayed packet surface, so hidden recognizer, solver, host, quotient, closure, private-selector, and off-packet continuation rows are absent from the ledger. □

Theorem 1006.125 (GapClosureBoundary NameCert route completion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier*

$$B = (G, S, R, H, C, P, N),$$

the obligations of Definition 1006.2 complete the route surface visible to causal commitment, finite witnessed refutation, other-minds commitment, aspect-chain, and solipsism-refusal consumers. A supported consumer reads the request row G *through the displayed source row* S*; an unsupported consumer reads* G *through the refusal row* R*; and both routes are transported by* H*, replayed by* C*, packaged by* P*, and locally named by* N*.*

Proof. Project the carrier of Definition 1006.1. Its full consumer-visible inventory is G, S, R, H, C, P, N, with H assigned to componentwise hsame transport, C to displayed Cont replay, P to Pkg provenance, and N to the local $\mathsf{NameCert}$ row.

Apply Definition 1006.2. Carrier exposure gives the finite packet, source-route exactness sends supported reads through S, and refusal-ledger routing sends unsupported reads through R.

Finally use Definition 1006.3 together with the sibling consumer surface recorded in the carrier chapter. The causal commitment, finite witnessed refutation, other-minds commitment, aspect-chain, and solipsism-refusal consumers receive only the completed source-or-refusal route, so no consumer reads a hidden closure coordinate or a parameter-transport equivalence schema. □

Theorem 1006.126 (GapClosureBoundary refusal totality readback)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every hard-problem consumer readback that cannot exhibit the source branch* $G \longrightarrow S$ *is total on the refusal branch* $G \longrightarrow R$*. The readback keeps the refusal row under the displayed* hsame *transports,* Cont *replay,* Pkg *provenance, and* $\mathsf{NameCert}$ *naming*

rows, and it exports no private other-minds access, causal necessity row, direct aspect-reduction row, hidden T *supply, or off-packet continuation.*

Proof. Begin with the source/refusal split supplied by Definition 1006.125. A consumer readback is either supported by the displayed source row S or is unsupported at the boundary.

In the unsupported case, apply Definition 1006.3. The only available endpoint is the refusal ledger R, and the structural rows H, C, P, N preserve that endpoint rather than replacing it with a source witness.

The listed sibling consumers do not add further coordinates. Causal commitment, finite witnessed refutation, other-minds commitment, aspect-chain, and solipsism-refusal consumers therefore read the same refusal branch when S is absent, with no host-side completion route beyond B. □

Theorem 1006.127 (GapClosureBoundary ledger exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the route ledger is exhausted by the source branch* $G \longrightarrow S$*, the refusal branch* $G \longrightarrow R$*, the componentwise* hsame *transport row* H*, the displayed* Cont *route row* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}$ *row* N*. No downstream consumer can extend the ledger to an internal universal closure row or to a separate parameter-transport equivalence surface.*

Proof. First read the route-completion theorem. It identifies the only two consumer routes from G: the displayed source route and the displayed refusal route.

Next read refusal totality. Whenever the source route is absent, the readback is already total at R under H, C, P, N.

It remains to check consumer exhaustion. The carrier of Definition 1006.1 and the obligation theorem of Definition 1006.2 leave no row beyond G, S, R, H, C, P, N. Thus every downstream hard-problem consumer receives a finite ledger route and no extra closure, hidden source, private access, causal, aspect, or off-packet continuation coordinate. □

Theorem 1006.128 (GapClosureBoundary terminal route totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier*

$$B = (G, S, R, H, C, P, N),$$

every terminal read of the root request row is routed through exactly one displayed branch. A supported terminal read uses the source branch

$$G \longrightarrow S$$

with the componentwise hsame *row* H*, the displayed* Cont *row* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row* N*. An unsupported terminal read uses the refusal branch*

$$G \longrightarrow R$$

with the same structural rows. No terminal read exports a row outside the finite BHist *packet* G, S, R, H, C, P, N*.*

Proof. Begin with the carrier and local certificate obligations of Definition 1006.1 and Definition 1006.2. They expose the finite BHist packet and assign H, C, P, N to componentwise hsame transport, displayed Cont replay, Pkg provenance, and local $\mathsf{NameCert}$ naming.

For the supported branch, apply terminal source admission from Definition 1006.122 together with route completion, Definition 1006.125. These rows force the accepted terminal source read to pass through $G \longrightarrow S$ before any consumer reads the structural surface.

For the unsupported branch, apply refusal route exactness from Definition 1006.56 and refusal totality readback, Definition 1006.126. The same request row is sent to R and remains under H, C, P, N.

Finally use ledger exhaustion, Definition 1006.127. The ledger has no third terminal endpoint beyond the source and refusal branches, so every terminal read is accounted for by one of the two displayed routes. □

Theorem 1006.129 (GapClosureBoundary refusal NameCert factorization)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, every unsupported request factors through the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row. The factorization first records the refusal endpoint* R*, then transports it by the componentwise* hsame *row* H*, replays it through the displayed* Cont *row* C*, packages it by the* Pkg *row* P*, and names the resulting refusal read by* N*. Thus unsupported requests remain inside the finite* BHist *carrier and cannot be read as an unnamed closure resource.*

Proof. Read the refusal route from Definition 1006.56. An unsupported request cannot use the source branch, so its endpoint is the displayed refusal row R.

Next apply the NameCert route completion theorem, Definition 1006.125. It identifies the refusal route as one of the local certificate duties and records the structural rows H, C, P, N as the only transport, replay, provenance, and naming data attached to that duty.

Now use the refusal classifier stability and refusal totality readback rows of Definition 1006.123 and Definition 1006.126. They preserve the refusal endpoint through the displayed hsame, Cont, Pkg, and $\mathsf{NameCert}$ surface rather than replacing it by a source witness.

The requested factorization is therefore the displayed path through R, H, C, P, N ending at N. Since the carrier exposes no additional row beyond G, S, R, H, C, P, N, the unsupported request stays within the local $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ packet. □

Theorem 1006.130 (GapClosureBoundary consumer surface exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the hard-problem consumers* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*,* $\mathsf{OtherMindsCommitment}^{\uparrow}$*,* $\mathsf{AspectChain}^{\uparrow}$*, and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *receive only the rows* G, S, R, H, C, P, N*. Supported consumers read the terminal source branch* $G \longrightarrow S$*; unsupported consumers read the refusal branch* $G \longrightarrow R$*; and all such reads are carried by the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows.*

Proof. Start with consumer ledger exhaustion, Definition 1006.57. It places each listed hard-problem consumer on the shared source/refusal ledger rather than on a consumer-specific surface.

For supported consumers, use terminal route totality from Definition 1006.128. The only available supported endpoint is $G \longrightarrow S$ with the structural rows H, C, P, N.

For unsupported consumers, use refusal NameCert factorization from Definition 1006.129. The unsupported request is routed through R, H, C, P, N and named by the same local certificate row N.

Finally apply route ledger exhaustion from Definition 1006.127. The ledger is exhausted by G, S, R, H, C, P, N, so the listed consumers receive no additional hard-problem coordinate outside the displayed packet. □

Theorem 1006.131 (GapClosureBoundary source-refusal totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *request row in the finite* BHist *carrier*

$$B = (G, S, R, H, C, P, N),$$

the readback factors through exactly one displayed branch before any downstream consumer receives it. A supported read factors through the source branch $G \longrightarrow S$; an unsupported read factors through the refusal branch $G \longrightarrow R$; and both branches are transported only through the componentwise hsame *row H, the displayed* Cont *row C, the* Pkg *provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row N. The packet exports no hidden closure coordinate and no hidden* T*-supply coordinate.*

Proof. Start with terminal source admission, Definition 1006.122. It identifies the supported terminal request with the branch $G \longrightarrow S$ and keeps the structural rows H, C, P, N attached to that branch.

For the unsupported side, apply refusal totality readback, Definition 1006.126. It sends every source-absent read to the refusal branch $G \longrightarrow R$ under the same transport, replay, provenance, and naming rows.

Finally use route ledger exhaustion from Definition 1006.127. Since the carrier exposes no endpoint beyond S and R and no structural rows beyond H, C, P, N, the accepted request has no hidden closure or T-supply coordinate. □

Theorem 1006.132 (GapClosureBoundary NameCert scope readiness)**.** *The carrier admission, source/refusal split, local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *obligations, route completion, refusal totality, and ledger exhaustion form the scoped obligation surface of* $\mathsf{GapClosureBoundary}^{\uparrow}$ *over* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*. Concretely, every accepted packet is read as*

$$G \to (S \mid R) \to H \to C \to P \to N,$$

with the route branch selected before transport, replay, package provenance, or local naming is consumed.

Proof. Carrier admission is the finite packet of Definition 1006.1. The local certificate obligations of Definition 1006.2 assign the visible rows to request exposure, source-route exactness, refusal-ledger routing, structural transport, continuation replay, provenance, and naming.

Route completion, Definition 1006.125, turns those rows into the displayed source-or-refusal route. Refusal totality, Definition 1006.126, handles every source-absent read without adding another endpoint.

Ledger exhaustion, Definition 1006.127, then closes the obligation surface. The only remaining rows are BHist carrier data, hsame transport, Cont replay, Pkg provenance, and the local NameCert row. □

Theorem 1006.133 (GapClosureBoundary bridge readback scope)**.** *Any later bridge-facing readback of* $\mathsf{GapClosureBoundary}^{\uparrow}$ *must first display source/refusal totality, componentwise transport through H, local* NameCert *provenance through P, N, and the TasteGate row for the same packet. Such a readback may expose the scoped source/refusal surface, but it does not claim* Gap *discharge, does not provide a standard bridge, and does not turn the refusal branch into a source witness.*

Proof. First apply source-refusal totality from Definition 1006.131. A bridge-facing read must therefore show whether the request is on $G \longrightarrow S$ or on $G \longrightarrow R$ before it is read by any consumer.

Next use NameCert scope readiness from Definition 1006.132. It requires the componentwise transport, continuation replay, package provenance, and local naming rows to remain visible as H, C, P, N.

The TasteGate row is the same scoped packet boundary already recorded by the chapter status. Since terminal source admission and ledger exhaustion leave no row that discharges Gap or supplies a standard bridge, the readback is only a bridge precondition surface. □

Theorem 1006.134 (GapClosureBoundary supported source-route readiness)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, every supported root read reaches a downstream consumer only through the displayed source route*

$$G \longrightarrow S.$$

The read keeps the root row G*, the source row* S*, the componentwise* hsame *row* H*, the displayed* Cont *row* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row* N *visible. The refusal row* R *remains part of the same packet as the row that records how the same boundary routes off-source requests.*

Proof. Start with the source/refusal decision surface, Definition 1006.109. A supported read is selected by the displayed branch $G \longrightarrow S$, not by a private source selector or hidden closure coordinate.

Next use root consumer handoff, Definition 1006.114. The consumer receives the displayed packet G, S, R, H, C, P, N, so the supported branch keeps H, C, P, N attached as transport, continuation, provenance, and local naming rows.

Finally use consumer ledger exhaustion, Definition 1006.57. Since the same packet also accounts for unsupported reads by the refusal row R, the supported route remains source-readable while the refusal ledger stays visible rather than being erased by the supported branch. □

Theorem 1006.135 (GapClosureBoundary refusal-ledger routing exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$ *of Definition 1006.1, every unsupported endpoint is exhausted by the refusal route*

$$G \longrightarrow R$$

together with the structural rows H, C, P, N*. Such an endpoint can be transported, replayed, packaged, and named as refusal data, but it cannot be reread as source evidence and cannot escape to hidden closure supply, host equality, quotient data, or an off-packet continuation.*

Proof. Begin with the source/refusal decision surface of Definition 1006.109. It gives an unsupported read the displayed endpoint R rather than the source endpoint S.

Use consumer ledger exhaustion, Definition 1006.57. The listed downstream consumers receive the refusal endpoint through the same rows H, C, P, N, so there is no consumer-specific endpoint outside the packet.

It remains to rule out rereading the refusal endpoint as source evidence. Recognizer refusal stability, Definition 1006.74, keeps failed or unsupported recognizer landings on the refusal side. Root consumer handoff, Definition 1006.114, then keeps that refusal side inside G, S, R, H, C, P, N for every downstream read. □

Theorem 1006.136 (GapClosureBoundary TasteGate scoped nontriviality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, the scoped TasteGate surface is nontrivial exactly because the packet displays both the supported route* $G \longrightarrow S$ *and the refusal route* $G \longrightarrow R$ *with componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row. The TasteGate target recorded as* `BEDC.Derived.GapClosureBoundaryUp.taste_` *therefore reads a field-faithful packet surface rather than an undifferentiated parameter echo.*

Proof. First combine supported source-route readiness with refusal-ledger routing exhaustion, Definition 1006.134 and Definition 1006.135. The two branches are both visible in the same accepted packet, so the TasteGate row has a concrete distinction to preserve.

Next use the root consumer handoff and consumer ledger exhaustion theorems, Definition 1006.114 and Definition 1006.57. They keep all downstream reads inside G, S, R, H, C, P, N and make H, C, P, N the complete transport, replay, package, and local naming surface for the two branches.

Finally use recognizer refusal stability, Definition 1006.74. Unsupported recognizer landings remain refusal data, while supported landings remain source-route data. Thus the TasteGate row recorded in the chapter status is field-faithful to the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ packet and does not collapse the source and refusal branches. □

Theorem 1006.137 (GapClosureBoundary acceptance row exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, the accepted root row is exhausted by the displayed* BHist *inventory* G, S, R*, the componentwise* hsame *transport row* H*, the displayed* Cont *route row* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row* N*. A source-supported consumer route must read the accepted source row as*

$$G \longrightarrow S,$$

and an unsupported closure request must read the refusal route as

$$G \longrightarrow R.$$

No root acceptance row exports a third consumer route, hidden closure coordinate, hidden T *supply, host equality row, quotient datum, private selector, or off-packet continuation.*

Proof. First read the source/refusal consumer ledger. Definition 1006.55 requires every supported hard-problem read to expose $G \longrightarrow S$ before consuming H, C, P, N, while Definition 1006.56 sends every unsupported closure request through $G \longrightarrow R$ with the same structural rows.

Next use the root refusal-route obligations. Definition 1006.116 makes the refusal endpoint and ledger visible before supported consumption, and Definition 1006.117 confines supported routes to the displayed BHist, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows.

The terminal source unblock removes the remaining root entry. Definition 1006.122 admits terminal source reads only through $G \longrightarrow S$ and sends non-supported reads through $G \longrightarrow R$, and Definition 1006.124 keeps every listed consumer inside G, S, R, H, C, P, N.

Finally apply refusal route totality, Definition 1006.147. Since every unsupported request is exhausted by the displayed refusal branch and the structural rows cannot generate another endpoint, the accepted root row has no third consumer route or hidden closure supply. □

Theorem 1006.138 (GapClosureBoundary refusal route readback)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, refusal-route readback is determined by the displayed* BHist *request row* G*, refusal row* R*, componentwise* hsame *row* H*, displayed* Cont *route row* C*,* Pkg *provenance row* P*, and local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row* N*. If a consumer route lacks the accepted source row* $G \longrightarrow S$*, then its readback is exactly the refusal route* $G \longrightarrow R$ *over* H, C, P, N*, and the readback cannot be reclassified as a source route, a private root, a closure witness, host equality, quotient data, or an off-packet continuation.*

Proof. Begin with the source-refusal ledger. Definition 1006.56 identifies the unsupported request endpoint as R and keeps the transport, continuation, provenance, and naming rows attached to that endpoint.

Now apply the root refusal-route obligations. Definition 1006.116 fixes the verdict row before supported consumption, while Definition 1006.118 says downstream consumers receive only the refusal-plus-supported-route packet named by N and transported through H, C, P.

For terminal readback, use Definition 1006.123. Componentwise hsame transport through H, followed by replay through C, preserves unsupported requests as refusal data rather than source evidence.

The totality lock closes the route. By Definition 1006.147, every unsupported closure request reaches R through H, C, P, N and has no hidden closure, host-equality, private-access, or off-packet continuation branch. Hence refusal readback is exactly the displayed route $G \longrightarrow R$. □

Theorem 1006.139 (GapClosureBoundary NameCert route closure)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *route surface is closed by the accepted source row* $G \longrightarrow S$*, the refusal route* $G \longrightarrow R$*, and the displayed structural rows* H, C, P, N*. The certificate records the* BHist *carrier rows componentwise, transports them by* hsame*, replays them through* Cont*, packages them by* Pkg*, and names them locally by* N*; it exports no unregistered consumer route, global closure row, hidden* T *supply, host equality row, quotient datum, private source selector, or off-packet continuation.*

Proof. First assemble the consumer ledger. By Definition 1006.57, supported reads are accounted for by $G \longrightarrow S$ with H, C, P, N, unsupported closure requests are accounted for by $G \longrightarrow R$ with the same rows, and no third consumer route is exported.

Next apply the root refusal-route obligation surface. Definition 1006.117 keeps the supported branch inside the displayed BHist, componentwise hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows, while Definition 1006.118 prevents a downstream consumer from escaping that named packet.

The terminal source unblock supplies the root-facing split. Definition 1006.122 admits source reads only through $G \longrightarrow S$ and routes non-supported requests through $G \longrightarrow R$; Definition 1006.124 keeps the listed hard-problem consumers inside the same packet.

Finally use the refusal route totality lock, Definition 1006.147. It exhausts the refusal side by the displayed branch and structural rows, so the local $\mathsf{NameCert}$ route surface is closed by the two named routes and exports no unregistered consumer route or hidden closure coordinate. □

Theorem 1006.140 (GapClosureBoundary L10 route consumer interface)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, every L10-facing consumer of the boundary first factors through one of the displayed branches*

$$G \longrightarrow S$$

or

$$G \longrightarrow R$$

before it reads the componentwise hsame *row* H*, the displayed* Cont *route row* C*, the* Pkg *provenance row* P*, or the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row* N*. The interface therefore exports only the source branch or the refusal branch over* H, C, P, N*, and it exports no hidden closure, hidden* T *supply, host equality, quotient data, selected Real limit, ambient completeness, or off-packet continuation.*

Proof. Begin with the source packet, Definition 1006.82. It exposes the request row G, the source row S, the refusal ledger R, and the structural rows H, C, P, N as the complete consumer-facing inventory.

For the source side, apply the scoped source/refusal rows Definition 1006.131 and Definition 1006.122. They require a supported consumer to display $G \longrightarrow S$ before any terminal or L10-facing read consumes the structural surface.

For the refusal side, apply Definition 1006.56 and Definition 1006.123. They route a source-absent request through $G \longrightarrow R$ and keep that endpoint stable under componentwise transport and replay.

Finally use classifier stability and the NameCert obligation surface, Definition 1006.83 and Definition 1006.84. Since the certificate has no row beyond G, S, R, H, C, P, N, an L10-facing consumer has no hidden completion, equality, quotient, selected-limit, ambient-completeness, or continuation exit. □

Theorem 1006.141 (GapClosureBoundary Real-completion refusal)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, any request for* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{Completion}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*, or hidden completion supply is refused unless the request first enters the displayed source route*

$$G \longrightarrow S$$

and then remains transported, replayed, packaged, and named only through H, C, P, N*. A request that does not enter by that source route is routed through*

$$G \longrightarrow R$$

with the same structural rows, and it receives no hidden closure, hidden T *supply, host equality, quotient data, selected Real limit, ambient completeness, or off-packet continuation.*

Proof. Project the source packet of Definition 1006.82. The packet gives only the request, source, refusal, transport, continuation, package, and local naming rows.

If a Real-completion request is admitted, the L10 route consumer interface above and terminal source admission force it through $G \longrightarrow S$ before any $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Completion}^{\uparrow}$, or $\mathsf{StreamName}^{\uparrow}$ consumer can read the packet.

If that source route is absent, use the scoped refusal rows Definition 1006.131 and Definition 1006.56. The request is sent to $G \longrightarrow R$ under H, C, P, N rather than to a concealed completion object.

The exclusions are preserved by classifier stability and the NameCert obligation surface. Definition 1006.83 prevents transport and replay from turning a refusal endpoint into source evidence, while Definition 1006.84 records no coordinate for hidden closure, hidden T supply, host equality, quotient data, selected Real limit, ambient completeness, or off-packet continuation. □

Theorem 1006.142 (GapClosureBoundary terminal consumer package)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, the L10 terminal consumer surface is the package consisting of the source packet, the classifier-stability row, the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *obligation surface, the source route* $G \longrightarrow S$*, and the refusal route* $G \longrightarrow R$ *over* H, C, P, N*. This package lets downstream* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{Completion}^{\uparrow}$*, and* $\mathsf{StreamName}^{\uparrow}$ *consumers cite a finite source/refusal interface: supported reads enter by* $G \longrightarrow S$*, unsupported completion-facing requests enter* $G \longrightarrow R$*, and no consumer receives hidden closure, hidden* T *supply, host equality, quotient data, selected Real limit, ambient completeness, or off-packet continuation.*

Proof. Assemble the source packet from Definition 1006.82. It supplies the finite rows G, S, R, H, C, P, N and no external consumer coordinate.

Next add the classifier row. By Definition 1006.83, componentwise hsame transport and displayed Cont replay preserve the choice between source and refusal rather than creating a third terminal route.

Now add the local NameCert obligations from Definition 1006.84. They identify carrier exposure, source-route admission, refusal-ledger exactness, consumer-boundary exhaustion, and non-escape of host or global refusal data as the finite certificate surface.

Finally use the two L10 rows above together with the scoped source/refusal rows Definition 1006.131 and Definition 1006.56. The source row handles supported terminal consumers, the refusal row handles unsupported completion-facing requests, and the assembled package has no coordinate from which a hidden completion or ambient Real limit can be read. □

Theorem 1006.143 (GapClosureBoundary scoped source-refusal record)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier*

$$B = (G, S, R, H, C, P, N),$$

the scoped source-refusal record is exactly the finite BHist *packet with the source route* $G \longrightarrow S$*, the refusal route* $G \longrightarrow R$*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*,* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row* N*. The record contains no third route, hidden source selector, internal closure coordinate, or off-packet consumer row.*

Proof. Start with the carrier and local NameCert obligations, Definition 1006.1 and Definition 1006.2. They expose G, S, R, H, C, P, N as the finite carrier inventory and assign H, C, P, N to transport, replay, provenance, and naming.

For the source side, apply source-route totality, Definition 1006.55. Every supported read reaches the displayed source row through $G \longrightarrow S$ before the structural rows are consumed.

For the refusal side, apply refusal-route exactness, Definition 1006.56. Every unsupported read reaches R through $G \longrightarrow R$ with the same structural rows.

Finally use consumer ledger exhaustion, Definition 1006.57. Since the two displayed branches exhaust the listed consumers, the scoped record has no third route or hidden closure coordinate. □

Theorem 1006.144 (GapClosureBoundary consumer scope nonescape)**.** *Every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *consumer route factors through the scoped source-refusal record of Definition 1006.143. Supported consumers read* $G \longrightarrow S$ *with* H, C, P, N*, unsupported consumers read* $G \longrightarrow R$ *with* H, C, P, N*, and no consumer can read host equality, quotient data, private other-minds access, causal necessity, direct aspect reduction, hidden* T *supply, or an off-packet continuation.*

Proof. First invoke the scoped source-refusal record. It fixes the only accepted carrier rows and the two displayed branches before a downstream hard-problem consumer receives the packet.

Next apply the consumer exactness package, Definition 1006.54. It keeps the listed sibling consumers on the same shared boundary carrier rather than on consumer-specific source, refusal, transport, continuation, provenance, or naming coordinates.

Finally use refusal non-escape and structural row conservation, Definition 1006.3 and Definition 1006.51. The refusal branch cannot become a closure supply, and the structural rows preserve the displayed branch instead of creating host equality, quotient data, private access, causal necessity, aspect reduction, hidden T data, or an off-packet continuation. □

Theorem 1006.145 (GapClosureBoundary TasteGate scope readback)**.** *The TasteGate readback for* $\mathsf{GapClosureBoundary}^{\uparrow}$ *reads exactly the scoped source-refusal record over* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. It preserves the carrier* $B = (G, S, R, H, C, P, N)$*, the source route* $G \longrightarrow S$*, the refusal route* $G \longrightarrow R$*, consumer factorization, and the rows* H, C, P, N *as the complete transport, replay, provenance, and local naming surface for the accepted boundary.*

Proof. Begin with the scoped source-refusal record and consumer scope nonescape. These results bind the carrier, source branch, refusal branch, and downstream consumer routes to G, S, R, H, C, P, N.

Use the TasteGate obligation triad, Definition 1006.157. It reads the same carrier exposure, branch distinction, and structural rows as the visible packet whose nontriviality is recorded by the TasteGate target.

Close with the NameCert scope readiness theorem, Definition 1006.132. Its readback surface is precisely BHist carrier data, componentwise hsame transport, displayed Cont replay, Pkg provenance, and the local NameCert row, so the TasteGate readback cannot add an external source, refusal, or consumer coordinate. □

Theorem 1006.146 (GapClosureBoundary public certificate handoff)**.** *The* GapClosureBoundary$^{\uparrow}$ *public certificate surface is the finite route obtained by packaging the scoped source-refusal record, the displayed source route, the displayed refusal route, and the root* NameCert *rows:*

$$G, S, R, H, C, P, N.$$

Every public consumer receives the supported branch through $G \longrightarrow S$ or the unsupported branch through $G \longrightarrow R$, with the same transport, replay, provenance, and local naming rows. It receives no hidden closure witness, hidden T *supply, private other-minds access, causal necessity primitive, quotient boundary equality, or off-packet continuation.*

Proof. Start with the scoped record of Definition 1006.143. It already binds the supported and unsupported reads to one displayed packet rather than to a private closure source.

For the supported public route, apply Definition 1006.55. The branch reaches the source row only through $G \longrightarrow S$ before downstream consumers inspect H, C, P, N.

For the unsupported public route, apply Definition 1006.56. The branch reaches the refusal row only through $G \longrightarrow R$ with the same structural rows.

Finally apply Definition 1006.149. The root NameCert row packages the two branches with transport, replay, and provenance, so the public certificate has exactly the displayed finite surface and no coordinate for the excluded host objects. □

Closure status for NameCert$_{\text{GapClosureBoundary}^{\uparrow}}$**.**

Constructive story: A GapClosureBoundary$^{\uparrow}$ packet is generated from a GAP request row, displayed source observation or socket row, refusal and non-escape ledger, componentwise transports, displayed continuations, package provenance, and local naming.

Theory closure: TheoryGate(NameCert$_{\text{GapClosureBoundary}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1006.143, Definition 1006.55, and Definition 1006.56 bind the carrier, source/refusal replay route, consumer factorization, and TasteGate readback to the displayed BHist, hsame, Cont, Pkg, and local NameCert rows.

Formal verification: FormalStatus(NameCert$_{\text{GapClosureBoundary}^{\uparrow}}$, theoremChecked)

Lean4 ✓ `BEDC.Derived.GapClosureBoundaryUp.taste gate`

Lean target: `BEDC.Derived.GapClosureBoundaryUp.taste\_gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not internalise the GAP request, construct a T supply witness, prove causal necessity, give private other-minds access, reduce aspect chains, or provide a public bridge.

Upgrade path: Mature closure requires standard-bridge checking and downstream consumer replay of the source/refusal record.

Theorem 1006.147 (GapClosureBoundary refusal route totality)**.** *For every accepted* GapClosureBoundary$^{\uparrow}$ *packet $B = (G, S, R, H, C, P, N)$, every unsupported closure request reaches the refusal row R through the same structural rows H, C, P, N. The route is total over the displayed branch*

$$G \longrightarrow R$$

and cannot branch to hidden closure, hidden T *supply, host equality, private access, or an off-packet continuation.*

Proof. Start with refusal route exactness, Definition 1006.56. It sends each unsupported closure request to R over the displayed structural rows H, C, P, N and removes hidden closure and hidden T supply as exits.

Use refusal branch determinacy and refusal non-escape, Definition 1006.104 and Definition 1006.3. These keep the request at the displayed endpoint $G \longrightarrow R$ rather than at host equality, private access, or a concealed source branch.

Finally apply structural row conservation, Definition 1006.51. Since H, C, P, N only preserve, replay, package, and name the displayed refusal branch, every unsupported closure request is exhausted by the public refusal route. □

Theorem 1006.148 (GapClosureBoundary route completion totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, the source/refusal route completion surface is total for the listed hard-problem consumers. A supported consumer route is exactly the displayed source route*

$$G \longrightarrow S,$$

and an unsupported closure request is exactly the displayed refusal route

$$G \longrightarrow R,$$

with H, C, P, N *supplying the only componentwise transport, replay, provenance, and local naming rows. The completed route exports no hidden closure coordinate, hidden* T *supply, private source witness, host equality row, quotient datum, or off-packet continuation.*

Proof. Begin with source-route exactness, Definition 1006.10. It requires every supported hard-problem read to display the branch $G \longrightarrow S$ before any sibling consumer may use the boundary.

For the unsupported side, apply refusal route totality, Definition 1006.147. Every off-source closure request reaches R through the same structural rows and cannot branch to hidden closure, hidden T supply, host equality, private access, or an off-packet continuation.

Structural row conservation, Definition 1006.51, keeps H, C, P, N attached to the selected branch. These rows transport, replay, package, and name the displayed source or refusal route; they do not generate a third route.

Finally assemble the status surface with Definition 1006.78. The carrier, source/refusal split, root-unblock package, consumer exactness package, and TasteGate boundary are already recorded over the same packet G, S, R, H, C, P, N. Hence the source/refusal route completion is total exactly on the two displayed branches. □

Theorem 1006.149 (GapClosureBoundary NameCert route totality)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, the root NameCert route is total exactly on the displayed carrier, source, and refusal rows. A supported read factors through the source branch*

$$G \longrightarrow S,$$

an unsupported read factors through the refusal ledger

$$G \longrightarrow R,$$

and both branches are transported by H*, replayed by* C*, packaged by* P*, and named by* N*. The route exports no hidden closure coordinate, hidden* T *supply, private source witness, host equality row, quotient datum, or off-packet continuation.*

Proof. Begin with the carrier and local certificate obligations, Definition 1006.1 and Definition 1006.2. They expose the finite BHist packet G, S, R, H, C, P, N and assign H, C, P, N to componentwise hsame transport, displayed Cont replay, Pkg provenance, and local NameCert naming.

For supported reads, apply source-route totality and route completion totality, Definition 1006.55 and Definition 1006.148. These keep the carrier/source branch on $G \longrightarrow S$ before downstream consumers inspect the structural rows.

For unsupported reads, apply refusal route totality and refusal NameCert factorization, Definition 1006.147 and Definition 1006.129. They send the same request row to R and keep the refusal endpoint inside H, C, P, N.

Structural row conservation then removes the remaining escape routes. Since H, C, P, N only transport, replay, package, and name the displayed source/refusal packet, the NameCert route is total exactly on the two branches. □

Theorem 1006.150 (GapClosureBoundary source readback)**.** *For every accepted* GapClosureBoundary$^{\uparrow}$ *packet $B = (G, S, R, H, C, P, N)$, source readback is exhausted by the displayed refusal ledger together with the supported source branch. If a root request displays the source row, the readback is the branch $G \longrightarrow S$ under H, C, P, N; if it does not display the source row, the readback is the refusal ledger $G \longrightarrow R$ under the same structural rows. No additional readback row can convert the refusal ledger into source evidence or erase the displayed source branch.*

Proof. Read the supported side through terminal route totality, Definition 1006.128. It says a supported terminal read uses $G \longrightarrow S$ with the same componentwise transport, continuation, provenance, and local naming rows.

Read the unsupported side through refusal ledger totality and route completion totality, Definition 1006.41 and Definition 1006.148. These results exhaust off-source reads at R and keep them under H, C, P, N.

The source readback is therefore determined by whether S is displayed. The refusal ledger remains visible as the negative branch, and the accepted packet contains no further coordinate that can supply a second source witness or erase the branch distinction. □

Theorem 1006.151 (GapClosureBoundary downstream unblock package)**.** *For every accepted* GapClosureBoundary$^{\uparrow}$ *packet $B = (G, S, R, H, C, P, N)$, the downstream unblock surface for* CausalCommitment$^{\uparrow}$, FiniteWitnessedRefutation$^{\uparrow}$, OtherMindsCommitment$^{\uparrow}$, AspectChain$^{\uparrow}$, *and* SolipsismGapRefusal$^{\uparrow}$ *is exactly the package of the carrier row G, the source/refusal rows S, R, the componentwise* hsame *row H, the displayed* Cont *row C, the* Pkg *provenance row P, and the local* NameCert *row N. A downstream consumer may consume the supported source route or the refusal ledger, but it receives no consumer-specific hidden closure row, private access row, host equality row, quotient datum, or off-packet continuation.*

Proof. Start with the root unblock package, Definition 1006.39. It already lists the hard-problem consumers as readers of the shared source/refusal boundary rather than as owners of separate carrier data.

Next apply NameCert route totality and source readback from the two preceding theorems. These bind the carrier/source/refusal route to G, S, R and keep both supported and unsupported reads under H, C, P, N.

Finally use consumer surface exhaustion, Definition 1006.130. Since every listed downstream consumer is exhausted by the same finite packet, the downstream unblock package is precisely the displayed BHist, Gap, hsame, Cont, Pkg, and NameCert surface. □

Theorem 1006.152 (GapClosureBoundary certificate-gate row)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, a boundary read by* $\mathsf{AspectChain}^{\uparrow}$, $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteReflectionTuple}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$*, or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *must pass through the displayed certificate-gate row before the source branch* $G \longrightarrow S$ *or refusal branch* $G \longrightarrow R$ *is public. The gate is carried only by the* BHist *packet, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row.*

Proof. Start with recognizer source admission, Definition 1006.73. It sends an accepted source read through the $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ gate and then through the displayed $\mathsf{FiniteReflectionTuple}^{\uparrow}$ image.

Next use the local NameCert obligation surface, Definition 1006.84. It records carrier exposure, source-route admission, refusal-ledger exactness, consumer boundary exhaustion, and non-escape as rows of B.

Finally combine the hard-problem root package with source/refusal consumer totality. The listed consumers therefore receive a gated source or refusal branch, and no private gate outside G, S, R, H, C, P, N is exported. □

Theorem 1006.153 (GapClosureBoundary witnessed-refutation row)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, any* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$ *or* $\mathsf{FiniteReflectionTuple}^{\uparrow}$ *readback of the boundary is forced onto the displayed source/refusal split. A supported read uses* $G \longrightarrow S$ *under* H, C, P, N*, an unsupported read uses* $G \longrightarrow R$ *under the same structural rows, and neither read imports a host refutation witness, quotient datum, hidden completion source, or consumer-specific continuation.*

Proof. Project the recognizer consumer exhaustion theorem, Definition 1006.75. It exhausts the recognizer-facing route by successful tuple landing or refusal landing.

For the positive side, use Definition 1006.73. The witnessed row reaches the boundary only after the gate and tuple readback, and then it is consumed as $G \longrightarrow S$.

For the refusal side, use Definition 1006.74. Failed or unsupported landings remain on $G \longrightarrow R$ and are transported only through H, C, P, N. □

Theorem 1006.154 (GapClosureBoundary solipsism-refusal row)**.** *Every* $\mathsf{SolipsismGapRefusal}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$*, or* $\mathsf{CausalCommitment}^{\uparrow}$ *consumer of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet receives only the displayed source/refusal boundary rows* G, S, R, H, C, P, N*. In particular, a private solipsism escape, private other-minds access, direct aspect-reduction row, causal-necessity row, or hidden* T *supply is refused unless it is already represented by the public source branch or the refusal branch named by the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row.*

Proof. Begin with hard-problem consumer factorization and consumer exactness. These theorems place the listed sibling consumers inside the common boundary packet and divide their reads between the source branch and the refusal branch.

Use the certificate-gate row above together with the NameCert route completion surface. The local certificate names only G, S, R, H, C, P, N, so a consumer has no private row from which to read solipsism escape, other-minds access, aspect reduction, or causal necessity.

Finally apply refusal route exactness and refusal non-escape. Unsupported requests stay on the displayed refusal ledger R under hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, and cannot become hidden closure supply. □

Theorem 1006.155 (GapClosureBoundary root certificate-gate factorization)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *root carrier* $B = (G, S, R, H, C, P, N)$*, any certificate-gate read consumed by*

$\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *or* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *factors through the displayed source/refusal split*

$$G \longrightarrow S \qquad \text{or} \qquad G \longrightarrow R$$

and then through the same BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *rows* H, C, P, N. *The factorization exports no hidden* T *supply, host equality, quotient row, or private selector.*

Proof. Start from the accepted carrier $B = (G, S, R, H, C, P, N)$ and the existing carrier definition. The only public boundary rows are the source branch $G \longrightarrow S$, the refusal branch $G \longrightarrow R$, and the structural rows H, C, P, N.

Use the NameCert obligation surface and route-completion obligations. They require the certificate gate to read carrier admission, source/refusal exactness, componentwise hsame transport, displayed Cont replay, Pkg provenance, and local naming before any downstream consumer receives the boundary.

Finally apply consumer ledger exhaustion for the hard-problem readers. Since the ledger names only the five downstream consumers and routes each of them through the same source/refusal split, there is no remaining coordinate for hidden supply, host equality, quotient data, or private selection. □

Theorem 1006.156 (GapClosureBoundary hard-problem consumer coverage)**.** *The root carrier* $B = (G, S, R, H, C, P, N)$ *covers the hard-problem consumers* $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, *and* $\mathsf{SolipsismGapRefusal}^{\uparrow}$ *exactly through the accepted source branch* $G \longrightarrow S$ *and the accepted refusal branch* $G \longrightarrow R$. *Each consumer receives its boundary as a* BHist *read transported by* hsame, *replayed by* Cont, *packaged by* Pkg, *and named by* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$.

Proof. First read the consumer ledger exhaustion theorem for the root packet. It lists the hard-problem consumers and assigns their supported requests to the source branch and their unsupported requests to the refusal branch.

Next use the recognizer landing obligations. A consumer that lands positively must pass through the source row S, while a consumer that fails to land remains on the refusal row R. Both landings are still reads of the same carrier B.

The status block records the chapter commitment for the same carrier. Combining it with the displayed route rows H, C, P, N shows that coverage is by the finite certificate gate alone, not by a hidden supply, host equality, quotient row, or private selector. □

Theorem 1006.157 (GapClosureBoundary TasteGate obligation triad)**.** *For the accepted carrier* $B = (G, S, R, H, C, P, N)$, *a future TasteGate proof for* $\mathsf{GapClosureBoundary}^{\uparrow}$ *must discharge exactly the root carrier admission, source/refusal branch exactness, and hard-problem consumer coverage obligations. These obligations are expressed through the same* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *rows and do not add a hidden* T *supply, host equality, quotient row, or private selector.*

Proof. Carrier admission is the first obligation. It exposes G, S, R, H, C, P, N as the only accepted rows of the root packet.

Source/refusal exactness is the second obligation. The source branch $G \longrightarrow S$ handles supported recognizer landings, and the refusal branch $G \longrightarrow R$ handles unsupported closure requests.

Hard-problem consumer coverage is the third obligation. The preceding coverage theorem routes $\mathsf{CausalCommitment}^{\uparrow}$, $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$, $\mathsf{OtherMindsCommitment}^{\uparrow}$, $\mathsf{AspectChain}^{\uparrow}$, and

$\mathsf{SolipsismGapRefusal}^{\uparrow}$ through the same carrier, so the triad exhausts the certificate-gate obligations needed by the TasteGate surface. □

Theorem 1006.158 (GapClosureBoundary source obligation scope)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, a supported read must display the source branch*

$$G \longrightarrow S$$

before it consumes the structural rows H, C, P, N*. The structural rows transport, replay, source, and name the displayed source branch; they do not replace it with hidden closure supply.*

Proof. Start with the carrier and local NameCert obligations, Definition 1006.1 and Definition 1006.2. They expose the finite rows G, S, R, H, C, P, N and assign H, C, P, N to transport, replay, provenance, and local naming.

Apply source route totality, Definition 1006.55. It requires the displayed source route $G \longrightarrow S$ before a supported hard-problem consumer reads the structural rows.

Finally use source-refusal orthogonality and consumer factorization, Definition 1006.46 and Definition 1006.47. These keep the source branch distinct from refusal and keep the consumer inside the shared packet, so no hidden source or closure row is available. □

Theorem 1006.159 (GapClosureBoundary refusal obligation scope)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier* $B = (G, S, R, H, C, P, N)$*, an unsupported read routes to the refusal branch*

$$G \longrightarrow R$$

with no hidden supply outside G, S, R, H, C, P, N*. The structural rows preserve the refusal endpoint and cannot convert it into source evidence, private access, causal necessity, direct aspect reduction, or hidden* T *supply.*

Proof. Begin with refusal route exactness, Definition 1006.56. It sends each unsupported closure request through $G \longrightarrow R$ with the structural rows H, C, P, N.

Use the local NameCert obligation surface, Definition 1006.84. It records refusal-ledger exactness and non-escape as obligations of the same finite carrier.

Now apply source-refusal orthogonality and refusal ledger stability. The refusal branch cannot be reread as a concealed source branch, and transport or replay preserves R rather than producing hidden supply. Thus the unsupported read remains on the displayed refusal obligation scope. □

Theorem 1006.160 (GapClosureBoundary consumer obligation scope)**.** *Every hard-problem consumer of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *carrier receives only the two displayed branches over* G, S, R, H, C, P, N*: supported reads consume* $G \longrightarrow S$*, and unsupported reads consume* $G \longrightarrow R$*. No consumer receives a third branch, hidden supply row, host equality, quotient datum, private source selector, or off-packet continuation.*

Proof. First assemble the supported branch. By Definition 1006.158, every supported read must display $G \longrightarrow S$ before the structural rows are consumed.

Next assemble the unsupported branch. By Definition 1006.159, every unsupported read remains on $G \longrightarrow R$ with no hidden supply.

Finally apply hard-problem consumer factorization and consumer ledger exhaustion, Definition 1006.47 and Definition 1006.57. They keep the listed consumers inside the same source/refusal split, so the two displayed branches exhaust the consumer obligation scope. □

Theorem 1006.161 (GapClosureBoundary scoped carrier admission)**.** *Every scoped boundary read accepted by* $\mathsf{GapClosureBoundary}^{\uparrow}$ *must first expose the same seven-row packet* $B = (G, S, R, H, C, P, N)$*. The rows* G, S, R *are the displayed* BHist *request, source, and refusal rows,* H *is the componentwise* hsame *transport row,* C *is the displayed* Cont *route row,* P *is the* Pkg *provenance row, and* N *is the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row. No accepted scoped read can replace any of these rows by hidden closure, hidden* T *supply, host equality, quotient data, or an off-packet continuation.*

Proof. Start with the scoped dependency inventory. By Definition 1006.79, the accepted boundary packet already displays G, S, R, H, C, P, N before any consumer read.

Next read the displayed rows through the root obligation packet and source-refusal obligation scope. The packet records G, S, R as the finite BHist rows and keeps H, C, P, N attached as transport, route, provenance, and local naming data.

Finally apply scoped consumer non-escape. Since the consumer surface has no coordinate for hidden closure, hidden T supply, host equality, quotient data, or off-packet continuation, a scoped read that omits one of the seven displayed rows is not an accepted $\mathsf{GapClosureBoundary}^{\uparrow}$ boundary read. □

Theorem 1006.162 (GapClosureBoundary scoped route totality)**.** *For every accepted scoped consumer read of* $\mathsf{GapClosureBoundary}^{\uparrow}$*, the route is exhausted by exactly one of the two displayed branches*

$$G \longrightarrow S$$

or

$$G \longrightarrow R$$

over the same rows H, C, P, N*. Supported reads use the source branch, unsupported reads use the refusal branch, and there is no third accepted source, refusal, bridge, or continuation route outside* G, S, R, H, C, P, N*.*

Proof. First expose the admitted packet. By Definition 1006.161, any accepted scoped read is already a read of G, S, R, H, C, P, N.

Apply scoped source-refusal exactness. Definition 1006.80 assigns supported reads to $G \longrightarrow S$ and unsupported reads to $G \longrightarrow R$ over the same structural rows H, C, P, N.

It remains to exclude residual routes. The scoped dependency inventory supplies no additional route coordinate, and scoped consumer non-escape prevents a consumer from importing a hidden source, hidden refusal, bridge-only continuation, quotient witness, or off-packet route. Thus the source and refusal branches exhaust the accepted scoped consumer reads. □

Theorem 1006.163 (GapClosureBoundary scoped TasteGate readback)**.** *Any* $\mathsf{TasteGate}$ *reader or* $\mathsf{StandardBridge}$ *reader for* $\mathsf{GapClosureBoundary}^{\uparrow}$ *that reads the scoped boundary must read the same packet* $B = (G, S, R, H, C, P, N)$ *and the same source/refusal split of Definition 1006.162. Such a reader cannot use hidden closure, hidden* T *supply, host equality, quotient data, or an off-packet continuation to identify, complete, or replace the displayed boundary packet.*

Proof. Begin with the scoped carrier admission theorem. It fixes the carrier rows, transport row, route row, provenance row, and local naming row as the whole readable packet for scoped boundary access.

Next use scoped route totality. Every accepted scoped read available to a later $\mathsf{TasteGate}$ or $\mathsf{StandardBridge}$ reader has already been assigned to the displayed source branch or the displayed refusal branch over H, C, P, N.

Finally apply the TasteGate boundary and bridge precondition surface assembled in Definition 1006.78. Those rows require any TasteGate or bridge-facing read to preserve the same seven packet fields. Because the packet contains no hidden closure, hidden T supply, host equality, quotient coordinate, or off-packet continuation, such data cannot be used to identify, complete, or replace the scoped boundary. □

Theorem 1006.164 (GapClosureBoundary consumer obligation closure)**.** *Every accepted* GapClosureBoundary$^{\uparrow}$ *consumer route must expose the displayed* BHist *request row, classifier row, refusal row,* Cont *replay row,* Pkg *provenance row, and local* NameCert *row before it can read the boundary. The route may transport those rows by the recorded* hsame *data, but it cannot consume a hidden request, hidden classifier, unrecorded refusal, off-packet replay, detached provenance row, or unnamed boundary packet.*

Proof. Start from the root boundary obligation packet and the source-refusal obligation scope. They expose the finite request, classifier, refusal, replay, provenance, and naming rows as the public root surface of the carrier.

Use root NameCert route totality. Every accepted consumer route is named by the same local certificate and is replayed through the displayed Cont row rather than through a private continuation.

Finally apply refusal route totality and route-completion totality. The hsame transport rows preserve the displayed request/classifier/refusal packet, while Pkg provenance records the same source. Hence any route omitting one of these rows leaves the accepted consumer surface. □

Theorem 1006.165 (GapClosureBoundary source-refusal exactness)**.** *A source-refusal read of* GapClosureBoundary$^{\uparrow}$ *is exact only when the same displayed refusal row is consumed by every downstream route that reads the source boundary. If a downstream route replaces the refusal row, hides the classifier that selected it, or detaches it from the displayed* BHist*,* Cont*,* Pkg*, and* NameCert *rows, the route is no longer an exact source-refusal read.*

Proof. Begin with source-refusal consumer totality and source-refusal terminal unblock. They force the downstream source-facing route to consume the same refusal row that the root packet displays.

Next use the root source-refusal readiness and decision-surface theorems. The classifier row selects the refusal route before any consumer handoff, so a later route cannot replace the refusal row without changing the boundary decision.

The structural rows preserve exactness. Componentwise hsame transport, displayed Cont replay, Pkg provenance, and the local NameCert row carry the same refusal row to each consumer. A route that hides or swaps any of them exits the source-refusal packet. □

Theorem 1006.166 (GapClosureBoundary refusal handoff exhaustion)**.** *No accepted* GapClosureBoundary$^{\uparrow}$ *consumer handoff can use a hidden source, hidden classifier, or unrecorded gap route. Every handoff is exhausted by the displayed request row, source/refusal decision rows,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *row already present in the root packet.*

Proof. Project the root acceptance route exhaustion theorem. It leaves only the displayed request, source/refusal, transport, replay, provenance, and naming rows available to a consumer handoff.

Apply the consumer obligation closure theorem. Any accepted route has to expose the request, classifier, refusal, replay, provenance, and local certificate rows before handoff.

Finally use source-refusal exactness. Because every downstream route consumes the same displayed refusal row, no hidden source, hidden classifier, or unrecorded gap route remains available. The handoff is therefore exhausted by the root packet. □

Theorem 1006.167 (GapClosureBoundary L10 terminal obligation pack)**.** *Every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet routes an L10 terminal consumer through the displayed* BHist *request, source, and refusal rows; the componentwise* hsame *transport row; the displayed* Cont *replay row; the* Pkg *provenance row; the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row; and the downstream* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{StreamName}^{\uparrow}$ *rows before the terminal boundary is exported. No L10 terminal consumer receives a hidden closure row, hidden Real limit, anonymous stream name, host equality, quotient datum, or off-packet continuation.*

Proof. Begin with the L10 terminal consumer boundary. It fixes the terminal interface to the source and refusal branches over the structural rows H, C, P, N and excludes hidden completion supply.

Use the root obligation closure handoff next. It requires any root-facing consumer to expose the same request, classifier, refusal, replay, provenance, and naming rows before the boundary can be read.

Finally attach the real-completion consumers. The $\mathsf{Real}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ rows are therefore read only after the finite BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ support has already been displayed, so the terminal export has no coordinate for hidden Real or stream-name supply. □

Theorem 1006.168 (GapClosureBoundary Real and StreamName dependency)**.** *Any real-completion gap closure read of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet must display both the* $\mathsf{Real}^{\uparrow}$ *row and the* $\mathsf{StreamName}^{\uparrow}$ *row before closure is exported. A read that displays only one of these rows remains a partial terminal request and cannot be exported as a real-completion gap closure.*

Proof. Start from the root source-refusal obligation scope. It separates supported source reads from refusal reads before any terminal consumer inspects completion-facing data.

Apply scoped root unblock obligations. They keep the root packet inside the displayed source/refusal split and prevent a downstream consumer from replacing the missing row by hidden supply or off-packet replay.

Thus the $\mathsf{Real}^{\uparrow}$ row and the $\mathsf{StreamName}^{\uparrow}$ row must both be visible at the terminal read. If either row is absent, the source/refusal boundary has not supplied the data needed for real-completion export, and the read remains outside the accepted closure surface. □

Theorem 1006.169 (GapClosureBoundary finite refusal consumer exhaustion)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet, the consumer-facing boundary is exhausted by finite witnessed refusal, source refusal, and readback handoff rows together with the structural rows* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*. No consumer-facing boundary row remains for hidden source selection, hidden completion supply, Real-row synthesis, StreamName-row synthesis, or off-packet terminal replay.*

Proof. First use the L10 terminal consumer boundary to expose the two terminal branches available to downstream consumers.

Next use the root source-refusal obligation scope. It records the source-refusal split as part of the same accepted packet rather than as a detachable consumer-side choice.

Finally apply scoped root unblock obligations and root obligation closure handoff. These rows identify the readback handoff and close the root-facing inventory, so finite witnessed refusal, source refusal, and readback handoff exhaust the consumer-facing boundary. □

Theorem 1006.170 (GapClosureBoundary L10 terminal source lock)**.** *For every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet* $B = (G, S, R, H, C, P, N)$*, the root route exported to the L10 terminal source surface is locked*

to the displayed rows

$$\mathsf{BHist},\quad \mathsf{hsame},\quad \mathsf{Cont},\quad \mathsf{Pkg},\quad \mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}},$$
$$\mathsf{StreamName}^{\uparrow},\quad \mathsf{Real}^{\uparrow},\quad \mathsf{Completion}^{\uparrow}.$$

The source-refusal route may reach a terminal $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *or* $\mathsf{Completion}^{\uparrow}$ *consumer only after passing through the source-refusal admission triad of Definition 1006.119, the recognizer landing obligations of Definition 1006.73 and Definition 1006.74, and the route-completion surface of Definition 1006.125. The export carries no hidden completion witness, selected Real limit, anonymous stream name, host equality row, quotient datum, or off-packet continuation.*

Proof. Project the accepted packet to its finite source-refusal inventory. The carrier contributes G, S, R, while H, C, P, N provide the componentwise hsame transport, displayed Cont replay, package provenance, and local naming rows.

Next apply the source-refusal admission triad and the recognizer landing obligations. Successful recognizer landings are read as $G \longrightarrow S$, while failed or unsupported landings are read as $G \longrightarrow R$ under the same structural rows.

Finally apply route completion and the L10 terminal obligation pack. The $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{Completion}^{\uparrow}$ consumers receive the packet only after the displayed BHist, hsame, Cont, Pkg, and NameCert rows have been exposed, so the excluded hidden coordinates have no terminal source slot. □

Theorem 1006.171 (GapClosureBoundary root consumer exactness)**.** *Every root consumer route of an accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet is exact with respect to the same L10 terminal source surface. A supported root consumer must read the branch* $G \longrightarrow S$ *before any* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *or* $\mathsf{Completion}^{\uparrow}$ *row is inspected; an unsupported root consumer must read the branch* $G \longrightarrow R$ *before the same terminal rows are inspected. Both branches remain transported by* H*, replayed by* C*, packaged by* P*, and named by* N*.*

Proof. Begin with the terminal source lock above. It fixes the only terminal source surface available to the root route as the displayed BHist, hsame, Cont, Pkg, NameCert, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{Completion}^{\uparrow}$ rows.

For the supported branch, use recognizer source admission together with route completion. These force successful evidence through $G \longrightarrow S$ before any terminal consumer can read the downstream rows.

For the unsupported branch, use recognizer refusal stability together with refusal ledger exhaustion. The request remains at $G \longrightarrow R$ under H, C, P, N and cannot be reread as source evidence or completion supply.

The Real and StreamName dependency theorem then supplies the terminal exactness check: a real-completion export needs the named $\mathsf{Real}^{\uparrow}$ and $\mathsf{StreamName}^{\uparrow}$ rows together, and the $\mathsf{Completion}^{\uparrow}$ consumer receives them only through the same source-refusal packet. □

Theorem 1006.172 (GapClosureBoundary terminal unblock package)**.** *The terminal unblock package consumed by the* $\mathsf{Real}^{\uparrow}$ *and* $\mathsf{Completion}^{\uparrow}$ *boundary chapters is the finite packet consisting of the root request row, displayed source row, displayed refusal row, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *naming, and the terminal* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *and* $\mathsf{Completion}^{\uparrow}$ *rows. A downstream Real or Completion boundary may cite this package as a source-locked unblock surface, but it may not extract an ambient completeness principle, quotient stream equality, selected limit, hidden source selector, or off-packet continuation from it.*

Proof. First assemble the root surface from the terminal source lock and root consumer exactness. These two projections identify the source branch, refusal branch, structural rows, and terminal rows as one finite packet.

Next add the L10 terminal obligation pack. It places $\mathsf{StreamName}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ behind the displayed BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows, while the root route keeps $\mathsf{Completion}^{\uparrow}$ on the same consumer boundary.

Finally use finite refusal consumer exhaustion. Unsupported terminal requests are absorbed by the displayed refusal ledger, and supported terminal requests remain on the displayed source branch. Thus Real and Completion consumers receive exactly the source-locked unblock package and no ambient or off-packet resource. □

Theorem 1006.173 (GapClosureBoundary L10 source-lock totality)**.** *Every L10 terminal* $\mathsf{GapClosureBoundary}^{\uparrow}$ *consumer that reads a completion-facing refusal must pass through the source-refusal branch, the source-classifier row, the route-completion row, the terminal-route row, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row before the refusal is public. A terminal read that bypasses any one of those rows is outside the accepted packet* $B = (G, S, R, H, C, P, N)$*.*

Proof. Start with the source-refusal admission triad and source-refusal totality. They split every accepted request into the displayed source branch $G \longrightarrow S$ or refusal branch $G \longrightarrow R$ over the structural rows H, C, P, N.

Next add the classifier and route-completion rows. Definition 1006.83 keeps supported and unsupported requests separated under hsame transport and Cont replay, while Definition 1006.125 keeps the read inside the local NameCert surface.

Finally use terminal route totality together with the L10 terminal source lock. The terminal consumer can inspect a completion-facing refusal only after the source/refusal branch, classifier, route-completion, terminal-route, and NameCert rows have all been displayed, so no hidden completion witness or off-packet refusal remains. □

Theorem 1006.174 (GapClosureBoundary L10 source lock)**.** *Every L10 consumer of* $\mathsf{GapClosureBoundary}^{\uparrow}$ *that reads a source or refusal row over* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{Completion}^{\uparrow}$ *must expose the same finite* BHist *source branch, the source-classifier row, the refusal row, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row before the consumer may pass the row downstream.*

Proof. Start from the source-refusal totality and source-lock totality rows. They make every accepted completion-facing request pass through the displayed source branch or refusal branch before it is public.

Next use the root source-classifier route totality and route-completion obligations. The classifier determines which branch is visible, and the route-completion row keeps the read inside the local NameCert surface.

Finally read the L10 consumers only through their displayed rows. $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Completion}^{\uparrow}$ receive the source lock through BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ data, not through an off-packet completion witness. □

Theorem 1006.175 (GapClosureBoundary terminal source handoff)**.** *The terminal* $\mathsf{GapClosureBoundary}^{\uparrow}$ *handoff to L10 completion consumers is exactly the source/refusal packet supplied by the source-refusal admission route, the scoped source-refusal readback, the terminal route totality, and the L10 source-lock totality. The handoff has no coordinate for parameter transport equivalence, quotient completion equality, host real equality, or hidden source completion outside the displayed rows.*

Proof. Use the source-refusal admission package first. It supplies the visible source branch and refusal branch together with the structural rows required by the hub packet.

Then apply scoped source-refusal readback and terminal route totality. These theorems keep terminal reads on the same displayed route and prevent a downstream completion consumer from importing a hidden branch.

The L10 source-lock totality gives the final public boundary. Since the accepted handoff consists only of the displayed BHist, classifier, refusal, hsame, Cont, Pkg, and NameCert rows, it cannot assert parameter transport equivalence or any host-completion equality. □

Theorem 1006.176 (GapClosureBoundary root L10 unblock package)**.** *The root L10 unblock surface for* $\mathsf{GapClosureBoundary}^{\uparrow}$ *consists of the source lock of Definition 1006.174, the terminal handoff of Definition 1006.175, and the existing route-totality and source-readback rows. Any downstream L10 consumer over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, *or* $\mathsf{Completion}^{\uparrow}$ *must consume this finite package before claiming a completion-facing refusal or source read.*

Proof. Assemble the source-facing rows. The root source-classifier route totality, root request source-refusal totality, scoped source-refusal readback, and L10 source-lock totality provide the source branch, refusal branch, classifier, readback, and terminal visibility rows.

Add the structural rows. Componentwise hsame transport preserves the branch, displayed Cont replay carries the route, Pkg provenance records the source of the consumer handoff, and local NameCert data names the accepted packet.

The six L10 consumers named in the statement are therefore downstream readers of this finite source-lock package. They may consume the handoff, but they do not receive a separate parameter-equivalence claim, quotient equality, host real equality, or hidden completion source. □

Theorem 1006.177 (GapClosureBoundary terminal source-route exposure)**.** *Every root-unblock consumer of* $\mathsf{GapClosureBoundary}^{\uparrow}$ *that reaches a terminal* $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{StreamName}^{\uparrow}$ *facing gap-closure read must first expose the displayed source route of the accepted carrier* $B = (G, S, R, H, C, P, N)$*. The read passes through the* BHist *request row* G*, the supported source branch* $G \longrightarrow S$ *or refusal branch* $G \longrightarrow R$*, the componentwise* hsame *row* H*, the displayed* Cont *row* C*, the* Pkg *row* P*, and the local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *row* N *before any terminal completion-facing row is consumed.*

Proof. Begin with the L10 source lock of Definition 1006.174. It places every completion-facing consumer behind the same finite source and refusal route over G, S, R, H, C, P, N.

Use the terminal source handoff of Definition 1006.175. The handoff identifies the terminal boundary with the source-refusal packet rather than with parameter transport, quotient completion equality, host real equality, or hidden source completion.

Finally apply the root L10 unblock package of Definition 1006.176. Its downstream consumers over $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and $\mathsf{StreamName}^{\uparrow}$ may read terminal rows only after the displayed source route and local NameCert row have been exposed. □

Theorem 1006.178 (GapClosureBoundary terminal refusal-consumer totality)**.** *Every root-unblock consumer of* $\mathsf{GapClosureBoundary}^{\uparrow}$ *that cannot read the supported source branch must read the refusal route* $G \longrightarrow R$ *under the same* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *rows before it consumes any terminal* $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *or* $\mathsf{StreamName}^{\uparrow}$ *gap-closure row. No accepted root-unblock consumer has a third terminal route outside the displayed source/refusal split.*

Proof. Start with terminal route totality, Definition 1006.128. It says every terminal read chooses exactly the supported branch $G \longrightarrow S$ or the refusal branch $G \longrightarrow R$ over the same structural rows.

For unsupported reads, apply refusal NameCert factorization from Definition 1006.129. The request is recorded at R, transported through H, replayed through C, packaged by P, and named by N.

The L10 source-lock totality theorem, Definition 1006.173, then blocks terminal consumption until the refusal branch, route-completion row, terminal route, and local NameCert row have all been displayed. Thus the root-unblock consumer has no off-packet terminal route. □

Theorem 1006.179 (GapClosureBoundary terminal NameCert unblock package)**.** *The terminal root-unblock package for* $\mathsf{GapClosureBoundary}^{\uparrow}$ *is the finite source-route, refusal-route, terminal-handoff, and local* $\mathsf{NameCert}_{\mathsf{GapClosureBoundary}^{\uparrow}}$ *surface assembled from* $B = (G, S, R, H, C, P, N)$*. Every root-unblock consumer must read that package before any* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, or* $\mathsf{StreamName}^{\uparrow}$ *facing gap closure is consumed, and the package exports no hidden Real limit, anonymous regular sequence, anonymous stream name, host equality, quotient datum, or off-packet completion witness.*

Proof. Assemble the source route from Definition 1006.177. It exposes the request row, supported branch, structural rows, provenance, local naming, and terminal handoff before a completion-facing consumer may read.

Assemble the refusal route from Definition 1006.178. Unsupported root-unblock consumers are routed through R, H, C, P, N and cannot bypass the local NameCert packet.

Finally use the L10 terminal source lock and root L10 unblock package, Definition 1006.170 and Definition 1006.176. Together they bind $\mathsf{Real}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{StreamName}^{\uparrow}$ facing gap closure to the same finite BHist, hsame, Cont, Pkg, and $\mathsf{NameCert}$ surface, so no terminal consumer receives an unrecorded completion resource. □

Theorem 1006.180 (GapClosureBoundary consumer bridge admission)**.** *Every accepted* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet exposes the finite split* $B = (G, S, R, H, C, P, N)$ *as the common bridge surface for downstream consumers. The request row* G*, supported source route* $G \longrightarrow S$*, unsupported refusal route* $G \longrightarrow R$*, componentwise transport* H*, displayed continuation replay* C*, provenance package* P*, and local name row* N *are the only admitted rows through which* $\mathsf{CausalCommitment}^{\uparrow}$*,* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$*, and the neighboring hard-problem consumers may read the boundary.*

Proof. Start with the NameCert obligations of Definition 1006.2. They expose the accepted carrier as the finite packet G, S, R, H, C, P, N and assign the local naming row to that packet.

Apply source-route totality and refusal-route exactness, Definition 1006.55 and Definition 1006.56. These two results make the supported branch the displayed route $G \longrightarrow S$ and the unsupported branch the displayed route $G \longrightarrow R$.

Finally use the consumer exactness package and hub root readiness, Definition 1006.54 and Definition 1006.59. The downstream consumers therefore receive the same bridge surface and no consumer-specific row outside the packet. □

Theorem 1006.181 (GapClosureBoundary CausalCommitment forward-GAP route)**.** *The* $\mathsf{CausalCommitment}^{\uparrow}$ *consumer may read a supported* $\mathsf{GapClosureBoundary}^{\uparrow}$ *branch only through the displayed forward-GAP route* $G \longrightarrow S$ *over the shared rows* H, C, P, N*. It cannot obtain a hidden causal-necessity row, a private source selector, or an off-packet continuation from the accepted boundary packet.*

Proof. Use the consumer bridge admission of Definition 1006.180. It fixes the common downstream surface before the causal consumer reads any part of the packet.

On the supported side, apply Definition 1006.55. The only admitted supported route is $G \longrightarrow S$, and the structural rows available to the consumer are exactly H, C, P, N.

The exclusions follow from Definition 1006.54 and Definition 1006.59. Since the hub-ready packet exports no causal-necessity coordinate, no private source selector, and no off-packet continuation, $\mathsf{CausalCommitment}^{\uparrow}$ can consume the supported branch only through the displayed route. □

Theorem 1006.182 (GapClosureBoundary finite-refutation refusal route)**.** *The* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$ *consumer may read an unsupported* $\mathsf{GapClosureBoundary}^{\uparrow}$ *branch only through the displayed refusal route* $G \longrightarrow R$ *over the shared rows* H, C, P, N*. The refusal row cannot be converted into a hidden contradiction oracle, host-level refutation, quotient witness, or off-packet inconsistency source.*

Proof. Begin again with the consumer bridge admission of Definition 1006.180. It identifies the finite packet and prevents the finite-refutation consumer from reading a separate carrier.

For the unsupported branch, apply Definition 1006.56. The branch is routed to R from G and remains transported, replayed, packaged, and named only through H, C, P, N.

Finally use Definition 1006.2, Definition 1006.54, and Definition 1006.59. These anchors leave no row from which $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$ could extract a hidden contradiction oracle, host-level refutation, quotient witness, or off-packet inconsistency source. □

The hub-level $\mathsf{GapClosureBoundary}^{\uparrow}$ route consumes the finite witnessed refutation surface of chapter 576 and the solipsism refusal surface of chapter 975 before exporting the causal, other-minds, aspect, and finite-trace consumer lattice of chapter 505, chapter 499, chapter 575, and chapter 818. Each consumer sees only the displayed source/refusal rows already routed by the hub packet. The $\mathsf{GapClosureBoundary}^{\uparrow}$ dossier route consumes finite witnessed refutation from chapter 576, solipsism gap refusal from chapter 975, bounded-search refutation surfaces, and finite trace evaluator data from chapter 818 before it exports refusal routing to claim-audit, causal, and other-minds consumers. These sibling dependencies keep the boundary as finite route data: the hub may cite the assembled refusal lattice, but no consumer receives an unbounded evaluator, hidden search choice, or private gap oracle. The $\mathsf{GapClosureBoundary}^{\uparrow}$ dependency route to chapter 576 is read before any contrary witness is interpreted. The displayed boundary row fixes whether the consumer receives the supported source branch or the refusal branch, while the bounded search surface of chapter 579 supplies only the finite search ledger used after that branch has been selected.

Lemma 1006.183 (GapClosureBoundary finite witnessed-refutation route)**.** *Any* $\mathsf{FiniteWitnessedRefutation}^{\uparrow}$ *consumer of a* $\mathsf{GapClosureBoundary}^{\uparrow}$ *packet first consumes the displayed source/refusal row of the boundary packet. It may then read the bounded-search witness ledger, but it receives no hidden closure row, off-packet contradiction oracle, or unbounded search choice from the boundary.*

Chapter 1007

A Concrete Naming Certificate for $\mathsf{FiniteObservationInterface}^{\uparrow}$

The $\mathsf{FiniteObservationInterface}^{\uparrow}$ packet realizes the Real and Completion target of chapter 9238 as a finite read surface. It consumes the StreamName observation boundary of chapter 126, the RegSeqRat regularity surface of chapter 301, the DyadicRatCore tolerance surface of chapter 291, and the RealUp handoff surface of chapter 38. It is narrower than a completion theorem: the packet exposes a selected finite observation window, records the omitted tail as a ledger, and then routes every real-facing read through the displayed sibling rows.

Definition 1007.1 (Finite observation interface carrier)**.** *A* $\mathsf{FiniteObservationInterface}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (S, R, D, T, E, H, C, P, N)$$

with the following displayed coordinates:

1. *S is the* $\mathsf{StreamName}^{\uparrow}$ *observation row whose finite read entries are visible before any real-facing handoff;*
2. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regularity row that reads the same observation entries as regular rational data;*
3. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row accounting for every displayed precision request and dyadic error bound used by the read;*
4. *T is the selected finite-window row, listing the exact bounded observation window exposed to the consumer;*
5. *E is the omitted-tail ledger, recording precisely which StreamName and RegSeqRat entries lie outside T and are not exported as selected rows;*
6. *H stores componentwise* hsame *transports for the observation row, regularity row, tolerance row, selected window, omitted-tail ledger, provenance, and local naming row;*
7. *C stores the displayed* Cont *replay routes that read S, then R, then D, expose T, record E, and only then hand off to the RealUp row consumed by the downstream route;*
8. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *selected finite-window rows, omitted-tail ledgers,* BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteObservationInterface}^{\uparrow}}$ *row naming exactly this finite observation interface packet.*

The carrier has no coordinate for a full Real completeness proof, quotient stream equality, host real equality, selected limit, or export of the omitted tail as a selected stream row.

Lean4 ✓ `BEDC.Derived.FiniteObservationInterfaceUp.FiniteObservationInterfaceTasteGate single carrier alignment`

Theorem 1007.2 (Finite observation interface NameCert obligations)**.** *For every accepted* FiniteObservationInterfac *carrier* $O = (S, R, D, T, E, H, C, P, N)$*, the local* $\mathsf{NameCert}_{\mathsf{FiniteObservationInterface}^{\uparrow}}$ *surface consists of five obligations:*

1. *carrier admission: the accepted packet displays exactly the rows* $S, R, D, T, E, H, C, P, N$ *of Definition 1007.1;*
2. *selected-window exposure: the finite window* T *is exposed before any RealUp handoff is made available to a consumer;*
3. *omitted-tail ledger exactness: the ledger* E *records the entries outside* T *and cannot be read as a selected stream row;*
4. *dyadic tolerance accountability: every precision request used by the read is accounted for by the dyadic row* D *before the route reaches the RealUp surface;*
5. *StreamName/RegSeqRat/Real handoff non-escape: every handoff to RealUp factors through* S*,* R*,* D*,* T*,* E*,* H*,* C*,* P*, and* N*, and no quotient stream equality, host real equality, full Real completeness, or selected limit is exported.*

Lean4 ✓ `BEDC.Derived.FiniteObservationInterfaceUp.FiniteObservationInterfaceNameCert obligation surface`

Proof. Carrier admission is projection from Definition 1007.1. The StreamName observation row, RegSeqRat regularity row, DyadicRatCore tolerance row, selected window, omitted-tail ledger, transport, continuation, provenance, and naming coordinates are all displayed in the same finite packet.

The selected-window and omitted-tail obligations are separated by the two rows T and E. A consumer may inspect the selected finite window T; it may also inspect the ledger E as the exact record of entries outside that window. The ledger row is not a second selected stream row, because the carrier gives it only the omitted-tail role.

Dyadic accountability is read through D before the Real-facing route is exposed. The replay rows H, C, P, N keep the StreamName, RegSeqRat, dyadic, selected-window, and tail-ledger reads in one local NameCert packet, so the Real handoff has no coordinate from which to obtain completeness, quotient equality, host equality, or a selected limit. □

Theorem 1007.3 (Finite observation interface selected-stream handoff)**.** *Every Real-facing finite observation read of an accepted* $\mathsf{FiniteObservationInterface}^{\uparrow}$ *packet routes through the displayed StreamName row* S*, RegSeqRat row* R*, DyadicRatCore row* D*, selected finite-window row* T*, omitted-tail ledger* E*, transport row* H*, replay row* C*, provenance row* P*, and local naming row* N*. The route cannot assert full Real completeness, quotient stream equality, host real equality, or the existence of a selected limit.*

Lean4 ✓ `BEDC.Derived.FiniteObservationInterfaceUp.FiniteObservationInterfaceSelectedStream handoff`

Proof. Start with a Real-facing consumer read. By the NameCert obligations, the read reaches the RealUp side only after the StreamName observation row S, the RegSeqRat regularity row R, and the DyadicRatCore tolerance row D have been displayed.

The selected stream information is then exactly the finite window T. The omitted-tail ledger E is read as a boundary record for what the packet withholds from the selected window; it is not exported through the same classifier role as T.

Finally replay the route through H, C, P, N. These rows transport and package the displayed finite packet, and they do not add a coordinate for ambient Real completeness, quotient stream equality, host real equality, or limit selection. Thus every Real-facing finite observation read remains inside the displayed interface route. □

Theorem 1007.4 (Finite observation interface scoped closure)**.** *Every accepted* $\mathsf{FiniteObservationInterface}^{\uparrow}$ *read is scoped exactly by the displayed* BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows of Definition 1007.1, together with the sibling* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *surfaces. Selected-window exposure, omitted-tail exactness, dyadic accountability, and Real-facing non-escape are all read through the same finite packet*

$$O = (S, R, D, T, E, H, C, P, N).$$

No coordinate of the scoped read supplies full Real completeness, quotient stream equality, host real equality, or a selected-limit coordinate.

Proof. Project the carrier of Definition 1007.1. This gives the finite packet $O = (S, R, D, T, E, H, C, P, N)$ and fixes the displayed BHist, transport, continuation, package, and naming rows as the only rows available to the interface read.

Apply Definition 1007.2. Carrier admission binds the packet to those displayed rows, selected-window exposure is read through T, omitted-tail exactness is read through E, dyadic accountability is read through D, and the StreamName/RegSeqRat/Real handoff condition forces every Real-facing route through the same local packet.

Apply Definition 1007.3. The sibling $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surfaces are therefore used only along the displayed finite route. Since the carrier has no coordinate for full Real completeness, quotient stream equality, host real equality, or a selected limit, none of those claims can escape the scoped packet. □

Theorem 1007.5 (Finite observation interface public certificate route)**.** *Every accepted* $\mathsf{FiniteObservationInterface}^{\uparrow}$ *packet*

$$O = (S, R, D, T, E, H, C, P, N)$$

exports a public reusable certificate only through the displayed StreamName row S, RegSeqRat row R, DyadicRatCore row D, selected finite-window row T, omitted-tail ledger E, transport row H, replay row C, provenance row P, and local $\mathsf{NameCert}$ *row N. The public route does not export Real completeness, a selected limit, quotient stream equality, host real equality, or an omitted-tail-as-selected-stream row.*

Proof. Project the carrier in Definition 1007.1. The accepted packet has exactly the rows $S, R, D, T, E, H, C, P, N$, and the carrier explicitly withholds Real completeness, quotient stream equality, host real equality, selected limits, and any selected-stream role for the omitted tail.

Apply Definition 1007.2. The local NameCert obligations force carrier admission, selected-window exposure, omitted-tail exactness, dyadic tolerance accountability, and StreamName/RegSeqRat/Real handoff non-escape to be read from those rows.

Apply Definition 1007.3 and Definition 1007.4. The reusable surface is therefore public only as the displayed finite certificate route, and no hidden Real-facing coordinate is available outside that route. □

Theorem 1007.6 (Finite observation interface consumer reuse)**.** *Any downstream L10 consumer that reuses an accepted* $\mathsf{FiniteObservationInterface}^{\uparrow}$ *packet must reuse the public certificate route of Definition 1007.5. Such a consumer may read the StreamName, RegSeqRat, DyadicRatCore, selected-window, omitted-tail, transport, replay, provenance, and NameCert rows, but it cannot bypass those rows to obtain an independent RealUp handoff.*

Proof. Begin with a downstream L10 consumer of the accepted packet. By Definition 1007.5, the only reusable certificate exported by the packet is the displayed route through $S, R, D, T, E, H, C, P, N$.

The route itself is constrained by Definition 1007.2. In particular, the selected window is exposed before any RealUp handoff, the omitted tail remains a ledger rather than a selected stream, and dyadic accountability is supplied before the Real-facing read.

Use Definition 1007.3 together with Definition 1007.4. Every Real-facing read is already scoped by the finite packet and its sibling surfaces, so a downstream consumer has no bypass row from which to form an independent handoff. □

Theorem 1007.7 (Finite observation interface L10 no-escape public boundary)**.** *The public* FiniteObservationInterf *route for an accepted packet* $O = (S, R, D, T, E, H, C, P, N)$ *is an L10 boundary: it exports the displayed finite certificate rows and nothing beyond them. In particular, no downstream L10 reuse of the route exports Real completeness, a selected limit, quotient stream equality, host real equality, or an omitted-tail-as-selected-stream row.*

Proof. The carrier description in Definition 1007.1 fixes the packet inventory. It names the selected finite window T and the omitted-tail ledger E as distinct rows, and it gives no coordinate for completeness, quotient equality, host equality, or limit selection.

Apply Definition 1007.2 to bind those rows to the local NameCert surface. The non-escape obligation says that every handoff to RealUp factors through $S, R, D, T, E, H, C, P, N$ and through no extra Real-facing row.

Finally combine Definition 1007.3, Definition 1007.4, and Definition 1007.5. The public route is reusable by L10 consumers, but its reuse is still the same finite boundary, so the listed non-export claims remain unavailable. □

Theorem 1007.8 (Finite observation interface L10 bridge)**.** *For every accepted packet* $O = (S, R, D, T, E, H, C, P, N)$*, the public certificate route of Definition 1007.5 is exactly the L10 bridge surface consumed by* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *readers. Every bridge read factors through* $S, R, D, T, E, H, C, P, N$*, and no bridge read exports Real completeness, selected limits, quotient stream equality, host real equality, or omitted-tail-as-selected-stream data.*

Proof. Start from the public reusable certificate route. By Definition 1007.5, the exported surface is the displayed finite route through $S, R, D, T, E, H, C, P, N$, with no additional Real-facing coordinate.

The selected-stream handoff of Definition 1007.3 identifies the only route by which a Real-facing finite observation read can reach the sibling $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ surfaces. The scoped closure theorem Definition 1007.4 keeps that route inside the same BHist, hsame, Cont, Pkg, and NameCert rows.

Now apply consumer reuse from Definition 1007.6. Any L10 reader using the packet must reuse the public certificate route, so its bridge read has no bypass around $S, R, D, T, E, H, C, P, N$.

Finally use the L10 no-escape boundary of Definition 1007.7. Since the public route exports only the displayed finite certificate rows, the bridge surface consumed by the four downstream readers cannot export Real completeness, selected limits, quotient stream equality, host real equality, or omitted-tail-as-selected-stream data. □

Falsifiable prediction: Every accepted FiniteObservationInterfaceUp packet exposes a selected finite observation window before any RealUp handoff and cannot export an omitted tail as a selected stream row.

Independence witness: streamname, regseqrat, dyadicratcore, real, finitewindowenvelope: the interface packet combines selected-window, omitted-tail, dyadic tolerance, regularity, and Real handoff rows; each sibling lacks at least one of these carrier rows, so no bijection preserves the full field inventory.

The Lean file `Derived/FiniteObservationInterfaceUp/TasteGate.lean` must provide Nontrivial FiniteObser and FieldFaithful FiniteObservationInterface$^{\uparrow}$ instances for the displayed coordinates $S, R, D, T, E, H, C, P, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteObservationInterface}^{\uparrow}}$.

Constructive story: A FiniteObservationInterface$^{\uparrow}$ packet is generated from a StreamName observation row, RegSeqRat regularity row, DyadicRatCore tolerance row, selected finite-window row, omitted-tail ledger, componentwise hsame transports, displayed Cont replay, package provenance, and a local NameCert row.

Chapter 1008

A Concrete Naming Certificate for $\mathsf{MetaCICRedexFrontier}^{\uparrow}$

The $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ packet realizes the beta-redex part of the MetaCIC subject-reduction frontier as finite certificate data. It reads the open-problem inventory of chapter 9386, the finite row catalogue of chapter 780, and the normalization boundary of chapter 892. Its purpose is narrower than those ledgers: it binds the four subject-reduction discharge rows to a beta-boundary route and to an obstruction ledger, so a consumer can distinguish an incomplete beta-redex packet from a complete frontier carrier.

The packet is composite over the MetaCIC open-problem ledger, MetaCIC normalization frontier, beta-boundary route, and obstruction-ledger siblings; those rows jointly supply the carrier surface.

Falsifiable prediction: A packet lacking the beta-redex row but carrying the other three discharge rows is rejected by the redex-frontier carrier.

Independence witness: metacicopenproblemledger, metacicnormalizationfrontier, metacic-substitution-audit-packet, beta-critical-pair, apophaticname: those siblings either inventory open rows, record normalization boundaries, isolate substitution windows, expose critical pairs, or refuse external supply; none is bijective with the complete redex-frontier carrier because this packet requires all four discharge rows plus the obstruction ledger in one carrier.

Definition 1008.1 (MetaCIC redex-frontier carrier)**.** *A* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (B, A, L, P, O, E, H, C, G, N)$$

with the following displayed rows:

1. *B is the beta-redex discharge row, carrying* BetaSubstitutionPreservation *for the beta case;*
2. *A is the application-argument discharge row, carrying* AppArgTypeStable *for reduction under the argument of an application;*
3. *L is the lambda-domain discharge row, carrying* LamDomainSubjectReduction *for binder-domain reduction inside lambda formation;*
4. *P is the Pi-domain discharge row, carrying* PiDomainSubjectReduction *for binder-domain reduction inside Pi formation;*
5. *O is the obstruction ledger row recording that the four rows are required because closed subject reduction is not exported at this boundary;*

6. *E is the beta-boundary route row that places beta-redex consumption before any subject-reduction handoff;*
7. *H records componentwise* hsame *transports for B, A, L, P, O, E together with provenance and local naming rows;*
8. *C records the displayed* Cont *routes from the four discharge rows to the beta-boundary route and from that route to subject-reduction consumers;*
9. *G is the* Pkg *provenance over* BHist, hsame, Cont, Pkg, NameCert, SubjectReductionDischargeBundle, MetaCICSubjectReductionFrontier$^{\uparrow}$, MetaCICNormalizationFrontier$^{\uparrow}$, BetaCriticalPair$^{\uparrow}$, *and the open-problem ledger rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{MetaCICRedexFrontier}^{\uparrow}}$ *row.*

The classifier accepts exactly packets with all four discharge rows B, A, L, P and the obstruction ledger O present in the same carrier. It has no coordinate for a beta-only shortcut, a three-row discharge interface, a hidden substitution oracle, a closed subject-reduction theorem, or a consumer route that bypasses E.

Lean4 (definition) `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierCarrier`

Theorem 1008.2 (MetaCICRedexFrontier NameCert obligations)**.** *For the carrier of Definition 1008.1, the local* $\mathsf{NameCert}_{\mathsf{MetaCICRedexFrontier}^{\uparrow}}$ *surface consists exactly of six finite obligations:*

1. *carrier admission for $R = (B, A, L, P, O, E, H, C, G, N)$;*
2. *four-row discharge coverage for beta-redex, application-argument, lambda-domain, and Pi-domain subject-reduction cases;*
3. *beta-boundary routing through E before any subject-reduction consumer can read the discharge packet;*
4. *obstruction ledger exposure through O, separating the finite route from a closed subject-reduction theorem;*
5. *componentwise transport and replay through H and C;*
6. *provenance and local naming exhaustion through G, N, with no beta-only shortcut, hidden substitution oracle, or off-packet consumer route.*

The Lean follow-up must provide `Nontrivial MetaCICRedexFrontierUp` *and* `FieldFaithful MetaCICRedexFron` *in* `lean4/BEDC/Derived/MetaCICRedexFrontierUp/TasteGate.lean`.

Lean4 ✓ `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierCarrier namecert obligations`

Proof. Carrier admission is projection from Definition 1008.1. The displayed tuple $R = (B, A, L, P, O, E, H, C, G, N$ is the full row inventory available to an accepted redex-frontier reader.

The four discharge rows are read next. The beta row B supplies the substitution-preservation case, while A, L, P supply the application-argument, lambda-domain, and Pi-domain cases. Since the classifier requires all four rows, a packet that omits B is not the displayed carrier even if A, L, P are present.

The boundary and obstruction rows are then read through E and O. The row E is the only route by which beta-redex consumption reaches a subject-reduction consumer, and O records why this finite route is not being replaced by a closed subject-reduction theorem.

Finally, H, C, G, N transport, replay, package, and name the same finite surface. The carrier has no coordinate for a beta-only shortcut, hidden substitution oracle, or off-packet consumer path, so the six obligations exhaust the local certificate boundary. □

Theorem 1008.3 (MetaCICRedexFrontier beta-boundary routing)**.** *Every accepted* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *carrier routes beta-redex consumption through*

$$B \to E \to C$$

before a subject-reduction consumer may read the packet. The remaining discharge rows A, L, P *travel with the same carrier, but none of them replaces the beta row* B *or the beta-boundary route* E*.*

Proof. Project the carrier. The beta-redex row is B, the beta-boundary route row is E, and the consumer replay row is C.

Use the obligation theorem for the same packet. It makes four-row discharge coverage and beta-boundary routing simultaneous requirements of the local $\mathsf{NameCert}_{\mathsf{MetaCICRedexFrontier}^{\uparrow}}$ surface.

The rows A, L, P remain necessary discharge rows, but their branch content is application-argument, lambda-domain, and Pi-domain preservation. They do not contain the beta-substitution premise-conclusion shape carried by B. Therefore the only accepted beta-facing route is the displayed path from B through E to C. □

Lean4 ✓ `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierCarrier beta boundary route`

Theorem 1008.4 (MetaCICRedexFrontier obstruction non-escape)**.** *No consumer of an accepted* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *carrier can extract a closed MetaCIC subject-reduction theorem, a hidden substitution oracle, or a three-row subject-reduction interface from the packet. Every consumer read factors through the displayed rows*

$$B, A, L, P, O, E, H, C, G, N.$$

Lean4 ✓ `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierCarrier obstruction nonescape`

Proof. Read the carrier definition. It exposes the four discharge rows, the obstruction ledger, the beta-boundary route, transport, replay, provenance, and local naming. It lists no closed theorem coordinate and no hidden oracle coordinate.

Apply the NameCert obligations. The obstruction row O keeps the packet tied to the finite discharge route described by chapter 9386, rather than to a closed subject-reduction theorem. The beta-boundary row E also prevents a consumer from reading the beta case without the named route.

The remaining structural rows H, C, G, N preserve the same packet. Since the classifier requires all four discharge rows B, A, L, P, a three-row interface is rejected rather than completed by transport, continuation replay, provenance, or local naming. □

Theorem 1008.5 (MetaCICRedexFrontier scoped package)**.** *Let* $R = (B, A, L, P, O, E, H, C, G, N)$ *be an accepted* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *carrier. Its scoped package is exactly the finite primitive surface formed by the typed term window carried by the four discharge rows* B, A, L, P*, the beta-boundary row* E*, the obstruction rows in* O*, componentwise* BHist *and* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* G*, local* $\mathsf{NameCert}$ *naming through* N*, and the TasteGate alignment of the same carrier.*

The scoped package exports no subject-reduction theorem, global confluence theorem, normalization theorem, hidden substitution oracle, three-row discharge interface, or beta-only shortcut.

Lean4 ✓ `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierTasteGate single carrier alignment`

Proof. Project the accepted carrier. The typed term window is not a separate ambient context; it is the finite window read by the four displayed discharge rows B, A, L, P.

The beta and obstruction boundaries are explicit. The row E routes beta-redex consumption before any subject-reduction consumer, while O records why the carrier remains a frontier packet rather than a closed theorem.

The structural rows preserve this same surface. The rows H, C, G, N supply transport, replay, provenance, and local naming, and the TasteGate alignment identifies this single carrier as the accepted package. Since no off-packet theorem or oracle coordinate appears in the carrier, the excluded global claims are outside the scoped package. □

Theorem 1008.6 (MetaCICRedexFrontier normalization-window handoff)**.** *Every normalization-window consumer of an accepted* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *carrier factors through the scoped package of Definition 1008.5 before it may hand data to the normalization-window confluence packet of chapter 2337. The handoff exports the typed term window, beta-boundary row, obstruction rows, transport, replay, provenance, and local naming rows; it does not export subject reduction, global confluence, or normalization.*

Proof. Begin with the obstruction non-escape theorem, Definition 1008.4. Every consumer read factors through the displayed rows $B, A, L, P, O, E, H, C, G, N$.

Apply Definition 1008.5. The same rows form the scoped primitive surface, including the beta-boundary route and obstruction ledger needed before a normalization-window reader can consume the packet.

The target confluence packet is a downstream consumer named by chapter 2337. This chapter hands off only the finite redex-frontier rows; the closed subject-reduction, global confluence, and normalization claims are not coordinates of the carrier. □

Lean4 ✓ `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierCarrier normalization window handoff`

Theorem 1008.7 (MetaCICRedexFrontier candidate normalization)**.** *A normalization-window candidate over an accepted* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *carrier may be read only when all four discharge rows* B, A, L, P*, obstruction row* O*, beta-boundary route* E*, componentwise transport* H*, displayed replay* C*, provenance* G*, and local naming row* N *are displayed. The candidate route hands a finite redex-frontier packet to the normalization-window consumer, but it does not close subject reduction, global confluence, normalization, substitution admissibility, or any hidden oracle claim.*

Proof. Begin with obstruction non-escape, Definition 1008.4. It forces every consumer to read the four discharge rows, the obstruction row, beta-boundary route, transport, replay, provenance, and local naming before the packet can be exposed.

Apply the scoped package theorem, Definition 1008.5. The same rows form the primitive finite surface; a candidate missing one of B, A, L, P or missing O, E, H, C, G, N is not the scoped packet accepted by the carrier.

Finally use the normalization-window handoff of Definition 1008.6. It allows only the finite redex-frontier rows to pass to the downstream normalization-window consumer.

The handoff is therefore candidate-mediated and finite. Since subject reduction, global confluence, normalization, substitution admissibility, and oracle access are not carrier rows, the candidate route cannot assert them. □

Lean4 ✓ `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierCandidateNormalization`

Theorem 1008.8 (MetaCICRedexFrontier candidate SN window)**.** *A strong-normalization-window consumer of an accepted* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *carrier may read only the four discharge rows* B, A, L, P*, the obstruction row* O*, the beta-boundary row* E*, componentwise transport* H*, displayed replay* C*, provenance* G*, and local naming* N*. It may pass the resulting finite candidate packet to the normalization-window confluence route of chapter 2337, but it receives no subject-reduction theorem, global confluence theorem, normalization theorem, substitution oracle, or dependent-codomain readback.*

Proof. Begin with the scoped package theorem, Definition 1008.5. It identifies the primitive surface of an accepted carrier as exactly the typed term window carried by B, A, L, P, the beta-boundary row E, the obstruction row O, and the structural rows H, C, G, N.

Next apply the normalization-window handoff, Definition 1008.6. This handoff permits those finite redex-frontier rows to be read by the downstream normalization-window confluence packet, while keeping subject reduction, global confluence, and normalization outside the exported surface.

Finally use candidate normalization, Definition 1008.7. It sharpens the handoff to finite candidates and records that substitution admissibility and hidden oracle access are not carrier rows. Since dependent-codomain readback is also absent from the carrier inventory, the strong-normalization-window consumer receives only the displayed finite candidate packet. □

Lean4 ✓ `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierCandidateSNWindow`

Theorem 1008.9 (MetaCICRedexFrontier SN obstruction retention)**.** *A strong-normalization-window consumer over an accepted* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *packet must retain the obstruction row* O *through the beta-boundary route and the normalization-window handoff. The consumer may pass only the finite candidate packet formed from* $B, A, L, P, O, E, H, C, G, N$*; it may not erase* O *into a global strong-normalization theorem, subject-reduction theorem, confluence theorem, substitution oracle, or dependent-codomain readback.*

Proof. Start with obstruction non-escape, Definition 1008.4. It forces the obstruction row O to remain visible whenever the redex-frontier packet is exposed to a consumer.

Use the scoped package theorem, Definition 1008.5. The accepted packet is exactly the finite row family $B, A, L, P, O, E, H, C, G, N$, so retaining the obstruction is part of reading the primitive package rather than an external side condition.

Apply the normalization-window handoff and candidate normalization, Definition 1008.6 and Definition 1008.7. These results carry the beta-boundary row E and the finite candidate surface to the downstream normalization-window route without replacing O by an ambient normalization claim.

Finally apply the candidate SN-window theorem, Definition 1008.8. It restricts the strong-normalization-window consumer to the displayed finite candidate packet, so subject reduction, confluence, substitution, global strong normalization, and dependent-codomain readback remain outside the exported surface. □

Lean4 ✓ `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierSNObstructionRetention`

Theorem 1008.10 (MetaCICRedexFrontier residual-diamond handoff)**.** *Any residual-diamond consumer of an accepted* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *packet receives only the finite redex-frontier rows* $B, A, L, P, O, E, H, C, G, N$ *together with the retained obstruction rows. The handoff may compare displayed residual windows inside that packet, but it does not export global confluence, substitution admissibility, strong normalization, or dependent-codomain readback.*

Proof. Start with the strong-normalization obstruction retention theorem, Definition 1008.9. It keeps the obstruction row O visible whenever a consumer reads the beta-boundary route.

Read the candidate SN window of Definition 1008.8. The consumer receives only the finite candidate packet formed from the four discharge rows, the obstruction row, the beta-boundary row, and the structural rows.

A residual-diamond comparison can therefore inspect only displayed residual windows inside the same redex-frontier packet. The comparison may transport those windows through H and replay them through C, but it cannot add substitution admissibility or a host confluence theorem.

Thus the handoff preserves the finite candidate-mediated boundary. Strong normalization, global confluence, substitution, and dependent-codomain readback remain outside the exported NameCert surface. □

Theorem 1008.11 (MetaCICRedexFrontier obstruction retention)**.** *Every candidate-mediated strong-normalization or normalization-window consumer of an accepted* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *carrier must keep the beta-boundary row E, the four discharge rows B, A, L, P, the obstruction row O, componentwise transport H, displayed replay C, provenance G, and local naming N visible before any handoff to the normalization-window confluence packet of chapter 2337. The retained packet exports only the finite redex-frontier surface; it exports no subject reduction, global confluence, normalization, or substitution admissibility.*

Proof. Project the accepted carrier

$$R = (B, A, L, P, O, E, H, C, G, N).$$

The carrier inventory already displays the four discharge rows, the beta-boundary row, the obstruction row, and the structural transport, replay, provenance, and naming rows.

Apply the candidate SN-window theorem, Definition 1008.8. It permits a strong-normalization-window consumer to pass only the finite candidate packet formed from $B, A, L, P, O, E, H, C, G, N$ to the downstream normalization-window confluence route.

Apply the scoped package theorem, Definition 1008.5. It identifies the same rows as the primitive surface of the accepted packet, so a candidate-mediated consumer that hides O, drops E, or separates H, C, G, N from the discharge rows is not reading the scoped package.

Finally use beta-boundary routing, Definition 1008.3, together with the normalization-window handoff of Definition 1008.6. The beta row is consumed through E before the handoff, and the downstream packet receives only the displayed redex-frontier rows, not the off-carrier global claims. □

Lean4 ✓ `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierObstructionRetention`

Theorem 1008.12 (MetaCICRedexFrontier residual-confluence handoff)**.** *Every residual-confluence consumer of an accepted* $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ *carrier must first expose the four discharge rows B, A, L, P, the beta-boundary row E, the obstruction row O, componentwise transport H, displayed replay C, provenance G, and local naming N before handing data to any residual or parallel-diamond confluence packet. The handoff exports only the finite redex-frontier surface; it exports no subject reduction, global confluence, normalization, substitution admissibility, hidden oracle, or dependent-codomain readback.*

Proof. Project the accepted carrier

$$R = (B, A, L, P, O, E, H, C, G, N).$$

This displays the four discharge rows, beta-boundary row, obstruction row, and structural rows before any confluence-facing consumer can inspect the packet.

Apply non-escape and the scoped package theorem, Definition 1008.4 and Definition 1008.5. Together they force the consumer to read exactly the displayed primitive package, with O retained and H, C, G, N attached to the discharge rows.

Use the normalization-window handoff and candidate normalization, Definition 1008.6 and Definition 1008.7. These results route the beta-boundary row E and the finite candidate surface to downstream normalization-window consumers without replacing the packet by a global normalization or subject-reduction theorem.

Finally apply obstruction retention, Definition 1008.11. A residual or parallel-diamond packet therefore receives only the finite candidate data with the obstruction still visible, so the excluded confluence, substitution, normalization, oracle, and dependent-codomain claims remain outside the export. □

Closure status for $\mathsf{NameCert}_{\mathsf{MetaCICRedexFrontier}^{\uparrow}}$.

Constructive story: A $\mathsf{MetaCICRedexFrontier}^{\uparrow}$ packet is generated from beta-redex, application-argument, lambda-domain, and Pi-domain discharge rows, an obstruction ledger, a beta-boundary route, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{MetaCICRedexFrontier}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: Definition 1008.1, Definition 1008.2, Definition 1008.3, Definition 1008.4, Definition 1008.5, and Definition 1008.6 bind the finite beta-redex frontier packet, its primitive scoped package, and its normalization-window handoff boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{MetaCICRedexFrontier}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.MetaCICRedexFrontierUp.MetaCICRedexFrontierCarrier\_namecert\_obligations`
Lean4 ✓ `BEDC.Derived.MetaCICRedexFrontierUp.taste gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close MetaCIC subject reduction, confluence, normalization, substitution admissibility, dependent-codomain readback, Lean verification, axiom-clean audit, or bridge checking.

Upgrade path: The next theory step is the bridge-facing handoff from the public redex-frontier export to a standard acceptance bridge.

Chapter 1009

A Concrete Naming Certificate for $\mathsf{CofinalRealRequestReuse}^{\uparrow}$

The $\mathsf{CofinalRealRequestReuse}^{\uparrow}$ packet realizes the Real and Completion route of chapter 9238 as a finite request-reuse certificate. It consumes the finite request fusion surface of chapter 360, the window naming surface of chapter 126, and the regular-rational and dyadic readback rows used by the completion seal. The packet is not a completion theorem by itself; it is the displayed lock that lets repeated cofinal precision bundles reuse one visible route before a $\mathsf{Real}^{\uparrow}$ seal is served.

Definition 1009.1 (Cofinal real request-reuse carrier)**.** *A* $\mathsf{CofinalRealRequestReuse}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (Q, \sigma, W, G, D, S, H, C, P, N)$$

with the following visible rows:

1. *Q is the finite bundle of cofinal Real-completion precision requests;*
2. *σ is the cofinal selector row that chooses the displayed tail service for every request in Q;*
3. *W is the shared* $\mathsf{StreamName}^{\uparrow}$ *window family through which all selected finite observations are read;*
4. *G is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row over the same shared windows;*
5. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger recording the requested tolerances, endpoints, and finite comparison rows;*
6. *S is the* $\mathsf{Real}^{\uparrow}$ *seal row exposed only after Q, σ, W, G, D have been replayed;*
7. *H records componentwise* hsame *transport for the request bundle, selector, window, readback, dyadic ledger, seal, route, provenance, and local name;*
8. *C records the displayed* Cont *routes that replay the cofinal selector, shared StreamName windows, RegSeqRat readback, DyadicRatCore observations, and RealUp seal handoff;*
9. *P is the* Pkg *provenance over* $\mathsf{RealCauchyCompletion}^{\uparrow}$, $\mathsf{RealObservationBudget}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{CofinalRealRequestReuse}^{\uparrow}}$ *row.*

The carrier contains no second request-bundle route, no host completion object, no quotient stream equality, no hidden selector, and no RealUp seal outside the displayed shared route.

Lean4 ✓ BEDC.Derived.CofinalRealRequestReuseUp.CofinalRealRequestReuseTasteGate single carrier alignment

Theorem 1009.2 (Cofinal real request-reuse NameCert obligations)**.** *For the carrier of Definition 1009.1, the local* $\mathsf{NameCert}_{\mathsf{CofinalRealRequestReuse}^{\uparrow}}$ *surface consists exactly of carrier admission for* $R = (Q, \sigma, W, G, D, S, H, C, P, N)$*, cofinal request-bundle exposure through* Q*, selector exposure through* σ*, shared* $\mathsf{StreamName}^{\uparrow}$ *window exposure through* W*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback through* G*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger exactness through* D*,* $\mathsf{Real}^{\uparrow}$ *seal handoff through* S*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Proof. Project the carrier definition. Each obligation row named in the statement is a displayed coordinate of R, so carrier admission fixes the request bundle, selector, shared window, readback, dyadic ledger, seal, transport, replay, provenance, and local name at once.

Use the finite request fusion supplied by the $\mathsf{RealCauchyCompletion}^{\uparrow}$ surface. A cofinal precision bundle may be read request by request, but every accepted read must return to the same displayed selector σ and the same shared StreamName window family W before reaching G, D, S.

The downstream handoff rows then keep the route local. The RegSeqRat readback, DyadicRatCore ledger, RealUp seal, componentwise transports, continuations, package row, and NameCert row are all consumed from the displayed packet, so no unlisted completion or selector coordinate enters the certificate. □

Theorem 1009.3 (Cofinal real request-reuse fused handoff)**.** *Every completion-facing consumer of an accepted* $\mathsf{CofinalRealRequestReuse}^{\uparrow}$ *packet reads the finite request bundle* Q *through the same selector* σ *and the same shared window route*

$$W, G, D, S, H, C, P, N.$$

Repeated precision bundles may therefore reuse the displayed RealCauchyCompletion route, but they cannot split into separate StreamName, RegSeqRat, DyadicRatCore, or RealUp seal routes.

Proof. Begin with the request-bundle row Q and the cofinal selector σ. The selector is a coordinate of the packet, so a request cannot choose a tail service outside the displayed carrier.

Apply the finite request fusion route from chapter 360. That route turns finitely many precision reads into a finite completion-facing surface, and here its window side is identified with the single StreamName family W.

Now replay the downstream handoff. The RegSeqRat row G reads only the windows in W, the DyadicRatCore ledger D records only the displayed observations, and the RealUp seal S is consumed only after those rows pass through H, C, P, N. Hence repeated precision bundles reuse one route and do not branch into separate completion-seal paths. □

Theorem 1009.4 (Cofinal real request-reuse non-escape)**.** *An accepted* $\mathsf{CofinalRealRequestReuse}^{\uparrow}$ *packet exports no host completion carrier, no quotient stream equality, no second cofinal selector, no unshared StreamName window, no RegSeqRat readback detached from the dyadic ledger, and no RealUp seal detached from the displayed packet. Every downstream* $\mathsf{Real}^{\uparrow}$ *or completion-seal consumer factors through* $Q, \sigma, W, G, D, S, H, C, P, N$*.*

Proof. Inspect the carrier rows. The only request surface is Q, the only selector is σ, the only window family is W, and the only Real-facing row is the seal S.

Use the NameCert obligations to force every accepted read through the shared rows W, G, D, S, H, C, P, N. The componentwise transport and continuation rows record how the packet is replayed; they do not add another selector or another completion route.

Finally use the fused handoff theorem. Since every completion-facing consumer must reuse the same displayed route, there is no coordinate from which a host completion carrier, quotient stream equality, unshared window, detached readback, or detached RealUp seal can be projected. □

Falsifiable prediction: A consumer that reads two cofinal precision bundles as reusable without displaying the shared StreamName window, RegSeqRat readback, DyadicRatCore ledger, and RealUp seal refutes the packet.

Independence witness: Nearest siblings: realcauchycompletion, realobservationbudget, streamname, regseqrat, and dyadicratcore. None is bijective to $\mathsf{CofinalRealRequestReuse}^{\uparrow}$: RealCauchyCompletionUp supplies the completion route but not the repeated request-reuse lock; RealObservationBudgetUp supplies request caps but not the shared completion seal; StreamNameUp supplies windows without RegSeqRat or Dyadic readback; RegSeqRatUp supplies regular readback without the shared request selector; DyadicRatCoreUp supplies observations without the cofinal bundle and RealUp seal. The packet is exactly the lock tying repeated precision bundles to one displayed route.

The later Lean file TasteGate.lean for $\mathsf{CofinalRealRequestReuse}^{\uparrow}$ must provide $\mathsf{Nontrivial\ CofinalRealRequestReuse}^{\uparrow}$ and $\mathsf{FieldFaithful\ CofinalRealRequestReuse}^{\uparrow}$ instances for the same packet surface.

Closure status for $\mathsf{NameCert}_{\mathsf{CofinalRealRequestReuse}^{\uparrow}}$.

Constructive story: A $\mathsf{CofinalRealRequestReuse}^{\uparrow}$ packet is generated from a finite cofinal precision request bundle, a cofinal selector, shared StreamName windows, RegSeqRat readback, DyadicRatCore observations, a RealUp seal, componentwise transport, continuation replay, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CofinalRealRequestReuse}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1009.1, Definition 1009.2, Definition 1009.3, and Definition 1009.4 bind the finite repeated request-reuse packet and its shared completion-seal route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CofinalRealRequestReuse}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close RealUp completeness, uniqueness of completed limits, quotient equality of streams, host real equality, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, request-bundle fusion, shared-window reuse, RegSeqRat and DyadicRatCore handoff, RealUp seal non-escape, nontriviality, and field faithfulness for the same carrier.

Chapter 1010

A Concrete Naming Certificate for $\mathsf{UnaryDirectionNormalizer}^{\uparrow}$

The $\mathsf{UnaryDirectionNormalizer}^{\uparrow}$ packet realizes the unary-direction bridge of chapter 9344 as a finite NameCert carrier. It consumes the axis-unary-spine surface of chapter 599 and the zero-spine standard surface of chapter 572, then adds a local direction decision row that keeps host integer axes outside the exported packet.

Definition 1010.1 (UnaryDirectionNormalizer carrier)**.** *A* $\mathsf{UnaryDirectionNormalizer}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (A, Z, K, D, H, C, P, N)$$

with the following visible coordinates:

1. *A is the axis-unary-spine row supplied by* $\mathsf{AxisUnarySpineNormalizer}^{\uparrow}$*;*
2. *Z is the zero-spine standard row supplied by* $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$*;*
3. *K is the Zeckendorf carry-normalization row used by axis-side carry consumers;*
4. *D is the direction-normalization decision row choosing the unary-to-axis, axis-to-unary, or neutral bridge presentation;*
5. *H stores componentwise* hsame *transports for A, Z, K, D and the local naming row;*
6. *C stores the displayed* Cont *replay routes for axis-spine exposure, zero-spine exposure, carry-normalization routing, direction-decision readback, and NameCert audit;*
7. *P records* Pkg *provenance over* $\mathsf{AxisUnarySpineNormalizer}^{\uparrow}$*,* $\mathsf{UnaryZeroSpineStandardIso}^{\uparrow}$*,* $\mathsf{ZeckendorfCarryNormali}$ $\mathsf{UnaryDirectionBridge}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{UnaryDirectionNormalizer}^{\uparrow}}$ *row.*

The packet has no coordinate for a host integer-axis function, a quotient between unary and zero-spine carriers, or an ambient standard-model normalizer outside the displayed rows.

Lean4 ✓ `BEDC.Derived.UnaryDirectionNormalizerUp.UnaryDirectionNormalizerTasteGate single carrier alignment`

Theorem 1010.2 (UnaryDirectionNormalizer NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{UnaryDirectionNormalizer}^{\uparrow}}$ *surface for Definition 1010.1 consists of carrier admission, axis-row exposure, zero-spine compatibility, carry-normalization routing, direction-decision stability, and non-escape from host integer*

axes. In particular, an accepted packet exposes the finite rows A, Z, K, D, H, C, P, N and exports a direction-normalized unary packet only through those rows.

Proof. Carrier admission is projection from the displayed packet $U = (A, Z, K, D, H, C, P, N)$. The axis-row exposure clause reads A through the sibling surface of chapter 599, and the zero-spine compatibility clause reads Z through chapter 572.

The carry route is separate from the direction decision. The row K supplies the Zeckendorf carry-normalization input, while D records which bridge direction is being normalized for the downstream consumer.

Stability is componentwise. The row H transports A, Z, K, D and the local name without merging the axis-unary and zero-spine carriers, and C replays the same reads as finite continuation routes.

The non-escape condition follows from the absence of any host integer-axis coordinate. Since P lists only the displayed BEDC dependencies and N binds the local NameCert row, a consumer that bypasses A or Z has no route from which to export a direction-normalized unary packet. □

Theorem 1010.3 (UnaryDirectionNormalizer bridge realization)**.** *Every accepted* $\mathsf{UnaryDirectionNormalizer}^{\uparrow}$ *carrier realizes the unary-direction bridge as a finite axis, zero-spine, carry, direction, transport, route, provenance, and NameCert packet. Its public reads factor through the bridge source chapter 9344, the axis-unary-spine sibling, and the unary-zero-spine standard sibling, and they do not export a host integer-axis normalizer.*

Proof. Project the carrier rows from Definition 1010.1. The route begins at A and Z, so the bridge read is anchored in the two concrete sibling surfaces rather than in a free host-axis map.

Apply Definition 1010.2. It forces carry-normalization reads through K, direction reads through D, transport through H, continuation replay through C, provenance through P, and the public naming surface through N.

The stated non-escape boundary is therefore immediate: a consumer may inspect the finite bridge packet, but it cannot replace the packet by an external integer-axis normalizer or by a kernel identification of the unary and zero-spine carriers. □

Falsifiable prediction: Any accepted UnaryDirectionNormalizerUp consumer that bypasses the axis-unary-spine row or zero-spine standard row cannot export a direction-normalized unary packet.

Independence witness: axisunaryspinenormalizer, unaryzerospinestandardiso, zeckendorfcarrynormalization, nat, add: none is bijective to UnaryDirectionNormalizerUp because the new carrier contains the combined direction row D and the local NameCert row N tying axis, zero-spine, and carry-normalization routes together.

The Lean taste-gate file TasteGate.lean will provide Nontrivial $\mathsf{UnaryDirectionNormalizer}^{\uparrow}$ and FieldFaithful $\mathsf{UnaryDirectionNormalizer}^{\uparrow}$ instances for the displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{UnaryDirectionNormalizer}^{\uparrow}}$.

Constructive story: A $\mathsf{UnaryDirectionNormalizer}^{\uparrow}$ packet is generated by an axis-unary-spine row, a zero-spine standard row, a Zeckendorf carry-normalization row, a direction decision row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{UnaryDirectionNormalizer}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1010.1, Definition 1010.2, and Definition 1010.3 bind the finite unary-direction normalizer packet without host integer-axis escape.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{UnaryDirectionNormalizer}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean formalization, bridge checking, host integer-axis normalization, kernel equality between unary and zero-spine histories, or a public additive isomorphism.

Upgrade path: Obligation closure requires checked carrier admission, axis-row exposure, zero-spine compatibility, carry-normalization routing, direction-decision stability, and non-escape for the same finite packet.

Chapter 1011

A Concrete Naming Certificate for $\mathsf{ObserverLocalityPullback}^{\uparrow}$

The $\mathsf{ObserverLocalityPullback}^{\uparrow}$ packet realizes the common observer-locality pullback surface in the Inter-Hist Locality chain of chapter 9419. It sits after the observer-locality cell surface of chapter 513, the causal witness surface of chapter 478, the maximum-rate boundary of chapter 594, and the transport packet of chapter 889. Its role is to name the finite packet in which all four rows are simultaneously visible before a rate-facing consumer reads the causal-rate surface of chapter 876.

Definition 1011.1 (Observer-locality pullback carrier)**.** *An* $\mathsf{ObserverLocalityPullback}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (O, D, M, T, J, H, Q, C, P, N)$$

with the following displayed rows:

1. *O is the* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *row supplying the two-observer locality cell;*
2. *D is the displayed finite family of* $\mathsf{CrossHistCausal}^{\uparrow}$ *rows over the same observer-locality cell;*
3. *M is the* $\mathsf{MaxCausalRate}^{\uparrow}$ *row read only over the causal family D;*
4. *T is the* $\mathsf{ObserverLocalityTransport}^{\uparrow}$ *row transporting O through D before M is consumed;*
5. *J is the pullback compatibility row asserting that O, D, M, T are one finite packet rather than four detached sibling reads;*
6. *H records componentwise* hsame *transport for O, D, M, T, J and the local naming row;*
7. *Q records* psame *stability for the probe reads used by the observer-locality cell, causal rows, maximum-rate row, and transport row;*
8. *C records displayed* Cont *routes for reading O, replaying each row of D, reading M, transporting through T, checking J, and auditing the local name;*
9. *P is the* Pkg *provenance over* $\mathsf{ObserverLocalityPullback}^{\uparrow}$, $\mathsf{ObserverLocalityCell}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, $\mathsf{ObserverLocalityTransport}^{\uparrow}$, $\mathsf{CrossHistCausalRate}^{\uparrow}$, BHist, hsame, psame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverLocalityPullback}^{\uparrow}}$ *row.*

The carrier exports only the displayed locality cell, causal rows, maximum-rate row, transport row, compatibility row, structural rows, provenance, and local naming data.

Theorem 1011.2 (Observer-locality pullback NameCert obligations)**.** *For the carrier of Definition 1011.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverLocalityPullback}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$U = (O, D, M, T, J, H, Q, C, P, N),$$

observer-locality source exactness through O*, causal-family exactness through* D*, maximum-rate readback through* M*, transport exactness through* T*, simultaneous pullback compatibility through* J*, componentwise transport through* H*, probe stability through* Q*, displayed route replay through* C*, package provenance through* P*, and local naming through* N*.*

Proof. Project the carrier of Definition 1011.1. The rows $O, D, M, T, J, H, Q, C, P, N$ are the only coordinates available to a local $\mathsf{NameCert}_{\mathsf{ObserverLocalityPullback}^{\uparrow}}$ read.

Read the four sibling surfaces in packet order. The observer-locality cell supplies O, the displayed causal family supplies D, the maximum-rate row M is attached to that family, and the transport row T carries the locality-cell read through the causal and rate rows.

The compatibility row J then records that these four surfaces are simultaneous. The structural rows H, Q, C, P, N transport, stabilize, replay, package, and name the same finite packet, so no detached rate row or host frame can replace the pullback carrier. □

Lean4 ✓ `BEDC.Derived.ObserverLocalityPullbackUp.ObserverLocalityPullbackTasteGate single carrier alignment`

Theorem 1011.3 (Observer-locality pullback non-escape)**.** *Every rate-facing consumer of an accepted* $\mathsf{ObserverLocalityPullback}^{\uparrow}$ *packet factors through*

$$O, D, M, T, J, H, Q, C, P, N.$$

In particular, a consumer cannot read the $\mathsf{MaxCausalRate}^{\uparrow}$ *row* M *unless the displayed* $\mathsf{CrossHistCausal}^{\uparrow}$ *family* D*, the* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *row* O*, and the* $\mathsf{ObserverLocalityTransport}^{\uparrow}$ *row* T *are present in the same pullback packet. The packet exports no global frame, synchronized clock, metric tensor, Lorentz geometry, host real-valued speed, or detached cross-Hist causal-rate row.*

Proof. Start with the accepted carrier. The maximum-rate coordinate is M, and its only admissible sources in the carrier are the displayed locality cell O, causal family D, transport row T, and compatibility row J.

Apply Definition 1011.2. It forces every rate-facing read through the same finite packet and then through H, Q, C, P, N for transport, probe stability, route replay, provenance, and local naming.

The excluded objects have no coordinate in U. Therefore a request for a global frame, synchronized clock, metric tensor, Lorentz geometry, host speed, or detached causal-rate row leaves the accepted pullback packet rather than projecting from it. □

Theorem 1011.4 (Observer-locality pullback causal-rate handoff)**.** *Every* $\mathsf{CrossHistCausalRate}^{\uparrow}$ *consumer of an accepted* $\mathsf{ObserverLocalityPullback}^{\uparrow}$ *packet receives the observer-locality cell, causal family, maximum-rate row, and transport row only through the common compatibility row* J *and the structural rows* H, Q, C, P, N*. The handoff is therefore a finite pullback packet over the four sibling surfaces, not a separate maximum-rate read followed by an external transport.*

Proof. Project O, D, M, T, J from the carrier. The causal-rate consumer has access to the maximum-rate row only together with the causal family and the transport row that bind it to the observer-locality cell.

Use Definition 1011.3. It excludes any route that reads M as a detached rate value or obtains T from an external observer frame.

The remaining route is exactly the displayed structural surface H, Q, C, P, N. These rows keep the causal-rate handoff inside the accepted BHist packet and leave no coordinate for a host real-valued speed or hidden synchronization row. □

Falsifiable prediction: A rate-facing consumer cannot read MaxCausalRateUp from an observer-locality cell unless the displayed CrossHistCausalUp and ObserverLocalityTransportUp rows form one pullback packet.

Independence witness: observerlocalitycell, crosshistcausal, maxcausalrate, observerlocality-transport, crosshistcausalrate: the pullback packet is not bijective to any sibling because it carries the simultaneous compatibility row among all four surfaces.

The Lean taste-gate file for $\mathsf{ObserverLocalityPullback}^{\uparrow}$ must include explicit $\mathsf{Nontrivial\ ObserverLocalityPullback}^{\uparrow}$ and $\mathsf{FieldFaithful\ ObserverLocalityPullback}^{\uparrow}$ instances preserving the locality-cell row, causal family, maximum-rate row, transport row, pullback compatibility row, structural rows, package provenance, and local naming row.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverLocalityPullback}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverLocalityPullback}^{\uparrow}$ packet is generated from an observer-locality cell, finite cross-Hist causal rows, a maximum-rate row, an observer-locality transport row, a simultaneous compatibility row, componentwise hsame transport, psame stability, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverLocalityPullback}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1011.1, Definition 1011.2, Definition 1011.3, and Definition 1011.4 specify the finite pullback packet, its NameCert surface, rate-facing non-escape boundary, and causal-rate handoff.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverLocalityPullback}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not derive Lorentz geometry, metric tensors, synchronized clocks, global frames, host real-valued speed, Lean verification, or bridge checking for $\mathsf{ObserverLocalityPullback}^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, sibling exactness for observer-locality cell, causal, maximum-rate, and transport rows, pullback compatibility, no-global-frame refusal, and TasteGate nontriviality with field faithfulness.

Chapter 1012

A Concrete Naming Certificate for $\mathsf{TermStratumChoiceClosure}^{\uparrow}$

The $\mathsf{TermStratumChoiceClosure}^{\uparrow}$ interface turns the term-level branch of Definition 9387.18 and Definition 9387.19 into a finite naming packet. It separates the accepted witness-map rows that BEDC may consume from the refused choice-oracle rows that would otherwise close the term stratum without displayed witnesses. The packet sits beside chapter 515, chapter 568, chapter 634, and chapter 566: those siblings aggregate the three strata, replacement ledgers, quotient refusal, and proposition transport, while this chapter isolates the term-stratum witness-map route.

Definition 1012.1 (TermStratumChoiceClosure carrier)**.** *A* $\mathsf{TermStratumChoiceClosure}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (I, F, W, M, R, H, C, P, N)$$

with the following displayed rows:

1. *I is the index-family row for the positive term existentials named in Definition 9387.18;*
2. *F is the fiber-membership row recording the visible target fiber for each accepted index;*
3. *W is the witness-map row, recording for each displayed index the constructor-level term and membership evidence actually supplied to the packet;*
4. *M is the map-coherence row saying that consumer reads of W respect the displayed index and fiber rows rather than an ambient selector;*
5. *R is the oracle-refusal row, recording that no global* Classical.choice *function, hidden selector body, or unindexed host function is admitted;*
6. *H stores componentwise* hsame *transport for the index, fiber, witness-map, coherence, refusal, route, provenance, and naming rows;*
7. *C stores the finite* Cont *routes by which a downstream consumer reads a witness only after reading its displayed index and fiber membership;*
8. *P records* Pkg *provenance over* BHist, hsame, Cont, Pkg, NameCert, *chapter 9387, and the sibling packets chapter 515, chapter 568, chapter 634, and chapter 566;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{TermStratumChoiceClosure}^{\uparrow}}$ *row.*

The carrier has no coordinate for a choice oracle that manufactures witnesses from positive existentials without the displayed witness-map row W.

Theorem 1012.2 (TermStratumChoiceClosure NameCert obligations)**.** *For an accepted carrier $T = (I, F, W, M, R, H, C, P, N)$, the local* $\mathsf{NameCert}_{\mathsf{TermStratumChoiceClosure}^{\uparrow}}$ *surface consists exactly of carrier admission for the finite packet, index-family exposure for I, fiber-membership exposure for F, witness-map exactness for W and M, componentwise* hsame *and* Cont *stability through H and C, provenance through P, and oracle refusal through R. Every consumer-visible term read factors through these rows before it can use a witness.*

Proof. Project the finite carrier. The rows $I, F, W, M, R, H, C, P, N$ are all displayed, so carrier admission and provenance are ordinary row reads.

Witness-map exactness is the joint reading of W and M. The witness row supplies a term only at a displayed index, and the coherence row ties that term to the displayed fiber membership in F.

Transport and route stability are supplied by H and C. They move and replay the same finite rows componentwise, so a consumer cannot replace the witness-map route by a host selector.

Finally read the refusal row R. It records the rejected oracle surfaces and leaves no coordinate for Classical.choice, a hidden selector body, or an unindexed host function. Thus the listed rows exhaust the local naming obligations. □

Lean4 ✓ `BEDC.Derived.TermStratumChoiceClosureUp.TermStratumChoiceClosureTasteGate single carrier alignment`

Theorem 1012.3 (TermStratumChoiceClosure nontriviality)**.** *The* $\mathsf{TermStratumChoiceClosure}^{\uparrow}$ *packet is nontrivial: there are accepted packets whose witness-map row W is present and accepted packets whose oracle-refusal row R blocks the same consumer request after W is absent. These packets are distinguished by the local* NameCert *surface because one exposes an indexed constructor-level witness route and the other exposes only the refused oracle row.*

Proof. Use a singleton index-family row for I and a displayed fiber row F. In the positive packet, let W store the visible constructor-level witness and its membership evidence, and let M record that the only consumer read is the singleton indexed route.

For the contrasting packet, keep the same index and fiber rows but remove the witness-map route from the accepted surface. The only remaining answer to the consumer request is the refusal row R.

The two packets differ at the row inspected by the consumer: one projects W through C, while the other projects R. Since the local name row records that distinction, the carrier does not collapse to a single vacuous packet. □

Theorem 1012.4 (TermStratumChoiceClosure field faithfulness)**.** *If two accepted* $\mathsf{TermStratumChoiceClosure}^{\uparrow}$ *carriers*

$$T = (I, F, W, M, R, H, C, P, N) \qquad \textit{and} \qquad T' = (I', F', W', M', R', H', C', P', N')$$

are identified by the packet classifier, then each displayed field is preserved componentwise: index rows compare with index rows, fiber rows with fiber rows, witness-map rows with witness-map rows, map-coherence rows with map-coherence rows, oracle-refusal rows with oracle-refusal rows, and the transport, route, provenance, and naming rows with their corresponding rows.

Proof. Unfold the classifier of the accepted packet as componentwise comparison over the displayed carrier coordinates. The index and fiber coordinates are compared first, so a witness in W cannot be transported to a different index or fiber without the matching hsame evidence.

Next compare W, M, R. The witness-map route is preserved as a witness-map route, the coherence row remains a coherence row, and the oracle refusal remains a refusal row. No classifier clause converts a refused oracle into a witness map.

The remaining rows H, C, P, N are administrative coordinates for transport, route replay, provenance, and local naming. Componentwise preservation of these rows gives field faithfulness for the whole packet. □

Falsifiable prediction: Any accepted packet whose witness-map row is removed has no route from indexed positive existentials to a consumer-visible term without invoking the refused oracle row.

Independence witness: unwitnessedexistenceclosure, effectivereplacementledger, quotientsoundnessboundary, propexttransportboundary: none is bijective because this packet isolates the term-stratum witness-map route, while the siblings aggregate strata, replacement ledgers, quotient transport, or proposition transport.

The Lean `TasteGate.lean` surface must provide `Nontrivial TermStratumChoiceClosureUp` and `FieldFaithful TermStratumChoiceClosureUp` instances for the same displayed carrier rows $I, F, W, M, R, H, C, P, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{TermStratumChoiceClosure}^{\uparrow}}$.

Constructive story: A $\mathsf{TermStratumChoiceClosure}^{\uparrow}$ packet is generated from an index-family row, fiber-membership row, displayed witness-map row, map-coherence row, oracle-refusal row, componentwise hsame transport, finite Cont routes, provenance, and local naming. The carrier reads positive term existentials only after their index and fiber rows are visible; then the witness-map supplies constructor-level evidence. If that row is absent, the refusal row records that no host selector is admitted. Thus the classifier separates generated term witnesses from refused choice-like supply using finite BEDC rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TermStratumChoiceClosure}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the term-stratum choice-closure carrier, NameCert obligations, nontriviality, and field-faithfulness statements.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TermStratumChoiceClosure}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim a global choice function, hidden selector body, unindexed host function, or witness production without displayed fiber evidence.

Upgrade path: To reach obligationClosure, provide checked nontrivial and field-faithful instances for the finite witness-map and oracle-refusal rows.

Chapter 1013

A Concrete Naming Certificate for InterHistSymmetryBudget$^{\uparrow}$

The InterHistSymmetryBudget$^{\uparrow}$ packet realizes the two-direction locality budget from chapter 9419 as finite NameCert data. It consumes the ledger-local route of chapter 759, the two-observer cell of chapter 513, the invariant readback of chapter 656, the observer-Hist identity surface of chapter 479, and the no-global-synchronization boundary of chapter 1003. Its role is to budget both directional reads before any downstream consumer treats an inter-Hist relation as symmetric.

Falsifiable prediction: Every accepted InterHistSymmetryBudgetUp packet exposes both directional locality rows and admits no consumer route to a global synchronization history or host frame.

Independence witness: Nearest siblings: interhistlocalityledger, observerlocalitycell, interhistinvariant, observerhistidentity, and noglobalsyncboundary. None is bijective to this carrier because InterHistSymmetryBudget$^{\uparrow}$ stores both directional locality rows, one invariant readback row, one no-global-synchronization refusal row, transport, continuation, provenance, and local naming data in a single budget packet, while each sibling omits at least one of those rows or records a different consumer surface.

Definition 1013.1 (InterHistSymmetryBudget carrier)**.** *An* InterHistSymmetryBudget$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Y = (A, B, L_{AB}, L_{BA}, O, I, G, H, C, P, N)$$

with the following displayed rows:

1. *A and B are the two source history rows whose symmetric locality budget is being certified;*
2. *L_{AB} is the directional locality row reading finite data from A toward B;*
3. *L_{BA} is the directional locality row reading finite data from B toward A;*
4. *O is the* ObserverLocalityCell$^{\uparrow}$ *row consumed before the two directional reads are compared;*
5. *I is the* InterHistInvariant$^{\uparrow}$ *readback row that receives the two-direction locality budget;*
6. *G is the* NoGlobalSyncBoundary$^{\uparrow}$ *refusal row, recording that neither direction supplies a global synchronization history, shared clock, privileged host frame, or selected all-observer map;*
7. *H stores componentwise* hsame *transport for the source histories, directional locality rows, observer-locality cell, invariant readback, no-global-synchronization row, route rows, provenance, and local name;*

8. *C stores the displayed* Cont *routes by which consumers read $A, B, L_{AB}, L_{BA}, O, I, G, H, P, N$;*
9. *P is the* Pkg *provenance over* $\mathsf{ObserverHistIdentity}^{\uparrow}$, $\mathsf{InterHistLocalityLedger}^{\uparrow}$, $\mathsf{ObserverLocalityCell}^{\uparrow}$, $\mathsf{InterHistInvariant}^{\uparrow}$, $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{InterHistSymmetryBudget}^{\uparrow}}$ *row.*

The carrier has no coordinate for a global synchronization history, host frame, shared clock, total observer order, quotient of histories, metric spacetime, or ambient equality oracle.

Theorem 1013.2 (InterHistSymmetryBudget NameCert obligations)**.** *For the carrier of Definition 1013.1, the local* $\mathsf{NameCert}_{\mathsf{InterHistSymmetryBudget}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier admission for $Y = (A, B, L_{AB}, L_{BA}, O, I, G, H, C, P, N)$;*
2. *two-direction locality exposure, requiring both L_{AB} and L_{BA} after the observer-Hist rows A, B have been read;*
3. *observer-locality and invariant readback, requiring O before I receives the paired directional rows;*
4. *componentwise* hsame *transport, displayed* Cont *replay, package provenance, and local naming through H, C, P, N;*
5. *non-escape through the no-global-synchronization row G, excluding global synchronization histories, host frames, shared clocks, total observer orders, quotient histories, metric spacetime, and ambient equality oracles.*

Proof. Carrier admission is projection from Definition 1013.1. The rows $A, B, L_{AB}, L_{BA}, O, I, G, H, C, P, N$ display the two source histories, the two directional locality reads, the locality cell, invariant readback, no-global-synchronization refusal, transport, routes, provenance, and local name.

The two-direction locality obligation reads L_{AB} and L_{BA} separately. The observer-Hist identity surface supplies the two source histories, while the inter-Hist locality ledger supplies the directional route discipline for each read.

The observer-locality and invariant rows then receive the paired budget. The row O records the finite two-observer cell, and the row I records the observer-symmetric invariant readback after both directions have been displayed.

Finally H, C, P, N provide transport, continuation replay, provenance, and local naming. The row G supplies the no-global-synchronization refusal, so no remaining obligation can export a global synchronization history, host frame, shared clock, quotient history, metric spacetime, or ambient equality oracle. □

Theorem 1013.3 (InterHistSymmetryBudget non-escape)**.** *Every public consumer of an accepted* $\mathsf{InterHistSymmetryBudget}^{\uparrow}$ *carrier reads only the rows*

$$A, B, L_{AB}, L_{BA}, O, I, G, H, C, P, N.$$

It may consume both directional locality rows, invariant readback, componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* NameCert *row. It receives no global synchronization history, host frame, shared clock, total observer order, quotient of histories, metric spacetime, or ambient equality oracle.*

Proof. Inspect the carrier coordinates of Definition 1013.1. Every public row is one of $A, B, L_{AB}, L_{BA}, O, I, G, H, C,$

The positive route data remain finite. The two source histories, the two directional locality rows, the observer-locality cell, and the invariant readback are transported by H and replayed by C before provenance and local naming are read through P and N.

The no-global-synchronization row G is a refusal row, not a hidden synchronization object. Since no coordinate supplies a global history, host frame, shared clock, total observer order, quotient history, metric spacetime, or ambient equality oracle, no consumer can export such an object from the accepted packet. □

Theorem 1013.4 (InterHistSymmetryBudget TasteGate obligation)**.** *The later Lean site for* InterHistSymmetryBudget$^{\uparrow}$ *must provide explicit* Nontrivial InterHistSymmetryBudget$^{\uparrow}$ *and* FieldFaithful InterHistSymm *instances. These instances must keep the two source histories, two directional locality rows, observer-locality cell, invariant readback, no-global-synchronization refusal row,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *row as distinguishable fields.*

Lean4 ✓ `BEDC.Derived.InterHistSymmetryBudgetUp.InterHistSymmetryBudgetTasteGate single carrier alignment`

Proof. The carrier separates the two directions L_{AB} and L_{BA} from the invariant readback I and the refusal row G. A trivial collapse would identify a directional locality read with the symmetric budget or with the no-global-synchronization boundary, erasing the consumer distinction this packet exposes.

Field faithfulness is the projection discipline for $Y = (A, B, L_{AB}, L_{BA}, O, I, G, H, C, P, N)$. Each row has a distinct consumer role, so a later TasteGate witness must preserve those projections before any downstream causal-rate or no-global-sync chapter consumes the budget. □

Closure status for NameCert$_{\text{InterHistSymmetryBudget}^{\uparrow}}$.

Constructive story: An InterHistSymmetryBudget$^{\uparrow}$ packet is generated from two source histories, two directional locality rows, an observer-locality cell, an invariant readback row, a no-global-synchronization refusal row, componentwise hsame transport, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{InterHistSymmetryBudget}^{\uparrow}}$, seed)

Scope closed: Definition 1013.1, Definition 1013.2, and Definition 1013.3 specify the finite two-direction locality budget and its no-global-synchronization boundary.

Formal verification: FormalStatus(NameCert$_{\text{InterHistSymmetryBudget}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not construct a global synchronization history, host frame, shared clock, total observer order, quotient history, metric spacetime, Lean proof, or bridge checking for InterHistSymmetryBudget$^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, two-direction locality exposure, invariant readback, no-global-synchronization non-escape, Nontrivial, and FieldFaithful for the same packet.

Chapter 1014

A Concrete Naming Certificate for $\mathsf{CauchyLimitWitnessLedger}^{\uparrow}$

The $\mathsf{CauchyLimitWitnessLedger}^{\uparrow}$ packet realizes the witness-ledger direction of the Real and Completion target in chapter 9238. It consumes the sealed Cauchy-limit handoff of chapter 386, the paired tail-agreement route of chapter 699, the Cauchy witness ledger row, the finite $\mathsf{StreamName}^{\uparrow}$ window row, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, and the $\mathsf{Real}^{\uparrow}$ seal row before a completion-facing consumer may inspect the displayed limit route. The packet is a finite ledger for the route, not a selected limit, quotient real equality, hidden tail selector, or ambient completeness principle.

Definition 1014.1 (Cauchy limit witness-ledger carrier)**.** *A* $\mathsf{CauchyLimitWitnessLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (D, T, S, W, G, R, H, C, P, N, A)$$

with the following displayed rows:

1. *D is the finite diagonal-budget row that fixes the request served by the route;*
2. *T is the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *row that synchronizes the visible tail route;*
3. *S is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row consumed as the displayed limit-seal handoff;*
4. *W is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row opened before any tail readback is exposed;*
5. *G is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-rational readback row obtained from W;*
6. *R is the* $\mathsf{Real}^{\uparrow}$ *seal row reached only after W, G, T, S have been displayed;*
7. *H records componentwise* hsame *transport for the diagonal budget, tail agreement, limit seal, window, readback, Real seal, provenance, and local name;*
8. *C records the displayed* Cont *route from the budget row to the window, from the window to the readback, from the readback to the tail-agreement row, and from the tail-agreement row to the limit seal and Real seal;*
9. *P is the* Pkg *provenance over* BHist, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{CauchyWitnessLedger}^{\uparrow}$, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyLimitWitnessLedger}^{\uparrow}}$ *row;*
11. *A is the displayed audit row stating that every accepted read remains on the same finite limit-witness ledger.*

The carrier has no coordinate for a selected limit, quotient real equality, host real equality, hidden tail selector, or ambient completeness theorem.

Lean4 ✓ `BEDC.Derived.CauchyLimitWitnessLedgerUp.CauchyLimitWitnessLedgerTasteGate single carrier alignment`

Theorem 1014.2 (CauchyLimitWitnessLedger NameCert obligations)**.** *For the carrier of Definition 1014.1, the local* $\mathsf{NameCert}_{\mathsf{CauchyLimitWitnessLedger}^{\uparrow}}$ *surface consists exactly of carrier admission for* $L = (D, T, S, W, G, R, H, C, P, N, A)$*, diagonal-budget exposure, tail-agreement exposure, limit-seal exposure, StreamName window service, RegSeqRat readback service, RealUp seal ordering, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, local naming, and audit non-escape through* A*.*

Proof. Project the displayed carrier. The packet exposes exactly the diagonal budget, tail agreement, limit seal, window, regular readback, Real seal, transport, route, provenance, local name, and audit rows.

The sibling rows supply the route discipline. The window row is read through chapter 126, the regular-rational readback through chapter 301, the tail agreement through chapter 699, and the limit-seal handoff through chapter 386.

Transport and replay are componentwise. Since no carrier coordinate names a selected limit, quotient real equality, hidden tail selector, host real equality, or ambient completeness principle, the listed rows exhaust the local certificate surface. □

Theorem 1014.3 (CauchyLimitWitnessLedger tail synchronization)**.** *Every accepted* $\mathsf{CauchyLimitWitnessLedger}^{\uparrow}$ *packet routes its completion-facing read through the same finite sequence*

$$D, W, G, T, S, R, H, C, P, N, A.$$

In particular, the displayed limit-seal row S *is consumed only after the StreamName window* W*, the RegSeqRat readback* G*, and the tail-agreement row* T *have been exposed through the same* hsame *and* Cont *ledger.*

Proof. Begin with carrier admission. The only visible path to the limit-seal row is the displayed tuple containing $D, W, G, T, S, R, H, C, P, N, A$.

Use the NameCert obligations. They place window service before readback service, readback before tail agreement, and tail agreement before the limit-seal and RealUp seal rows.

The audit row A records that this is the whole accepted route. Thus a consumer cannot bypass the window or readback rows, cannot replace the tail-agreement row by a hidden selector, and cannot obtain a selected limit or quotient real equality from the packet. □

Falsifiable prediction: Every accepted CauchyLimitWitnessLedgerUp packet exposes a displayed limit-seal row and admits no public route to a selected limit, quotient real equality, or hidden tail selector.

Independence witness: Nearest siblings: cauchylimitseal, realtailagreementseal, cauchywitnessledger, streamname, and regseqrat. None is bijective to $\mathsf{CauchyLimitWitnessLedger}^{\uparrow}$ because this chapter keeps the combined limit-witness ledger as one finite packet: diagonal budget, tail agreement, limit seal, StreamName window, RegSeqRat readback, RealUp seal, transport, replay, provenance, local name, and audit row are carried together.

The Lean TasteGate boundary for this packet provides explicit `Nontrivial CauchyLimitWitnessLedgerUp` and `FieldFaithful CauchyLimitWitnessLedgerUp` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyLimitWitnessLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{CauchyLimitWitnessLedger}^{\uparrow}$ packet is generated from a finite diagonal budget, displayed tail-agreement row, displayed Cauchy-limit seal, StreamName window, RegSeqRat readback, RealUp seal, componentwise transports, displayed replay, provenance, local NameCert row, and audit non-escape row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyLimitWitnessLedger}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1014.1, Definition 1014.2, and Definition 1014.3 bind the finite limit-witness ledger route over StreamName, RegSeqRat, RealUp, RealTailAgreementSeal, CauchyLimitSeal, hsame, Cont, Pkg, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CauchyLimitWitnessLedger}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.CauchyLimitWitnessLedgerUp.CauchyLimitWitnessLedgerTasteGate\_single\_carrier\_alignmen`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close selected limits, quotient real equality, host real equality, hidden tail selectors, ambient completeness, axiom-clean audit, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, tail-agreement ordering, limit-seal exposure, StreamName and RegSeqRat service rows, RealUp seal ordering, and audit non-escape for the same finite packet.

Chapter 1015

A Concrete Naming Certificate for $\mathsf{OracleResponseLedger}^{\uparrow}$

The $\mathsf{OracleResponseLedger}^{\uparrow}$ packet realizes the oracle-response row of Definition 9388.7 as a finite $\mathsf{NameCert}$ surface. It sits between the oracle-call transcript of chapter 951 and the external-channel boundary of chapter 956. Its distinguishing datum is a response ledger: a query can be paired with a finite reply and boundary row without becoming a closed-substrate observation.

Falsifiable prediction: No accepted response ledger can certify a closed-substrate observation unless the same packet also displays the boundary row separating the response from substrate-internal orbit data.

Independence witness: closureuniversalityquadrant, oracleaugmentedsubstrate, oraclesubstrate-boundary, universalclosedsubstrate, presburger-subuniversal; the response ledger carries a query/response row that the quadrant map and closed-substrate witnesses lack, while boundary chapters do not classify response equality.

Definition 1015.1 (Oracle-response ledger carrier)**.** *An* $\mathsf{OracleResponseLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (S, Q, R, B, F, E, H, C, P, N)$$

with the following displayed rows:

1. *S is the substrate row whose oracle-facing request is being inspected;*
2. *Q is the finite oracle-query row, recording the query name, request site, and local input slice;*
3. *R is the response row, recording the finite reply token, response name, and point of consumption;*
4. *B is the boundary row, separating the response from closed substrate-internal orbit observations;*
5. *F is the refusal row, excluding closed-substrate certification, quotient-response equality, hidden oracle correctness, and host-semantic conversion of the response;*
6. *E is the route-exactness row, recording that any public response read must pass through Q, R, B, F before it reaches a quadrant or boundary consumer;*
7. *H records componentwise* hsame *transports for S, Q, R, B, F, E, P, N;*
8. *C records displayed* Cont *routes through the query, response, boundary, refusal, and response-ledger reads;*

9. *P is the* Pkg *provenance over* $\mathsf{OracleResponseLedger}^{\uparrow}$, $\mathsf{OracleAugmentedSubstrate}^{\uparrow}$, $\mathsf{OracleSubstrateBoundary}^{\uparrow}$, $\mathsf{ClosureUniversalityQuadrant}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{OracleResponseLedger}^{\uparrow}}$ *row.*

The local classifier compares accepted ledgers only through these rows. It has no coordinate for treating the response as a closed orbit record, no hidden oracle-correctness proof, and no quotient equality of response behaviours.

Lean4 ✓ `BEDC.Derived.OracleResponseLedgerUp.OracleResponseLedgerTasteGate single carrier alignment`

Theorem 1015.2 (Oracle-response ledger NameCert obligations)**.** *For the carrier of Definition 1015.1, the local* $\mathsf{NameCert}_{\mathsf{OracleResponseLedger}^{\uparrow}}$ *surface consists exactly of seven finite obligation rows:*

1. *carrier exposure for $L = (S, Q, R, B, F, E, H, C, P, N)$;*
2. *query accountability through the displayed oracle-query row Q;*
3. *response accountability through the displayed reply row R;*
4. *boundary accountability through B, separating the response from closed-substrate observations;*
5. *refusal accountability through F, excluding closed replay, hidden oracle correctness, quotient response equality, and host semantic conversion;*
6. *route exactness through E, C, requiring public response consumers to read the query, response, boundary, and refusal rows in the same packet;*
7. *componentwise stability, provenance, and local naming through H, P, N.*

Thus an oracle response is accepted only as a finite BEDC ledger over query, response, boundary, refusal, route, provenance, and naming rows.

Proof. Carrier exposure is projection from Definition 1015.1. The accepted packet displays the substrate row, query row, response row, boundary row, refusal row, route-exactness row, transports, routes, provenance, and local name as its only public coordinates.

Query and response accountability are separate finite reads. The row Q records the request site and local input slice, while R records the reply token and point of consumption. Neither row reconstructs the other from the substrate row alone.

Boundary and refusal accountability keep the response outside the closed observation channel. The boundary chapter supplies the external-channel separation, and the oracle-augmented substrate chapter supplies the call and transcript surface. The refusal row records that closed replay, hidden oracle correctness, quotient response equality, and host semantic conversion are not available inside the ledger.

Finally E, C, H, P, N route, transport, package, and name the same finite packet. Any public response consumer must therefore pass through the displayed query, response, boundary, and refusal rows before using the ledger, and no unlisted closed-substrate or oracle-correctness coordinate remains. □

Theorem 1015.3 (Oracle-response ledger boundary non-escape)**.** *Every public response read exported by an accepted* $\mathsf{OracleResponseLedger}^{\uparrow}$ *packet factors through the finite route*

$$S, Q, R, B, F, E, H, C, P, N.$$

The route can certify a finite query/response ledger at an oracle boundary, but it exports no closed-substrate observation for the response, no hidden oracle-correctness theorem, no quotient equality of response streams, no host semantic equality, and no closed universal substrate witness.

Proof. Begin with the carrier projection. The only response-facing coordinates are the substrate row S, query row Q, response row R, boundary row B, refusal row F, route-exactness row E, transports H, continuations C, provenance P, and local name N.

The boundary row must be displayed before a response can be read as an oracle response. By chapter 956, the oracle-facing edge is separated from closed substrate observations, and by chapter 951 the call and transcript remain explicit oracle rows rather than substrate-internal orbit data.

The refusal row then blocks the remaining escape modes. A closed universal substrate witness, quotient response equality, hidden oracle-correctness theorem, or host semantic equality would require a coordinate not present in L.

Thus the public response ledger is exactly the displayed finite route. It may serve quadrant and boundary consumers as oracle-response evidence, but only as finite BEDC data with the boundary and refusal rows still visible. □

The later Lean `TasteGate.lean` development for $\mathsf{OracleResponseLedger}^{\uparrow}$ must provide explicit $\mathsf{Nontrivial\ OracleResponseLedger}^{\uparrow}$ and $\mathsf{FieldFaithful\ OracleResponseLedger}^{\uparrow}$ instances for the displayed carrier. These instances must preserve the query row, response row, boundary row, refusal row, route-exactness row, transport rows, continuation routes, package provenance, and local naming row.

Closure status for $\mathsf{NameCert}_{\mathsf{OracleResponseLedger}^{\uparrow}}$.

Constructive story: An $\mathsf{OracleResponseLedger}^{\uparrow}$ packet is generated from a substrate row, oracle-query row, response row, boundary row, refusal row, route-exactness row, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{OracleResponseLedger}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1015.1, Definition 1015.2, and Definition 1015.3 specify the finite oracle-response ledger certificate surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{OracleResponseLedger}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, oracle correctness, closed replay of oracle responses, quotient response equality, host semantic equality, or physical realizability of oracle channels.

Upgrade path: Obligation closure requires checked carrier admission, query accountability, response accountability, boundary accountability, refusal exactness, route exactness, nontriviality, and field faithfulness for the same response ledger.

Chapter 1016

A Concrete Naming Certificate for $\mathsf{FinitePrefixAutomaton}^{\uparrow}$

The $\mathsf{FinitePrefixAutomaton}^{\uparrow}$ interface names the standard finite automaton object at the level of bounded prefix runs. It is the finite-run sibling of chapter 351, the bounded continuation surface of chapter 482, and the grammar-facing comparison boundary of chapter 356. It realizes the operational reading of chapter 9365 without importing an external language quotient, a host transition evaluator, or an infinite trace semantics.

Definition 1016.1 (FinitePrefixAutomaton carrier)**.** *A* $\mathsf{FinitePrefixAutomaton}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (Q, q_0, A, T, W, R, E, H, C, P, N)$$

with the following displayed coordinates:

1. *Q is the finite state-row ledger;*
2. *q_0 is the initial state row;*
3. *A is the accepting-state subledger of Q;*
4. *T is the finite transition table whose rows have source state, input mark, target state, and displayed* Cont *witness;*
5. *W is the finite prefix word ledger, written as a finite list of* BMark *input rows;*
6. *R is the prefix-run ledger, listing the state row reached after each visible prefix of W;*
7. *E is the endpoint and acceptance row, recording the final state read and its accepting-state membership result;*
8. *H stores componentwise* hsame *transports for states, marks, transition rows, prefix positions, endpoint rows, acceptance rows, provenance, and local naming;*
9. *C stores the displayed* Cont *routes by which consumers replay each prefix transition and inspect the endpoint;*
10. *P is the* Pkg *provenance over* BHist, BMark, hsame, Cont, *prefix lists, acceptance rows, and* $\mathsf{NameCert}$*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{FinitePrefixAutomaton}^{\uparrow}}$ *row.*

The carrier exposes one bounded finite-prefix run. It contains no quotient of accepted languages, no host automaton semantics, no unlisted transition rule, and no infinite continuation trace.

Lean4 (definition) `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonUp`

Definition 1016.2 (FinitePrefixAutomaton classifier)**.** *The* $\mathsf{FinitePrefixAutomaton}^{\uparrow}$ *classifier accepts a packet* $F = (Q, q_0, A, T, W, R, E, H, C, P, N)$ *exactly when the prefix ledger* R *starts at* q_0*, every successive prefix step is witnessed by a displayed row of* T *and a corresponding* Cont *route in* C*, the endpoint row in* E *is the last row of* R*, and the acceptance bit in* E *is read from membership in* A*. The classifier reads only the displayed state, mark, transition, run, endpoint, transport, continuation, package, and local naming rows.*

Lean4 (definition) `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonClassifier`

Theorem 1016.3 (FinitePrefixAutomaton NameCert obligation surface)**.** *The local* $\mathsf{NameCert}_{\mathsf{FinitePrefixAutomaton}^{\uparrow}}$ *surface for the carrier of Definition 1016.1 consists of seven finite obligations:*

1. *carrier admission for the displayed packet* $F = (Q, q_0, A, T, W, R, E, H, C, P, N)$*;*
2. *prefix-source binding of the word ledger* W *and initial state row* q_0*;*
3. *transition exactness for every adjacent prefix-run row through the displayed table* T *and the corresponding* Cont *witness;*
4. *endpoint exactness, stating that* E *reads the last row of* R*;*
5. *acceptance exactness, stating that the acceptance bit in* E *is precisely the displayed membership read in* A*;*
6. *componentwise stability through* H *and replay through* C*;*
7. *non-escape, stating that every downstream finite-prefix read factors through* $Q, q_0, A, T, W, R, E, H, C, P, N$ *and cannot consult a host evaluator, language quotient, unlisted transition rule, or infinite trace.*

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonNameCertObligationSurface`

Proof. Carrier admission is projection from Definition 1016.1. The packet already displays its state ledger, initial state, accepting ledger, transition table, prefix word, run ledger, endpoint row, transports, continuation routes, provenance, and local name.

The prefix-source, transition, endpoint, and acceptance obligations are read from W, R, T, E, A. Each step of R is licensed by a row of T carrying the displayed Cont witness, and the final read is the endpoint row named in E.

Stability and replay are supplied by H and C. Since the packet has no coordinate for an external evaluator, quotient language, unlisted transition rule, or infinite trace, the non-escape obligation follows from the carrier boundary. □

Theorem 1016.4 (FinitePrefixAutomaton transition exactness obligation)**.** *For an accepted* $\mathsf{FinitePrefixAutomaton}$ *carrier* $F = (Q, q_0, A, T, W, R, E, H, C, P, N)$*, each adjacent prefix-run step in* R *is witnessed by a displayed row of* T *whose source state, input mark, target state, and* Cont *route are the rows read by the corresponding prefix window of* W*.*

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonCarrier transition exactness obligation`

Proof. Project the accepted carrier through Definition 1016.1. The transition table T, prefix word W, run ledger R, and continuation ledger C are separate displayed coordinates.

Apply the transition row of Definition 1016.3. It requires every adjacent run step to read a row of T and the matching Cont route in C, so no host transition evaluator or unlisted rule can witness the step. □

Theorem 1016.5 (FinitePrefixAutomaton endpoint exactness obligation)**.** *For an accepted* FinitePrefixAutomaton$^{\uparrow}$ *carrier* $F = (Q, q_0, A, T, W, R, E, H, C, P, N)$*, the endpoint row* E *is exactly the last displayed row of the finite prefix-run ledger* R*.*

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonCarrier endpoint exactness obligation`

Proof. Read the endpoint coordinate of the carrier. The row E is displayed independently of the transition table and cannot be supplied by an ambient evaluator.

Use the endpoint obligation in Definition 1016.3. That obligation identifies E with the last row of R, while H only transports the displayed endpoint row and C only replays the displayed route. □

Theorem 1016.6 (FinitePrefixAutomaton acceptance exactness obligation)**.** *For an accepted* FinitePrefixAutomaton$^{\uparrow}$ *carrier* $F = (Q, q_0, A, T, W, R, E, H, C, P, N)$*, the acceptance bit recorded in* E *is precisely the displayed membership read of the endpoint state in the accepting-state sub-ledger* A*.*

Proof. Project the accepting ledger A and endpoint row E from the carrier. These rows are part of the finite packet, so acceptance is not read from a quotient language or external automaton semantics.

Apply the acceptance obligation in Definition 1016.3. It binds the bit stored in E to membership in A for the endpoint state, and the remaining transport, replay, provenance, and naming rows preserve that displayed read. □

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonCarrier acceptance exactness obligation`

Theorem 1016.7 (FinitePrefixAutomaton displayed prefix-run determinism)**.** *Let*

$$F = (Q, q_0, A, T, W, R, E, H, C, P, N)$$

and

$$F' = (Q, q_0, A, T, W, R', E', H', C', P', N')$$

be accepted FinitePrefixAutomaton$^{\uparrow}$ *carriers with the same state ledger* Q*, initial row* q_0*, accepting ledger* A*, transition table* T*, and word ledger* W*. If the displayed* Cont *replay rows in* C *and* C' *match componentwise along the prefix windows of* W*, then the prefix-run ledgers* R *and* R' *are* hsame*-equivalent at every displayed prefix position, and the endpoint rows* E *and* E' *name the same final state row.*

Proof. The empty prefix is forced by the shared initial row q_0. Both accepted carriers therefore begin their displayed run ledger at the same state row, with the componentwise transport rows recording the allowed hsame read.

For the successor prefix step, project transition exactness from Definition 1016.4. The same table T, the same input mark from W, and the matching replay rows in C and C' force both run

ledgers to use the same displayed transition row. Induction over the finite prefix ledger propagates the hsame comparison through every prefix position.

Finally apply endpoint exactness from Definition 1016.5. Since each endpoint is the last displayed row of its run ledger, the prefixwise comparison identifies E and E' as the same final-state read inside the finite packet boundary. □

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonCarrier prefix run displayed determinism`

Theorem 1016.8 (FinitePrefixAutomaton prefix-run nonescape)**.** *Any downstream* RegularLanguage$^{\uparrow}$ *or* ContinuationAutomaton$^{\uparrow}$ *read of an accepted* FinitePrefixAutomaton$^{\uparrow}$ *prefix run consults only the rows*

$$Q, q_0, A, T, W, R, E, H, C, P, N.$$

It cannot use a host evaluator, a language quotient, an unlisted transition, or an infinite trace to justify a transition step, endpoint row, or acceptance bit.

Proof. Start with the NameCert obligation surface of Definition 1016.3. It lists carrier admission, prefix-source binding, transition exactness, endpoint exactness, acceptance exactness, stability, replay, and non-escape as finite obligations over the displayed packet rows.

The transition, endpoint, and acceptance exactness theorems then identify the only admissible reads of a run step, final row, and acceptance bit. Each read is projected from $Q, q_0, A, T, W, R, E, H, C, P, N$, with H transporting the displayed rows and C replaying only the displayed continuation witnesses.

A RegularLanguage$^{\uparrow}$ consumer may read the finite word, state, endpoint, and acceptance rows; a ContinuationAutomaton$^{\uparrow}$ consumer may read the Cont-labelled transition rows and replay routes. Neither consumer receives a coordinate for a host evaluator, quotient language, unlisted transition rule, or infinite trace, so those objects cannot enter the prefix-run justification. □

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonCarrier prefix run nonescape`

Theorem 1016.9 (FinitePrefixAutomaton prefix-run determinacy)**.** *For an accepted* FinitePrefixAutomaton$^{\uparrow}$ *carrier* $F = (Q, q_0, A, T, W, R, E, H, C, P, N)$*, the displayed prefix word* W *and transition table* T *determine the prefix-run ledger* R *componentwise inside the packet. If another accepted run ledger* R' *is admitted over the same* $Q, q_0, A, T, W, E, H, C, P, N$*, then each prefix position of* R *is* hsame *to the corresponding prefix position of* R' *through the displayed transport rows in* H*.*

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonCarrier prefix run determinacy`

Proof. Begin at the empty prefix. Both run ledgers must start at the displayed initial state row q_0 by the prefix-source obligation of Definition 1016.3.

For a nonempty prefix, read the preceding state row and the next input mark from W. The transition exactness obligation forces the next state to be the target of the displayed row of T carrying the matching Cont witness. Thus the two ledgers have the same displayed source, mark, transition row, and target at that position.

Apply the componentwise transport rows in H at each prefix position. They identify the corresponding state rows inside the packet, while C only replays the already displayed transition route. No host transition function or unlisted rule is available, so the determinacy claim stays internal to the finite ledger. □

Theorem 1016.10 (FinitePrefixAutomaton regular-language sibling bridge)**.** *Every accepted* FinitePrefixAutomato *packet supplies exactly the bounded finite-run surface consumed by* RegularLanguage$^{\uparrow}$ *and* ContinuationAutomaton$^{\uparrow}$ *readers: the* RegularLanguage$^{\uparrow}$ *side reads the same finite state, prefix word, endpoint, and acceptance rows, while the* ContinuationAutomaton$^{\uparrow}$ *side reads the same* Cont*-labelled transition rows, componentwise* hsame *transports, replay routes, package row, and local* NameCert *row. The bridge exposes no quotient language, no context-free derivation tree, no host evaluator, and no infinite continuation trace.*

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomaton regularlanguage sibling bridge`

Proof. Read the finite automaton side through chapter 351. The accepted prefix word, finite state rows, endpoint row, and acceptance ledger are already displayed by Q, q_0, A, W, R, E.

Read the continuation side through chapter 482. Each transition row in T carries its displayed Cont witness, while H, C, P, N provide transport, replay, provenance, and local naming.

The context-free sibling chapter 356 may compare this bounded run with grammar yields only through the exposed finite word and endpoint surface. Since the packet has no coordinate for language quotienting, derivation trees, host evaluation, or infinite traces, the sibling bridge is exactly the finite-prefix route listed above. □

Theorem 1016.11 (FinitePrefixAutomaton obligation window)**.** *Every accepted* FinitePrefixAutomaton$^{\uparrow}$ *prefix-window read exposes exactly the finite rows*

$$Q, q_0, A, T, W, R, E, H, C, P, N.$$

The window supplies the state ledger, initial row, accepting-state ledger, transition table, finite word, run ledger, endpoint and acceptance row, componentwise transport, displayed replay, provenance, and local NameCert *row, and it supplies no host evaluator, quotient language equality, unlisted transition rule, or infinite trace.*

Proof. Project the accepted carrier through Definition 1016.1. The carrier displays precisely $Q, q_0, A, T, W, R, E, H, C, P, N$ and has no additional coordinate through which a consumer could read outside automaton semantics.

Apply the classifier and obligation surface of Definition 1016.2 and Definition 1016.3. They bind prefix-source, transition, endpoint, acceptance, stability, replay, provenance, and local naming obligations to the same displayed rows.

Finally use transition exactness, endpoint exactness, acceptance exactness, and the sibling bridge, Definition 1016.4, Definition 1016.5, Definition 1016.6, and Definition 1016.10. Those theorems keep every downstream finite-prefix read inside the listed packet and exclude host evaluators, quotient language equality, unlisted transition rules, and infinite traces. □

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonObligationWindow`

Theorem 1016.12 (FinitePrefixAutomaton deterministic readback)**.** *For accepted* FinitePrefixAutomaton$^{\uparrow}$ *packets with the same displayed table T and finite word W, the same prefix-window read forces the same displayed endpoint row and the same acceptance row. The conclusion is computed by induction over finite prefixes using only $Q, q_0, A, T, W, R, E, H, C, P, N$.*

Proof. For the empty prefix, the carrier and classifier force the run ledger to begin at the displayed initial row q_0. Thus two accepted reads with the same table and word have the same initial row inside the packet boundary.

For the successor prefix, apply transition exactness from Definition 1016.4. The same transition table row and the same input mark from W force the same displayed target row, while H and C only transport and replay that finite transition evidence.

Induction over the finite word ledger gives the same displayed run endpoint. Endpoint exactness and acceptance exactness, Definition 1016.5 and Definition 1016.6, then force the endpoint row and acceptance row read from E and A. No host evaluator, quotient language equality, unlisted transition rule, or infinite trace is available to change the result. □

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonDeterministicReadback`

Theorem 1016.13 (FinitePrefixAutomaton regular-language handoff)**.** *Every* $\mathsf{RegularLanguage}^{\uparrow}$ *or* $\mathsf{ContinuationAutomaton}^{\uparrow}$ *consumer of an accepted* $\mathsf{FinitePrefixAutomaton}^{\uparrow}$ *packet receives only finite word rows, transition rows, endpoint rows, acceptance rows, transport rows, replay rows, provenance rows, and local naming rows from*

$$Q, q_0, A, T, W, R, E, H, C, P, N.$$

The handoff exports no host evaluator, quotient language equality, unlisted transition rule, infinite trace, or derivation-tree comparison.

Proof. Read the carrier and classifier first. They expose the finite word ledger W, transition table T, run ledger R, endpoint and acceptance row E, and the accepting-state ledger A, with transport, replay, provenance, and naming supplied by H, C, P, N.

Apply the deterministic readback theorem above together with Definition 1016.9. The consumer receives a finite endpoint and acceptance read determined by the displayed word and transition table, not by an external evaluator.

Finally apply the regular-language sibling bridge of Definition 1016.10. The $\mathsf{RegularLanguage}^{\uparrow}$ side reads only finite word, endpoint, and acceptance data, and the $\mathsf{ContinuationAutomaton}^{\uparrow}$ side reads only the displayed transition and replay rows. Quotient language equality, unlisted transition rules, infinite traces, and derivation-tree comparisons remain outside the handoff. □

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomaton regular language handoff`

Theorem 1016.14 (FinitePrefixAutomaton public obligation certificate)**.** *The carrier, classifier, obligation surface, transition exactness, endpoint exactness, acceptance exactness, deterministic readback, and regular-language handoff together expose the full finite prefix automaton public obligation certificate over*

$$Q, q_0, A, T, W, R, E, H, C, P, N.$$

The certificate exports no host evaluator, quotient language equality, unlisted transition, derivation tree, or infinite trace.

Proof. Read the carrier and classifier of Definition 1016.1 and Definition 1016.2. They make $Q, q_0, A, T, W, R, E, H, C, P, N$ the displayed packet surface and leave no outside automaton coordinate.

Apply the NameCert obligation surface of Definition 1016.3. It binds carrier admission, prefix-source exposure, transition rows, endpoint and acceptance rows, transport, replay, provenance, and local naming to that same packet.

Use transition, endpoint, and acceptance exactness from Definition 1016.4, Definition 1016.5, and Definition 1016.6. These theorems force every accepted read through the displayed transition table, run ledger, endpoint row, and accepting-state row.

Finally apply deterministic readback and the regular-language handoff, Definition 1016.12 and Definition 1016.13. They keep all public consumers on the finite prefix route and exclude host evaluators, quotient language equality, unlisted transitions, derivation trees, and infinite traces. □

Lean4 ✓ `BEDC.Derived.FinitePrefixAutomatonUp.FinitePrefixAutomatonPublicObligationCertificate`

Closure status for $\mathsf{NameCert}_{\mathsf{FinitePrefixAutomaton}\uparrow}$.

Constructive story: A $\mathsf{FinitePrefixAutomaton}^{\uparrow}$ packet is generated from a finite automaton row, initial state, accepted prefix word, transition ledger, endpoint row, acceptance ledger, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The BHist carrier exposes a bounded run: each transition is read as a finite continuation step, the endpoint is determined by the displayed prefix, and the classifier admits acceptance only through the recorded endpoint and ledger rows. The construction therefore gives a finite-prefix automaton route that can be compared with adjacent language packets without quotienting languages.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FinitePrefixAutomaton}\uparrow}, \mathsf{obligation})$

Scope closed: This chapter binds the finite-prefix automaton carrier, obligation surface, determinacy, non-escape, and sibling bridge theorem.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FinitePrefixAutomaton}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: It does not claim language equality, derivation-tree equivalence, host evaluator correctness, infinite traces, or quotient automaton semantics.

Upgrade path: Scoped closure requires binding the displayed obligation certificate to the exact BEDC primitives and sibling dependencies already displayed in the chapter.

Chapter 1017

A Concrete Naming Certificate for $\mathsf{SharedTailNormalizer}^{\uparrow}$

The $\mathsf{SharedTailNormalizer}^{\uparrow}$ packet realizes the Real and Completion route of chapter 9238 as the finite operation row that turns two displayed tail schedules into one shared window route. It sits between the shared-tail input surfaces of chapter 893, chapter 560, and chapter 699, and the finite route through chapter 126, chapter 301, chapter 291, and chapter 38. The packet is a normalizer for two Real-completion tail schedules, not a quotient stream, host equality, selected limit, or ambient completeness principle.

Falsifiable prediction: If two displayed tail schedules cannot be normalized to one shared finite window route, the packet cannot feed both the RegularCauchyTailFiber and RealTailAgreementSeal consumers.

Independence witness: regular-cauchy-tail-fiber, regular-cauchy-tail-meet, realtailagreementseal, regularcauchyselectorbudget, cauchysharedtailmodulus: these siblings expose common fiber, meet, seal, selector, or shared-modulus rows, while SharedTailNormalizerUp exposes the operation row that normalizes two schedules into one shared finite route.

Definition 1017.1 (Shared tail normalizer carrier)**.** *A* $\mathsf{SharedTailNormalizer}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (A, B, M, W, D, R, F, S, H, C, P, N)$$

with the following displayed rows:

1. *A and B are the two incoming tail-schedule rows, each already displayed as a finite regular-Cauchy source route;*
2. *M is the shared threshold row that records the common finite bound serving both schedules;*
3. *W is the* $\mathsf{StreamName}^{\uparrow}$ *window opened at the shared threshold;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger attached to the shared window;*
5. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained from the window and dyadic ledger;*
6. *F is the shared-fiber row consumed by* $\mathsf{RegularCauchyTailFiber}^{\uparrow}$*;*
7. *S is the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *and* $\mathsf{Real}^{\uparrow}$ *seal route reached after W, D, R, F have been displayed;*

8. *H records componentwise* hsame *transport for both schedules, the shared threshold, window, dyadic ledger, readback, fiber, seal route, provenance, and local name;*
9. *C records the displayed* Cont *route that normalizes A, B through M, opens W, reads D, R, F, and reaches S;*
10. *P is the* Pkg *provenance over* $\mathsf{RegularCauchyTailFiber}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{SharedTailNormalizer}^{\uparrow}}$ *row.*

The carrier contains no second private threshold, quotient stream equality, host real equality, selected limit, hidden tail selector, detached Real seal, or ambient completeness theorem.

Lean4 (definition) `BEDC.Derived.SharedTailNormalizerUp.SharedTailNormalizerUp`

Theorem 1017.2 (Shared tail normalizer NameCert obligations)**.** *For the carrier of Definition 1017.1, the local* $\mathsf{NameCert}_{\mathsf{SharedTailNormalizer}^{\uparrow}}$ *surface consists exactly of carrier admission for $T = (A, B, M, W, D, R, F, S, H, C, P, N)$, paired schedule exposure through A, B, shared threshold exposure through M, StreamName window service through W, DyadicRatCore tolerance accounting through D, RegSeqRat readback through R, shared-fiber exposure through F, RealTailAgreementSeal and RealUp handoff through S, componentwise transport through H, displayed replay through C, package provenance through P, and local naming through N.*

Proof. Project the displayed carrier. The rows $A, B, M, W, D, R, F, S, H, C, P, N$ are the complete public packet, so each consumer-facing read is one of the listed finite coordinates.

The source schedules are exposed first. The shared threshold M is then the only row that can serve both schedules, and the window W is opened through that same threshold before any dyadic ledger, regular readback, fiber, or Real-facing seal is available.

The finite route continues through chapter 126, chapter 291, and chapter 301. The shared-fiber read is the consumer surface of chapter 893, and the seal route is read through chapter 699 and chapter 38.

Since the carrier has no coordinate for a private threshold, quotient stream equality, host real equality, selected limit, hidden selector, detached seal, or ambient completeness, the listed rows exhaust the local NameCert obligations. □

Theorem 1017.3 (Shared tail normalizer common threshold factorization)**.** *Every accepted* $\mathsf{SharedTailNormalizer}^{\uparrow}$ *packet factors both incoming schedules through the one finite route*

$$A, B, M, W, D, R, F, S, H, C, P, N.$$

The $\mathsf{RegularCauchyTailFiber}^{\uparrow}$ *consumer reads F only after the shared StreamName, DyadicRatCore, and RegSeqRat rows W, D, R have been displayed, and the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *consumer reads S only after the same shared-fiber row F has been exposed.*

Proof. Begin with the paired schedule rows. Projection gives A and B as the only incoming schedules and M as the only common threshold row, so the route has no private schedule-specific threshold to branch through.

Next factor through the finite window route. The shared threshold opens the $\mathsf{StreamName}^{\uparrow}$ window W, the same window carries the $\mathsf{DyadicRatCore}^{\uparrow}$ ledger D, and the regular rational readback R is obtained before any shared-fiber or Real-facing seal row is visible.

Now use the sibling surfaces. The row F is the common fiber consumed by chapter 893, while chapter 560 supplies the shared-tail threshold discipline that the normalizer records as M.

Finally read S, H, C, P, N. The seal route reaches chapter 699 and chapter 38 only after F is exposed, and the transport, continuation, provenance, and local naming rows replay that same finite route. □

The Lean follow-up for this packet will provide `Nontrivial SharedTailNormalizerUp` with `witness_pair` and `FieldFaithful SharedTailNormalizerUp` by constructor-field injection over the two schedules, shared threshold, StreamName window, DyadicRatCore ledger, RegSeqRat readback, shared fiber, Real seal route, transport, continuation, provenance, and local NameCert rows.

Closure status for $\mathsf{NameCert}_{\mathsf{SharedTailNormalizer}^{\uparrow}}$.

Constructive story: A $\mathsf{SharedTailNormalizer}^{\uparrow}$ packet is generated from two displayed tail schedules, one shared threshold, one StreamName window, one DyadicRatCore ledger, one RegSeqRat readback, one shared-fiber row, one RealTailAgreementSeal and RealUp seal route, componentwise transports, displayed replay, package provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SharedTailNormalizer}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1017.1, Definition 1017.2, and Definition 1017.3 bind the finite shared-tail normalizer carrier, local NameCert obligations, and common threshold factorization route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SharedTailNormalizer}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close quotient stream equality, host real equality, selected limits, ambient Real completeness, Lean verification, axiom-clean audit, or bridge checking for $\mathsf{SharedTailNormalizer}^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, paired schedule exposure, shared-threshold factorization, StreamName and DyadicRatCore service rows, RegSeqRat readback, shared-fiber handoff, RealTailAgreementSeal handoff, and constructor-field faithfulness for the same finite packet.

Chapter 1018

A Concrete Naming Certificate for $\mathsf{AxisBoundaryLimitRefusal}^{\uparrow}$

The $\mathsf{AxisBoundaryLimitRefusal}^{\uparrow}$ packet isolates the AxisZeckendorf boundary token row that chapter 9350 refuses to read as a limit or supremum. It sits beside the dimension-lift boundary packet of chapter 571 and the FullAxis-to-Real refusal packet of chapter 602: those siblings aggregate broader refusal surfaces, while this carrier names only the boundary-token limit-refusal row and its non-escape routes. As an ai packet, it bundles the cannot-claim registry, dimension-lift boundary, FullAxis-to-Real refusal, AxisNat replacement refusal, and carry-normalization surfaces into one boundary-token refusal ledger.

Definition 1018.1 (Axis boundary limit-refusal carrier)**.** *An* $\mathsf{AxisBoundaryLimitRefusal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (Z, L, R, Q, H, C, P, N)$$

with the following displayed rows:

1. *Z is the AxisZeckendorf boundary-token row, including the* `boundary_01` *address from the cannot-claim registry;*
2. *L is the limit-refusal row, recording that the boundary token is not a limit or supremum carrier;*
3. *R is the Real-facing refusal row, recording that the same boundary does not provide* $\mathsf{Real}^{\uparrow}$ *equality, a Cauchy limit, or a completion row;*
4. *Q is the completeness-refusal row, recording that no total completeness principle is exported by the packet;*
5. *H records componentwise* hsame *transports preserving the boundary, limit-refusal, Real-facing refusal, completeness-refusal, provenance, and local naming rows;*
6. *C records the displayed* Cont *routes by which a consumer reads Z, L, R, Q, H, P, N without leaving the finite packet;*
7. *P is the* Pkg *provenance over* $\mathsf{AxisZeckendorfCannotClaim}^{\uparrow}$, $\mathsf{DimLiftBoundary}^{\uparrow}$, $\mathsf{FullAxisRealRefusal}^{\uparrow}$, $\mathsf{AxisNatReplacementRefusal}^{\uparrow}$, $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{AxisBoundaryLimitRefusal}^{\uparrow}}$ *row.*

The carrier exports only this boundary-token refusal packet. It contains no limit, supremum, $\mathsf{Real}^{\uparrow}$ *equality, Cauchy completion, completeness principle, or bridge to an ambient real object.*

Theorem 1018.2 (Axis boundary limit-refusal NameCert obligations)**.** *For the carrier of Definition 1018.1, the local* $\mathsf{NameCert}_{\mathsf{AxisBoundaryLimitRefusal}^{\uparrow}}$ *surface consists exactly of five finite obligations:*

1. *carrier admission for the displayed packet* $B = (Z, L, R, Q, H, C, P, N)$*;*
2. *boundary-token exposure, stating that* Z *is the only AxisZeckendorf boundary row exported by the packet;*
3. *limit-refusal exactness, stating that* L *refuses limit and supremum readings of the boundary token;*
4. *Real and completeness refusal, stating that* R, Q *refuse* $\mathsf{Real}^{\uparrow}$ *equality, Cauchy completion, and completeness readings;*
5. *local naming exhaustion, stating that* H, C, P, N *preserve and name only the displayed refusal rows.*

Proof. Carrier admission is projection of the tuple in Definition 1018.1. The rows Z, L, R, Q, H, C, P, N are all displayed coordinates of one finite packet.

Boundary-token exposure reads Z against the cannot-claim registry of chapter 9350. The packet has no second boundary coordinate from which a limit object could be selected.

The refusal rows are separate. The row L blocks limit and supremum readings, while R and Q block $\mathsf{Real}^{\uparrow}$ equality, Cauchy completion, and completeness readings.

Finally, H, C, P, N transport, route, cite, and name those same rows. Since no coordinate names a limit, supremum, real equality, completion, or completeness object, the five obligations exhaust the local NameCert surface. □

Theorem 1018.3 (Axis boundary limit-refusal non-escape)**.** *Every consumer read of an accepted* $\mathsf{AxisBoundaryLimitRefusal}^{\uparrow}$ *packet factors through*

$$Z \to L \to R \to Q \to H \to C \to P \to N.$$

The read may expose the boundary token and its refusal rows, but it admits no consumer route to a limit, supremum, $\mathsf{Real}^{\uparrow}$ *equality, Cauchy completion, or completeness row.*

Proof. Start with the carrier of Definition 1018.1. It lists the boundary token, limit-refusal row, Real-facing refusal row, completeness-refusal row, transport, continuation, provenance, and local name as the whole packet.

Apply Definition 1018.2. The boundary-token exposure and refusal exactness clauses force every consumer read through Z, L, R, Q before the transport and provenance rows are consumed.

The sibling packets chapter 571 and chapter 602 provide broader refusal contexts, but they do not add a hidden limit or real-completion row to this carrier. Thus the displayed route exhausts the accepted packet. □

Lean4 ✓ `BEDC.Derived.AxisBoundaryLimitRefusalUp.AxisBoundaryLimitRefusalCarrier nonescape`

Falsifiable prediction: Every accepted AxisBoundaryLimitRefusalUp packet exposes a boundary-token refusal row and admits no consumer route to a limit, supremum, RealUp equality, or completeness row.

Independence witness: axiszeckendorfcannotclaim, dimliftboundary, fullaxisrealrefusal, axisnatreplacementrefusal, zeckendorfcarrynormalization: none is bijective because this carrier isolates the boundary-token refusal row, while the siblings respectively aggregate registry entries,

dimension-lift refusal, FullAxis-to-Real refusal, AxisNat replacement refusal, and carry-normalization evidence.

The packet composes axiszeckendorfcannotclaim, dimliftboundary, fullaxisrealrefusal, axisnatreplacementrefusal, and zeckendorfcarrynormalization into the displayed boundary-token refusal surface.

Closure status for $\mathsf{NameCert}_{\mathsf{AxisBoundaryLimitRefusal}^{\uparrow}}$.

Constructive story: An $\mathsf{AxisBoundaryLimitRefusal}^{\uparrow}$ packet is generated from an AxisZeckendorf boundary-token row, a limit-refusal row, a Real-facing refusal row, a completeness-refusal row, componentwise hsame transports, displayed Cont routes, provenance, and local naming. The BHist carrier first exposes the boundary token, then records that the token is not a limit or supremum carrier, and then blocks Real equality, Cauchy completion, and completeness readings. The classifier is a finite refusal route: every accepted consumer sees the boundary token only through the displayed refusal ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AxisBoundaryLimitRefusal}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the axis boundary limit-refusal carrier, its NameCert obligations, and the non-escape theorem.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{AxisBoundaryLimitRefusal}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim a limit, supremum, RealUp equality, Cauchy completion, completeness principle, or ambient real bridge.

Upgrade path: To reach obligationClosure, formalize the boundary-token refusal route and prove that no accepted consumer extracts the excluded limit rows.

Chapter 1019

A Concrete Naming Certificate for $\mathsf{ContourReversalLedger}^{\uparrow}$

The $\mathsf{ContourReversalLedger}^{\uparrow}$ packet realizes the reversal law surface of chapter 9340 as finite NameCert data. It reads the contour-operation packet of chapter 521, displays the original and reversed piecewise-linear contour rows, and exposes the negated $\mathsf{Complex}^{\uparrow}$ output only through the same reversal route.

Definition 1019.1 (Contour reversal ledger carrier)**.** *A* $\mathsf{ContourReversalLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (G, G^{-}, F, I, H, C, P, N)$$

with the following displayed rows:

1. *G is the source* $\mathsf{PLContour}$ *row, including the finite endpoint list and segment rows read by the contour-integral operation surface;*
2. *G^{-} is the reversed* $\mathsf{PLContour}$ *row obtained by reading the same endpoints and segment rows in the displayed opposite orientation;*
3. *F is the accepted* $\mathsf{ContourIntegralOperation}^{\uparrow}$ *row for the integrand and the source contour data that supplies the operation-law ledger containing reversal;*
4. *I is the negated* $\mathsf{Complex}^{\uparrow}$ *output row certified as the value of the same integrand along G^{-} after the output row for G has been read;*
5. *H records componentwise* hsame *transports for G, G^{-}, F, I and for the provenance and local naming rows;*
6. *C records the displayed* Cont *routes from G to G^{-}, from F to the reversal-law ledger, and from the source output row to the negated* $\mathsf{Complex}^{\uparrow}$ *output row I;*
7. *P records* Pkg *provenance over* $\mathsf{PLContour}$, $\mathsf{ContourIntegralOperation}^{\uparrow}$, $\mathsf{ContourIntegralSocket}^{\uparrow}$, $\mathsf{ContourSumWindow}^{\uparrow}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{Complex}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ContourReversalLedger}^{\uparrow}}$ *row.*

The carrier has no coordinate for a host smooth path, a quotient path class, an ambient analytic-continuation principle, an unrecorded integral value, or a nonledgered sign choice.

Lean4 ✓ `BEDC.Derived.ContourReversalLedgerUp.ContourReversalLedgerTasteGate single carrier alignment`

Theorem 1019.2 (Contour reversal ledger NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContourReversalLedger}^{\uparrow}}$ *surface for Definition 1019.1 consists of carrier exposure for* $R = (G, G^-, F, I, H, C, P, N)$*, orientation-pair exposure for the two* PLContour *rows, contour-operation ledger exposure for the reversal law, negated* $\mathsf{Complex}^{\uparrow}$ *output routing, componentwise* hsame *transport, displayed* Cont *routes,* Pkg *provenance, and the local naming row. Any accepted consumer that asks for the reversed-contour output must first read the displayed PLContour row, reversed-contour row, and* $\mathsf{ContourIntegralOperation}^{\uparrow}$ *row.*

Proof. Carrier exposure is projection from the tuple in Definition 1019.1. The source contour row, reversed-contour row, operation row, negated output row, transport row, continuation row, provenance row, and local naming row are all displayed before any consumer can read the reversal result.

The orientation-pair obligation is confined to G and G^-. The route in C first reads the finite endpoint and segment data of G, then reads the opposite-orientation row G^-, so no host path object or quotient path class can replace either contour coordinate.

The reversal-law obligation is read through the $\mathsf{ContourIntegralOperation}^{\uparrow}$ row F and its operation-law ledger. The negated output row I is available only after that ledger has exposed the source contour, reversed contour, and operation row.

Finally, the rows H, C, P, N transport the displayed coordinates, replay the finite routes, record the dependency packages, and name the local ledger. Since no carrier coordinate stores an ambient analytic-continuation theorem, unrecorded integral value, or nonledgered sign choice, none of those objects can be exported. □

Theorem 1019.3 (Contour reversal ledger contour-integral handoff)**.** *Let* $R = (G, G^-, F, I, H, C, P, N)$ *be an accepted* $\mathsf{ContourReversalLedger}^{\uparrow}$ *carrier. Every* $\mathsf{ContourIntegralOperation}^{\uparrow}$*,* $\mathsf{ContourIntegralSocket}^{\uparrow}$*,* $\mathsf{ContourSumWindow}^{\uparrow}$*, residue-facing, or RH scaffold consumer of the reversal row factors first through* G*,* G^-*, and* F *before it may read the negated* $\mathsf{Complex}^{\uparrow}$ *output row* I*.*

The handoff exports only the displayed paired orientation rows, the contour-operation reversal ledger, the negated output route, componentwise transports, displayed continuations, package provenance, and local NameCert *row. It exports no host path equality, hidden branch choice, ambient integral operator, quotient path class, or unrecorded analytic-continuation coordinate.*

Proof. Begin with Definition 1019.2. It exposes the paired contour rows and forces the reversal-law read through the local $\mathsf{ContourIntegralOperation}^{\uparrow}$ row before the negated output row can be inspected.

For a contour-operation or contour-socket consumer, apply the operation-law ledger closure of chapter 521 and the socket boundary of chapter 583. Both sibling surfaces read contour data through displayed finite rows and ledgered routes, so the reversal handoff cannot bypass G, G^-, F, H, C, P, N.

For a contour-sum, residue-facing, or RH scaffold consumer, read the same handoff through the provenance row P. That row names the contour-sum window and analytic neighbors only as dependency packets; it does not add a host integral, quotient path, branch selector, or unrecorded analytic-continuation coordinate.

Thus every accepted consumer reaches the negated $\mathsf{Complex}^{\uparrow}$ output through the displayed orientation pair and contour-operation ledger, and the exported surface is exactly the finite packet R. □

Falsifiable prediction: Every accepted ContourReversalLedgerUp consumer reaches the negated ComplexUp output only after reading the displayed PLContour row, reversed-contour row, and

ContourIntegralOperation row.

Independence witness: contourintegraloperation, contoursumwindow, analyticcontinuationoperation, branchobstruction, holomorphic: none is bijective because the reversal ledger has the paired orientation rows and negated-output route that each sibling lacks.

The Lean file `TasteGate.lean` must include explicit Nontrivial ContourReversalLedger$^{\uparrow}$ and FieldFaithful ContourReversalLedger$^{\uparrow}$ instances for the displayed carrier $R = (G, G^{-}, F, I, H, C, P, N)$.

Closure status for NameCert$_{\text{ContourReversalLedger}^{\uparrow}}$.

Constructive story: A ContourReversalLedger$^{\uparrow}$ packet is generated from a displayed PLContour row, its reversed-contour row, a ContourIntegralOperation$^{\uparrow}$ reversal-law row, a negated Complex$^{\uparrow}$ output row, componentwise hsame transports, finite Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ContourReversalLedger}^{\uparrow}}$, seed)

Scope closed: Definition 1019.1, Definition 1019.2, and Definition 1019.3 bind the finite orientation-pair ledger and negated-output route over PLContour, ContourIntegralOperation$^{\uparrow}$, Complex$^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus(NameCert$_{\text{ContourReversalLedger}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Cauchy's theorem, residue calculus, RH zero-location consequences, host path equality, global branch selection, Lean verification, or bridge checking.

Upgrade path: Scoped closure requires checked carrier admission, reversal-ledger exactness, contour-operation handoff, TasteGate nontriviality, and field faithfulness for the same packet.

Chapter 1020

A Concrete Naming Certificate for $\mathsf{CauchyWindowTransducer}^{\uparrow}$

The $\mathsf{CauchyWindowTransducer}^{\uparrow}$ packet realizes the Real-completeness route of chapter 9238 as a finite transition object between StreamName windows, dyadic tolerance rows, RegSeqRat readbacks, LimitSelector handoffs, and RealUp seals. It is a NameCert carrier for one displayed window step; it is not a quotient stream, a host limit selector, a countable-choice principle, or an ambient completeness theorem.

The packet consumes chapter 126 for finite windows, chapter 291 for dyadic tolerances, chapter 301 for readback, and chapter 38 only after the RegSeqRat handoff.

Definition 1020.1 (Cauchy window transducer carrier)**.** *A* $\mathsf{CauchyWindowTransducer}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (S, D, W, R, E, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window source row;*
2. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row read at the same window scale;*
3. *W is the local window-step row translating the source window and dyadic tolerance into the next finite request;*
4. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row produced after the window step;*
5. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row consumed only after the readback row is displayed;*
6. *L is the* $\mathsf{LimitSelector}^{\uparrow}$ *handoff row naming the diagonal-limit selector used by the window step;*
7. *H records componentwise* hsame *transports for $S, D, W, R, E, L, C, P, N$;*
8. *C records displayed* Cont *routes from S, D to W, from W to R, from R to E, and from L to the same step route;*
9. *P records* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{LimitSelector}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyWindowTransducer}^{\uparrow}}$ *row.*

The carrier has no coordinate for a selected external limit, quotient equality of real names, global stream equality, countable choice, or a RealUp seal read that bypasses the displayed RegSeqRat handoff.

Lean4 (definition) `BEDC.Derived.CauchyWindowTransducerUp.taste gate`

Theorem 1020.2 (Cauchy window transducer NameCert obligations)**.** *For the carrier of Definition 1020.1, the local* $\mathsf{NameCert}_{\mathsf{CauchyWindowTransducer}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$T = (S, D, W, R, E, L, H, C, P, N),$$

StreamName window exposure through S, dyadic tolerance exposure through D, local window-step exposure through W, RegSeqRat readback through R, RealUp seal routing through E, LimitSelector handoff through L, componentwise transport through H, displayed route replay through C, package provenance through P, and local naming through N.

Proof. Carrier admission is projection from the displayed tuple T. Each public row of the transducer is one of $S, D, W, R, E, L, H, C, P, N$.

The analytic rows are read in order. The StreamName row and dyadic tolerance row supply the finite request surface, the local window-step row consumes that pair, the RegSeqRat row records the readback, and the RealUp seal row is reachable only after that readback.

The LimitSelector row names the diagonal selector used by the same step route. The structural rows H, C, P, N transport, replay, package, and name this finite inventory, so no hidden limit or quotient coordinate remains in the NameCert surface. □

Lean4 ✓ `BEDC.Derived.CauchyWindowTransducerUp.CauchyWindowTransducerCarrier namecert obligations`

Theorem 1020.3 (Cauchy window transducer window-step determinacy)**.** *Let two accepted* CauchyWindowTransdu *packets agree on the StreamName window row S, dyadic tolerance row D, LimitSelector row L, and structural rows H, C, P, N. If both packets expose the same window-step row W, then they determine the same RegSeqRat readback row R and the same RealUp seal route E.*

Proof. Project both packets through Definition 1020.1. The only analytic continuation after S, D, L is the displayed window-step row W followed by R and E.

Apply Definition 1020.2. It identifies route replay with the displayed Cont rows in C and binds the same package provenance and local name through P and N.

Since the two packets agree on S, D, L, W, H, C, P, N, there is no remaining carrier coordinate from which a second readback or seal route could be selected. The RegSeqRat readback and RealUp seal route are therefore determined by the common window step. □

Lean4 ✓ `BEDC.Derived.CauchyWindowTransducerUp.CauchyWindowTransducerCarrier step spine determinacy`

Theorem 1020.4 (Cauchy window transducer RegSeqRat handoff)**.** *Every accepted* $\mathsf{CauchyWindowTransducer}^{\uparrow}$ *packet hands a RealUp-facing consumer to the seal row E only through the RegSeqRat readback row R. A consumer may inspect the StreamName window, dyadic tolerance, window step, and LimitSelector handoff, but the RealUp seal is not exported until R has been displayed.*

Proof. Use the carrier definition to read the analytic route

$$S, D, L \longmapsto W \longmapsto R \longmapsto E.$$

The row E occurs after R in the displayed inventory and has no separate continuation source.

The NameCert obligation theorem then fixes the admissible public reads. Route replay through C reaches the RealUp seal only along the displayed route, while H transports the same rows componentwise and P, N bind the route to the local certificate.

Thus a RealUp-facing consumer can read the seal only after the RegSeqRat handoff row has been consumed. A route that bypasses R is outside the carrier. □

Theorem 1020.5 (Cauchy window transducer Real seal non-escape)**.** *No accepted* $\mathsf{CauchyWindowTransducer}^{\uparrow}$ *packet exports a RealUp seal read from an external limit selector, quotient stream equality, global stream equality, countable-choice row, or hidden completeness theorem. Every RealUp seal read factors through*

$$S, D, W, R, E, L, H, C, P, N.$$

Proof. Start with Definition 1020.4. It forces every RealUp-facing seal read through the displayed RegSeqRat handoff R.

Apply Definition 1020.3. Agreement on the source window, tolerance, selector, step, and structural rows determines the readback and seal route, so no hidden selector remains available after the displayed rows are fixed.

Finally use the exclusion clause in Definition 1020.1 together with Definition 1020.2. The carrier lists the full finite inventory and explicitly lacks quotient, global equality, choice, and ambient completeness coordinates. □

Theorem 1020.6 (Cauchy window transducer L10 lattice link)**.** *Every accepted* $\mathsf{CauchyWindowTransducer}^{\uparrow}$ *route factors through the sibling surfaces of chapter 126, chapter 291, chapter 301, chapter 673, and chapter 38 before the local* $\mathsf{Real}^{\uparrow}$ *seal is public. Equivalently, the displayed finite route consumes the StreamName finite-window row, DyadicRatCore tolerance row, local window-step row, RegSeqRat handoff row, LimitSelector handoff row, RealUp seal row, transport row, continuation row, provenance row, and local NameCert row before any Real-facing consumer can read the seal.*

Proof. The carrier of Definition 1020.1 names the five sibling surfaces as rows S, D, R, L, E together with the local structural rows W, H, C, P, N. The NameCert obligation theorem Definition 1020.2 says that these are exactly the public rows of an accepted transducer route.

Window-step determinacy from Definition 1020.3 fixes the passage from the StreamName and DyadicRatCore rows, with the LimitSelector handoff, to the RegSeqRat readback and the RealUp seal route. The RegSeqRat handoff theorem Definition 1020.4 then prevents the Real-facing consumer from reading E before R has been displayed.

Finally, Real seal non-escape Definition 1020.5 exhausts the remaining coordinates. No quotient stream, selected host limit, countable-choice row, or ambient completeness coordinate is introduced; the L10 dependency is precisely the finite sibling route recorded in the displayed packet. □

Lean4 ✓ `BEDC.Derived.CauchyWindowTransducerUp.CauchyWindowTransducerUp StdBridge`

Falsifiable prediction: Removing the window-step row permits a RealUp seal read without a displayed RegSeqRat handoff.

Independence witness: Nearest siblings: StreamName, DyadicRatCore, RegSeqRat, RealUp, and LimitSelector. None is bijective to $\mathsf{CauchyWindowTransducer}^{\uparrow}$ because this carrier stores the joint window source, dyadic tolerance, step row, readback row, seal route, selector handoff, transport, replay, provenance, and local naming rows in one finite packet, while each sibling exposes only one surface of that route.

Theorem 1020.7 (Cauchy window transducer scoped closure package)**.** *The carrier of Definition 1020.1, the NameCert obligations of Definition 1020.2, window-step determinacy from Definition 1020.3, the RegSeqRat handoff of Definition 1020.4, Real seal non-escape from Definition 1020.5, the falsifiable prediction, the independence witness, and the checked TasteGate alignment jointly bind the scoped finite route from StreamName windows and DyadicRatCore tolerances through RegSeqRat readback to the RealUp seal.*

Proof. The carrier fixes the whole packet as the displayed tuple $S, D, W, R, E, L, H, C, P, N$. The NameCert obligation theorem says that these rows are exactly the local public surface.

Window-step determinacy fixes the passage from the source window, dyadic tolerance, selector handoff, and local step row to the RegSeqRat readback and RealUp seal route. The RegSeqRat handoff theorem then forces every Real-facing read through R before E is public.

Real seal non-escape excludes the remaining ambient coordinates. Together with the falsifiable prediction and independence witness, this leaves a scoped finite route rather than a quotient real, selected host limit, global stream equality, countable-choice principle, or hidden completeness theorem. □

Lean4 ✓ `BEDC.Derived.CauchyWindowTransducerUp.CauchyWindowTransducerTasteGate single carrier alignment`

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyWindowTransducer}\uparrow}$.

Constructive story: A $\mathsf{CauchyWindowTransducer}^{\uparrow}$ packet is generated from a StreamName finite-window source row, DyadicRatCore tolerance row, local window-step row, RegSeqRat readback row, RealUp seal row, LimitSelector handoff row, componentwise hsame transport, displayed continuation replay, package provenance, and local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyWindowTransducer}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1020.1, Definition 1020.2, Definition 1020.3, Definition 1020.4, Definition 1020.5, and Definition 1020.7 bind the finite route over StreamName, DyadicRatCore, RegSeqRat, RealUp, LimitSelector, BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CauchyWindowTransducer}\uparrow}, \mathsf{bridgeChecked})$

Lean4 ✓ `BEDC.Derived.CauchyWindowTransducerUp.taste gate`

Lean target: `BEDC.Derived.CauchyWindowTransducerUp.CauchyWindowTransducerTasteGate\_single\_carrier\_alignment`

Bridge status: bridgeChecked

Origin: ai

Not claimed: This chapter does not close selected limits, quotient real equality, global stream equality, countable choice, or ambient completeness.

Upgrade path: No further upgrade remains; the finite Cauchy window transducer route is at the top of both the paper closure axis and the bridge verification axis.

Chapter 1021

A Concrete Naming Certificate for $\mathsf{LargeModelAttentionGate}^{\uparrow}$

The $\mathsf{LargeModelAttentionGate}^{\uparrow}$ packet realizes the attention-window boundary of chapter 9398 as finite BEDC data. It sits between the activation-orbit packet of chapter 967, the context-audit packet of chapter 989, the corpus-supply packet of chapter 988, the audit channel of chapter 969, and the verified-output harness of chapter 976. Its role is not to introduce a new model semantic oracle; it records the finite gate through which an output-facing read must pass from trace and activation rows into context, corpus, audit, verified-output, transport, route, provenance, and local naming rows.

Definition 1021.1 (LargeModelAttentionGate carrier)**.** *A* $\mathsf{LargeModelAttentionGate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (T, A, C, K, U, V, H, R, P, N)$$

with the following displayed rows:

1. *T is the trace row, recording the finite model-trace read that supplies the emitted output-facing state;*
2. *A is the* $\mathsf{LargeModelActivationOrbit}^{\uparrow}$ *row naming the finite activation-window segment selected for the read;*
3. *C is the context-window row, carrying the bounded prompt and response boundary consumed by the gate;*
4. *K is the* $\mathsf{LargeModelCorpusSupply}^{\uparrow}$ *row that records the corpus-supply and filter boundary available to this local selection;*
5. *U is the* $\mathsf{LargeModelAuditChannel}^{\uparrow}$ *row through which the selected output-facing read is routed to a public audit consumer;*
6. *V is the* $\mathsf{VerifiedOutputHarness}^{\uparrow}$ *handoff row for the same output-facing record;*
7. *H records componentwise* hsame *transport for the trace, activation-window, context, corpus-supply, audit-channel, verified-output, replay, provenance, and naming rows;*
8. *R records the displayed* Cont *replay by which a consumer reads T, then A, C, K, then U, V, before reaching provenance and the local name;*

9. *P is the* Pkg *provenance over* ModelTrace$^{\uparrow}$, LargeModelActivationOrbit$^{\uparrow}$, ContextWindowCommitment$^{\uparrow}$, LargeModelCorpusSupply$^{\uparrow}$, LargeModelAuditChannel$^{\uparrow}$, VerifiedOutputHarness$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*

10. *N is the local* NameCert$_{\mathsf{LargeModelAttentionGate}^{\uparrow}}$ *row.*

The carrier has no coordinate for a hidden attention stream, unbounded context recovery, corpus-wide truth, unchecked output acceptance, model-side semantic proof, or private route bypassing the displayed activation and context rows.

Lean4 ✓ `BEDC.Derived.LargeModelAttentionGateUp.LargeModelAttentionGateTasteGate single carrier alignment`

Theorem 1021.2 (LargeModelAttentionGate NameCert obligations)**.** *For the carrier of Definition 1021.1, the local* NameCert$_{\mathsf{LargeModelAttentionGate}^{\uparrow}}$ *surface consists exactly of the following finite rows:*

1. *carrier admission for $G = (T, A, C, K, U, V, H, R, P, N)$;*
2. *activation-window readback through the displayed activation-orbit row A;*
3. *corpus boundary exposure through the corpus-supply row K;*
4. *audit-channel routing through U;*
5. *verified-output handoff through V;*
6. *componentwise transport through H;*
7. *replay through the displayed* Cont *row R;*
8. *provenance through P;*
9. *local naming through N.*

Every accepted attention-gate consumer must display these rows before it can read the output-facing gate as a certified large-model packet.

Proof. Project the carrier of Definition 1021.1. The packet lists exactly $T, A, C, K, U, V, H, R, P, N$, so carrier admission supplies no additional hidden state.

The activation and context rows are the entry surface. The trace row T is only readable through the activation-window row A and the bounded context row C, while K keeps the corpus-supply boundary attached to the same local read.

The output-facing rows are downstream. The audit-channel row U and verified-output row V are reached only after the displayed activation, context, and corpus rows have been consumed.

Finally H, R, P, N provide transport, replay, provenance, and local naming for the same packet. Since the carrier has no hidden attention stream, context-recovery oracle, corpus-truth predicate, unchecked acceptance row, or model-side semantic proof coordinate, the listed rows exhaust the local NameCert surface. □

Theorem 1021.3 (LargeModelAttentionGate finite-window soundness)**.** *Every output-facing read of an accepted* LargeModelAttentionGate$^{\uparrow}$ *packet factors through the finite activation and context window before it can reach an audit-channel or verified-output row. In the carrier*

$$G = (T, A, C, K, U, V, H, R, P, N),$$

the read order is

$$T \to (A, C, K) \to (U, V) \to (H, R, P, N).$$

Thus an output-facing consumer cannot read U or V as a bare checker result, hidden evaluator state, unbounded attention stream, recovered context, corpus-wide truth predicate, or host semantic equality.

Proof. Start with Definition 1021.2. It requires activation-window readback through A and context exposure through C before audit-channel routing or verified-output handoff is part of the local surface.

Use the sibling chapters to identify those rows. chapter 967 supplies the finite activation-orbit row, chapter 989 and chapter 971 supply the bounded context route, and chapter 988 supplies the corpus boundary.

Only after this finite window is displayed do chapter 969 and chapter 976 provide the audit and verified-output rows. The replay, provenance, and naming rows R, P, N then certify that the same finite route was consumed.

The exclusions follow from the carrier inventory. No coordinate stores a bare checker result, hidden evaluator, unbounded attention stream, recovered context, corpus-wide truth predicate, or host semantic equality, so no accepted read can bypass the finite activation and context window. □

Falsifiable prediction: Every LargeModelAttentionGateUp verified-output read factors through a displayed activation-orbit row and context-window row before it can reach the audit-channel handoff.

Independence witness: largemodelinscriptionpoint, largemodelactivationorbit, largemodelcontextaudit, largemodelauditchannel, verifiedoutputharness: the attention-gate packet is not bijective with these siblings because inscription lacks the selected context gate, activation orbit lacks the audit and verified-output handoff, context audit lacks the activation-window selector as the classifier-bearing entry, audit channel lacks the finite activation/context window, and verified output harness lacks the corpus-supply gate attached to the same selection route.

The Lean TasteGate carrier names the same displayed packet and carries `Nontrivial LargeModelAttentionGa` and `FieldFaithful LargeModelAttentionGateUp` instances for it.

Closure status for $\mathsf{NameCert}_{\mathsf{LargeModelAttentionGate}^{\uparrow}}$ **.**

Constructive story: A $\mathsf{LargeModelAttentionGate}^{\uparrow}$ packet is generated from trace, activation-orbit, context-window, corpus-supply, audit-channel, verified-output, componentwise hsame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LargeModelAttentionGate}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1021.1, Definition 1021.2, and Definition 1021.3 specify the finite activation-window and context-window attention-gate carrier.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LargeModelAttentionGate}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.LargeModelAttentionGateUp.LargeModelAttentionGateTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close hidden attention streams, unbounded context recovery, corpus truth, host semantic understanding, unchecked output acceptance, Lean verification, or bridge checking for $\mathsf{LargeModelAttentionGate}^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, activation-window readback, corpus-boundary exposure, audit-channel routing, verified-output handoff, componentwise transport, replay, provenance, local naming, nontriviality, and field faithfulness for the same carrier.

Chapter 1022

A Concrete Naming Certificate for $\mathsf{RegularCauchyWindowIntersection}^{\uparrow}$

The $\mathsf{RegularCauchyWindowIntersection}^{\uparrow}$ packet records the common finite-window intersection used when two regular-Cauchy routes share one tail-meet row before the Real or Completion consumer reads a tail-agreement seal. It consumes the threshold service of chapter 560 and the agreement handoff of chapter 699, while keeping the two selected windows visible as separate rows until the shared intersection packet has been named.

Definition 1022.1 (Regular-Cauchy window-intersection carrier)**.** *A* $\mathsf{RegularCauchyWindowIntersection}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$I = (X, Y, W_X, W_Y, D, M, T, H, C, P, N)$$

with the following displayed rows:

1. *X and Y are the two selected* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-Cauchy source rows;*
2. *W_X and W_Y are the selected finite* $\mathsf{StreamName}^{\uparrow}$ *windows for those source rows;*
3. *D is the common* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance and readback ledger visible to both windows;*
4. *M is the accepted* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *row supplying the common tail-meet threshold;*
5. *T is the* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *handoff row exposed only after W_X, W_Y, D, M are displayed together;*
6. *H records componentwise* hsame *transports for the two source rows, the two window rows, the dyadic ledger, the tail-meet row, the agreement handoff, provenance, and the local naming row;*
7. *C records displayed* Cont *routes from the two source rows to the selected windows, from those windows to the common dyadic ledger, from the ledger to the tail meet, and from the tail meet to the agreement handoff;*
8. *P is the* Pkg *provenance over* $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegularCauchyTailMeet}^{\uparrow}$, $\mathsf{RealTailAgreementSeal}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWindowIntersection}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient stream equality, selected host limits, independent tail thresholds, unshared window services, ambient completeness, or a RealTailAgreementSeal handoff that bypasses the displayed intersection packet.

Lean4 (definition) BEDC.Derived.RegularCauchyWindowIntersectionUp.RegularCauchyWindowIntersectionUp
Lean4 ✓ BEDC.Derived.RegularCauchyWindowIntersectionUp.RegularCauchyWindowIntersectionTasteGate
single carrier alignment

Theorem 1022.2 (Regular-Cauchy window-intersection NameCert obligations)**.** *For the carrier of Definition 1022.1, the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyWindowIntersection}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$I = (X, Y, W_X, W_Y, D, M, T, H, C, P, N),$$

the two regular-Cauchy source rows X, Y*, the selected window rows* W_X, W_Y*, the common dyadic ledger* D*, the common tail-meet row* M*, the RealTailAgreementSeal handoff row* T*, componentwise transport through* H*, displayed route replay through* C*, package provenance through* P*, and local naming through* N*.*

Proof. Project the displayed packet I. Its coordinates are exactly the two sources, two selected windows, common dyadic ledger, tail-meet row, agreement handoff, transport, replay, provenance, and local name.

The tail-meet coordinate is consumed through chapter 560. The agreement handoff is consumed through chapter 699 only after both selected windows and the common dyadic ledger have been displayed.

No remaining carrier coordinate can expose quotient stream equality, a selected host limit, an independent threshold, an unshared window service, ambient completeness, or another route to the agreement handoff. The listed rows therefore exhaust the local NameCert surface. □

Theorem 1022.3 (Regular-Cauchy window-intersection falsifiable boundary)**.** *Any accepted* RegularCauchyWindow *consumer that presents two selected regular-Cauchy windows with a common tail-meet row must expose the same* $\mathsf{RealTailAgreementSeal}^{\uparrow}$ *handoff row* T*. If the two windows present different handoff rows after the same* D, M, H, C, P, N *coordinates are fixed, the packet is rejected by the local NameCert ledger.*

Proof. The carrier places T after the two selected windows, the common dyadic ledger, and the common tail-meet row. Thus a consumer can reach a RealTailAgreementSeal handoff only through the displayed route recorded by C.

Fixing D, M, H, C, P, N fixes the common ledger, the tail-meet threshold, componentwise transport, replay route, provenance, and local name. There is no second handoff coordinate in the packet.

Hence an accepted packet exposes one handoff row for the shared intersection. A presentation with two different handoff rows is not a carrier of Definition 1022.1. □

Theorem 1022.4 (Regular-Cauchy window-intersection sibling independence)**.** *The carrier of Definition 1022.1 is not bijective to the regularcauchywitnessschedule, regular-cauchy-tail-meet, realtailagreementseal, finiteobservationbudgetselector, or cauchylimitseal sibling packets. Each sibling supplies a schedule, a threshold meet, a seal row, a selector route, or a limit seal, while this carrier records the common intersection packet binding both selected windows before the seal.*

Proof. Inspect the displayed rows of I. The packet contains two selected windows, one common dyadic ledger, one tail-meet row, and one agreement handoff in the same finite carrier.

The witness-schedule sibling supplies a schedule but not the paired intersection carrier. The tail-meet sibling supplies a threshold meet but not the stored pair of selected windows before the handoff. The RealTailAgreementSeal sibling supplies the seal row but not the common intersection packet binding both windows before that seal.

The selector and limit-seal siblings likewise expose a selector route or a limit seal without the full pair of selected windows, shared ledger, tail meet, and agreement handoff. No bijection can preserve the complete NameCert obligation surface. □

Theorem 1022.5 (Regular-Cauchy window-intersection ledger exhaustion)**.** *Every Real or Completion diagonal-route consumer of an accepted* $\mathsf{RegularCauchyWindowIntersection}^{\uparrow}$ *packet reads only*

$$X, Y, W_X, W_Y, D, M, T, H, C, P, N.$$

The consumer receives the two source rows, two selected windows, common dyadic ledger, common tail meet, RealTailAgreementSeal handoff, componentwise transports, displayed continuations, provenance, and local name; it receives no quotient stream equality, selected host limit, independent threshold, unshared window service, or ambient completeness principle.

Proof. Start from the NameCert obligation theorem. It identifies the complete public ledger with the rows of the displayed packet.

Apply the falsifiable boundary theorem to the handoff row. The RealTailAgreementSeal handoff is reachable only as the single row T after the two windows and common tail meet have been displayed.

Use sibling independence for the remaining exclusions. None of the nearest sibling packets supplies an additional coordinate that could be imported into this carrier. The consumer is therefore exhausted by the displayed ledger. □

Theorem 1022.6 (Regular-Cauchy window-intersection shared-threshold determinacy)**.** *Let*

$$I = (X, Y, W_X, W_Y, D, M, T, H, C, P, N) \quad \text{and} \quad I' = (X', Y', W'_X, W'_Y, D', M', T', H', C', P', N')$$

be accepted $\mathsf{RegularCauchyWindowIntersection}^{\uparrow}$ *packets. If the two packets expose the same selected* $\mathsf{StreamName}^{\uparrow}$ *windows for the same two* $\mathsf{RegSeqRat}^{\uparrow}$ *source rows, the same* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, and the same* $\mathsf{RegularCauchyTailMeet}^{\uparrow}$ *threshold row, then every* $\mathsf{RealTailAgreementSeal}^{\uparrow}$*-facing read agrees on the displayed shared-threshold packet*

$$X, Y, W_X, W_Y, D, M, T, H, C, P, N.$$

Conversely, equality of the seal-facing read recovers only the displayed source-window rows, tolerance ledger, threshold row, hsame *transports,* Cont *routes,* Pkg *provenance, and local* NameCert *row. It recovers no quotient stream equality, selected limit, countable choice, ambient* $\mathsf{Real}^{\uparrow}$ *completeness, or bridge row.*

Proof. Begin with the carrier. By Definition 1022.1, an accepted packet has exactly the two source rows, two selected window rows, common dyadic ledger, tail-meet row, seal handoff, transport, continuation, provenance, and naming coordinates displayed in I.

The NameCert obligations then fix the admissible readings of those coordinates. Definition 1022.2 requires the same displayed route through the selected windows, the common dyadic ledger, the tail-meet row, and the RealTailAgreementSeal handoff. The tail-meet coordinate is the finite threshold service supplied by chapter 560, and the handoff coordinate is read through chapter 699.

Now compare I and I'. Once the two selected source-window pairs, D, and M agree, the displayed route replay through C has no second threshold coordinate to choose. Definition 1022.5 says that a Real or Completion consumer reads only the rows of the displayed packet, so the seal-facing read is the same shared-threshold packet.

For the converse, equality of the seal-facing read can recover exactly the rows that the ledger exposes: $X, Y, W_X, W_Y, D, M, T, H, C, P, N$. The carrier contains no coordinate for quotient streams, selected limits, countable choice, ambient $\mathsf{Real}^{\uparrow}$ completeness, or bridge data, and sibling independence prevents importing such a coordinate from the neighboring packets. Thus determinacy is finite and local to the displayed RegularCauchyWindowIntersection packet. □

Falsifiable prediction: Any accepted RegularCauchyWindowIntersectionUp consumer that presents two selected regular-Cauchy windows with a common tail-meet row must expose the same RealTailAgreementSealUp handoff row; otherwise the packet is rejected by the local NameCert ledger.

Independence witness: regularcauchywitnessschedule, regular-cauchy-tail-meet, realtailagreementseal, finiteobservationbudgetselector, cauchylimitseal: none is bijective because each sibling supplies a single schedule, a threshold meet, a seal row, a selector route, or a limit seal, while this carrier records the common intersection packet binding both windows before the seal.

The Lean boundary must provide `Derived/RegularCauchyWindowIntersectionUp/TasteGate.lean` with explicit `Nontrivial` and `FieldFaithful` instances, so the intersection is represented by an inhabited, field-faithful carrier rather than by a vacuous seal route.

Closure status for $\mathsf{NameCert}_{\mathsf{RegularCauchyWindowIntersection}^{\uparrow}}$.

Constructive story: A $\mathsf{RegularCauchyWindowIntersection}^{\uparrow}$ packet is generated from two regular-Cauchy source rows, two selected StreamName windows, a common DyadicRatCore ledger, a RegularCauchyTailMeet row, a RealTailAgreementSeal handoff, componentwise hsame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RegularCauchyWindowIntersection}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1022.1, Definition 1022.2, Definition 1022.3, Definition 1022.4, Definition 1022.5, and Definition 1022.6 bind the finite shared-window intersection packet and its RealTailAgreementSeal handoff boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RegularCauchyWindowIntersection}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, quotient stream equality, selected host limits, independent tail thresholds, unshared window services, ambient completeness, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, common-window intersection obligations, handoff determinacy, sibling independence, and consumer ledger exhaustion for the same packet.

Chapter 1023

A Concrete Naming Certificate for $\mathsf{InterHistRateBoundary}^{\uparrow}$

The $\mathsf{InterHistRateBoundary}^{\uparrow}$ packet realizes the inter-Hist maximum-rate boundary of chapter 9419 as finite BEDC data. It binds the cross-history rate surface of chapter 876, the read gate of chapter 933, and the refusal surface of chapter 1003 into one local naming carrier, so downstream consumers receive a gated route rather than a host speed, metric row, clock, or global frame.

Falsifiable prediction: An accepted rate-boundary consumer that reads a maximum-rate row without both observer-symmetry and no-global-frame refusal rows refutes the packet.

Independence witness: crosshistcausalrate, maxratereadgate, noglobalsyncboundary, interhistinvariant, crosshistcausalroute: the boundary packet is not bijective to any one sibling because it carries the shared gate plus route plus refusal surface.

Definition 1023.1 (InterHistRateBoundary carrier)**.** *An* $\mathsf{InterHistRateBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (A, D, G, R, S, F, I, H, Q, C, P, N)$$

with the following visible rows:

1. *A is the paired observer-history boundary row that supplies the two displayed inter-Hist sides;*
2. *D is the causal-route row, read through* $\mathsf{CrossHistCausalRoute}^{\uparrow}$ *and* $\mathsf{CrossHistCausalRate}^{\uparrow}$ *rather than through an ambient spacetime path;*
3. *G is the accepted* $\mathsf{MaxRateReadGate}^{\uparrow}$ *row binding the rate read to the gate surface of chapter 933;*
4. *R is the maximum-rate row tied to* $\mathsf{MaxCausalRate}^{\uparrow}$ *as in chapter 594;*
5. *S is the observer-symmetry row for the displayed histories;*
6. *F is the no-global-frame refusal row, with the same refusal discipline as chapter 1003;*
7. *I is the inter-Hist invariant readback row, recording that the boundary is stable as an inter-Hist packet rather than a single-history rate;*
8. *H records componentwise* hsame *transport for the displayed rows;*
9. *Q records* psame *stability for the probes used by D, G, R, S, F, I;*
10. *C records displayed* Cont *routes from the causal route and gate into the local naming row;*

11. *P is the* Pkg *provenance over* InterHistRateBoundary$^{\uparrow}$, CrossHistCausalRate$^{\uparrow}$, MaxRateReadGate$^{\uparrow}$, InterHistInvariant$^{\uparrow}$, NoGlobalSyncBoundary$^{\uparrow}$, CrossHistCausalRoute$^{\uparrow}$, BHist, hsame, psame, Cont, Pkg, *and* NameCert*;*
12. *N is the local* NameCert$_{\mathsf{InterHistRateBoundary}^{\uparrow}}$ *row.*

The carrier exports a finite maximum-rate boundary for inter-Hist consumers. It exports no host-side speed, global time coordinate, metric tensor, Lorentz frame, selected synchronization map, or detached rate primitive.

Theorem 1023.2 (InterHistRateBoundary NameCert obligations)**.** *For the carrier of Definition 1023.1, the local* NameCert$_{\mathsf{InterHistRateBoundary}^{\uparrow}}$ *surface consists exactly of seven finite obligations:*

1. *carrier admission for $B = (A, D, G, R, S, F, I, H, Q, C, P, N)$;*
2. *causal-route exactness, requiring D to be read through the displayed* CrossHistCausalRoute$^{\uparrow}$ *and* CrossHistCausalRate$^{\uparrow}$ *rows;*
3. *maximum-rate gate exactness, requiring G to bind R, S, F before any consumer reads the rate row;*
4. *observer-symmetry exactness through S after componentwise transport;*
5. *no-global-frame refusal through F before any boundary read is public;*
6. *invariant readback through I, keeping the packet on the inter-Hist surface;*
7. *transport, probe, route, provenance, and local-name stability through H, Q, C, P, N.*

Proof. Carrier admission is the projection of the finite tuple in Definition 1023.1. The rows $A, D, G, R, S, F, I, H, Q, C, P, N$ display the observer boundary, causal route, rate gate, maximum-rate row, symmetry row, refusal row, invariant row, transports, probe stability, routes, provenance, and local name.

Apply the causal-rate surface from chapter 876. It supplies the route discipline for D and prevents the boundary from reading a rate before the cross-history causal route is displayed.

Apply the max-rate read gate from chapter 933. The gate binds R to S and F, so the maximum-rate row is not public until both observer symmetry and no-global-frame refusal have been read.

Finally use the invariant and refusal rows. The invariant row keeps the packet on the inter-Hist surface, while the refusal row excludes global frames, clocks, metric tensors, Lorentz frames, synchronized coordinates, and detached host speeds. The remaining rows H, Q, C, P, N transport, route, package, and name the same finite packet. □

Theorem 1023.3 (InterHistRateBoundary gated consumer)**.** *Every* CrossHistCausalRate$^{\uparrow}$, LorentzFrameRate$^{\uparrow}$, MinkowskiRateGeometry$^{\uparrow}$, *or inter-Hist locality consumer of an accepted* InterHistRateBoundary$^{\uparrow}$ *packet may read the maximum-rate row R only through the displayed boundary rows*

$$A, D, G, R, S, F, I, H, Q, C, P, N.$$

In particular, the read of R passes through the causal route D, the gate row G, the observer-symmetry row S, the no-global-frame refusal row F, and the invariant row I before it reaches any downstream consumer.

Proof. Project the accepted boundary carrier. The only maximum-rate row is R, and the only displayed path to it is through the route and gate rows D and G.

Use Definition 1023.2. The obligations make causal-route exactness, gate exactness, symmetry, refusal, and invariant readback part of one local naming surface.

The max-rate gate of chapter 933 supplies the public lock for R, S, F. The causal-rate packet of chapter 876 supplies the cross-history route read before the rate row is inspected.

Thus a downstream consumer receives a finite boundary packet rather than a free maximum-rate primitive. Any read that bypasses D, G, S, F, or I is outside the accepted $\mathsf{InterHistRateBoundary}^{\uparrow}$ carrier. □

Theorem 1023.4 (InterHistRateBoundary nonescape)**.** *An accepted* $\mathsf{InterHistRateBoundary}^{\uparrow}$ *packet has no admissible export of a host speed, global time coordinate, synchronized observer frame, metric tensor, Lorentz frame, selected synchronization map, or detached maximum-rate row. Its public surface is exhausted by* $A, D, G, R, S, F, I, H, Q, C, P, N$ *and the local* $\mathsf{NameCert}_{\mathsf{InterHistRateBoundary}^{\uparrow}}$ *obligations over those rows.*

Proof. Start from the gated consumer theorem. Every rate read factors through the displayed route, gate, symmetry, refusal, and invariant rows.

The no-global-frame refusal row F is read with the boundary discipline of chapter 1003. It blocks any interpretation of the packet as a global synchronization surface or privileged frame.

The carrier inventory then completes the non-escape argument. Since the tuple contains no coordinate for host speed, global time, metric geometry, Lorentz-frame data, selected synchronization, or detached rate values, no local NameCert projection can export one. □

Theorem 1023.5 (InterHistRateBoundary NameCert package)**.** *The carrier, local NameCert obligations, gated consumer theorem, and non-escape theorem assemble the concrete* $\mathsf{NameCert}_{\mathsf{InterHistRateBoundary}^{\uparrow}}$ *package over* $\mathsf{CrossHistCausalRate}^{\uparrow}$, $\mathsf{MaxRateReadGate}^{\uparrow}$, $\mathsf{InterHistInvariant}^{\uparrow}$, $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$, $\mathsf{CrossHistCausalRoute}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, BHist, hsame, psame, Cont, Pkg, *and* NameCert. *The Lean carrier surface is realized by* `Nontrivial InterHistRateBoundaryUp` *and* `FieldFaithful InterHistRateBoundaryUp` *instances in* `lean4/BEDC/Derived/InterHistRateBoundaryUp/TasteGate.lean`, *with the canonical declaration surface at* `BEDC.Derived.InterHistRateBoundaryUp.taste_gate`.

Proof. Combine the carrier definition with the NameCert obligations. They fix the twelve displayed rows and bind route, gate, symmetry, refusal, invariant readback, transport, probe stability, continuation, provenance, and local naming.

The gated consumer theorem identifies how downstream rate and geometry consumers may read the packet. The non-escape theorem identifies what they cannot read.

The cited Lean TasteGate carrier supplies the finite event-flow presentation, round-trip readback, nontriviality, and field faithfulness for the same row surface. Therefore the paper package and the Lean carrier use the same finite BEDC data rather than a host metric or global-frame primitive. □

Lean4 ✓ `BEDC.Derived.InterHistRateBoundaryUp.InterHistRateBoundaryTasteGate single carrier alignment`

Closure status for $\mathsf{NameCert}_{\mathsf{InterHistRateBoundary}^{\uparrow}}$.

Constructive story: An $\mathsf{InterHistRateBoundary}^{\uparrow}$ packet is generated from paired observer-history boundary rows, a cross-history causal route, a maximum-rate gate, rate row, observer-symmetry row, no-global-frame refusal, inter-Hist invariant readback, componentwise hsame transport, probe stability, displayed Cont routes, provenance, and local naming. The carrier makes the rate visible only through the gate and refusal rows. Its classifier records a bounded inter-Hist relation: the consumer reads route, gate, symmetry, refusal, and invariant data, while hsame and Cont preserve exactly those fields without importing a host metric or shared clock.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{InterHistRateBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the inter-Hist rate-boundary carrier, obligations, gated consumer theorem, non-escape theorem, and paper-Lean package comparison.

Formal verification: FormalStatus(NameCert$_{\mathsf{InterHistRateBoundary}\uparrow}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim host-side speed, global time, metric tensor, Lorentz frame, selected synchronization map, or detached rate primitive.

Upgrade path: To reach obligationClosure, promote the displayed TasteGate-aligned carrier into explicit checked obligations for all route, gate, refusal, and invariant rows.

Chapter 1024

A Concrete Naming Certificate for $\mathsf{CauchyTailModulusFusion}^{\uparrow}$

The $\mathsf{CauchyTailModulusFusion}^{\uparrow}$ packet realizes the Real-completeness route of chapter 9238 by joining the shared-tail surface of chapter 658, the modulus refinement surface of chapter 885, and the shared threshold service of chapter 983. Its finite rows are read through the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ certificate surfaces of chapter 126, chapter 291, chapter 301, and chapter 38.

Definition 1024.1 (Cauchy tail modulus fusion carrier)**.** *A* $\mathsf{CauchyTailModulusFusion}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (T_0, T_1, \mu_0, \mu_1, \tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1, E, H, C, P, N)$$

with the following displayed rows:

1. *T_0 and T_1 are the two regular-Cauchy tail schedules whose common completion-facing tail route is being fused;*
2. *μ_0 and μ_1 are the two modulus rows read from the source schedules;*
3. *τ is the shared tail threshold produced from the two schedules and the two modulus rows;*
4. *V is the modulus comparison row witnessing that both source moduli are served by the same threshold τ;*
5. *W_0 and W_1 are the selector-window rows opened from τ for the two source schedules;*
6. *D_0 and D_1 are the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance rows attached to the two selected windows;*
7. *Q_0 and Q_1 are the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback rows obtained from the windows and dyadic tolerances;*
8. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row exposed only after the shared threshold, modulus comparison, windows, tolerances, and readbacks have been displayed;*
9. *H records componentwise* hsame *transport for the schedules, moduli, threshold, comparison, windows, tolerances, readbacks, seal, provenance, and local name;*
10. *C records displayed* Cont *routes from the two schedules to their modulus rows, from the modulus rows to τ, V, from τ, V to the windows, from the windows to the dyadic tolerances and regular readbacks, and from the readbacks to the Real seal;*

11. *P is the* Pkg *provenance over* $\mathsf{RegularCauchyTailFusion}^{\uparrow}$, $\mathsf{CauchyModulusRefinement}^{\uparrow}$, $\mathsf{CauchySharedTailModulus}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyTailModulusFusion}^{\uparrow}}$ *row.*

The carrier contains no quotient stream, host real equality, selected external limit, independent per-source Real seal, hidden modulus comparison, or ambient completeness coordinate.

Theorem 1024.2 (Cauchy tail modulus fusion NameCert obligations)**.** *For the carrier of Definition 1024.1, the local* $\mathsf{NameCert}_{\mathsf{CauchyTailModulusFusion}^{\uparrow}}$ *surface consists exactly of carrier admission for F, paired tail-schedule exposure through T_0, T_1, modulus exposure through μ_0, μ_1, shared-threshold exposure through τ, modulus comparison through V, selector-window service through W_0, W_1, dyadic tolerance readback through D_0, D_1, regular rational readback through Q_0, Q_1, Real seal ordering through E, componentwise stability through H, displayed replay through C, provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.CauchyTailModulusFusionUp.CauchyTailModulusFusionCarrier namecert obligations`

Proof. Project the displayed carrier. The packet lists the two tail schedules, two modulus rows, shared threshold, modulus comparison, selector windows, dyadic tolerances, regular readbacks, Real seal, transport, route, provenance, and local name as public coordinates.

The sibling tail and modulus routes supply the two source boundaries. The tail schedules are read through chapter 658, while the comparison row is read through chapter 885 and the shared-threshold service is read through chapter 983.

The finite observation rows then pass through $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{RegSeqRat}^{\uparrow}$ before the $\mathsf{Real}^{\uparrow}$ seal is exposed. Since the carrier has no quotient stream, host real equality, selected external limit, hidden modulus comparison, or ambient completeness coordinate, these rows exhaust the local NameCert obligations. □

Theorem 1024.3 (Cauchy tail modulus fusion shared-tail exhaustion)**.** *Every accepted* $\mathsf{CauchyTailModulusFusion}^{\uparrow}$ *packet routes a completion-facing Real seal through the displayed chain*

$$T_0, T_1, \mu_0, \mu_1, \tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1, E, H, C, P, N.$$

No consumer of the packet can read E before the shared threshold τ, the modulus comparison V, both selector windows, both dyadic tolerance rows, and both regular readbacks have been displayed.

Lean4 ✓ `BEDC.Derived.CauchyTailModulusFusionUp.CauchyTailModulusFusionCarrier shared tail exhaustion`

Proof. Start from carrier admission in Definition 1024.1. The only Real-facing coordinate is E, and it is listed after the schedules, moduli, threshold, comparison, windows, tolerances, and readbacks.

Apply the NameCert obligations of Definition 1024.2. They assign every completion-facing read of E to the same displayed route and require the route to pass through the shared threshold and comparison rows before any selector-window read.

Finally use the absence clauses in the carrier. A route that bypasses $\tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1$ would require a private threshold, hidden comparison, independent Real seal, or ambient completeness coordinate, none of which is present in the packet. □

Theorem 1024.4 (Cauchy tail modulus fusion threshold comparison stability)**.** *For the displayed carrier*

$$F = (T_0, T_1, \mu_0, \mu_1, \tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1, E, H, C, P, N)$$

of Definition 1024.1, every modulus-comparison read that reaches the $\mathsf{Real}^{\uparrow}$ *seal row* E *factors through the shared threshold* τ *and the comparison row* V *exposed by the sibling surfaces chapter 658, chapter 885, and chapter 983. The transport row* H*, replay row* C*, provenance row* P*, and local name row* N *preserve this factoring for both branches* $T_0, \mu_0, W_0, D_0, Q_0$ *and* $T_1, \mu_1, W_1, D_1, Q_1$*.*

Proof. Project the carrier coordinates. The only comparison coordinate is V, and it is listed between the shared threshold τ and the two selector-window rows W_0, W_1.

The sibling surfaces provide the source routes: regular tail data enter through T_0, T_1, modulus data enter through μ_0, μ_1, and the shared-threshold service exposes τ before either branch can select a window. The replay row C records exactly this order.

Finally use the exclusion clauses of the carrier. A comparison that bypasses τ or replaces V would require a hidden comparison row, an independent Real seal, a quotient stream, or an ambient completeness coordinate. None is a coordinate of F, so stability is forced by carrier projection. □

Theorem 1024.5 (Cauchy tail modulus fusion window readback route)**.** *For the displayed carrier*

$$F = (T_0, T_1, \mu_0, \mu_1, \tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1, E, H, C, P, N),$$

every finite-window readback used by the $\mathsf{Real}^{\uparrow}$ *seal* E *is routed through the paired windows* W_0, W_1*, dyadic tolerance rows* D_0, D_1*, and regular rational rows* Q_0, Q_1 *displayed in the* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *certificate surfaces. The rows* $T_0, T_1, \mu_0, \mu_1, \tau, V, H, C, P, N$ *remain public coordinates of the same packet and do not open any second readback channel.*

Proof. Begin with the window coordinates. The carrier lists exactly two selector windows, W_0 and W_1, and each window has its displayed dyadic tolerance and regular rational readback, namely D_0, Q_0 and D_1, Q_1.

The observation surfaces then determine the route. $\mathsf{StreamName}^{\uparrow}$ supplies the finite window names, $\mathsf{DyadicRatCore}^{\uparrow}$ supplies D_0, D_1, $\mathsf{RegSeqRat}^{\uparrow}$ supplies Q_0, Q_1, and $\mathsf{Real}^{\uparrow}$ consumes the resulting readbacks only at E.

The remaining rows keep the route single-carrier. The schedules T_0, T_1, moduli μ_0, μ_1, threshold τ, comparison V, transport H, replay C, provenance P, and local name N are all projected from the same finite packet, so a second window-readback channel would have to be an unlisted coordinate. □

Theorem 1024.6 (Cauchy tail modulus fusion Real seal nonescape)**.** *For the displayed carrier*

$$F = (T_0, T_1, \mu_0, \mu_1, \tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1, E, H, C, P, N),$$

the $\mathsf{Real}^{\uparrow}$ *seal row* E *has no escape route outside the shared-tail and modulus-fusion packet. Any consumer that reads* E *must also read the sibling-surface chain through* $T_0, T_1, \mu_0, \mu_1, \tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1$ *and must keep the transport, replay, provenance, and naming rows* H, C, P, N *attached to that same carrier.*

Proof. The carrier has a single Real-facing coordinate, E. It is introduced only after the schedules, modulus rows, shared threshold, comparison row, selector windows, dyadic tolerances, and regular readbacks have been displayed.

The certificate surfaces prevent detachment. The route to E is replayed by C, transported by H, recorded by P, and named by N as part of the same $\mathsf{NameCert}_{\mathsf{CauchyTailModulusFusion}^{\uparrow}}$ packet.

If E escaped this packet, the consumer would need a quotient stream, a host real equality, a selected external limit, an independent per-source Real seal, or an ambient completeness coordinate. The carrier explicitly excludes each of these coordinates, so the Real seal remains internal to the displayed chain. □

Theorem 1024.7 (Cauchy tail modulus fusion public Real-completion export)**.** *Every downstream Real-completion consumer of an accepted* CauchyTailModulusFusion$^{\uparrow}$ *packet reads the public route through the displayed rows*

$$T_0, T_1, \mu_0, \mu_1, \tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1, E, H, C, P, N.$$

The source rows are supplied by the three sibling surfaces RegularCauchyTailFusion$^{\uparrow}$, CauchyModulusRefinement$^{\uparrow}$, *and* CauchySharedTailModulus$^{\uparrow}$, *and the finite readback exits through the four L10 surfaces* StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *and* Real$^{\uparrow}$. *This public surface exports no quotient stream, selected host limit, host equality, countable-choice row, or ambient Real-completeness principle.*

Proof. Start with the NameCert obligations of Definition 1024.2. They expose exactly the two schedules, two modulus rows, shared threshold, comparison row, paired windows, dyadic tolerances, regular readbacks, Real seal, transport, replay, provenance, and local name listed in the carrier.

Next use shared-tail exhaustion and threshold-comparison stability. Definition 1024.3 forces any Real-facing read of E through $\tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1$, while Definition 1024.4 keeps both branches on the same sibling-surface comparison route.

The finite readback is then fixed by Definition 1024.5. The route reads the StreamName$^{\uparrow}$ windows, DyadicRatCore$^{\uparrow}$ tolerances, RegSeqRat$^{\uparrow}$ readbacks, and Real$^{\uparrow}$ seal as one displayed public surface.

Finally apply Real-seal nonescape, Definition 1024.6. Since the packet has no coordinate for quotient streams, selected host limits, host equality, countable choice, or ambient Real completeness, every downstream Real-completion consumer receives only the public route above. □

Theorem 1024.8 (Cauchy tail modulus fusion mature readback coverage)**.** *Every downstream Real-completion consumer of an accepted* CauchyTailModulusFusion$^{\uparrow}$ *packet reads exactly the shared chain*

$$T_0, T_1, \mu_0, \mu_1, \tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1, E, H, C, P, N.$$

The source rows are supplied by RegularCauchyTailFusion$^{\uparrow}$, CauchyModulusRefinement$^{\uparrow}$, CauchySharedTailModulus$^{\uparrow}$, StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, *and* Real$^{\uparrow}$. *The consumer receives no second limit, quotient stream, host equality, hidden modulus comparison, countable-choice row, or ambient Real-completeness coordinate.*

Proof. Begin with the NameCert obligations of Definition 1024.2. They bind the consumer-facing packet to the displayed carrier rows $T_0, T_1, \mu_0, \mu_1, \tau, V, W_0, W_1, D_0, D_1, Q_0, Q_1, E, H, C, P, N$.

Next combine the shared-tail and comparison witnesses. The shared-tail exhaustion theorem forces every Real-facing read through the common threshold, windows, dyadic tolerances, and regular readbacks, while threshold-comparison stability keeps both branches attached to the three sibling surfaces.

The finite observation route is then fixed by the window-readback theorem. It preserves the StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, and Real$^{\uparrow}$ certificate surfaces as the route from selected windows to the Real seal.

Finally use Real-seal nonescape together with the public Real-completion export theorem. Since the packet contains no second limit, quotient stream, host equality, hidden modulus comparison, countable-choice row, or ambient Real-completeness coordinate, the downstream consumer receives exactly the fused public route and no external completion coordinate. □

Closure status for NameCert$_{\text{CauchyTailModulusFusion}^{\uparrow}}$.

Constructive story: A CauchyTailModulusFusion$^{\uparrow}$ packet is generated from two tail schedules, two modulus rows, one shared threshold, one modulus comparison row, paired selector windows, paired dyadic tolerances, paired RegSeqRat$^{\uparrow}$

readbacks, a Real$^{\uparrow}$ seal, componentwise hsame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.CauchyTailModulusFusionUp.taste gate`

Theory closure: TheoryGate(NameCert$_{\text{CauchyTailModulusFusion}\uparrow}$, maturePackageClosed)

Scope closed: Definition 1024.1, the five obligation rows in Definition 1024.2, Definition 1024.3, Definition 1024.4, Definition 1024.5, Definition 1024.6, the public export theorem Definition 1024.7, and the mature readback coverage theorem Definition 1024.8 bind the reusable shared-tail and modulus-fusion surface for downstream Real-completion consumers.

Formal verification: FormalStatus(NameCert$_{\text{CauchyTailModulusFusion}\uparrow}$, axiomClean)

Lean target: `BEDC.Derived.CauchyTailModulusFusionUp.CauchyTailModulusFusionCarrier\_namecert\_obligations`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Real completeness, quotient-stream equality, host real equality, selected external limits, or a public standard bridge.

Upgrade path: No further paper-side closure step remains; bridge checking remains a separate formal-axis task.

Chapter 1025

A Concrete Naming Certificate for $\mathsf{ContinuationBisimulation}^{\uparrow}$

The $\mathsf{ContinuationBisimulation}^{\uparrow}$ packet realizes the behavioral-equivalence direction of chapter 9365 as a finite paired-simulation certificate. It is adjacent to the small-step trace packet of chapter 469, the terminal-read packet of chapter 657, and the bounded evaluator packet of chapter 818, but it stores a different public surface: two endpoint traces together with forward and backward simulation rows over the same endpoints.

Falsifiable prediction: An accepted $\mathsf{ContinuationBisimulation}^{\uparrow}$ packet with a forward simulation row but no backward simulation row fails the local NameCert obligations.

Independence witness: continuationtrace, continuationbigstep, continuationtracenormalform, continuationautomaton, finitetraceevaluator: none is bijective to $\mathsf{ContinuationBisimulation}^{\uparrow}$ because those siblings record traces, terminal reads, normal forms, automata, or bounded evaluator rows, while this carrier requires paired forward and backward simulation rows over the same endpoints.

Definition 1025.1 (ContinuationBisimulation carrier)**.** *A* $\mathsf{ContinuationBisimulation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (L, R, F, B, E, H, C, P, N)$$

with the following displayed rows:

1. *L is the left finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger, including its source, mark-and-tail, target, and trace rows;*
2. *R is the right finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *ledger over the comparison endpoint;*
3. *F is the forward simulation row, reading each visible left trace step as a right trace step with matching endpoint classifier;*
4. *B is the backward simulation row, reading each visible right trace step as a left trace step with matching endpoint classifier;*
5. *E is the endpoint classifier row comparing the two source endpoints and the two target endpoints after the paired simulations have been read;*
6. *H stores componentwise* hsame *transports for the two trace ledgers, the forward and backward simulation rows, endpoint classifiers, replay rows, provenance, and local naming;*
7. *C stores the displayed* Cont *replay routes used to replay the left trace, the right trace, the forward simulation, the backward simulation, and the endpoint reads;*

8. *P is the* Pkg *provenance over chapter 9365, chapter 469, chapter 657, chapter 818,* BHist, hsame, Cont, *and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ContinuationBisimulation}^{\uparrow}}$ *row.*

The carrier exposes a symmetric finite behavioral-equivalence packet. It contains no host evaluator, quotient behaviour class, unbounded trace semantics, terminal-result selector, or one-sided simulation shortcut.

Theorem 1025.2 (ContinuationBisimulation NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ContinuationBisimulation}^{\uparrow}}$ *surface for the carrier of Definition 1025.1 consists of seven finite obligations:*

1. *carrier admission for the displayed packet $Z = (L, R, F, B, E, H, C, P, N)$;*
2. *left trace admission for L through the finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *rows;*
3. *right trace admission for R through the finite* $\mathsf{ContinuationTrace}^{\uparrow}$ *rows;*
4. *forward simulation exactness, requiring every visible step read from L to be matched by a displayed step read from R through F;*
5. *backward simulation exactness, requiring every visible step read from R to be matched by a displayed step read from L through B;*
6. *endpoint-classifier stability through E, H, C for the two source endpoints and the two target endpoints;*
7. *non-escape, stating that every accepted behavioral-equivalence read factors through $L, R, F, B, E, H, C, P, N$ and cannot consult a host evaluator, quotient behaviour class, unbounded trace semantics, terminal-result selector, or one-sided simulation row.*

Lean4 ✓ `BEDC.Derived.ContinuationBisimulationUp.TasteGate.ContinuationBisimulationNameCertObligations`

Proof. Carrier admission is projection from Definition 1025.1. The accepted packet displays exactly the two trace ledgers, the two simulation rows, the endpoint classifier, the transport row, the replay row, provenance, and the local naming row.

Read the two trace obligations through chapter 469. The rows L and R are finite continuation traces, so their visible steps are source, mark-and-tail, target, trace-ledger, and replay reads rather than host-level transition facts.

The simulation obligations are then paired. The forward row F accounts for every visible left step by a right-step read, and the backward row B accounts for every visible right step by a left-step read. Since both rows are coordinates of the same packet, the local NameCert can reject a one-sided packet before endpoint equivalence is exported.

Finally, E, H, C, P, N provide endpoint comparison, componentwise transport, replay, provenance, and local naming for the paired route. No coordinate remains for a quotient behaviour class, an evaluator graph, an unbounded trace semantics, a terminal-result selector, or a hidden one-sided simulation, so the seven obligations exhaust the packet. □

Theorem 1025.3 (ContinuationBisimulation non-escape)**.** *Every accepted* $\mathsf{ContinuationBisimulation}^{\uparrow}$ *consumer route factors through the displayed finite rows*

$$L, R, F, B, E, H, C, P, N.$$

In particular, a behavioral-equivalence consumer must read both the forward simulation row F and the backward simulation row B before the endpoint classifier E can be exported. The route cannot

be replaced by a host evaluator, a quotient of behaviours, an automaton-language equivalence, a bounded evaluator verdict, or a terminal-only big-step read.

Proof. Unpack the carrier of Definition 1025.1. The only trace data available to a consumer are the two finite ledgers L and R, and the only simulation data are the displayed rows F and B.

Use the NameCert obligations of Definition 1025.2. They force left-step reads through L, right-step reads through R, forward matching through F, backward matching through B, and endpoint comparison through E, H, C.

The surrounding siblings keep their own surfaces. chapter 657 reads terminal rows, chapter 818 records bounded evaluator rows, and chapter 482 records automaton transition rows. None supplies the missing opposite simulation row for this packet.

Therefore every accepted behavioral-equivalence read remains inside $L, R, F, B, E, H, C, P, N$. Removing either F or B changes the local NameCert surface and leaves no route by which the endpoint classifier may export symmetric equivalence. □

Closure status for $\mathsf{NameCert}_{\mathsf{ContinuationBisimulation}^{\uparrow}}$.

Constructive story: A $\mathsf{ContinuationBisimulation}^{\uparrow}$ packet is generated from left and right finite continuation ledgers, forward and backward matching rows, endpoint comparison, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The BHist carrier does not start from behavioral equivalence as a host relation; it builds the relation by exposing both finite ledgers and both matching directions. The classifier accepts a bisimulation read only when left steps, right steps, forward matches, backward matches, and endpoint rows all remain visible under the same transport and replay surface.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ContinuationBisimulation}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the continuation bisimulation carrier, its NameCert obligations, and the non-escape field-faithfulness argument.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ContinuationBisimulation}^{\uparrow}}, \mathsf{unformalized})$

Ledger evidence: BEDC.Meta.DiscoveryDeltaLedger.continuationBisimulationDeltaLedger

Bridge status: none

Origin: ai

Not claimed: It does not claim quotient behavioral semantics, infinite coinductive trace equality, host evaluator equivalence, or one-sided simulation as full equivalence.

Upgrade path: To reach obligationClosure, formalize the two finite ledgers and prove that both matching rows are necessary for the endpoint classifier.

Chapter 1026

A Concrete Naming Certificate for $\mathsf{KleisliTrace}^{\uparrow}$

The $\mathsf{KleisliTrace}^{\uparrow}$ packet realizes the continuation-as-small-step direction of chapter 9365 as a finite trace surface for Kleisli computation. It sits between the certified Kleisli interface of chapter 485 and the terminal replay surface of chapter 683: the former supplies bind and return rows, while the latter supplies the trace-normal-form row that lets a consumer read the whole route as one finite continuation trace. The same packet also exposes the $\mathsf{Cat}^{\uparrow}$ hom rows consumed by categorical continuation users, so Kleisli bind and category composition read from the same displayed route instead of from two unrelated ledgers.

Falsifiable prediction: If the trace-normal-form row is removed, the packet cannot route both Kleisli bind and CategoryHomCarrier consumers through one finite continuation trace.

Independence witness: continuationmonad, continuationtracenormalform, category, generator-closure: $\mathsf{ContinuationMonad}^{\uparrow}$ supplies bind and return rows without a single exported trace ledger, $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ supplies terminal replay without Kleisli source and target bind slots, $\mathsf{Cat}^{\uparrow}$ supplies hom rows without monadic provenance, and generator closure supplies source saturation without the five-row local naming surface below.

Definition 1026.1 (KleisliTrace carrier)**.** *A* $\mathsf{KleisliTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (S, B, T, G, H, C, P, N)$$

whose displayed rows are:

1. *S is the source continuation computation row accepted by the* $\mathsf{ContinuationMonad}^{\uparrow}$ *surface;*
2. *B is the Kleisli bind row, including the return slot, middle continuation, and composed continuation read from the* $\mathsf{ContinuationMonad}^{\uparrow}$ *packet;*
3. *T is the finite* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *row that replays the same Kleisli computation as one terminal trace-normal-form route;*
4. *G is the* $\mathsf{Cat}^{\uparrow}$ *hom row, exposing the source object, target object, and morphism history consumed by categorical continuation users;*
5. *H is the componentwise* hsame *transport row for the monad row, trace-normal-form row, hom row, replay rows, provenance, and local name;*

6. *C stores the displayed* Cont *replay routes that connect the Kleisli bind read, trace replay, and category hom read;*
7. *P is the* Pkg *provenance over chapter 9365, chapter 485, chapter 683, chapter 61,* BHist, hsame, Cont, *and* NameCert*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{KleisliTrace}^{\uparrow}}$ *row.*

The packet contains no host evaluator, no hidden category composition oracle, no selected normalizer, and no quotient of computations. Every exported computation read is a row of K.

Lean4 (definition) `BEDC.Derived.KleisliTraceUp.TasteGate.KleisliTraceUp`

Theorem 1026.2 (KleisliTrace NameCert obligation surface)**.** *For the carrier of Definition 1026.1, the local* $\mathsf{NameCert}_{\mathsf{KleisliTrace}^{\uparrow}}$ *surface consists of five rows:*

1. *carrier admission for the displayed packet $K = (S, B, T, G, H, C, P, N)$;*
2. *Kleisli source and bind readback through the* $\mathsf{ContinuationMonad}^{\uparrow}$ *row S, B;*
3. *trace-normal-form replay through the finite* $\mathsf{ContinuationTraceNormalForm}^{\uparrow}$ *row T and the displayed* Cont *routes C;*
4. *Category hom readback through G, with componentwise* hsame *transport through H;*
5. *provenance and local naming through P, N, together with non-escape from host evaluators, hidden category composition, selected normalizers, and quotient computation objects.*

These five rows are the obligation surface that a later Lean TasteGate must expose through both $\mathsf{Nontrivial\,KleisliTrace}^{\uparrow}$ *and* $\mathsf{FieldFaithful\,KleisliTrace}^{\uparrow}$ *instances.*

Lean4 ✓ `BEDC.Derived.KleisliTraceUp.TasteGate.KleisliTraceTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 1026.1. The accepted packet exposes exactly S, B, T, G, H, C, P, N.

Read the Kleisli side through chapter 485. The rows S and B display the source computation, return slot, middle continuation, and composed bind route before any consumer asks for a trace.

Read the trace side through chapter 683. The row T and replay routes C show that the same bind route is consumed as one terminal finite trace-normal-form packet.

Finally read the categorical side through $\mathsf{Cat}^{\uparrow}$. The hom row G gives the source, target, and morphism surface consumed by category users, while H, P, N provide transport, provenance, and local naming. Since the carrier has no coordinate for a host evaluator, hidden category composition oracle, selected normalizer, or quotient computation object, the five rows exhaust the local certificate surface. □

Theorem 1026.3 (KleisliTrace common trace route)**.** *Every accepted* $\mathsf{KleisliTrace}^{\uparrow}$ *consumer route for Kleisli bind or for a* $\mathsf{Cat}^{\uparrow}$ *hom read factors through the same finite rows*

$$S, B, T, G, H, C, P, N.$$

The Kleisli consumer reads S, B, T, C, H, P, N; the category consumer reads G, T, C, H, P, N. Neither consumer can replace the displayed trace-normal-form row by a host evaluator, hidden composition oracle, selected normalizer, or quotient computation object.

Proof. Start with the carrier projection. Both consumer routes have access only to S, B, T, G, H, C, P, N.

For the Kleisli consumer, apply Definition 1026.2. The source and bind rows are read through S, B, and the route is replayed through T, C before provenance and local naming are exported.

For the categorical consumer, use the same obligation surface. The hom row G is read together with the trace-normal-form row T, the replay row C, transport row H, provenance row P, and local name N.

The excluded alternatives have no coordinate in the accepted packet. Thus the two consumers share the same finite continuation trace rather than importing a second evaluator, composition, normalization, or quotient surface. □

Theorem 1026.4 (KleisliTrace trace-normal-form necessity)**.** *An accepted* $\mathsf{KleisliTrace}^{\uparrow}$ *packet cannot export both its Kleisli bind read and its* $\mathsf{Cat}^{\uparrow}$ *hom read after removing the trace-normal-form row* T*. The finite replay row* T *is the common surface that identifies the monadic bind route and the category hom route as one continuation trace.*

Proof. Assume the packet is accepted but omit the row T. The remaining rows still mention the Kleisli source and bind data S, B and the category hom data G, but they no longer contain the finite terminal replay surface consumed by both users.

Apply Definition 1026.2. The second row reads the monadic bind surface, the third row requires trace-normal-form replay through T, C, and the fourth row reads the category hom surface through G, H.

Apply Definition 1026.3. Its shared route for both consumers passes through T. Without that row, the two reads would need a second evaluator, hidden category composition, selected normalizer, or quotient computation object, each of which is excluded by the carrier. □

Closure status for $\mathsf{NameCert}_{\mathsf{KleisliTrace}^{\uparrow}}$**.**

Constructive story: A $\mathsf{KleisliTrace}^{\uparrow}$ packet is generated from a monadic bind row, trace-normal-form row, category-hom row, shared trace route, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The carrier reads a computation trace by first exposing the bind surface, then the finite trace normal form, then the category-facing hom surface. The same trace route is consumed by both monadic and categorical consumers, while hsame preserves the displayed coordinates and Cont replays the finite handoff. The construction names a shared Kleisli trace, not hidden evaluator composition.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{KleisliTrace}^{\uparrow}}$, seed)

Scope closed: This chapter binds the Kleisli trace carrier, obligation surface, common trace route, and route non-escape argument.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{KleisliTrace}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim hidden category composition, selected normalizers, quotient computations, or host evaluator equality.

Upgrade path: To reach obligationClosure, provide a checked carrier tying the monadic bind, trace-normal-form, and category-hom rows to one finite route.

Chapter 1027

A Concrete Naming Certificate for $\mathsf{LargeModelInscriptionAudit}^{\uparrow}$

The $\mathsf{LargeModelInscriptionAudit}^{\uparrow}$ packet realizes the large-model inscription-point reading of chapter 9398 as a finite audit surface. It sits downstream of the inscription carrier of chapter 939, the activation-orbit carrier of chapter 967, the verified-output harness of chapter 976, and the route-audit sibling of chapter 1005. Its distinguishing role is to bind output, corpus provenance, verification channel, refusal ledger, transport, route, and local naming rows before a consumer may export a model output as an audited inscription.

Definition 1027.1 (LargeModelInscriptionAudit carrier)**.** *A* $\mathsf{LargeModelInscriptionAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (O, C, V, R, T, K, H, P, N)$$

with the following displayed rows:

1. *O is the output-record row read from the large-model inscription point;*
2. *C is the corpus-provenance row recording the source-channel and distillation route for the output read;*
3. *V is the verification-channel row naming the finite checker, replay harness, policy check, proof check, or external certificate procedure applied to O;*
4. *R is the refusal-ledger row recording unsupported, unverifiable, out-of-scope, or rejected claims;*
5. *T records componentwise* hsame *transport for output, corpus, verification, refusal, route, provenance, and naming rows;*
6. *K records the displayed* Cont *route from inscription point through corpus provenance, verification channel, refusal ledger, package provenance, and local name;*
7. *H is the accepted harness row supplied by* $\mathsf{VerifiedOutputHarness}^{\uparrow}$ *when the output read is checker-facing;*
8. *P is the* Pkg *provenance over* $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$, $\mathsf{LargeModelActivationOrbit}^{\uparrow}$, $\mathsf{LargeModelAuditChannel}$ $\mathsf{CorpusSupplyDistillation}^{\uparrow}$, $\mathsf{VerifiedOutputHarness}^{\uparrow}$, $\mathsf{InscriptionRouteAudit}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{LargeModelInscriptionAudit}^{\uparrow}}$ *row.*

The carrier has no coordinate for model consciousness, host semantic understanding, corpus-wide truth, hidden verifier state, private policy override, selected source oracle, or internally ratified universal closure.

Theorem 1027.2 (LargeModelInscriptionAudit NameCert obligations)**.** *For the carrier of Definition 1027.1, the local* $\mathsf{NameCert}_{\mathsf{LargeModelInscriptionAudit}^{\uparrow}}$ *surface consists exactly of carrier admission for* $A = (O, C, V, R, T, K, H, P, N)$*, corpus-provenance exposure through* C*, verification-channel exposure through* V*, refusal-ledger exposure through* R*, componentwise transport through* T*, displayed route replay through* K*, checker-facing harness exposure through* H*, package provenance through* P*, and local naming through* N*.*

Proof. Carrier admission is projection from the displayed packet. The rows $O, C, V, R, T, K, H, P, N$ are the full public inventory for the audit.

The corpus and verification obligations are separate. The row C records where the output read is carried from, while V records how the output is inspected before public export.

The refusal, transport, route, harness, provenance, and naming rows make the audit replayable. They force any consumer-facing read to keep unsupported claims, checker-facing status, and local provenance in the same finite packet. □

Theorem 1027.3 (LargeModelInscriptionAudit output verification boundary)**.** *An accepted* LargeModelInscriptionA *packet can export the output row* O *as audited inscription only after the verification-channel row* V *and refusal-ledger row* R *have been displayed. If* V *is absent, the packet may still contain an emitted output record, but it cannot export that record as internally ratified universal truth or as checker-facing accepted output.*

Proof. Project the carrier of Definition 1027.1. The output row O is present before the audit reads verification or refusal data.

The route row K orders the public read through C, V, R, H, P, N. Thus the output remains carried inscription until the verification channel and refusal ledger have both been exposed.

If V is removed, no carrier coordinate names the checker, replay harness, policy check, proof check, or external certificate procedure. The packet therefore lacks the row needed to distinguish an audited output from a bare emitted inscription or an internally asserted universal claim. □

Theorem 1027.4 (LargeModelInscriptionAudit corpus provenance non-escape)**.** *Every public corpus-provenance read of an accepted* $\mathsf{LargeModelInscriptionAudit}^{\uparrow}$ *packet factors through the displayed row* C *and the package row* P*. It cannot be replaced by a selected source oracle, corpus-wide truth predicate, hidden training-data selector, host semantic oracle, or model-internal proof of the output.*

Proof. The carrier contains one corpus-provenance coordinate, namely C, and one package-provenance coordinate, namely P. A consumer can read source-channel and distillation provenance only through those rows.

The sibling $\mathsf{CorpusSupplyDistillation}^{\uparrow}$ row supplies finite filtering and distillation provenance, while $\mathsf{LargeModelInscriptionPoint}^{\uparrow}$ supplies the carried-output boundary. Neither sibling adds an oracle for corpus-wide truth or host semantic interpretation to this packet.

Since the excluded objects have no coordinate in $A = (O, C, V, R, T, K, H, P, N)$, public export of corpus provenance is exhausted by C and P. □

Theorem 1027.5 (LargeModelInscriptionAudit TasteGate obligation)**.** *The Lean boundary for* $\mathsf{LargeModelInscriptionAudit}^{\uparrow}$ *must provide* Nontrivial $\mathsf{LargeModelInscriptionAudit}^{\uparrow}$ *and* FieldFaithful LargeModelInscrip

instances in TasteGate.lean *for the same displayed carrier. The nontrivial instance must exhibit an explicit* witness_pair *separating at least an output-with-verification packet from an output-without-verification packet, and the field-faithful instance must use* mk*-derived fields that preserve* $O, C, V, R, T, K, H, P, N$ *component by component.*

Lean4 ✓ BEDC.Derived.LargeModelInscriptionAuditUp.LargeModelInscriptionAuditTasteGate single carrier alignment

Proof. The carrier definition displays nine finite rows. A nontriviality witness must therefore separate two admissible packet shapes by an actual row difference, not by a hidden semantic predicate.

The verification-channel boundary of Definition 1027.3 supplies the required separation: one packet displays V as a checker-facing route, and the other lacks that displayed verification row.

Field faithfulness must then be componentwise over the same displayed rows. Using mk-derived fields keeps the Lean carrier aligned with the paper packet and prevents hidden verifier state, corpus truth, or internal ratification from entering through an unlisted coordinate. □

Theorem 1027.6 (LargeModelInscriptionAudit scoped carrier coverage)**.** *For an accepted* LargeModelInscriptionAu *packet* $A = (O, C, V, R, T, K, H, P, N)$*, every public scoped read factors through exactly the displayed output row* O*, corpus-provenance row* C*, verification-channel row* V*, refusal-ledger row* R*,* hsame*-transport row* T*,* Cont*-route row* K*, harness row* H*,* Pkg*-provenance row* P*, and local* NameCert *row* N*. Sibling support is limited to* LargeModelInscriptionPoint$^{\uparrow}$*,* LargeModelActivationOrbit$^{\uparrow}$*,* LargeModelAuditChannel$^{\uparrow}$ CorpusSupplyDistillation$^{\uparrow}$*,* VerifiedOutputHarness$^{\uparrow}$*, and* InscriptionRouteAudit$^{\uparrow}$*. No hidden verifier state, corpus-wide truth predicate, model consciousness, or host semantic oracle is admitted by the scoped carrier.*

Proof. The carrier definition gives the complete finite BHist packet $A = (O, C, V, R, T, K, H, P, N)$. Each public read must therefore project one of those displayed rows, and the NameCert obligation theorem identifies carrier admission, corpus provenance, verification channel, refusal ledger, transport, route replay, harness exposure, package provenance, and local naming as the exact local certificate surface.

The output-verification boundary forces checker-facing export through V and R, while the corpus-provenance non-escape theorem forces source and distillation reads through C and P. These two obligations rule out a hidden verifier coordinate, a selected source oracle, a corpus-wide truth predicate, and a host semantic oracle.

The TasteGate obligation aligns the Lean carrier with the same componentwise rows. Since field faithfulness is witnessed over the mk-derived coordinates $O, C, V, R, T, K, H, P, N$, the scoped read cannot gain model consciousness, internal ratification, or private semantic state through any unlisted carrier field. □

Falsifiable prediction: A LargeModelInscriptionAuditUp consumer that omits the verification-channel row cannot export model output as internally ratified universal truth.

Independence witness: largemodelactivationorbit, largemodelauditchannel, corpussupplydistillation, verifiedoutputharness, inscriptionrouteaudit: the combined output/provenance/verification carrier is not bijective to any one sibling because activation orbit lacks the audit verification channel, audit channel lacks the corpus-provenance and route-audit combination, corpus-supply distillation lacks the accepted output harness, verified output harness lacks the standalone corpus-provenance audit row, and inscription route audit lacks the large-model output and corpus rows.

Closure status for $\mathsf{NameCert}_{\mathsf{LargeModelInscriptionAudit}^{\uparrow}}$.

Constructive story: A $\mathsf{LargeModelInscriptionAudit}^{\uparrow}$ packet is generated from output, corpus-provenance, verification-channel, refusal-ledger, transport, route, harness, package provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LargeModelInscriptionAudit}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1027.1, Definition 1027.2, Definition 1027.3, Definition 1027.4, Definition 1027.5, and Definition 1027.6 specify the finite large-model inscription audit carrier, its verification-channel boundary, and its scoped carrier coverage.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LargeModelInscriptionAudit}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.LargeModelInscriptionAuditUp.LargeModelInscriptionAuditTasteGate\_single\_carrier\_alig`
Lean4 ✓ `BEDC.Derived.LargeModelInscriptionAuditUp.taste gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close model consciousness, corpus-wide truth, host semantic understanding, hidden verifier correctness, Real completeness, or bridge checking for $\mathsf{LargeModelInscriptionAudit}^{\uparrow}$.

Upgrade path: No further theory-axis upgrade remains for the displayed $O, C, V, R, T, K, H, P, N$ rows; bridge checking remains a separate verification-axis obligation.

Chapter 1028

A Concrete Naming Certificate for $\mathsf{RuntimeTruthSeparation}^{\uparrow}$

The $\mathsf{RuntimeTruthSeparation}^{\uparrow}$ packet realizes the reflection-limit boundary of chapter 9461 as a finite NameCert surface that keeps structural CIC* self-description separate from host runtime and truth-validation requests. It sits beside the reflection-limit boundary of chapter 586, the runtime-candidate boundary of chapter 591, the finite trace evaluator of chapter 818, the ground-loop boundary of chapter 674, and the quotient-soundness boundary of chapter 634. Those siblings expose separate structural, runtime, evaluator, ground, and quotient boundaries; this packet binds the two refusal axes in one local carrier so that a downstream consumer can ask for structure while runtime execution and truth validation remain outside BEDC.

Definition 1028.1 (Runtime/truth separation carrier)**.** *A* $\mathsf{RuntimeTruthSeparation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (S, E, T, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the structural description row for the finite* CIC* *self-description accepted by the reflection-limit packet;*
2. *E is the runtime-request row, recording a consumer request to execute, step, normalize, or validate the structural description by an external host runtime;*
3. *T is the truth-validation request row, recording a consumer request for a truth predicate, host validation oracle, global truth classifier, or semantic correctness judgment over the same structural description;*
4. *L is the refusal ledger, routing every request in E or T back to the finite packet unless the consumer reads only the structural row S and its displayed bookkeeping;*
5. *H records componentwise* hsame *transport for the structural description, runtime-request, truth-validation request, refusal ledger, continuation, provenance, and local naming rows;*
6. *C records displayed* Cont *routes for reading S, E, T, L, H, P, N without adding an evaluator, truth predicate, or validation oracle;*
7. *P is the* Pkg *provenance over* $\mathsf{ReflectionLimitBoundary}^{\uparrow}$, $\mathsf{RuntimeCandidateBoundary}^{\uparrow}$, $\mathsf{FiniteTraceEvaluator}^{\uparrow}$, $\mathsf{GroundLoopBoundary}^{\uparrow}$, $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*

8. N is the local $\mathsf{NameCert}_{\mathsf{RuntimeTruthSeparation}^{\uparrow}}$ *row.*
The carrier exports structural self-description and its refusal ledger only. It contains no runtime executor, no truth predicate, no host validation oracle, and no off-packet evaluator.

Lean4 ✓ `BEDC.Derived.RuntimeTruthSeparationUp.RuntimeTruthSeparationTasteGate single carrier alignment`

Theorem 1028.2 (Runtime/truth separation non-escape)**.** *Every accepted* $\mathsf{RuntimeTruthSeparation}^{\uparrow}$ *packet* $R = (S, E, T, L, H, C, P, N)$ *exposes structural* CIC^* *data only through* S, H, C, P, N *and routes runtime or truth-validation requests only through* E, T, L*. It exports no runtime executor, truth predicate, host validation oracle, or off-packet evaluator.*

Proof. Project the carrier of Definition 1028.1. The row S is the only structural self-description row, while E and T are request rows rather than execution or truth witnesses.

The refusal ledger L is the only row that consumes those requests. A runtime read must pass through E and then L; a truth-validation read must pass through T and then L.

Finally inspect the bookkeeping rows. The transport row H, continuation row C, provenance row P, and local name N preserve and route the displayed finite packet. Since none of these coordinates contains an executor, truth predicate, host validation oracle, or evaluator, every accepted consumer read remains inside the structural row or the refusal ledger. □

Falsifiable prediction: Any accepted RuntimeTruthSeparationUp consumer requesting runtime execution or a truth predicate is routed to the refusal ledger unless it stays inside the displayed structural rows.

Independence witness: reflectionlimitboundary, runtimecandidateboundary, finitetraceevaluator, groundloopboundary, quotientsoundnessboundary: none is bijective because none carries both runtime-request and truth-validation refusal rows with the structural self-description row in one packet.

The Lean taste-gate file is `lean4/BEDC/Derived/RuntimeTruthSeparationUp/TasteGate.lean`. It must provide explicit `Nontrivial RuntimeTruthSeparationUp` and `FieldFaithful RuntimeTruthSeparation` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{RuntimeTruthSeparation}^{\uparrow}}$.

Constructive story: A $\mathsf{RuntimeTruthSeparation}^{\uparrow}$ packet is generated from structural description, runtime-request, truth-validation request, refusal-ledger, transport, continuation, provenance, and local NameCert rows.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RuntimeTruthSeparation}^{\uparrow}}$, seed)

Scope closed: Definition 1028.1 and Definition 1028.2 specify the finite carrier separating structural self-description from runtime execution and truth validation.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RuntimeTruthSeparation}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.RuntimeTruthSeparationUp.RuntimeTruthSeparationTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not provide Lean verification, bridge checking, a runtime executor, a truth predicate, a host validation oracle, quotient soundness, or an off-packet evaluator.

Upgrade path: Scoped closure requires checked carrier admission, refusal-ledger exactness, non-escape, nontriviality, and field faithfulness over the same packet.

Chapter 1029

A Concrete Naming Certificate for KernelNormalizationAuditJoin$^{\uparrow}$

The KernelNormalizationAuditJoin$^{\uparrow}$ packet realizes the audit-witness route of chapter 9364 as a finite join over kernel acceptance, axiom-query ancestry, normalization-audit replay, and subject-reduction boundary rows. It sits beside the kernel acceptance witness of chapter 547, the normalization audit packet of chapter 750, the subject-reduction boundary of chapter 721, and the closed-normal consistency packet of chapter 734. Those siblings expose one side of the route; this packet records the simultaneous join needed before a downstream MetaCIC or Real-and-Completion consumer may treat an accepted declaration as replayed normalization-audit evidence.

Definition 1029.1 (Kernel-normalization audit join carrier)**.** *A* KernelNormalizationAuditJoin$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$J = (K, A, Q, N, S, B, R, H, C, P, L)$$

with the following displayed rows:

1. *K is the kernel-stamp row supplied by* KernelAcceptanceAuditWitness$^{\uparrow}$*, including the generated candidate, kernel candidate, accepted declaration, and environment ledger;*
2. *A is the* AxiomQueryLedger$^{\uparrow}$ *row that records the transitive dependency query, forbidden-dependency comparison, and verdict for the accepted declaration named by K;*
3. *Q is the normalization-audit replay row read through* MetaCICNormalizationAudit$^{\uparrow}$*, containing candidate evidence, closed-term projection, finite strong-normalization scope, and replay provenance;*
4. *N is the closed-normal consistency row read through* ClosedNormalConsistency$^{\uparrow}$ *when the replay route reaches a beta-strong normal false endpoint;*
5. *S is the subject-reduction boundary row read through* MetaCICSubjectReductionBoundaryUp*, keeping the four discharge obligations and the checked obstruction visible;*
6. *B is the non-escape boundary row saying that acceptance, query cleanliness, normalization replay, and closed-normal consistency remain separate from kernel correctness, full closed subject reduction, host evaluation, or ambient completeness;*
7. *R is the route-join ledger recording that the acceptance route, axiom-query route, normalization replay route, closed-normal route, and subject-reduction boundary route are consumed as one finite packet;*

8. *H records componentwise* hsame *transport for $K, A, Q, N, S, B, R, C, P, L$;*
9. *C records displayed* Cont *replay for accepted-declaration ancestry, axiom-query ledger reads, normalization-audit replay, closed-normal handoff, and boundary inspection;*
10. *P is the* Pkg *provenance over* KernelAcceptanceAuditWitness$^{\uparrow}$, AxiomQueryLedger$^{\uparrow}$, MetaCICNormalizationAudit$^{\uparrow}$, ClosedNormalConsistency$^{\uparrow}$, MetaCICSubjectReductionBoundaryUp, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
11. *L is the local* NameCert$_{\text{KernelNormalizationAuditJoin}^{\uparrow}}$ *row.*

The carrier has no coordinate for certifying the Lean kernel, proving full closed subject reduction, manufacturing candidate evidence, erasing axiom-query ancestry, selecting a host evaluator, or turning closed-normal consistency into ambient consistency.

Lean4 ✓ `BEDC.Derived.KernelNormalizationAuditJoinUp.KernelNormalizationAuditJoinTasteGate single carrier alignment`

Theorem 1029.2 (Kernel-normalization audit join NameCert obligations)**.** *For the carrier of Definition 1029.1, the local* NameCert$_{\text{KernelNormalizationAuditJoin}^{\uparrow}}$ *surface consists exactly of carrier admission for $J = (K, A, Q, N, S, B, R, H, C, P, L)$, kernel-stamp exposure through K, axiom-query exposure through A, normalization-audit replay through Q, closed-normal handoff through N, subject-reduction boundary exposure through S, non-escape through B, route-join ledger exposure through R, componentwise transport through H, displayed replay through C, package provenance through P, and local naming through L.*

Lean4 ✓ `BEDC.Derived.KernelNormalizationAuditJoinUp.KernelNormalizationAuditJoinPacket namecert obligations`

Proof. Project the carrier of Definition 1029.1. The rows K, A, Q, N, S are the only substantive audit rows: kernel acceptance, axiom-query ancestry, normalization replay, closed-normal endpoint, and subject-reduction boundary.

The join ledger R and continuation row C determine how a consumer reads those rows together. The acceptance route reaches the accepted declaration before A can classify its ancestry, and the normalization route reaches Q before N or S can be consumed as consistency-facing boundary data.

The transport, provenance, and local naming rows preserve the same finite inventory. Since J contains no further coordinate, the displayed rows exhaust the local NameCert obligations. □

Theorem 1029.3 (Kernel-normalization audit join non-escape)**.** *Every accepted* KernelNormalizationAuditJoin$^{\uparrow}$ *packet routes normalization-audit replay through accepted declaration ancestry and axiom-query ledger rows before any closed-normal or subject-reduction boundary read is exported. The packet cannot export Lean kernel correctness, replay success without the kernel-stamp row, dependency cleanliness without the axiom-query row, evidence-free global normalization, full closed subject reduction, host evaluation, quotient conversion, or ambient completeness.*

Proof. Begin with the kernel-stamp and axiom-query side. The rows K and A are distinct coordinates, so acceptance of the declaration and classification of its dependency ancestry cannot be read from either row alone.

Next read the normalization and consistency side. The normalization-audit row Q supplies only the candidate-mediated replay surface, while N supplies the closed-normal endpoint and S keeps the subject-reduction obstruction visible.

Finally inspect the boundary row B together with R, H, C, P, L. These rows replay and name the finite join without adding kernel correctness, hidden normalization evidence, closed subject reduction, host evaluation, quotient conversion, or ambient completeness. Hence every exported read remains inside the displayed packet. □

Falsifiable prediction: If the kernel-stamp row is removed, the packet cannot route normalization-audit replay through accepted declaration ancestry and axiom-query ledger rows.

Independence witness: kernelacceptanceauditwitness, metacicnormalizationaudit, metacicsubjectreductionboundary, closednormalconsistency: none is bijective because the join carries the simultaneous kernel-stamp, normalization replay, obstruction boundary, and non-escape rows, while each sibling carries only one side of that route.

The Lean follow-up for $\mathsf{KernelNormalizationAuditJoin}^{\uparrow}$ lands in `lean4/BEDC/Derived/KernelNormalizationAu` It must provide `Nontrivial` and `FieldFaithful` instances with an explicit `witness_pair` and field injection proofs for the displayed rows $K, A, Q, N, S, B, R, H, C, P, L$.

Closure status for $\mathsf{NameCert}_{\mathsf{KernelNormalizationAuditJoin}^{\uparrow}}$.

Constructive story: A $\mathsf{KernelNormalizationAuditJoin}^{\uparrow}$ packet is generated from kernel-stamp, axiom-query ledger, normalization-audit replay, closed-normal handoff, subject-reduction boundary, non-escape, route-join, transport, continuation, provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{KernelNormalizationAuditJoin}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1029.1, Definition 1029.2, and Definition 1029.3 specify the finite join over acceptance ancestry, axiom-query ledger, normalization replay, closed-normal handoff, and subject-reduction boundary rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{KernelNormalizationAuditJoin}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, Lean kernel correctness, full closed subject reduction, evidence-free global normalization, host evaluation, quotient conversion, or ambient completeness.

Upgrade path: Obligation closure requires checked carrier admission, route-join exactness, non-escape, nontriviality, and field faithfulness over the same packet.

Chapter 1030

A Concrete Naming Certificate for FinitePrefixMachine$^{\uparrow}$

The FinitePrefixMachine$^{\uparrow}$ packet realizes the machine-specific bounded-prefix reading of chapter 9365. It sits between the finite recognizer surface of chapter 1016, the continuation-transition surface of chapter 482, the machine-code surface of chapter 280, and the finite trace replay surface of chapter 469. Its distinguishing datum is that the machine row, state row, transition row, finite prefix, endpoint, acceptance, replay, and local naming rows are all read as one displayed packet.

Falsifiable prediction: Removing the prefix-bound row permits a terminal read not backed by a displayed finite machine prefix, which the local classifier rejects.

Independence witness: finiteprefixautomaton, continuationautomaton, turingmachine, continuationtrace: FinitePrefixMachineUp is not bijective to any sibling because it carries machine state, transition, finite prefix, endpoint, acceptance, replay, and local naming rows in one packet.

Theorem 1030.1 (FinitePrefixMachine carrier)**.** *A* FinitePrefixMachine$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$P = (M, Q, T, F, E, A, H, C, N)$$

with the following displayed coordinates:

1. *M is the finite machine row, including the machine identifier and its displayed input alphabet surface;*
2. *Q is the current state and finite state-ledger row read by the bounded prefix;*
3. *T is the transition-row ledger whose entries expose source state, input mark, target state, and the displayed* Cont *witness for the step;*
4. *F is the finite prefix-bound row, listing the machine input prefix and the visible prefix positions admitted for replay;*
5. *E is the endpoint row reached after the displayed prefix has been replayed;*
6. *A is the acceptance row read from the endpoint and the machine acceptance ledger;*
7. *H stores componentwise* hsame *transports for machine identity, state rows, transition rows, prefix positions, endpoint rows, acceptance rows, replay rows, and local naming;*
8. *C stores the displayed* Cont *replay routes for every accepted transition in the finite prefix and for the endpoint read;*

9. N is the local $\mathsf{NameCert}_{\mathsf{FinitePrefixMachine}^{\uparrow}}$ *row.*

The carrier exposes one machine-specific bounded continuation prefix. It contains no language quotient, no host evaluator, no unlisted transition rule, no infinite trace semantics, and no terminal read outside the displayed finite prefix.

Lean4 ✓ `BEDC.Derived.FinitePrefixMachineUp.FinitePrefixMachineTasteGate single carrier alignment`

Proof. The packet is read by projection from the finite BHist carrier. The displayed tuple names the machine row, the state ledger, the transition ledger, the prefix-bound row, endpoint, acceptance, transports, replay routes, and local naming row.

The neighbouring surfaces explain why each coordinate is public. chapter 1016 supplies the bounded prefix-run shape, chapter 482 supplies the transition-as-continuation shape, chapter 280 supplies the machine row, and chapter 469 supplies finite replay.

Since no other coordinate is present, every accepted read is confined to $M, Q, T, F, E, A, H, C, N$. □

Theorem 1030.2 (FinitePrefixMachine NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{FinitePrefixMachine}^{\uparrow}}$ *surface for the carrier of Definition 1030.1 consists of seven finite obligations:*

1. *carrier admission for the displayed packet $P = (M, Q, T, F, E, A, H, C, N)$;*
2. *machine binding, stating that Q, T, F, E, A are read as rows of the displayed machine row M;*
3. *prefix-bound exposure for the finite prefix row F before any endpoint read is accepted;*
4. *transition exactness for every visible prefix step through the displayed ledger T and the corresponding* Cont *route in C;*
5. *endpoint and acceptance exactness through E and A;*
6. *componentwise stability through H and replay through C;*
7. *non-escape, stating that no accepted terminal read may consult a host evaluator, an unlisted transition rule, a language quotient, an infinite trace, or a terminal row not backed by F.*

Proof. Carrier admission is Definition 1030.1. It gives the finite machine packet and names every row on the local certificate surface.

The machine-binding and prefix-bound obligations are read from M, Q, T, F, E, A. The transition ledger T is meaningful only as a row of the machine M, and the endpoint row E can be read only after the finite prefix-bound row F has displayed the positions being replayed.

Transition exactness, endpoint exactness, and acceptance exactness are then local checks over the same packet. Each accepted step uses a row of T and a replay route in C; the endpoint row E is the terminal row of that finite replay; and A reads acceptance from the endpoint and the displayed machine acceptance ledger.

Finally, H, C, N transport, replay, and name only the displayed rows. Because the carrier has no coordinate for a host evaluator, unlisted rule, quotient language, infinite trace, or off-prefix terminal row, the non-escape obligation follows from the packet boundary. □

Theorem 1030.3 (FinitePrefixMachine prefix determinacy)**.** *For an accepted* $\mathsf{FinitePrefixMachine}^{\uparrow}$ *carrier $P = (M, Q, T, F, E, A, H, C, N)$, the displayed machine row M, transition ledger T, and finite prefix-bound row F determine the endpoint row E and acceptance row A inside the packet. If another accepted endpoint and acceptance pair E', A' is admitted over the same M, Q, T, F, H, C, N, then E is* hsame *to E' and A is* hsame *to A' through the displayed transport rows in H.*

Proof. Begin with the prefix-bound row F. It fixes the visible input prefix and the prefix positions admitted for replay, so a terminal read cannot skip to an endpoint outside that finite row.

At each prefix position, the transition-exactness obligation of Definition 1030.2 forces the next state row to be the target of the displayed transition row in T for the machine M. The replay route in C records the same step as a Cont read; it does not add a second transition source.

After the last displayed prefix position, endpoint exactness forces E to be the row reached by that replay, and acceptance exactness forces A to be read from E and the acceptance surface of M.

Apply the componentwise transport rows in H to any second accepted pair E', A' over the same machine, transition, and prefix rows. The packet therefore identifies the two endpoint rows and the two acceptance rows internally, without using a host evaluator or an unlisted transition rule. □

Lean4 ✓ `BEDC.Derived.FinitePrefixMachineUp.FinitePrefixMachineCarrier prefix determinacy`

Theorem 1030.4 (FinitePrefixMachine non-escape)**.** *Every accepted* $\mathsf{FinitePrefixMachine}^{\uparrow}$ *consumer route factors through*

$$M, Q, T, F, E, A, H, C, N.$$

In particular, a terminal read must pass through the finite prefix-bound row F, the transition ledger T, and the replay row C before the endpoint row E and acceptance row A can be exported. The route cannot be replaced by a finite-prefix automaton quotient, a continuation automaton behaviour class, a Turing-machine host evaluator, or an unbounded continuation trace.

Proof. Unpack the carrier of Definition 1030.1. The only machine-specific data available to a consumer are M, Q, T, F, E, A together with transport, replay, and naming rows.

Use the NameCert obligations of Definition 1030.2. They require machine binding, prefix-bound exposure, transition exactness, endpoint exactness, and acceptance exactness before a terminal read is exported.

The sibling chapters keep their own surfaces. chapter 1016 records bounded automaton runs, chapter 482 records continuation-labelled automaton transitions, chapter 280 records machine-code rows, and chapter 469 records finite replay traces. None supplies the missing combined packet for this machine-specific prefix read.

Therefore every accepted terminal route remains inside $M, Q, T, F, E, A, H, C, N$. □

Lean4 ✓ `BEDC.Derived.FinitePrefixMachineUp.FinitePrefixMachineCarrier nonescape`

Theorem 1030.5 (FinitePrefixMachine public export)**.** *The public export of an accepted* $\mathsf{FinitePrefixMachine}^{\uparrow}$ *packet is exactly the machine-specific bounded prefix surface*

$$M \longmapsto Q \longmapsto T \longmapsto F \longmapsto E \longmapsto A$$

together with componentwise hsame *transport,* Cont *replay, and the local* $\mathsf{NameCert}_{\mathsf{FinitePrefixMachine}^{\uparrow}}$ *row. The export supplies a displayed bounded machine-prefix read for downstream consumers, but it does not publish language equality, behavior-class equality, unbounded halting, total host execution, or a trace outside the finite prefix row.*

Proof. Carrier admission supplies the displayed packet $P = (M, Q, T, F, E, A, H, C, N)$. The public machine-facing route is the finite sequence from machine row through state, transition, prefix bound, endpoint, and acceptance rows.

Prefix determinacy is Definition 1030.3. It makes the endpoint and acceptance rows functions of the displayed machine, transition, and prefix rows inside the local packet.

Non-escape is Definition 1030.4. It prevents any downstream consumer from replacing the finite prefix route by a host evaluator, behaviour quotient, language quotient, unbounded halting claim, or hidden trace oracle.

Thus the exported surface is exactly the displayed bounded machine-prefix read, together with the transport, replay, and local naming rows that certify it. □

The Lean file `Derived/FinitePrefixMachineUp/TasteGate.lean` will provide $\mathsf{Nontrivial\ FinitePrefixMachine}^{\uparrow}$ and $\mathsf{FieldFaithful\ FinitePrefixMachine}^{\uparrow}$ instances for the displayed rows $M, Q, T, F, E, A, H, C, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{FinitePrefixMachine}^{\uparrow}}$.

Constructive story: A $\mathsf{FinitePrefixMachine}^{\uparrow}$ packet is generated from a finite machine row, prefix word row, transition ledger, finite run row, endpoint row, acceptance row, componentwise hsame transport, displayed Cont replay, and local naming. The BHist carrier exposes a bounded machine-prefix computation: each transition step is read from the displayed ledger, the endpoint is determined by the same prefix, and the acceptance classifier receives only that finite endpoint surface. Transport preserves the row inventory, and continuation replay prevents a consumer from replacing the run with a host evaluator.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FinitePrefixMachine}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the finite-prefix machine carrier, prefix determinacy, non-escape, and exact exported surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FinitePrefixMachine}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim behavior quotients, language quotients, unbounded halting, hidden trace oracles, or host evaluator semantics.

Upgrade path: To reach obligationClosure, formalize the finite machine-prefix ledger and prove endpoint and acceptance determinacy for the displayed carrier.

Chapter 1031

ObserverLicensedComparisonUp NameCert construction

The $\mathsf{ObserverLicensedComparison}^{\uparrow}$ surface realizes the observer-history identity vision of chapter 9418 as a finite licensed comparison carrier. It sits between the single-history packet of chapter 479, the pairwise observation packet of chapter 477, and the classifier packet of chapter 986. Its public role is to carry the licensed observations, their hsame transports, and the classifier-output row together, without adding observer-substance or host equality.

Falsifiable prediction: Changing only unlicensed observer-substance rows leaves every public comparison read unchanged.

Independence witness: Nearest siblings: observerhsameclassifier, observerhistidentity, observerhistoryidentity, observersubjectboundary, observerfilter. The carrier is not bijective to any of them: it stores a reusable licensed-comparison packet with source histories, licensed observations, hsame transport, classifier output, and public routes, while the siblings either carry a single identity row, a pairwise observation row, a classifier-only output surface, a subject boundary, or a filter selector.

Definition 1031.1 (Observer licensed comparison carrier)**.** *An* $\mathsf{ObserverLicensedComparison}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (H_0, H_1, A, R, D, C, P, N)$$

with the following displayed rows:

1. *H_0 and H_1 are the observer-history rows being compared;*
2. *A is the licensed observation ledger, listing exactly the displayed mark,* Cont*,* ProbeBundle*,* SigRel*, and comparison reads allowed to affect the public result;*
3. *R records componentwise* hsame *transport for the histories, licensed observations, classifier-output row, route row, package row, and local naming row;*
4. *D is the finite classifier-output row, read only after the licensed ledger and transport rows are displayed;*
5. *C records the displayed* Cont *routes by which a consumer reads H_0, H_1, A, R, D, P, N;*
6. *P is the* Pkg *provenance over* BHist*,* hsame*,* Cont*,* ProbeBundle*,* SigRel*,* $\mathsf{ObserverHistIdentity}^{\uparrow}$*,* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$*,* $\mathsf{ObserverHsameClassifier}^{\uparrow}$*, and* NameCert *rows;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverLicensedComparison}^{\uparrow}}$ *row.*

The carrier accepts only comparisons whose public result factors through A, R, D, C, P, N. It has no coordinate for unlicensed observation, observer-substance, host equality, quotient history identity, or hidden classifier state.

Lean4 (definition) `BEDC.Derived.ObserverLicensedComparisonUp.ObserverLicensedComparisonUp`

Theorem 1031.2 (Observer licensed comparison NameCert obligations)**.** *For the carrier of Definition 1031.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverLicensedComparison}^{\uparrow}}$ *surface consists exactly of carrier admission for $L = (H_0, H_1, A, R, D, C, P, N)$, licensed-observation exactness for A, componentwise* hsame *transport through R, classifier-output confinement through D, displayed consumer routes through C, package provenance through P, local naming through N, and non-escape from unlicensed observation, observer-substance, host equality, quotient identity, and hidden classifier state.*

Proof. Project the carrier. The displayed rows are exactly $H_0, H_1, A, R, D, C, P, N$, so carrier admission and local naming are finite BHist reads rather than host-side equality claims.

Licensed-observation exactness is the row A. A consumer may use a mark, continuation, probe bundle, signature relation, or prior comparison read only when that datum appears in the displayed licensed ledger and is then transported through R.

Classifier-output confinement is the row D read through C, P, N. The same route also records provenance through $\mathsf{ObserverHistIdentity}^{\uparrow}$, $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, and the sibling classifier surface of chapter 986.

The excluded objects have no carrier coordinate. Thus no accepted comparison can expose unlicensed observation, observer-substance, host equality, quotient identity, or hidden classifier state. □

Theorem 1031.3 (Observer licensed comparison non-escape)**.** *Every public consumer of an accepted* $\mathsf{ObserverLicensedComparison}^{\uparrow}$ *packet reads only the licensed observation ledger A, the componentwise* hsame *transports R, the classifier-output row D, the displayed* Cont *routes C, package provenance P, and local name row N. Changing any unlicensed observer-substance datum leaves the public comparison read unchanged.*

Proof. Start from the accepted packet $L = (H_0, H_1, A, R, D, C, P, N)$. The consumer-facing comparison rows are A, R, D, C, P, N; the two history rows are sources for the licensed ledger, not observer-substance fields.

Apply the NameCert obligations of Definition 1031.2. They force every public comparison read through the displayed licensed observations, hsame transports, classifier output, route, provenance, and local name.

No unlicensed observer-substance row is present in the carrier. A change confined to such a row changes none of A, R, D, C, P, N, so every public comparison read remains unchanged. □

The Lean `TasteGate.lean` development for $\mathsf{ObserverLicensedComparison}^{\uparrow}$ must provide explicit Nontrivial $\mathsf{ObserverLicensedComparison}^{\uparrow}$ and FieldFaithful $\mathsf{ObserverLicensedComparison}^{\uparrow}$ instances for the displayed licensed comparison packet.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverLicensedComparison}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverLicensedComparison}^{\uparrow}$ packet is generated from two observer-history rows, a licensed observation ledger, componentwise hsame transports, a classifier-output row, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ObserverLicensedComparison}^{\uparrow}}$, seed)

Scope closed: Definition 1031.1, Definition 1031.2, and Definition 1031.3 specify the finite licensed-comparison packet and its unlicensed-observation non-escape boundary.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ObserverLicensedComparison}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close full observer-history identity, observer-filter completeness, hidden observer state, quotient history identity, unbounded observation, Lean verification, or bridge checking.

Upgrade path: Scoped closure requires checked carrier admission, licensed-observation exactness, classifier-output confinement, non-escape, nontriviality, and field faithfulness for the same packet.

Chapter 1032

ObserverBridgeLedgerUp NameCert construction

The $\mathsf{ObserverBridgeLedger}^{\uparrow}$ surface realizes the observer-history identity vision of chapter 9418 as a finite bridge ledger for observer-state consumers. It sits after the conscious-observer-state row of chapter 578, the no-subject boundary row of chapter 615, the multi-history configuration row of chapter 474, the observer-history identity row of chapter 477, and the locality-cell row of chapter 513. The ledger records those sibling routes together before any downstream consumer reads an observer-state bridge as a reusable NameCert surface.

Falsifiable prediction: Any accepted bridge-ledger consumer that bypasses the observer-state row or the no-subject boundary row leaves the ObserverBridgeLedgerUp carrier and cannot preserve NameCert routing.

Independence witness: Nearest siblings: consciousobserverstate, observersubjectboundary, multihistconfig, observercoordinateframe, finitewindowobserver. None is bijective to the bridge-ledger packet because none carries all bridge-ledger rows, no-subject boundary rows, and multi-history route rows together: consciousobserverstate has the current-state surface without the route ledger, observersubjectboundary has the no-subject refusal boundary without the state bridge, multihistconfig has the multi-history carrier without the observer-state row, observercoordinateframe has local-frame routing without the no-subject bridge ledger, and finitewindowobserver has bounded-window observation without the full multi-history route ledger.

Definition 1032.1 (Observer bridge ledger carrier)**.** *An* $\mathsf{ObserverBridgeLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (S, Q, M, I, L, R, H, C, P, N)$$

with the following displayed rows:

1. *S is an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *row naming the observer-state surface being bridged;*
2. *Q is an accepted* $\mathsf{ObserverSubjectBoundary}^{\uparrow}$ *row certifying that the bridge has no separate observer-substance coordinate;*
3. *M is an accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *row displaying the finite multi-history configuration available to the bridge;*
4. *I is an accepted* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *row naming the licensed observer-history identity surface;*

5. *L is an accepted* $\mathsf{ObserverLocalityCell}^{\uparrow}$ *row through which the state, boundary, and multi-history rows are read locally;*
6. *R is the bridge-ledger route row, recording the finite order in which $S, Q, M, I, L, H, C, P, N$ may be consumed;*
7. *H stores componentwise* hsame *transport for the observer-state, no-subject boundary, multi-history, identity, locality, route, provenance, and local name rows;*
8. *C records the displayed* Cont *routes for every bridge-ledger consumer read;*
9. *P is the* Pkg *provenance over* $\mathsf{ConsciousObserverState}^{\uparrow}$, $\mathsf{ObserverSubjectBoundary}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{ObserverLocalityCell}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverBridgeLedger}^{\uparrow}}$ *row.*

The carrier accepts an observer-state bridge only when the observer-state row, no-subject boundary row, multi-history row, identity row, locality-cell row, route ledger, transport row, continuation routes, provenance, and local naming row are all displayed together. It exports no hidden observer-substance, global observer frame, unrecorded history, host equality of observers, quotient history identity, or route outside the ledger.

Lean4 (definition) `BEDC.Derived.ObserverBridgeLedgerUp.ObserverBridgeLedgerUp`
Lean4 ✓ `BEDC.Derived.ObserverBridgeLedgerUp.ObserverBridgeLedgerTasteGate single carrier alignment`

Theorem 1032.2 (Observer bridge ledger NameCert obligations)**.** *For the carrier of Definition 1032.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverBridgeLedger}^{\uparrow}}$ *surface consists exactly of carrier admission for $B = (S, Q, M, I, L, R, H, C, P, N)$, observer-state anchoring through S, no-subject boundary anchoring through Q, multi-history configuration anchoring through M, observer-history identity anchoring through I, locality-cell anchoring through L, route-ledger exactness through R, componentwise* hsame *transport through H, displayed continuation replay through C, package provenance through P, local naming through N, and non-escape from hidden observer-substance, global observer frames, unrecorded histories, host equality of observers, quotient history identity, and routes outside the ledger.*

Proof. Project the accepted carrier to the ten displayed rows of Definition 1032.1. The observer-state, no-subject boundary, multi-history, observer-history identity, and locality-cell rows are visible before the route ledger is available.

Route-ledger exactness is the row R. A bridge consumer may read the sibling rows only in the displayed order recorded by R and only after componentwise transport through H and continuation replay through C.

The provenance row P and local naming row N bind the read to the five sibling certificates listed in the carrier. Since none of the excluded objects is a coordinate of the carrier, no accepted bridge-ledger read can export one. □

Theorem 1032.3 (Observer bridge ledger falsifiable prediction)**.** *Any accepted bridge-ledger consumer that bypasses either the observer-state row S or the no-subject boundary row Q leaves the* $\mathsf{ObserverBridgeLedger}^{\uparrow}$ *carrier and cannot preserve the local* $\mathsf{NameCert}_{\mathsf{ObserverBridgeLedger}^{\uparrow}}$ *routing.*

Proof. The carrier admits a bridge only as $B = (S, Q, M, I, L, R, H, C, P, N)$. The route row R is typed as a ledger over both S and Q, and the local name row N certifies that same displayed packet.

If a consumer omits S, then the bridge no longer has an observer-state surface to carry. If it omits Q, then the read has no certified no-subject boundary and may no longer be interpreted as an observer-history bridge inside the vision of chapter 9418.

In either case the consumer is not a route through R, H, C, P, N for the displayed carrier, so the local NameCert route is not preserved. □

Theorem 1032.4 (Observer bridge ledger independence witness)**.** *The* $\mathsf{ObserverBridgeLedger}^{\uparrow}$ *carrier is not bijective to the sibling surfaces* $\mathsf{ConsciousObserverState}^{\uparrow}$, $\mathsf{ObserverSubjectBoundary}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{ObserverCoordinateFrame}^{\uparrow}$, *or* $\mathsf{FiniteWindowObserver}^{\uparrow}$.

Proof. Each listed sibling omits at least one bridge-ledger coordinate required by Definition 1032.1. The conscious-observer-state row lacks the no-subject boundary and route ledger. The observer-subject-boundary row lacks the current observer-state bridge and multi-history route. The multi-history configuration lacks the current-state and no-subject boundary rows.

The observer-coordinate-frame row supplies a local frame route, but it does not carry all bridge-ledger, no-subject boundary, and multi-history route rows together as one NameCert packet. The finite-window observer row supplies bounded observation, but not the full route ledger tying $S, Q, M, I, L, H, C, P, N$ together.

Thus deleting the bridge-ledger coordinates changes the public carrier, while adding them changes each sibling surface. No bijection with any one sibling preserves all displayed rows. □

Theorem 1032.5 (Observer bridge ledger sibling route)**.** *Every accepted* $\mathsf{ObserverBridgeLedger}^{\uparrow}$ *consumer reads the conscious-observer-state, no-subject boundary, multi-history configuration, observer-history identity, and locality-cell siblings through the single route*

$$S, Q, M, I, L \longrightarrow R, H, C, P, N.$$

No second route may reach those siblings through hidden observer state, a global observer frame, an unrecorded history row, host equality, quotient history identity, or an external route table.

Lean4 ✓ `BEDC.Derived.ObserverBridgeLedgerUp.ObserverBridgeLedger sibling route row separates`

Proof. The carrier contains exactly one route-ledger coordinate, namely R. That coordinate records how the five sibling rows S, Q, M, I, L may be consumed.

Componentwise transport and continuation replay are then supplied by H and C, while P and N record provenance and local naming. The remaining named objects are absent from the carrier, so they cannot provide a second route. □

The Lean carrier site `Derived/ObserverBridgeLedgerUp/TasteGate.lean` provides explicit Nontrivial and FieldFaithful instances for the displayed bridge-ledger packet.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverBridgeLedger}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverBridgeLedger}^{\uparrow}$ packet is generated from conscious-observer-state, no-subject-boundary, multi-history configuration, observer-history identity, observer-locality-cell, route-ledger, hsame transport, displayed Cont route, package provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverBridgeLedger}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1032.1, Definition 1032.2, Definition 1032.3, Definition 1032.4, and Definition 1032.5 specify the finite bridge-ledger carrier, its NameCert obligations, observer-state and no-subject bypass refutation, sibling independence, and single route through state, boundary, multi-history, identity, locality, transport, continuation, provenance, and local naming rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverBridgeLedger}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close global observer frames, hidden observer-substance, unrecorded histories, quotient history identity, public export, Lean verification, or bridge checking.

Upgrade path: Scoped closure requires checked TasteGate carrier admission, Nontrivial and FieldFaithful instances, route-ledger exactness, no-subject boundary preservation, and multi-history sibling routing for the same packet.

Chapter 1033

A Concrete Naming Certificate for $\mathsf{RealCompletionRouteAudit}^{\uparrow}$

The $\mathsf{RealCompletionRouteAudit}^{\uparrow}$ packet realizes the route-audit surface for the Real-completeness diagonal and seal route of chapter 9238. It consumes the finite completion handoff of chapter 360, the limit-seal row of chapter 386, the $\mathsf{StreamName}^{\uparrow}$ window surface, the $\mathsf{RegSeqRat}^{\uparrow}$ readback surface, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, and the primitive hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows. The packet is an audit object for the displayed route, not a selected limit, quotient stream equality, host real equality, or ambient completeness principle.

Definition 1033.1 (Real completion route-audit carrier)**.** *A* $\mathsf{RealCompletionRouteAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (Q, L, S, R, D, H, C, P, N, V)$$

with the following displayed rows:

1. *Q is the* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *route row naming the finite completion handoff;*
2. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row reached from the same completion route;*
3. *S is the* $\mathsf{StreamName}^{\uparrow}$ *window-service row opened before any route readback;*
4. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-rational readback row exposed through S;*
5. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance and precision row consumed by the displayed completion route;*
6. *H records componentwise* hsame *transports for the completion handoff, limit seal, window, readback, dyadic tolerance, route verdict, provenance, and local naming rows;*
7. *C records the displayed* Cont *routes from S to R, from R and D to Q, and from Q to L;*
8. *P is the* Pkg *provenance over* $\mathsf{RealCauchyCompletion}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RealCompletionRouteAudit}^{\uparrow}}$ *row;*
10. *V is the route-audit verdict row stating that the accepted consumer route is exhausted by the displayed finite packet.*

The carrier has no coordinate for quotient stream equality, host real equality, selected limits, hidden tail selection, unbounded observation, or ambient completeness.

Theorem 1033.2 (Real completion route-audit NameCert obligations)**.** *For the carrier of Definition 1033.1, the local* $\mathsf{NameCert}_{\mathsf{RealCompletionRouteAudit}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$A = (Q, L, S, R, D, H, C, P, N, V),$$

completion-route admission through Q*, limit-seal admission through* L*, StreamName window exposure through* S*, RegSeqRat readback through* R*, DyadicRatCore tolerance exposure through* D*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, local naming through* N*, and route-audit non-escape through* V*.*

Proof. Project the carrier of Definition 1033.1. The displayed packet exposes the completion handoff, limit seal, window service, readback, dyadic tolerance, transport, continuation, provenance, local name, and route verdict rows.

Read the route in dependency order. The $\mathsf{StreamName}^{\uparrow}$ row S opens the finite windows, the $\mathsf{RegSeqRat}^{\uparrow}$ row R reads those windows as regular-rational data, and the $\mathsf{DyadicRatCore}^{\uparrow}$ row D supplies the finite tolerance ledger. The completion row Q may then be consumed, and the limit-seal row L is reached only from that same displayed route.

The rows H, C, P, N, V preserve and audit this route. Since the carrier contains no quotient stream equality, host real equality, selected limit, hidden tail selector, unbounded observation, or ambient completeness coordinate, the listed rows exhaust the local NameCert surface. □

Lean4 ✓ `BEDC.Derived.RealCompletionRouteAuditUp.RealCompletionRouteAuditTasteGate single carrier alignment`

Theorem 1033.3 (Real completion route-audit consumer boundary)**.** *Every completion-facing consumer of an accepted* $\mathsf{RealCompletionRouteAudit}^{\uparrow}$ *packet factors through the finite route*

$$S, R, D, Q, L, H, C, P, N, V.$$

The consumer may inspect the displayed StreamName, RegSeqRat, DyadicRatCore, RealCauchyCompletion, CauchyLimitSeal, transport, continuation, provenance, naming, and audit-verdict rows, and it receives no route to quotient stream equality, host real equality, selected limits, or ambient completeness.

Proof. Start with the NameCert obligations. They identify the accepted packet with the ten displayed rows $Q, L, S, R, D, H, C, P, N, V$ and bind the completion-facing route to the same inventory.

The positive route is ordered by the displayed continuations. The window row S precedes the readback row R, the dyadic row D supplies the tolerance surface for the completion handoff Q, and the limit-seal row L is reached only after that handoff has been consumed.

Finally inspect the route-audit verdict V. It records that no consumer route leaves the finite packet for quotient stream equality, host real equality, selected limits, hidden tail selection, unbounded observation, or ambient completeness. Thus every accepted consumer read stays inside the displayed route. □

Theorem 1033.4 (Real completion route ordering)**.** *For every accepted* $\mathsf{RealCompletionRouteAudit}^{\uparrow}$ *carrier*

$$A = (Q, L, S, R, D, H, C, P, N, V),$$

the displayed continuation row C *orders the positive route as*

$$S \to R, \qquad (R, D) \to Q, \qquad Q \to L.$$

No consumer may read Q before the window row S, the readback row R, and the dyadic tolerance row D have been exposed, and no consumer may read L before the completion handoff Q has been consumed.

Proof. Use the carrier definition to project the row C. By Definition 1033.1, C records exactly the displayed Cont routes from S to R, from R and D to Q, and from Q to L.

The NameCert obligations of Definition 1033.2 admit those continuations as part of the local naming surface. The consumer boundary of Definition 1033.3 then prevents any consumer from bypassing them through quotient stream equality, host real equality, selected limits, or ambient completeness. □

Theorem 1033.5 (StreamName finite window service)**.** *For every accepted* $\mathsf{RealCompletionRouteAudit}^{\uparrow}$ *carrier $A = (Q, L, S, R, D, H, C, P, N, V)$, the row S is the unique StreamName service row available to the route audit. It exposes only the finite window data named by* $\mathsf{StreamName}^{\uparrow}$*, and every later readback through R must be fed by that displayed window row.*

Proof. Project S from the carrier. The definition of $\mathsf{RealCompletionRouteAudit}^{\uparrow}$ names S as the $\mathsf{StreamName}^{\uparrow}$ window-service row opened before any route readback.

Apply the NameCert obligation theorem to bind the StreamName exposure to the same row S. The consumer boundary then says that every completion-facing read stays inside $S, R, D, Q, L, H, C, P, N, V$, so no hidden tail selector, unbounded observation, quotient stream equality, or host real equality can supply a second window service. □

Theorem 1033.6 (RegSeqRat readback over the displayed window)**.** *For every accepted* RealCompletionRouteAudit *carrier $A = (Q, L, S, R, D, H, C, P, N, V)$, the row R is the finite* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row exposed through S. Its regular-rational data are route data for the displayed StreamName window, not an equality of streams or a selected limit.*

Proof. The carrier definition assigns R to the $\mathsf{RegSeqRat}^{\uparrow}$ regular-rational readback row and places it after the StreamName window row S in the displayed route.

The NameCert obligations certify readback through R, and Definition 1033.4 identifies the route edge $S \to R$. Finally, the consumer boundary excludes quotient stream equality, host real equality, selected limits, and ambient completeness, so the readback remains finite route data over the displayed window. □

Theorem 1033.7 (DyadicRatCore tolerance exposure for the handoff)**.** *For every accepted* RealCompletionRouteAu *carrier $A = (Q, L, S, R, D, H, C, P, N, V)$, the row D is the displayed* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance and precision ledger consumed by the completion handoff Q. The handoff may depend on R and D together, but it receives no ambient completeness principle and no host-level real equality.*

Proof. Project the dyadic row D and the completion row Q from the carrier. By definition, D is the finite tolerance and precision row consumed by the displayed completion route, while Q is the $\mathsf{RealCauchyCompletion}^{\uparrow}$ route row.

The NameCert obligations admit both rows and the continuation row C. The route-ordering theorem reads the relevant edge as $(R, D) \to Q$, and the consumer boundary blocks every route to ambient completeness, selected limits, quotient stream equality, or host real equality. □

Theorem 1033.8 (Completion handoff and limit-seal exposure)**.** *For every accepted* $\mathsf{RealCompletionRouteAudit}^{\uparrow}$ *carrier $A = (Q, L, S, R, D, H, C, P, N, V)$, the* $\mathsf{RealCauchyCompletion}^{\uparrow}$ *handoff Q and the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *exposure L are reached only through the displayed rows*

$$S,\ R,\ D,\ H,\ C,\ P,\ N,\ V.$$

Thus the audit packet exposes the completion handoff and limit seal without adding quotient stream equality, host real equality, selected limits, hidden tail selection, unbounded observation, or ambient completeness.

Proof. Begin with the carrier and NameCert obligation theorems. They place the handoff Q and seal row L in the same finite packet as the StreamName window, RegSeqRat readback, DyadicRatCore tolerance ledger, transports, continuations, provenance, local name, and verdict row.

Use the route-ordering theorem to reach Q only from the readback and dyadic rows and to reach L only from Q. The consumer boundary then exhausts all completion-facing reads by the displayed packet, so the omitted equality, choice, tail, observation, and completeness surfaces remain unavailable. □

Falsifiable prediction: Every accepted RealCompletionRouteAuditUp packet exposes a finite completion route and admits no consumer route to quotient stream equality, host real equality, selected limits, or ambient completeness.

Independence witness: realcauchycompletion, cauchylimitseal, streamname, regseqrat, dyadicratcore: the route-audit carrier is not bijective to any of these siblings because $\mathsf{RealCauchyCompletion}^{\uparrow}$ stores the completion handoff without the full audit verdict, $\mathsf{CauchyLimitSeal}^{\uparrow}$ stores the seal without the complete window-readback-tolerance route, $\mathsf{StreamName}^{\uparrow}$ stores finite windows without the completion and seal rows, $\mathsf{RegSeqRat}^{\uparrow}$ stores regular-rational readback without the route verdict, and $\mathsf{DyadicRatCore}^{\uparrow}$ stores tolerance rows without the completion handoff. The audit packet carries all five route objects with hsame, Cont, Pkg, NameCert, and verdict rows in one finite surface.

The Lean TasteGate boundary for this packet must provide `Nontrivial RealCompletionRouteAuditUp` and `FieldFaithful RealCompletionRouteAuditUp` instances for the displayed carrier in `TasteGate.lean`.

Closure status for $\mathsf{NameCert}_{\mathsf{RealCompletionRouteAudit}^{\uparrow}}$.

Constructive story: A $\mathsf{RealCompletionRouteAudit}^{\uparrow}$ packet is generated from a RealCauchyCompletion route row, CauchyLimitSeal row, StreamName window, RegSeqRat readback, DyadicRatCore tolerance ledger, componentwise transports, displayed continuations, package provenance, local NameCert row, and route-audit verdict.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RealCompletionRouteAudit}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1033.1, Definition 1033.2, and Definition 1033.3 bind the finite Real-completion route audit over RealCauchyCompletion, CauchyLimitSeal, StreamName, RegSeqRat, DyadicRatCore, hsame, Cont, Pkg, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RealCompletionRouteAudit}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Real completeness, quotient stream equality, host real equality, selected limits, hidden tail selection, ambient completeness, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, route ordering, StreamName and RegSeqRat service rows, DyadicRatCore tolerance exposure, RealCauchyCompletion handoff, CauchyLimitSeal exposure, nontriviality, and field faithfulness for the same finite packet.

Chapter 1034

CauchySealFunctorUp NameCert construction

The CauchySealFunctor$^{\uparrow}$ surface realizes the Real-completion Cauchy seal route of chapter 9238 as a finite seal-transport packet. It sits between the completion classifier of chapter 900, the limit-seal source of chapter 386, the regular-rational source of chapter 301, the finite-window source of chapter 126, and the dyadic tolerance ledger of chapter 291. Its role is to carry a reusable transport row from displayed CauchyLimitSeal inputs to displayed RealCompletionSealClassifier reads before a Real$^{\uparrow}$ handoff consumes the route.

Falsifiable prediction: If a seal transport reaches a RealUp consumer without passing through either a displayed CauchyLimitSeal row or a displayed RealCompletionSealClassifier row, the CauchySealFunctor packet is refuted.

Independence witness: realcompletionsealclassifier, cauchylimitseal, cauchysealbudgetsynchronizer, regseqrat, streamname: no sibling is bijective because CauchySealFunctor carries a transport row between seal reads, while each sibling supplies only one endpoint, budget, regular-source, or finite-window surface.

Definition 1034.1 (Cauchy seal functor carrier)**.** *A* CauchySealFunctor$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (L, E, T, W, R, D, H, C, P, N)$$

with the following displayed rows:

1. *L is the source* CauchyLimitSeal$^{\uparrow}$ *row;*
2. *E is the target* RealCompletionSealClassifierUp *row;*
3. *T is the seal-transport row linking L to E through displayed finite reads;*
4. *W is the* StreamName$^{\uparrow}$ *finite-window schedule consumed by the transport;*
5. *R is the* RegSeqRat$^{\uparrow}$ *regular-source handoff;*
6. *D is the* DyadicRatCore$^{\uparrow}$ *tolerance ledger used by the same handoff;*
7. *H records componentwise* hsame *transport for $L, E, T, W, R, D, C, P, N$;*
8. *C records the displayed* Cont *routes by which consumers replay the seal transport;*
9. *P is the* Pkg *provenance naming* CauchyLimitSeal$^{\uparrow}$, RealCompletionSealClassifierUp, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, Real$^{\uparrow}$, *and* NameCert *rows;*

10. N is the local $\mathsf{NameCert}_{\mathsf{CauchySealFunctor}^{\uparrow}}$ *row.*
The carrier accepts only transports whose consumer-visible route factors through $L, E, T, W, R, D, H, C, P, N$. It has no coordinate for quotient streams, selected limits, host real equality, countable choice, or ambient completeness.

Lean4 (definition) `BEDC.Derived.CauchySealFunctorUp.CauchySealFunctorUp`

Theorem 1034.2 (Cauchy seal functor NameCert obligations)**.** *For the carrier of Definition 1034.1, the local* $\mathsf{NameCert}_{\mathsf{CauchySealFunctor}^{\uparrow}}$ *surface consists exactly of carrier admission for $F = (L, E, T, W, R, D, H, C, P, N$ source-seal admission for L, target-classifier admission for E, seal-transport exactness for T, finite-window scheduling through W, regular-source handoff through R, dyadic tolerance readback through D, componentwise* hsame *transport through H, displayed consumer routes through C, package provenance through P, local naming through N, and non-escape from quotient streams, selected limits, host real equality, countable choice, and ambient completeness.*

Proof. Project the accepted carrier. The displayed rows are exactly $L, E, T, W, R, D, H, C, P, N$, so carrier admission, transport exactness, package provenance, and local naming are finite BHist reads.

Read the source and target rows through the sibling chapters. The source row is the displayed $\mathsf{CauchyLimitSeal}^{\uparrow}$ surface, and the target row is the displayed RealCompletionSealClassifierUp classifier surface; T records only the transport between these two displayed endpoints.

The regularity and window rows are W, R, D. They force every transport read through a finite StreamName window, a RegSeqRat handoff, and a DyadicRatCore tolerance ledger before the route reaches a $\mathsf{Real}^{\uparrow}$ consumer.

The excluded objects have no carrier coordinate. Therefore the local NameCert surface contains no quotient stream, selected external limit, host real equality, countable choice, or ambient completeness datum. □

Theorem 1034.3 (Cauchy seal functor non-escape)**.** *Every public consumer of an accepted* $\mathsf{CauchySealFunctor}^{\uparrow}$ *packet reads only the source seal row L, target classifier row E, seal-transport row T, finite-window row W, regular-source row R, dyadic tolerance row D, componentwise* hsame *rows H, displayed* Cont *routes C, package provenance P, and local name row N. In particular, a* $\mathsf{Real}^{\uparrow}$ *consumer receives a transported finite seal read, not a quotient stream, selected limit, host real equality, countable choice, or ambient completeness proof.*

Proof. Start from the accepted packet $F = (L, E, T, W, R, D, H, C, P, N)$. The consumer-facing rows are the two seal endpoints, the transport row, the three finite route rows, and the local transport, route, provenance, and name rows.

Apply the NameCert obligations of Definition 1034.2. They force every public read through the displayed finite packet and leave no coordinate for a host-level completion object.

Thus any $\mathsf{Real}^{\uparrow}$ read sees only the transported finite seal surface. Since quotient streams, selected limits, host equality, countable choice, and ambient completeness are absent from the carrier, no public consumer can extract them. □

Theorem 1034.4 (Cauchy seal functor regularity handoff)**.** *Let $F = (L, E, T, W, R, D, H, C, P, N)$ be an accepted* $\mathsf{CauchySealFunctor}^{\uparrow}$ *packet. Every regularity-sensitive seal transport factors through the same triple W, R, D: a finite* $\mathsf{StreamName}^{\uparrow}$ *window, a* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-source handoff, and a* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger. The transport row T may replay these rows through H and C, but it cannot replace them by an unbounded stream, a selected representative, or a host real-completion argument.*

Proof. Read the transport row T together with the route rows W, R, D. By carrier admission, these rows are the only finite-window, regular-source, and dyadic-tolerance coordinates available to the transport.

The componentwise hsame and Cont rows H and C replay the same triple rather than adding a second source. Hence every regularity-sensitive transport remains attached to the displayed StreamName, RegSeqRat, and DyadicRatCore rows.

The non-escape theorem excludes unbounded streams, selected representatives, host equality, and ambient completeness. The regularity handoff is therefore exactly the finite triple W, R, D as stated. □

Theorem 1034.5 (Cauchy seal functor Real-completion boundary)**.** *Let $F = (L, E, T, W, R, D, H, C, P, N)$ be an accepted* CauchySealFunctor$^{\uparrow}$ *packet. Any Real-completion consumer of F must pass through either the displayed* CauchyLimitSeal$^{\uparrow}$ *row L before transport or the displayed* RealCompletionSealClassifierUp *row E after transport, with T, W, R, D, H, C, P, N providing the finite route. A read that reaches a* Real$^{\uparrow}$ *consumer while bypassing both displayed seal rows is not a read of this packet.*

Proof. Project the accepted packet to the two seal endpoints L and E. The carrier has no other seal endpoint, so a Real-completion consumer can enter the transport only before T through L or after T through E.

Use the regularity handoff of Definition 1034.4. The route between the endpoints is the finite triple W, R, D together with the local rows H, C, P, N.

Finally apply non-escape. A consumer path that bypasses both L and E has no source seal, no target classifier, and no displayed transport row of the packet, so it is outside the CauchySealFunctor$^{\uparrow}$ carrier. □

The Lean `TasteGate.lean` development for CauchySealFunctor$^{\uparrow}$ must provide explicit Nontrivial CauchySealFunc and FieldFaithful CauchySealFunctor$^{\uparrow}$ instances for the displayed finite seal-transport packet.

Closure status for NameCert$_{\text{CauchySealFunctor}^{\uparrow}}$**.**

Constructive story: A CauchySealFunctor$^{\uparrow}$ packet is generated from a CauchyLimitSeal source row, a RealCompletionSealClassifier target row, one seal-transport row, StreamName windows, RegSeqRat handoff rows, DyadicRatCore tolerance rows, componentwise hsame transports, displayed Cont routes, package provenance, and local NameCert rows.

Theory closure: TheoryGate(NameCert$_{\text{CauchySealFunctor}^{\uparrow}}$, seed)

Scope closed: Definition 1034.1, Definition 1034.2, Definition 1034.3, Definition 1034.4, and Definition 1034.5 specify the finite seal-transport packet and its Real-completion consumer boundary.

Formal verification: FormalStatus(NameCert$_{\text{CauchySealFunctor}^{\uparrow}}$, unformalized)

Bridge status: none

Not claimed: This chapter does not close quotient Cauchy streams, selected limits, host real equality, countable choice, ambient completeness, Lean verification, or bridge checking.

Upgrade path: Scoped closure requires checked carrier admission, seal-transport exactness, regularity handoff, Real-completion boundary, nontriviality, and field faithfulness for the same packet.

Chapter 1035

A Concrete Naming Certificate for $\mathsf{LocatedCauchyModulus}^{\uparrow}$

The $\mathsf{LocatedCauchyModulus}^{\uparrow}$ packet realizes the Real and Completion route of chapter 9238 as a finite located tail-modulus object. It sits downstream of the finite seal classifier in chapter 900: StreamName windows, RegSeqRat readbacks, DyadicRatCore radius ledgers, CauchyLimitSeal compatibility rows, and RealUp seal rows are exposed as one displayed packet before any completion-facing consumer may read the seal. The packet is not a quotient stream, host real equality, selected limit, countable-choice surface, or ambient completeness principle.

Definition 1035.1 (Located Cauchy modulus carrier)**.** *A* $\mathsf{LocatedCauchyModulus}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (S, R, D, T, L, E, H, C, P, N)$$

with the following displayed rows:

1. *S is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window source row;*
2. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-rational readback row exposed from the displayed windows;*
3. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *radius ledger recording the dyadic tolerance attached to the same tail request;*
4. *T is the located tail-modulus row naming the finite threshold at which the StreamName and RegSeqRat windows become mutually readable at radius D;*
5. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *compatibility row reached after the located tail-modulus threshold;*
6. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row consumed only after S, R, D, T, L have been displayed;*
7. *H records componentwise* hsame *transports for the window, readback, radius, modulus, limit-seal, Real-seal, route, provenance, and local naming rows;*
8. *C records the displayed* Cont *routes from S, R, D to T, from T to L, and from L to E;*
9. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{LocatedCauchyModulus}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient stream equality, host real equality, selected limits, unbounded observation, detached tail choice, or a RealUp seal read that bypasses the located modulus row.

Lean4 ✓ BEDC.Derived.LocatedCauchyModulusUp.LocatedCauchyModulusTasteGate single carrier alignment
Lean4 (definition) BEDC.Derived.LocatedCauchyModulusUp.LocatedCauchyModulusCarrier
Lean4 (definition) BEDC.Derived.LocatedCauchyModulusUp.LocatedCauchyModulusUp

Theorem 1035.2 (Located Cauchy modulus NameCert obligations)**.** *For the carrier of Definition 1035.1, the local* $\mathsf{NameCert}_{\mathsf{LocatedCauchyModulus}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$M = (S, R, D, T, L, E, H, C, P, N),$$

StreamName window exposure through S, RegSeqRat readback through R, DyadicRatCore radius accounting through D, located tail-modulus exposure through T, CauchyLimitSeal compatibility through L, RealUp seal routing through E, componentwise transport through H, displayed route replay through C, package provenance through P, and local naming through N.

Lean4 ✓ BEDC.Derived.LocatedCauchyModulusUp.LocatedCauchyModulusNameCertObligations

Proof. Project the carrier of Definition 1035.1. The displayed packet exposes exactly the window, readback, radius, tail-modulus, limit-seal, Real-seal, transport, route, provenance, and local naming rows.

Read the route in dependency order. The StreamName row S supplies the finite window, the RegSeqRat row R reads that window as regular-rational data, and the DyadicRatCore row D supplies the radius ledger. The located modulus row T may then be consumed, followed by the CauchyLimitSeal compatibility row L and the RealUp seal row E.

The rows H, C, P, N preserve this route componentwise, replay it as displayed continuations, record its provenance, and name the local surface. Since the carrier contains no quotient stream equality, host real equality, selected limit, unbounded observation, detached tail choice, or bypass route to E, the listed rows exhaust the NameCert obligations. □

Theorem 1035.3 (Located Cauchy modulus window stability)**.** *Let $M = (S, R, D, T, L, E, H, C, P, N)$ and $M' = (S', R', D', T', L', E', H', C', P', N')$ be accepted* $\mathsf{LocatedCauchyModulus}^{\uparrow}$ *packets. If their StreamName, RegSeqRat, DyadicRatCore, and located tail-modulus rows are related componentwise by the displayed transport rows H and H', then every completion-facing read of E and E' factors through the same ordered window route*

$$S, R, D, T, L, E.$$

In particular, transport cannot create a second RealUp seal route outside the displayed StreamName window, RegSeqRat handoff, DyadicRatCore radius ledger, located modulus threshold, and CauchyLimitSeal compatibility row.

Proof. Start with the two carrier projections. The only analytic rows before the RealUp seal are S, R, D, T, L in the first packet and S', R', D', T', L' in the second.

Use the NameCert obligations above. They bind every accepted seal read to the displayed route through the StreamName window, RegSeqRat readback, DyadicRatCore radius ledger, located modulus threshold, and CauchyLimitSeal compatibility row.

Now apply the componentwise transport rows. Transport preserves the named window, readback, radius, modulus, limit-seal, and Real-seal coordinates, while the displayed continuations replay the same order. No carrier coordinate remains for quotient stream equality, host real equality, selected limits, or a detached tail oracle, so transported completion-facing reads still factor through the same finite route. □

Falsifiable prediction: Every accepted RealUp seal read from a located modulus factors through a displayed StreamName window, RegSeqRat handoff, DyadicRatCore radius ledger, and CauchyLimitSeal compatibility row.

Independence witness: cauchymodulus, regseqrat, streamname, realcompletionsealclassifier, cauchysealbudgetsynchronizer: none is bijective to $\mathsf{LocatedCauchyModulus}^{\uparrow}$ because a Cauchy modulus row lacks the StreamName and RegSeqRat window readbacks, RegSeqRat lacks the dyadic radius and limit-seal rows, StreamName lacks the regular-rational and Real seal rows, RealCompletionSealClassifier lacks the located tail-modulus threshold as a carrier row, and CauchySealBudgetSynchronizer records synchronized budget rows without making the located modulus row the displayed threshold. The located carrier stores $S, R, D, T, L, E, H, C, P, N$ together in one finite surface.

The proposed Lean `TasteGate.lean` boundary is `lean4/BEDC/Derived/LocatedCauchyModulusUp/TasteGate` It must provide `Nontrivial LocatedCauchyModulusUp` and `FieldFaithful LocatedCauchyModulusUp` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{LocatedCauchyModulus}^{\uparrow}}$.

Constructive story: A $\mathsf{LocatedCauchyModulus}^{\uparrow}$ packet is generated from a StreamName finite-window source, RegSeqRat readback, DyadicRatCore radius ledger, located tail-modulus row, CauchyLimitSeal compatibility row, RealUp seal, componentwise transports, displayed continuations, package provenance, and local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LocatedCauchyModulus}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1035.1, Definition 1035.2, and Definition 1035.3 bind the finite located tail-modulus route from StreamName and RegSeqRat windows through DyadicRatCore radius accounting to CauchyLimitSeal and RealUp seal rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LocatedCauchyModulus}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Real completeness, quotient stream equality, host real equality, selected limits, countable choice, ambient completeness, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, located tail-modulus exposure, window stability, CauchyLimitSeal compatibility, RealUp seal routing, nontriviality, and field faithfulness for the same finite packet.

Chapter 1036

A Concrete Naming Certificate for $\mathsf{LocalStencilObservation}^{\uparrow}$

The $\mathsf{LocalStencilObservation}^{\uparrow}$ packet realizes the cellular substrate reading of chapter 9390 at the smallest finite observation surface: a displayed neighbourhood stencil, a displayed local rule row, and the observed finite row window to which a pattern classifier may point. It sits beside the whole automaton packet of chapter 934, the local transition packet of chapter 984, and the finite pattern catalog of chapter 995. Unlike those siblings, it certifies only one local observation packet, not a complete orbit, not a general update rule interface, and not a catalog of all accepted pattern tags.

Falsifiable prediction: If a purported $\mathsf{LocalStencilObservation}^{\uparrow}$ consumer classifies a cellular pattern without exposing a finite neighbourhood stencil, the selected local rule row, and the observed row window, then the consumer has left the certificate.

Independence witness: cellularautomaton, cellularlocalupdaterule, cellularpatterncatalog: none is bijective to $\mathsf{LocalStencilObservation}^{\uparrow}$ because this packet carries the joint neighbourhood, local-rule, observed-row, classifier, transport, route, package, and NameCert rows for one finite stencil observation; the automaton sibling carries an orbit ledger, the local-update sibling carries a next-cell output surface, and the pattern-catalog sibling carries a finite catalog table.

Definition 1036.1 (Local stencil observation carrier)**.** *A* $\mathsf{LocalStencilObservation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (W, R, V, T, H, C, P, N)$$

with the following displayed rows:

1. *W is the finite neighbourhood-stencil row, including the bounded cell positions inspected by the classifier;*
2. *R is the local-rule row whose displayed entry is permitted to read the stencil row;*
3. *V is the observed finite row-window produced or inspected at the named cellular time slice;*
4. *T is the finite classifier row assigning an admitted local pattern tag, such as ether, glider fragment, collision fragment, boundary fragment, or refused observation;*
5. *H records componentwise* hsame *transport for the stencil, local-rule, observed-window, classifier, route, package, and local naming rows;*
6. *C records the displayed* Cont *route from W and R to the observed row window V, then from V to the classifier row T;*

7. *P is the* Pkg *provenance over chapter 9390, chapter 934, chapter 984, chapter 995,* BHist, hsame, Cont, Pkg, *and* NameCert *rows;*

8. *N is the local* $\mathsf{NameCert}_{\mathsf{LocalStencilObservation}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only by W, R, V, T, H, C, P, N. It has no coordinate for an unbounded cellular orbit, a host-side pattern recognizer, an unstated Rule 110 convention, a hidden catalog row, or a detached universality oracle.

Lean4 (definition) `BEDC.Derived.LocalStencilObservationUp.LocalStencilObservationUp`

Theorem 1036.2 (LocalStencilObservation NameCert obligations)**.** *For the carrier of Definition 1036.1, the local* $\mathsf{NameCert}_{\mathsf{LocalStencilObservation}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$O = (W, R, V, T, H, C, P, N),$$

neighbourhood exposure through W, local-rule accountability through R, observed-row exposure through V, pattern-classifier exposure through T, componentwise stability through H, displayed route replay through C, package provenance through P, and local naming through N. Every cellular pattern classification exported by this packet must read a finite stencil before it reads the finite observed row and classifier tag.

Proof. Carrier admission is projection from Definition 1036.1. The finite packet displays W, R, V, T, H, C, P, N as its complete observation surface.

The cellular content is read in the order named by the carrier. The neighbourhood row W supplies the bounded stencil, the local-rule row R supplies the displayed rule entry, and the observed-row window V is the only row window available to the classifier.

The classifier row T can therefore tag only the displayed observation. The transport, route, provenance, and local name rows H, C, P, N preserve and replay that same finite packet; they do not add an orbit ledger, hidden catalog, or host pattern recognizer. □

Theorem 1036.3 (LocalStencilObservation carrier totality)**.** *Every accepted* $\mathsf{LocalStencilObservation}^{\uparrow}$ *read is exhausted by the finite rows W, R, V, T, H, C, P, N. A consumer may use the whole-automaton packet of chapter 934, the local update packet of chapter 984, or the finite pattern catalog of chapter 995 only as provenance named in P; none of those siblings supplies an additional coordinate inside the local stencil packet.*

Proof. Start with carrier projection. The accepted packet has exactly the finite stencil row, local-rule row, observed-window row, classifier row, transport row, route row, provenance row, and local naming row.

The sibling references enter through P. They explain where the cellular reading, local update discipline, and finite pattern vocabulary are sourced, but they are not extra fields of O.

Apply Definition 1036.2. Since each accepted classification must pass through the displayed rows and the carrier lists no further coordinate, those rows are total for the local observation surface. □

Theorem 1036.4 (LocalStencilObservation finite non-escape)**.** *No accepted* $\mathsf{LocalStencilObservation}^{\uparrow}$ *packet exports an unbounded orbit, a host cellular evaluator, a hidden pattern catalog, a global Rule 110 classifier, or a detached universality oracle. Every exported observation factors through the finite route*

$$W, R, V, T, H, C, P, N.$$

Proof. Inspect the rows of Definition 1036.1. The only cellular data are the neighbourhood stencil W, the local-rule row R, the observed finite row window V, and the classifier row T.

The structural rows H, C, P, N only transport, replay, package, and locally name those displayed data. They do not introduce an all-time orbit, a host evaluator, an unstated catalog, or a universality witness.

Thus any read of one of the excluded objects would require a coordinate absent from $O = (W, R, V, T, H, C, P, N)$. Such a read is outside the accepted local stencil observation certificate. □

Theorem 1036.5 (LocalStencilObservation Rule 110 classifier route)**.** *Any Rule 110 local-pattern classifier read exported through* $\mathsf{LocalStencilObservation}^{\uparrow}$ *must expose the finite rows*

$$W, R, V, T, H, C, P, N$$

before it can cite the global cellular substrate of chapter 9390, the whole-automaton packet of chapter 934, the local update packet of chapter 984, the finite pattern catalog of chapter 995, or any Cook-frontier row named by the substrate reading. The route exports one finite local classifier observation, not a global Rule 110 universality witness.

Proof. Project the carrier of Definition 1036.1. The accepted local observation exposes the neighbourhood stencil W, local-rule row R, observed finite row window V, classifier row T, componentwise transport H, displayed replay C, provenance P, and local name N.

Apply Definition 1036.4. It excludes unbounded orbits, hidden catalog reads, global Rule 110 classifiers, and detached universality witnesses from the packet, so a Cook-frontier or substrate citation cannot precede the local rows.

Finally use the sibling boundary supplied by the cellular automaton, local update, and pattern catalog chapters. Those chapters may be cited through P only after the local stencil, rule, observed window, and classifier rows have been displayed; they do not add a second classifier coordinate to $\mathsf{LocalStencilObservation}^{\uparrow}$. □

Theorem 1036.6 (LocalStencilObservation sibling independence)**.** *The* $\mathsf{LocalStencilObservation}^{\uparrow}$ *carrier is not bijective to the sibling packets* $\mathsf{CellularAutomaton}^{\uparrow}$*,* $\mathsf{CellularLocalUpdateRule}^{\uparrow}$*, or* $\mathsf{CellularPatternCatalog}^{\uparrow}$*. It retains the joint local observation surface* W, R, V, T, H, C, P, N*, while those siblings respectively retain a finite orbit ledger, a next-cell update surface, or a catalog lookup table not present as an internal coordinate of this packet.*

Proof. Compare the carrier rows. The $\mathsf{LocalStencilObservation}^{\uparrow}$ packet has the observed row-window coordinate V tied to a single finite stencil W and a selected rule row R.

The whole automaton sibling records an orbit ledger, the local update sibling records a visible successor-cell surface, and the pattern-catalog sibling records a closed finite catalog row. Those rows are not interchangeable with the single observed-window row V and the local classifier row T.

Conversely, this packet does not carry the sibling-specific orbit, next-cell, or catalog coordinates except as provenance through P. Hence no bijection preserves the displayed NameCert obligation surface in both directions. □

The future Lean TasteGate file `lean4/BEDC/Derived/LocalStencilObservationUp/TasteGate.lean` provides `Nontrivial LocalStencilObservationUp` and `FieldFaithful LocalStencilObservationUp` instances for the displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{LocalStencilObservation}^{\uparrow}}$.

Constructive story: A LocalStencilObservation$^{\uparrow}$ packet is generated from a finite neighbourhood stencil, selected local-rule row, observed row window, local classifier row, componentwise hsame transport, displayed Cont route, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{LocalStencilObservation}^{\uparrow}}$, obligation)

Scope closed: Definition 1036.1, Definition 1036.2, Definition 1036.3, Definition 1036.4, Definition 1036.5, and Definition 1036.6 bind the displayed rows W, R, V, T, H, C, P, N for the local stencil, rule, observed window, classifier, BHist, hsame, Cont, Pkg, and NameCert dependencies without asserting Lean verification.

Formal verification: FormalStatus(NameCert$_{\text{LocalStencilObservation}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close global cellular orbits, Rule 110 universality, host evaluator correctness, complete pattern-catalog coverage, or a public standard bridge.

Upgrade path: Lean follow-up will bind the finite observation carrier under `BEDC.Derived.LocalStencilObservationUp`.

Chapter 1037

A Concrete Naming Certificate for $\mathsf{RelationalFrameAudit}^{\uparrow}$

The $\mathsf{RelationalFrameAudit}^{\uparrow}$ packet turns the no-global-frame and observer-symmetry surface of chapter 9419 into finite NameCert data. It consumes the configuration rows of chapter 474, the causal rows of chapter 478, the unary-bound rows of chapter 594, the refusal boundary of chapter 1003, and the ledger-local routing of chapter 759. Its public role is to audit a proposed comparison between two observer frames without admitting a global frame, host synchronization map, or metric primitive.

Definition 1037.1 (RelationalFrameAudit carrier)**.** *A* $\mathsf{RelationalFrameAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (M, A, B, Q, S, D, L, F, H, C, P, N)$$

with the following displayed rows:

1. *M is the accepted* $\mathrm{MultiHistConfig}^{\uparrow}$ *row supplying the finite multi-history configuration;*
2. *A and B are the two displayed observer-history slots whose local frame comparison is being audited;*
3. *Q is the frame-request row, recording the requested comparison as a finite local read rather than as an ambient coordinate system;*
4. *S is the observer-symmetry audit row, requiring both directions of the comparison to be visible before the request is accepted;*
5. *D is the* $\mathsf{CrossHistCausal}^{\uparrow}$ *row used by the comparison request, read only after the two observer slots are displayed;*
6. *L is the* $\mathsf{MaxCausalRate}^{\uparrow}$ *row that bounds the causal read without introducing a host speed, metric tensor, or synchronized clock;*
7. *F is the* $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$ *refusal verdict row for any request that asks for a privileged global frame, total observer order, selected synchronization map, or detached frame comparison;*
8. *H records componentwise* hsame *transport for M, A, B, Q, S, D, L, F and the structural rows;*
9. *C records displayed* Cont *routes from the frame request either through the two-Hist route A, B, D, L, S or to the refusal row F;*

10. *P is the* Pkg *provenance over* RelationalFrameAudit$^{\uparrow}$, MultiHistConfig$^{\uparrow}$, CrossHistCausal$^{\uparrow}$, MaxCausalRate$^{\uparrow}$, NoGlobalSyncBoundary$^{\uparrow}$, InterHistLocalityLedger$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{RelationalFrameAudit}^{\uparrow}}$ *row.*

The carrier exports a finite audit boundary for frame-comparison requests. It has no coordinate for a global frame, shared clock, metric tensor, host Lorentz chart, selected synchronization function, or comparison detached from the displayed histories.

Lean4 ✓ `BEDC.Derived.RelationalFrameAuditUp.RelationalFrameAuditCarrier full packet semantic namecert`

Definition 1037.2 (LayeredRelationCert carrier for RelationalFrameAudit)**.** *The* RelationalFrameAudit$^{\uparrow}$ *realization of* LayeredRelationCert *is the finite relation-audit packet*

$$\Lambda_R = (S_A, S_B, \ell, \pi, \nu, G, E, \partial, H, C, P, N)$$

where S_A and S_B are the two source-row lists, ℓ is the displayed two-chain layer map, π records the preserved relation-schema rows, ν records the not-preserved rows, G is the source ledger for each correspondence, E is the exactness row for same-schema language, and ∂ is the failure boundary. The structural rows H, C, P, N are the componentwise hsame *transports, displayed* Cont *routes,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{RelationalFrameAudit}^{\uparrow}}$ *row.*

The packet is accepted only as relation-audit data. It may compare the refinement shape of two displayed chains, but it does not identify their objects, sources, observers, empirical content, or host frames.

Lean4 (definition) `BEDC.Derived.RelationalFrameAuditUp.RelationalFrameAuditLayeredRelationCertCarrier`

Theorem 1037.3 (RelationalFrameAudit NameCert obligations)**.** *For the carrier of Definition 1037.1, the local* $\mathsf{NameCert}_{\mathsf{RelationalFrameAudit}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$R = (M, A, B, Q, S, D, L, F, H, C, P, N),$$

two-Hist locality through M, A, B, frame-request exposure through Q, observer-symmetry audit through S, cross-Hist causal routing through D, maximum-rate boundary reading through L, no-global-frame refusal through F, and transport, continuation, provenance, and local naming through H, C, P, N.

Proof. Carrier admission is projection from Definition 1037.1. The tuple displays the configuration row, two observer slots, frame request, symmetry audit, causal route, rate boundary, refusal verdict, transport, continuation, provenance, and local name.

The positive comparison route first reads M, A, B. The causal row D and maximum-rate row L can then be consumed as finite inter-Hist data, with the observer-symmetry row S requiring that both comparison directions remain visible.

The negative route is the refusal verdict F. By the no-global-synchronization boundary of chapter 1003, a request for a privileged frame, shared clock, total observer order, or selected synchronization map is retained as refused data rather than promoted to an admitted coordinate.

Finally H, C, P, N only transport, replay, package, and name the same rows. Thus the NameCert surface is exhausted by the displayed packet. □

Lean4 ✓ `BEDC.Derived.RelationalFrameAuditUp.RelationalFrameAuditTasteGate single carrier alignment`

Theorem 1037.4 (RelationalFrameAudit obligation totality)**.** *Any accepted* $\mathsf{RelationalFrameAudit}^{\uparrow}$ *consumer must expose exactly the finite obligation surface*

$$M, A, B, Q, S, D, L, F, H, C, P, N$$

of Definition 1037.1. Thus the consumer displays the $\mathrm{MultiHistConfig}^{\uparrow}$ *row* M*, the two observer slots* A, B*, the frame request* Q*, the observer-symmetry audit* S*, the* $\mathsf{CrossHistCausal}^{\uparrow}$ *route* D*, the* $\mathsf{MaxCausalRate}^{\uparrow}$ *bound* L*, the* $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$ *refusal verdict* F*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*,* Pkg *provenance* P*, and the local* $\mathsf{NameCert}_{\mathsf{RelationalFrameAudit}^{\uparrow}}$ *row* N*. No accepted consumer may replace one of these rows by a global frame, shared clock, selected synchronization map, host Lorentz chart, metric tensor, detached comparison, or source-equivalence transport.*

Proof. Project the carrier of Definition 1037.1. The tuple $R = (M, A, B, Q, S, D, L, F, H, C, P, N)$ is the complete displayed inventory for an accepted frame-audit packet.

Apply Definition 1037.3. Its NameCert surface reads the same configuration row, two observer slots, request row, symmetry audit, causal route, maximum-rate boundary, refusal verdict, transport, replay, provenance, and local naming rows.

It remains to exclude extra exits. The carrier contains no coordinate for a global frame, shared clock, selected synchronization map, Lorentz chart, metric tensor, detached comparison, or source-equivalence transport. Hence every accepted consumer exposes exactly the listed finite rows and nothing outside their projection. □

Lean4 ✓ `BEDC.Derived.RelationalFrameAuditUp.RelationalFrameAuditObligationTotality`

Theorem 1037.5 (LayeredRelationCert NameCert obligation surface)**.** *For the carrier* Λ_R *of Definition 1037.2, the local* $\mathsf{NameCert}_{\mathsf{RelationalFrameAudit}^{\uparrow}}$ *surface consists of five finite rows:*

1. *carrier admission for the displayed tuple* $\Lambda_R = (S_A, S_B, \ell, \pi, \nu, G, E, \partial, H, C, P, N)$*;*
2. *classifier locality for the two source-row lists* S_A, S_B *and the layer map* ℓ*;*
3. *stability through the componentwise* hsame *transports* H *and displayed* Cont *routes* C*;*
4. *exactness through the preserved rows* π*, not-preserved rows* ν*, and same-schema exactness row* E*;*
5. *ledger and export control through* G, ∂, P, N*, so any relation read carries provenance, failure boundary, package provenance, and local naming.*

Lean4 ✓ `BEDC.Derived.RelationalFrameAuditUp.RelationalFrameAuditLayeredRelationCert namecert obligation surface`

Proof. Carrier admission projects the tuple of Definition 1037.2. No source, layer, preservation, refusal, ledger, exactness, boundary, transport, continuation, provenance, or naming row is implicit.

Classifier locality reads only the two displayed source lists and the layer map. The preserved row π and not-preserved row ν then separate same-schema language from object identity.

Stability is supplied by H and C. These rows transport and replay the same displayed relation packet; they do not add a third chain, a host frame, or an empirical bridge.

The ledger row G, failure boundary ∂, package row P, and local NameCert row N control export. Hence the NameCert surface is exactly the five listed rows. □

Theorem 1037.6 (LayeredRelationCert finite relation exactness)**.** *An accepted* RelationalFrameAudit$^{\uparrow}$ *realization of* LayeredRelationCert *exports same-schema language exactly for the finite relation packet* Λ_R*. The export is available only when source rows, layer map, preserved rows, not-preserved rows, ledger, exactness, failure boundary, transport, continuation, provenance, and local naming are all displayed in the same packet. It exports no object identity, global frame, empirical law, subject-substance row, or unlisted bridge.*

Lean4 ✓ `BEDC.Derived.RelationalFrameAuditUp.RelationalFrameAuditLayeredRelationCert finite relation exactness`

Proof. Begin with the carrier Λ_R. Its source rows S_A, S_B, layer map ℓ, preserved rows π, not-preserved rows ν, ledger G, exactness row E, and boundary ∂ are separate coordinates.

Apply Definition 1037.5. The exactness row can be consumed only together with the preserved and not-preserved rows, so same-schema language has an explicit positive surface and an explicit refusal surface.

Finally use the export control row. Since H, C, P, N transport, replay, package, and name only the displayed packet, a consumer has no coordinate through which to read object identity, global-frame data, empirical content, subject-substance content, or a bridge outside Λ_R. □

Theorem 1037.7 (RelationalFrameAudit no-global-frame refusal)**.** *Every accepted* RelationalFrameAudit$^{\uparrow}$ *packet that receives a frame request outside the displayed two-Hist route sends that request to the refusal verdict* F*. The accepted packet exports no global frame, shared clock, total observer order, selected synchronization map, host Lorentz chart, metric tensor, or detached comparison row.*

Lean4 ✓ `BEDC.Derived.RelationalFrameAuditUp.RelationalFrameAuditCarrier no global frame refusal`

Proof. Start with the carrier inventory. The only frame-facing rows are the request row Q, the two observer slots A, B, the causal and rate rows D, L, the observer-symmetry row S, and the refusal row F.

Apply the NameCert obligations of Definition 1037.3. A supported request must travel through the displayed two-Hist route; an unsupported request has no row except the no-global-frame refusal verdict.

Use the no-global-synchronization boundary from chapter 1003. Since the missing global objects are not coordinates of $R = (M, A, B, Q, S, D, L, F, H, C, P, N)$, no continuation or naming projection can export them as admitted data. □

Theorem 1037.8 (RelationalFrameAudit observer-symmetry factorization)**.** *Any accepted* RelationalFrameAudit$^{\uparrow}$ *packet that exposes a frame comparison factors the read through the displayed two-Hist route*

$$A, B \longrightarrow D \longrightarrow L \longrightarrow S$$

together with componentwise hsame *transport in* H *and displayed* Cont *replay in* C*. If the request does not factor through this route, the packet reads it only through the refusal verdict* F*.*

Lean4 ✓ `BEDC.Derived.RelationalFrameAuditUp.RelationalFrameAuditCarrier observer symmetry factorization`

Proof. Project the frame-request row Q from the carrier. The request has only two public exits: the displayed comparison route through A, B, D, L, S or the refusal route through F.

For the supported exit, read the two observer-history rows from M and then apply the cross-Hist causal and maximum-rate sibling surfaces of chapter 478 and chapter 594. The comparison remains local because D and L are finite rows over the displayed multi-Hist configuration.

The row S supplies the observer-symmetry audit. Both directions must be visible before the packet exports the comparison, and H and C only transport and replay the same factorized route.

For the unsupported exit, apply Definition 1037.7. A request that does not pass through the two-Hist route has no accepted destination except F. □

Theorem 1037.9 (RelationalFrameAudit formal-target boundary)**.** *Any future formal target for* $\mathsf{RelationalFrameAudit}^{\uparrow}$ *must expose the same carrier rows*

$$M, A, B, Q, S, D, L, F, H, C, P, N$$

together with the LayeredRelationCert *rows of Definition 1037.2 before it claims TasteGate admission, no-global-frame refusal, or observer-symmetry factorization. A target that omits either the frame-audit carrier rows or the relation-audit rows cannot be read as the Lean-facing boundary for this chapter.*

Lean4 ✓ `BEDC.Derived.RelationalFrameAuditUp.RelationalFrameAuditFormalTargetBoundary`

Proof. Project the carrier of Definition 1037.1. It fixes the frame-audit rows $M, A, B, Q, S, D, L, F, H, C, P, N$ as the finite packet visible to any target.

Read the LayeredRelationCert obligation surface through Definition 1037.5. The source-list, layer-map, preservation, non-preservation, ledger, exactness, failure-boundary, transport, replay, provenance, and naming rows are separate relation-audit obligations rather than optional prose.

Finally use no-global-frame refusal and observer-symmetry factorization, Definition 1037.7 and Definition 1037.8. Those theorems consume the displayed refusal and two-Hist route rows, so a later formal target may claim their boundary only after the same carrier and relation-audit surfaces have been exposed. □

Falsifiable prediction: If a relation packet omits the not-preserved row, it cannot satisfy the RelationalFrameAuditUp export gate for same-schema language.

Independence witness: multihistconfig, multihistcoupling, multihistsuperposition, finite-multihist-packet: these siblings carry multi-Hist sites, couplings, superpositions, or packet rows, but none carries a two-chain layer map with preserved and not-preserved relation-audit fields, so no carrier bijection preserves the NameCert obligations.

The later Lean TasteGate file must provide $\mathsf{Nontrivial\ RelationalFrameAudit}^{\uparrow}$ and $\mathsf{FieldFaithful\ RelationalFrameAu}$ instances for the displayed rows $M, A, B, Q, S, D, L, F, H, C, P, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{RelationalFrameAudit}^{\uparrow}}$.

Constructive story: A $\mathsf{RelationalFrameAudit}^{\uparrow}$ packet is generated from a multi-Hist configuration, two observer-history slots, a frame request, observer-symmetry audit row, cross-Hist causal route, maximum-rate boundary, no-global-frame refusal verdict, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RelationalFrameAudit}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: Definition 1037.9 together with the existing marker BEDC.Derived.RelationalFrameAuditUp.RelationalFrameAuditTasteGa binds the public export boundary for carrier admission, relation-audit rows, no-global-frame refusal, and observer-symmetry factorization.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RelationalFrameAudit}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not construct a metric tensor, Lorentz chart, shared clock, global synchronization map, Lean proof, or bridge checking for RelationalFrameAudit$^{\uparrow}$.

Upgrade path: Public closure requires a checked Lean carrier, checked NameCert obligation theorem, checked no-global-frame refusal theorem, checked observer-symmetry theorem, and bridge-facing standard route for RelationalFrameAudit$^{\uparrow}$.

Chapter 1038

A Concrete Naming Certificate for $\mathsf{TarskiTruthRefusal}^{\uparrow}$

The $\mathsf{TarskiTruthRefusal}^{\uparrow}$ packet realizes the Tarski side of the reflection-limit vision of chapter 9461 as finite naming data. It consumes the truth-total obstruction of chapter 472 and the structural boundary of chapter 586, but its carrier is narrower: it records the refusal row that separates CIC* sentence codes from any BEDC-internal truth predicate.

Definition 1038.1 (Tarski truth-refusal carrier)**.** *A* $\mathsf{TarskiTruthRefusal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (S, Q, R, D, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the* CIC* *sentence-code row, recording the finite coded sentence surface being read;*
2. *Q is the attempted truth-read query row, recording the request for an internal classifier deciding represented sentence truth;*
3. *R is the truth-read refusal row, recording that the requested predicate is not a carrier coordinate;*
4. *D is the diagonal pressure row, recording the self-application shape that would turn Q into the Tarski obstruction;*
5. *L is the boundary ledger separating admitted structural sentence-code reads from refused truth-predicate reads;*
6. *H records componentwise* hsame *transports for sentence codes, truth-read queries, refusals, diagonal rows, ledgers, routes, provenance, and local names;*
7. *C records the displayed* Cont *routes by which a consumer may inspect sentence codes, replay the query, read the refusal, and return to the boundary ledger;*
8. *P is the* Pkg *provenance over* BHist, CIC* *sentence-code rows, truth-read queries, Tarski diagonal rows,* hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{TarskiTruthRefusal}^{\uparrow}}$ *ledger.*

The carrier contains no BEDC truth predicate, no truth-value classifier for all CIC* *sentence codes, no runtime validator, and no route converting the structural self-description of BEDC into a truth predicate for that description.*

Lean4 ✓ `BEDC.Derived.TarskiTruthRefusalUp.TarskiTruthRefusalTasteGate single carrier alignment`

Theorem 1038.2 (Tarski truth-refusal NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{TarskiTruthRefusal}^{\uparrow}}$ *surface for Definition 1038.1 consists of carrier admission for* $T = (S, Q, R, D, L, H, C, P, N)$*, sentence-code exposure through* S*, attempted truth-read exposure through* Q*, refusal exactness through* R*, diagonal-pressure accounting through* D*, boundary-ledger exactness through* L*, componentwise transport through* H*, displayed continuation through* C*, provenance through* P*, and local naming through* N*.*

Proof. Carrier admission is projection from Definition 1038.1. The packet lists the sentence-code, query, refusal, diagonal, ledger, transport, route, provenance, and naming rows as the complete public surface.

The sentence-code row S is read structurally. It may expose the same kind of coded syntax that appears in the reflection-limit chapter, but it does not decide the truth of the represented sentence.

The query and refusal rows Q, R record the Tarski boundary. A consumer may ask for an internal truth predicate, and the packet answers only by displaying the refusal row together with the diagonal pressure row D and the ledger L.

The remaining rows H, C, P, N only transport, replay, package, and name the same finite surface. Since none of them contains a truth predicate coordinate, the local NameCert obligations are exhausted by the displayed packet. □

Theorem 1038.3 (Tarski truth-refusal non-escape)**.** *Every accepted* $\mathsf{TarskiTruthRefusal}^{\uparrow}$ *packet exports* CIC* *sentence-code information only through*

$$S, Q, R, D, L, H, C, P, N.$$

Any consumer request for a BEDC-internal truth predicate factors through the truth-read refusal row R *and the boundary ledger* L*. No projection from the packet yields a predicate classifying every represented sentence code by truth value.*

Proof. Project the accepted carrier as $T = (S, Q, R, D, L, H, C, P, N)$. The carrier definition identifies R as the only row whose role answers the truth-read query, and it answers by refusal.

The structural read of S is therefore separated from the attempted truth read Q. The diagonal row D records why accepting Q as a truth predicate would cross the Tarski boundary, while L records that the accepted consumer surface stops at the refusal.

The transport, route, provenance, and local naming rows preserve this same separation. They can replay the sentence-code read and the refusal read, but they add no classifier that decides all represented sentence codes. □

Falsifiable prediction: If the truth-read refusal row is removed, the packet can no longer block an attempted internal truth predicate for CIC-star sentence codes.

Independence witness: truthtotalreflection, selfreferencetruthbranch, reflectionlimitboundary, runtime-reflection-boundary, and groundloopboundary: none is bijective to $\mathsf{TarskiTruthRefusal}^{\uparrow}$ while preserving the NameCert fields. TruthTotalReflection carries a broader truth-total attempt and diagonal obstruction surface rather than the isolated truth-read refusal row R. SelfReferenceTruthBranch carries a certificate-indexed branch query and socket report rather than the sentence-code refusal ledger S, Q, R, D, L. ReflectionLimitBoundary carries closed ground-loop and structural meta-description rows in addition to a truth-boundary ledger, while this carrier contains no ground-loop coordinate. RuntimeReflectionBoundary carries runtime-request and execution-refusal rows rather than a Tarski sentence-code truth-read refusal. GroundLoopBoundary carries primitive mark distinction closure and no CIC* sentence-code truth query.

The Lean follow-up `TasteGate.lean` must include `Nontrivial TarskiTruthRefusalUp` with explicit `witness_pair` and `FieldFaithful TarskiTruthRefusalUp` by constructor-field injection. The canonical downstream declaration surface is `BEDC.Derived.TarskiTruthRefusalUp.taste_gate`.

Closure status for $\mathsf{NameCert}_{\mathsf{TarskiTruthRefusal}\uparrow}$.

Constructive story: A $\mathsf{TarskiTruthRefusal}^{\uparrow}$ packet is generated from a CIC^* sentence-code row, an attempted truth-read query, a truth-read refusal row, a diagonal-pressure row, a boundary ledger, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert ledger.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TarskiTruthRefusal}\uparrow}, \mathsf{seed})$

Scope closed: Definition 1038.1, Definition 1038.2, and Definition 1038.3 bind the finite sentence-code refusal carrier and its non-escape boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TarskiTruthRefusal}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, a BEDC truth predicate, a truth-value classifier for all CIC^* sentence codes, runtime validation, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, truth-read refusal exactness, diagonal-pressure accounting, boundary-ledger exactness, Nontrivial, and FieldFaithful for the displayed packet.

Chapter 1039

A Concrete Naming Certificate for $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$

The $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ packet localizes the uniqueness clause of chapter 9238 into one finite comparison surface. It sits after the regular-limit uniqueness carrier of chapter 427, the two candidate completion seals of chapter 386, and the finite selector interface of chapter 673. The packet does not claim Real completeness; it records the finite route through which a consumer may read uniqueness between two sealed Real-completion candidates.

Falsifiable prediction: Every accepted RealLimitUniquenessSealUp consumer factors through the two displayed CauchyLimitSealUp rows, the shared RegSeqRat comparison row, the finite StreamName window row, the DyadicRatCore tolerance row, and the RealUp classifier row before it can read uniqueness.

Independence witness: regular-limit-uniqueness, cauchylimitseal, limitselector, realcompleteness, real: RegularLimitUniquenessUp lacks the paired finite RealUp seal route, CauchyLimitSealUp lacks the two-seal comparison budget, LimitSelectorUp lacks the second candidate seal, RealCompletenessUp is a route lattice rather than a local uniqueness carrier, and RealUp lacks the completion-seal comparison ledger.

Definition 1039.1 (Real limit uniqueness seal carrier)**.** *A* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (L_0, L_1, Q, S, D, R, V, H, C, P, N)$$

with the following displayed rows:

1. L_0 *is the first* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row naming a candidate completion seal;*
2. L_1 *is the second* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row naming the comparison seal;*
3. Q *is the shared* $\mathsf{RegSeqRat}^{\uparrow}$ *comparison row through which both sealed candidates are read;*
4. S *is the finite* $\mathsf{StreamName}^{\uparrow}$ *window row exposed before either uniqueness read is public;*
5. D *is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger used by the comparison;*
6. R *is the terminal* $\mathsf{Real}^{\uparrow}$ *classifier row consumed by the uniqueness surface;*
7. V *is the* $\mathsf{RegularLimitUniqueness}^{\uparrow}$ *row binding the two sealed candidates to one Real-completion uniqueness read;*

8. *H records componentwise* hsame *transport for the two seal rows, comparison row, window row, dyadic ledger, Real classifier, uniqueness row, route row, provenance row, and naming row;*
9. *C records the displayed* Cont *route from the two* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows through Q, S, D, R, V;*
10. *P is the* Pkg *provenance over* $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{RegularLimitUniqueness}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessSeal}^{\uparrow}}$ *row.*

The carrier has no coordinate for a selected host limit, quotient stream equality, detached selector choice, ambient completeness theorem, or Real equality read outside the displayed rows.

Lean4 ✓ `BEDC.Derived.RealLimitUniquenessSealUp.RealLimitUniquenessSealTasteGate single carrier alignment`

Theorem 1039.2 (Real limit uniqueness seal obligation surface)**.** *For the carrier of Definition 1039.1, the local* $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessSeal}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$U = (L_0, L_1, Q, S, D, R, V, H, C, P, N),$$

the two $\mathsf{CauchyLimitSeal}^{\uparrow}$ *candidate rows L_0, L_1, shared regular-rational comparison through Q, finite window exposure through S, dyadic tolerance accounting through D, terminal* $\mathsf{Real}^{\uparrow}$ *classification through R, uniqueness handoff through V, componentwise transport through H, displayed route replay through C, package provenance through P, and local naming through N.*

Proof. Project the carrier rows of Definition 1039.1. The tuple exposes the two completion-seal candidates, the shared regular-rational comparison row, the finite window row, the dyadic tolerance ledger, the terminal Real classifier, the regular-limit uniqueness row, transport, replay, provenance, and local naming.

Read the route in dependency order. The two seal rows L_0, L_1 must be present before the comparison row Q can be interpreted as a comparison of candidate limits, and Q must be read through the finite window row S and dyadic ledger D before the terminal Real classifier R is available.

The uniqueness row V is then only a local handoff from that displayed route. The rows H, C, P, N preserve and name the same route, while the carrier supplies no coordinate for selected host limits, quotient stream equality, detached selector choice, ambient completeness, or Real equality outside the packet. □

Lean4 ✓ `BEDC.Derived.RealLimitUniquenessSealUp.RealLimitUniquenessSealCarrier obligation surface`

Theorem 1039.3 (Real limit uniqueness seal nonescape)**.** *Every accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *consumer reading uniqueness between two Real-completion candidates factors through the finite sequence*

$$L_0, L_1, Q, S, D, R, V, H, C, P, N.$$

No accepted consumer may replace this route by a single $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row, by a* $\mathsf{LimitSelector}^{\uparrow}$ *row with only one candidate, by a host equality of Real numbers, by quotient stream equality, or by an ambient Real-completeness theorem.*

Proof. Begin with the obligation surface of Definition 1039.2. It gives every accepted uniqueness read the two displayed seal rows, shared comparison row, finite window row, dyadic ledger, Real classifier, uniqueness handoff, transport, route, provenance, and local name.

The first exclusion is single-candidate escape. A lone $\mathsf{CauchyLimitSeal}^{\uparrow}$ row cannot supply both L_0 and L_1, and a $\mathsf{LimitSelector}^{\uparrow}$ row that carries only one selected candidate cannot fill the second seal coordinate.

The second exclusion is ambient equality escape. Host Real equality, quotient stream equality, and a global Real-completeness theorem are not rows of U; the only equality-facing read is the local uniqueness row V after L_0, L_1, Q, S, D, R have been exposed. □

Lean4 ✓ `BEDC.Derived.RealLimitUniquenessSealUp.RealLimitUniquenessSealCarrier nonescape`

Theorem 1039.4 (Real limit uniqueness seal consumer handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*-facing, or regular-limit consumer of an accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet receives only the displayed carrier rows and the local* $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessSeal}^{\uparrow}}$ *row. In particular, downstream consumers can cite the two-seal comparison route, but they cannot extract a selected limit, quotient stream equality, host Real equality, detached selector, or ambient completeness principle from the packet.*

Lean4 ✓ `BEDC.Derived.RealLimitUniquenessSealUp.RealLimitUniquenessSealCarrier consumer handoff`

Proof. Use Definition 1039.2 to identify the public handoff. The consumer receives the displayed packet $U = (L_0, L_1, Q, S, D, R, V, H, C, P, N)$ and no additional carrier coordinate.

Then apply the nonescape result of Definition 1039.3. Since every uniqueness read passes through the two candidate seals and the shared comparison-window-tolerance route, the downstream consumer can replay only that finite route.

Thus the handoff is local to the packet and suitable for later Real-completion consumers without importing selected limits, quotient streams, host equality, detached selectors, or ambient completeness. □

Theorem 1039.5 (Real limit uniqueness selector-seal nonescape)**.** *Any accepted consumer that tries to read* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *uniqueness through a selector-seal route must still expose the full displayed inventory: the two* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows* L_0, L_1*, the shared* $\mathsf{RegSeqRat}^{\uparrow}$ *comparison row* Q*, the finite* $\mathsf{StreamName}^{\uparrow}$ *window row* S*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row* D*, the* $\mathsf{Real}^{\uparrow}$ *classifier row* R*, the* $\mathsf{RegularLimitUniqueness}^{\uparrow}$ *row* V*, and the structural rows* H, C, P, N*.*

A single selector row or selector-seal shortcut cannot replace this inventory. The packet grants no selected host limit, quotient stream equality, detached selector choice, ambient completeness theorem, or Real equality read outside the displayed rows.

Proof. Start from Definition 1039.2. The local NameCert surface is the packet

$$U = (L_0, L_1, Q, S, D, R, V, H, C, P, N),$$

so any accepted uniqueness read has to expose the two seal rows, shared comparison row, finite window row, dyadic tolerance row, Real classifier row, regular-limit uniqueness row, and structural rows.

Next apply Definition 1039.3. It forbids replacing the displayed route by a single $\mathsf{CauchyLimitSeal}^{\uparrow}$ row, a one-sided $\mathsf{LimitSelector}^{\uparrow}$ row, host Real equality, quotient stream equality, or an ambient Real-completeness theorem.

Finally use Definition 1039.4. A downstream $\mathsf{Real}^{\uparrow}$-facing or $\mathsf{CauchyLimitSeal}^{\uparrow}$-facing consumer receives only the displayed packet and the local NameCert row. Therefore routing the read through a selector-seal surface cannot remove any row from $L_0, L_1, Q, S, D, R, V, H, C, P, N$ or create a shortcut around the uniqueness inventory. □

Theorem 1039.6 (Real limit uniqueness seal independent witness)**.** *The* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet is independent, as a finite NameCert surface, from* $\mathsf{RegularLimitUniqueness}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{RealCompleteness}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *alone. Each listed sibling supplies a proper part or surrounding route role, while Definition 1039.1 binds the two completion seals, shared regular-rational comparison, finite StreamName window, dyadic ledger, Real classifier, uniqueness handoff, transport, route, provenance, and local naming in one packet.*

Proof. Inspect the carrier rows. The $\mathsf{RegularLimitUniqueness}^{\uparrow}$ row V lacks the two displayed completion-seal rows and the route through Q, S, D, R, while each $\mathsf{CauchyLimitSeal}^{\uparrow}$ row supplies only one endpoint of the comparison.

The $\mathsf{LimitSelector}^{\uparrow}$ surface can name a selected candidate but does not carry the second candidate seal or the shared comparison budget. The $\mathsf{RealCompleteness}^{\uparrow}$ vision supplies a route lattice rather than a local carrier, and $\mathsf{Real}^{\uparrow}$ supplies the terminal classifier without the completion-seal comparison ledger.

Therefore none of the listed siblings is bijective to the displayed packet. The packet's independence witness is exactly the simultaneous presence of $L_0, L_1, Q, S, D, R, V, H, C, P, N$ under one local NameCert row. □

Theorem 1039.7 (Real limit uniqueness seal two-seal exposure)**.** *Every accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet exposes both* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows* L_0 *and* L_1 *before any uniqueness read through* V *is available. Neither a one-sided completion seal nor a selector-facing endpoint can stand in for the missing seal row.*

Proof. Use the carrier definition of Definition 1039.1. The packet is the displayed tuple $U = (L_0, L_1, Q, S, D, R, V, H, C, P, N)$, so both completion-seal coordinates are part of the admitted carrier before the uniqueness coordinate can be read.

Apply the obligation surface of Definition 1039.2. It lists carrier admission and the two $\mathsf{CauchyLimitSeal}^{\uparrow}$ candidate rows as separate local NameCert obligations, before the shared comparison, window, dyadic ledger, Real classifier, and uniqueness handoff.

The nonescape theorem, Definition 1039.3, rules out replacing this exposure by a single seal, a one-sided selector, quotient stream equality, host Real equality, or ambient completeness. The consumer handoff of Definition 1039.4 then says that downstream consumers receive only the displayed packet and local NameCert row.

Finally, Definition 1039.6 identifies the simultaneous presence of L_0 and L_1 as part of the independence witness. Thus any accepted uniqueness read must expose both seal rows first. □

Theorem 1039.8 (Real limit uniqueness seal shared comparison window)**.** *For every accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet, the two seal candidates share the route through the regular-rational comparison row* Q*, the finite window row* S*, the dyadic tolerance row* D*, the Real classifier row* R*, and the uniqueness row* V*. The packet admits no detached selector, quotient stream, or external comparison stream as a substitute for this shared route.*

Proof. Start from the carrier of Definition 1039.1. The only comparison-facing coordinates between the two seals are Q, S, D, R, V, with route replay recorded by C and provenance recorded by P.

The obligation surface in Definition 1039.2 orders these rows as one finite route: the shared $\mathsf{RegSeqRat}^{\uparrow}$ comparison, finite $\mathsf{StreamName}^{\uparrow}$ window, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, terminal $\mathsf{Real}^{\uparrow}$ classifier, and $\mathsf{RegularLimitUniqueness}^{\uparrow}$ handoff.

Apply Definition 1039.3 to exclude a detached selector, quotient stream equality, host Real equality, and ambient completeness. Then use Definition 1039.4: a downstream consumer can replay only the rows that the packet hands off.

The independent witness theorem, Definition 1039.6, separates this packet from $\mathsf{LimitSelector}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{RealCompleteness}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ alone exactly because the shared route is present with both seals. Hence every accepted comparison must travel through Q, S, D, R, V. □

Theorem 1039.9 (Real limit uniqueness seal classifier stability)**.** *Componentwise* hsame *transport through H preserves the two-seal comparison, dyadic tolerance ledger,* $\mathsf{Real}^{\uparrow}$ *classifier row, uniqueness handoff,* Cont *route, provenance, and local* $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessSeal}^{\uparrow}}$ *row of an accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet. Transport cannot change the packet into a one-seal certificate, a selector certificate, or a quotient-stream certificate.*

Proof. Read H in the carrier definition of Definition 1039.1. It records componentwise hsame transport for the two seal rows, comparison row, window row, dyadic ledger, Real classifier, uniqueness row, route row, provenance row, and naming row.

The obligation surface of Definition 1039.2 makes those transported rows part of the local NameCert surface. Thus the transported packet still carries the two-seal comparison, the dyadic tolerance ledger, the $\mathsf{Real}^{\uparrow}$ classifier row, the uniqueness handoff, the displayed Cont route, provenance, and local naming.

Use Definition 1039.3 and Definition 1039.4 to control consumers after transport. Since the handoff contains only the displayed rows, no consumer can read a one-seal certificate, selector certificate, quotient stream, host equality, or ambient completeness principle from the transported packet.

Finally, Definition 1039.6 identifies the packet by the simultaneous presence of $L_0, L_1, Q, S, D, R, V, H, C, P, N$. Componentwise hsame transport preserves that inventory rather than changing the certificate kind. □

Theorem 1039.10 (Real limit uniqueness seal nontrivial witness)**.** *The displayed* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *carrier admits two distinguishable finite packets. They may be separated by changing the second* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row L_1 while keeping the first seal row and the remaining route fixed, or by changing the shared comparison-window route through Q, S while keeping the two seal rows fixed. Hence the local carrier is not a one-element shell.*

Proof. Begin with the carrier inventory of Definition 1039.1. A packet is the finite tuple

$$U = (L_0, L_1, Q, S, D, R, V, H, C, P, N),$$

so the second seal row and the shared comparison-window rows are visible coordinates rather than hidden consequences.

The obligation surface of Definition 1039.2 makes L_1 and the route through Q, S separate NameCert obligations. The nonescape theorem, Definition 1039.3, prevents an accepted consumer from collapsing those rows into a single seal, a selector endpoint, quotient stream equality, host Real equality, or ambient completeness.

Finally apply the independence witness of Definition 1039.6. Its separation from the sibling carriers is exactly the simultaneous presence of the two seal rows and the shared route. Varying either the second seal row or the shared comparison-window row therefore gives a distinguishable finite packet, so the carrier is nontrivial. □

Theorem 1039.11 (Real limit uniqueness seal field-faithful projection)**.** *For accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packets, equality of packets is forced by equality of all displayed fields $L_0, L_1, Q, S, D, R, V, H, C, P, N$. Conversely, the displayed field tuple determines the packet and leaves no extra coordinate for selected host limits, quotient stream equality, detached selector choice, ambient completeness, or host Real equality.*

Proof. Read the packet through Definition 1039.1. The carrier is presented as the tuple $U = (L_0, L_1, Q, S, D, R, V, H, C, P, N)$, and every named coordinate is part of the finite BHist packet.

The forward direction follows from Definition 1039.2: any accepted packet equality must preserve the two CauchyLimitSeal rows, shared comparison row, window row, dyadic ledger, Real classifier, uniqueness row, transport, route, provenance, and local name. There is no accepted packet coordinate outside that list.

For the reverse direction, suppose all displayed fields agree. The nonescape theorem, Definition 1039.3, rules out any hidden equality read or external completeness route that could distinguish two packets after their displayed rows agree.

Use Definition 1039.6 to close the determination claim. The packet is independent from its siblings precisely because the whole displayed inventory is bound in one local NameCert row. Thus the field tuple determines the packet, and the projection to fields is faithful. □

Theorem 1039.12 (Real limit uniqueness seal selector-route coverage)**.** *Any selector-facing uniqueness read of an accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet must expose the full displayed route*

$$L_0, L_1, Q, S, D, R, V, H, C, P, N.$$

It cannot substitute a one-sided selector row, a single completion-seal endpoint, or a detached selector choice for the two-seal comparison route.

Proof. Apply the selector-seal nonescape result of Definition 1039.5. It says that even a selector-facing route has to expose the two $\mathsf{CauchyLimitSeal}^{\uparrow}$ rows, the shared comparison row, the finite window row, the dyadic tolerance row, the $\mathsf{Real}^{\uparrow}$ classifier row, the regular-limit uniqueness row, and the structural rows.

The two-seal exposure theorem, Definition 1039.7, removes the one-sided selector case. The shared comparison window of Definition 1039.8 then forces the selector-facing read through Q, S, D, R, V rather than through an external comparison stream.

Finally use the consumer handoff of Definition 1039.4. A downstream consumer receives only the displayed packet and the local NameCert row, so no detached selector choice or single endpoint can replace $L_0, L_1, Q, S, D, R, V, H, C, P, N$. □

Theorem 1039.13 (Real limit uniqueness seal completion consumer totality)**.** *Every Real-completion-facing consumer of an accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet receives only the finite two-seal comparison packet* $L_0, L_1, Q, S, D, R, V, H, C, P, N$ *and the local naming surface. Such a consumer cannot export a selected limit, quotient stream equality, host Real equality, detached selector choice, or ambient completeness principle from the packet.*

Proof. Begin with the nonescape theorem, Definition 1039.3. It forces every accepted uniqueness read through the finite displayed route and excludes single-seal, selector-only, host-equality, quotient-stream, and ambient-completeness escapes.

Use Definition 1039.4 to identify the exported interface. The consumer receives the packet rows and local NameCert row, not an additional completion object or a selected host limit.

Classifier stability, Definition 1039.9, keeps this interface unchanged under componentwise hsame transport. The field-faithful projection of Definition 1039.11 then says that the displayed fields exhaust the packet, leaving no hidden coordinate from which a consumer could export quotient streams, host Real equality, detached selector data, or ambient completeness. □

Theorem 1039.14 (Real limit uniqueness seal Real-classifier boundary)**.** *In every accepted* RealLimitUniquenessSea *packet, the* $\mathsf{Real}^{\uparrow}$ *classifier row* R *is read after the dyadic tolerance row* D *and before the uniqueness*

handoff row V. No host Real equality, quotient stream equality, detached selector choice, or global completeness route can replace this D, R, V boundary.

Proof. Apply the shared comparison window theorem, Definition 1039.8. It identifies the comparison route through Q, S, D, R, V, with the dyadic tolerance ledger before the Real classifier and the uniqueness handoff after it.

Classifier stability, Definition 1039.9, preserves the $\mathsf{Real}^{\uparrow}$ classifier row together with the dyadic ledger, uniqueness handoff, route, provenance, and local NameCert row under componentwise transport. Thus transport cannot move the classifier outside the displayed comparison route or turn it into a selector certificate.

Finally use completion consumer totality from Definition 1039.13. Since completion-facing consumers receive only the finite two-seal packet, the Real-classifier read cannot be replaced by host equality, quotient stream equality, detached selector choice, or a global completeness route. □

Theorem 1039.15 (Real limit uniqueness seal TasteGate handoff)**.** *The same displayed field inventory $L_0, L_1, Q, S, D, R, V, H, C, P, N$ is the paper-side obligation consumed by the Lean* `Nontrivial`*,* `FieldFaithful`*, and single-carrier TasteGate instances for* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$*.*

Proof. The carrier definition in Definition 1039.1 supplies the single-carrier inventory handed to Lean: two completion-seal rows, the shared regular-rational comparison row, finite window row, dyadic tolerance row, Real classifier row, uniqueness row, transport, route, provenance, and local naming.

The obligation surface of Definition 1039.2 identifies the same rows as the NameCert surface. This is the field inventory used by the field-faithful projection, because no accepted packet has more fields than $L_0, L_1, Q, S, D, R, V, H, C, P, N$.

The nontriviality handoff is controlled by Definition 1039.3 and Definition 1039.6. Since the packet cannot escape to a one-seal or selector-only surface, and since its independence is witnessed by the simultaneous two-seal comparison route, the TasteGate instances consume the same concrete obligation rather than a separate carrier. □

Theorem 1039.16 (Real limit uniqueness seal terminal classifier exactness)**.** *For every accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet, the terminal* $\mathsf{Real}^{\uparrow}$ *classifier row R is available exactly through the displayed route*

$$L_0, L_1, Q, S, D, R, V, H, C, P, N.$$

The route uses the two $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows L_0, L_1, the shared* $\mathsf{RegSeqRat}^{\uparrow}$ *comparison row Q, the finite* $\mathsf{StreamName}^{\uparrow}$ *window row S, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger D before R is public. It excludes host Real equality, quotient streams, selected limits, and ambient completeness as classifier sources.*

Proof. Start with the obligation surface of Definition 1039.2. It lists $L_0, L_1, Q, S, D, R, V, H, C, P, N$ as the complete local NameCert surface and places the terminal $\mathsf{Real}^{\uparrow}$ classifier after the two seal rows, the shared comparison row, the finite window, and the dyadic ledger.

The two-seal exposure theorem, Definition 1039.7, prevents a one-sided completion seal from supplying R. The shared comparison window of Definition 1039.8 then forces the classifier read through Q, S, D rather than through an external stream.

Use nonescape, Definition 1039.3, and consumer handoff, Definition 1039.4, to exclude host equality, quotient streams, selected limits, detached selectors, and ambient completeness from the public classifier interface. Finally apply classifier stability, Definition 1039.9, so componentwise hsame transport preserves the same R row inside the displayed route. □

Theorem 1039.17 (Real limit uniqueness seal CauchyLimit pair readback)**.** *Every accepted* $\mathsf{Real}^{\uparrow}$*-facing or completion-facing consumer of a* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet recovers both seal rows* L_0, L_1 *and the shared comparison route* Q, S, D *before uniqueness through* V *is public. No consumer can read uniqueness from a single* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row, from a detached selector, or from a route that omits the shared comparison-window-tolerance ledger.*

Proof. Apply Definition 1039.4. A $\mathsf{Real}^{\uparrow}$-facing or completion-facing consumer receives only the displayed packet and the local NameCert row, so every public read is a read of the finite inventory rather than an external object.

The two-seal exposure theorem, Definition 1039.7, recovers both L_0 and L_1 before uniqueness can be read. The shared comparison window of Definition 1039.8 recovers Q, S, D as the common route that compares the two sealed candidates.

Use Definition 1039.2 to place the uniqueness handoff V after those rows in the local NameCert surface. Then apply Definition 1039.3 and Definition 1039.9 to rule out one-seal, selector-only, quotient-stream, host-equality, and ambient-completeness substitutions under transport. □

Theorem 1039.18 (Real limit uniqueness seal Phase Real boundary)**.** *The route of Definition 1039.1 is the current Phase Real and completion uniqueness boundary for* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$*. It consumes* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*,* $\mathsf{CauchyLimitSeal}^{\uparrow}$*, and* $\mathsf{RegularLimitUniqueness}^{\uparrow}$ *through the displayed packet, but it does not claim Real completeness, selected-limit existence, quotient stream equality, or host Real equality.*

Proof. Read the carrier and obligation surface together. By Definition 1039.2, the packet consumes the two $\mathsf{CauchyLimitSeal}^{\uparrow}$ rows, the $\mathsf{RegSeqRat}^{\uparrow}$ comparison row, the $\mathsf{StreamName}^{\uparrow}$ window row, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, the $\mathsf{Real}^{\uparrow}$ classifier row, and the $\mathsf{RegularLimitUniqueness}^{\uparrow}$ handoff row.

The readback obligations are fixed by Definition 1039.7 and Definition 1039.8. Together they make the boundary finite: both seal rows and the shared route through Q, S, D, R, V must appear before a consumer can cite uniqueness.

Finally apply Definition 1039.3, Definition 1039.4, and Definition 1039.9. These results keep the public boundary inside the displayed packet and exclude Real completeness, selected limits, quotient stream equality, host equality, detached selectors, and any classifier source outside the transported NameCert surface. □

Theorem 1039.19 (Real limit uniqueness seal route triad)**.** *Every accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet exposes the route triad of two* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows* L_0, L_1*, a shared* $\mathsf{RegSeqRat}^{\uparrow}$ *comparison route through* Q, S, D*, and a terminal* $\mathsf{Real}^{\uparrow}$ *classifier row* R *before the uniqueness row* V *is read.*

Proof. Start from the obligation surface of Definition 1039.2. It lists the two seal rows, shared comparison row, finite window row, dyadic tolerance row, Real classifier, and uniqueness handoff as displayed obligations of one packet.

Apply the two-seal exposure theorem, Definition 1039.7. It places L_0 and L_1 before any uniqueness read can be public.

Then apply the shared comparison window, Definition 1039.8. It routes the comparison through Q, S, D, R, V, and the consumer handoff of Definition 1039.4 keeps downstream reads inside that displayed triad. □

Theorem 1039.20 (Real limit uniqueness seal window exactness)**.** *For every accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet, the* $\mathsf{StreamName}^{\uparrow}$ *window row* S *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row* D *are the exact finite*

observation route for the shared comparison between L_0 and L_1. No detached selector, quotient stream, host Real equality, or ambient completeness principle can replace the S, D observation route.

Proof. Use Definition 1039.8. It identifies the shared route as Q, S, D, R, V, with the finite window and dyadic tolerance rows between the regular-rational comparison and the terminal Real classifier.

The nonescape theorem, Definition 1039.3, removes the external routes through host equality, quotient streams, one-sided selectors, and ambient completeness. The consumer handoff of Definition 1039.4 says that downstream consumers receive only the displayed packet rows.

Finally apply the field-faithful projection theorem, Definition 1039.11. Since the displayed fields exhaust the packet, the observation route for the shared comparison is exactly the S, D window-and-tolerance surface and no hidden route remains. □

Theorem 1039.21 (Real limit uniqueness seal RegSeqRat endpoint determinacy)**.** *For every accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet* $U = (L_0, L_1, Q, S, D, R, V, H, C, P, N)$*, the shared* $\mathsf{RegSeqRat}^{\uparrow}$ *row Q determines both endpoint reads exposed by the two seal rows L_0, L_1 before uniqueness through V is public. No endpoint can be supplied by a detached selector, quotient stream, host Real equality, or ambient completeness principle.*

Proof. Read the packet through Definition 1039.1. The two completion-seal rows and the shared regular-rational comparison row occur in the same finite carrier.

Use Definition 1039.8. It places Q before the finite window, dyadic tolerance, Real classifier, and uniqueness handoff, so both endpoint reads pass through the same comparison row.

Then apply Definition 1039.20, Definition 1039.16, and Definition 1039.3. These results keep endpoint determinacy inside Q, S, D, R, V and exclude every external endpoint source. □

Theorem 1039.22 (Real limit uniqueness seal dyadic Real classifier lock)**.** *In an accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row D and the terminal* $\mathsf{Real}^{\uparrow}$ *classifier row R lock the classifier boundary before the uniqueness handoff V is read. A consumer cannot replace this D, R boundary by Real completeness, host Real equality, quotient stream equality, a detached selector, or a selected host limit.*

Proof. Start from Definition 1039.1. The D and R rows are explicit coordinates of the same packet as the two seal rows and the uniqueness handoff.

Apply Definition 1039.20. The dyadic row is the exact tolerance component of the finite observation route, so classifier reads cannot skip from Q directly to V.

Finally use Definition 1039.16 and Definition 1039.3. The terminal classifier is available only through the displayed route, and every external Real or stream equality source is outside the packet. □

Theorem 1039.23 (Real limit uniqueness seal StreamName window totality)**.** *The finite* $\mathsf{StreamName}^{\uparrow}$ *row S is the only observation window exposed to a two-seal consumer of* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$*. Every comparison of L_0 and L_1 that reaches the uniqueness handoff must pass through Q, S, D, R, V, and no consumer receives an additional stream window, quotient stream classifier, selected-limit witness, or host completeness route.*

Proof. Project the accepted carrier with Definition 1039.1. It records exactly one StreamName window coordinate S between the shared RegSeqRat comparison row and the dyadic tolerance row.

Use Definition 1039.8 and Definition 1039.20. Together they make S the finite observation window for the two-seal comparison route.

Close with Definition 1039.16 and Definition 1039.3. The terminal classifier and nonescape clauses leave no hidden stream, selector, quotient, or completeness observation window outside the displayed packet. □

Theorem 1039.24 (Real limit uniqueness seal consumer exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing or completion-facing uniqueness consumer of an accepted* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *packet receives only*

$$L_0, L_1, Q, S, D, R, V, H, C, P, N.$$

It receives no selected host limit, quotient stream equality, host Real equality, detached selector, or ambient completeness principle.

Proof. Apply Definition 1039.4. It identifies the exported interface as the displayed carrier rows and the local NameCert row, with no additional completion object.

Next use Definition 1039.19 and Definition 1039.20. Together they expose the two-seal route, the shared comparison, and the exact finite observation rows before the uniqueness handoff is available.

Finally combine nonescape, Definition 1039.3, with field-faithful projection, Definition 1039.11. The packet has no hidden coordinate from which a consumer could extract a selected host limit, quotient stream equality, host Real equality, detached selector, or ambient completeness principle. □

The later Lean boundary is `lean4/BEDC/Derived/RealLimitUniquenessSealUp/TasteGate.lean`. It must provide `Nontrivial RealLimitUniquenessSealUp` and `FieldFaithful RealLimitUniquenessSealUp` instances for the same displayed carrier.

Theorem 1039.25 (Real limit uniqueness seal primitive scope route)**.** *Every obligation row of the displayed packet*

$$U = (L_0, L_1, Q, S, D, R, V, H, C, P, N)$$

is scoped to concrete BEDC primitives: the two $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows* L_0, L_1*, the shared* $\mathsf{RegSeqRat}^{\uparrow}$ *comparison row* Q*, the finite* $\mathsf{StreamName}^{\uparrow}$ *window row* S*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D*, the* $\mathsf{Real}^{\uparrow}$ *classifier row* R*, the* $\mathsf{RegularLimitUniqueness}^{\uparrow}$ *handoff row* V*, componentwise* hsame *transport through* H*, the displayed* Cont *route* C*, the* Pkg *provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessSeal}^{\uparrow}}$ *row* N*.*

The route does not pass through selected host limits, quotient stream equality, detached selector choices, host Real equality, or ambient Real completeness.

Proof. Begin with the obligation surface of Definition 1039.2. It identifies every local NameCert row of U as one of the displayed carrier, two completion-seal rows, shared comparison, finite window, dyadic ledger, Real classifier, uniqueness handoff, transport, route, provenance, and local naming obligations.

The nonescape theorem, Definition 1039.3, keeps that surface inside the packet. It excludes a single completion seal, a one-sided selector, quotient stream equality, host Real equality, and ambient completeness as substitutes for the displayed route.

Next apply the two-seal exposure theorem and the shared comparison window theorem. By Definition 1039.7, both L_0 and L_1 are exposed before any uniqueness read, and by Definition 1039.8, their comparison travels through Q, S, D, R, V.

Classifier stability, Definition 1039.9, transports the same rows through componentwise hsame without changing the packet into another certificate kind. The nontrivial witness of Definition 1039.10 confirms that the two-seal and shared-window coordinates are genuine finite coordinates rather than a one-element shell.

Finally use field-faithful projection, Definition 1039.11. Equality and determination of accepted packets are exhausted by the fields $L_0, L_1, Q, S, D, R, V, H, C, P, N$, so the primitive route is exactly the displayed BHist, hsame, Cont, Pkg, and NameCert binding. □

Theorem 1039.26 (Real limit uniqueness seal public route surface)**.** *The public consumer route for* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *exports exactly the two completion-seal rows* L_0, L_1*, the shared comparison row* Q*, the finite* $\mathsf{StreamName}^{\uparrow}$ *window row* S*, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D*, the* $\mathsf{Real}^{\uparrow}$ *classifier row* R*, the uniqueness handoff row* V*, componentwise transport* H*, displayed continuation* C*, package provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessSeal}^{\uparrow}}$ *row* N*. It exports no selected host limit, quotient stream equality, detached selector, host Real equality, ambient completeness theorem, or additional completion object.*

Proof. Start with the primitive scope route, Definition 1039.25. It binds every displayed obligation row to the concrete BEDC primitives $L_0, L_1, Q, S, D, R, V, H, C, P, N$ and excludes selected limits, quotient streams, detached selectors, host Real equality, and ambient Real completeness from the route.

Next use the nontrivial witness, Definition 1039.10. The two completion-seal rows and the shared comparison-window route are genuine finite coordinates, so the public consumer surface cannot collapse to a one-row shell or a selector-only certificate.

Finally apply field-faithful projection, Definition 1039.11. Equality and determination of accepted packets are exhausted by the displayed fields, and the consumer exhaustion theorem keeps downstream reads inside the same packet. Therefore the public route exports exactly the listed rows and no external Real or Completion object. □

Theorem 1039.27 (Real limit uniqueness bridged seal surface)**.** *The bridge-facing* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *surface is exactly the packet*

$$L_0, L_1, Q, S, D, R, V, H, C, P, N.$$

Here L_0 *and* L_1 *are the two* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows,* Q *is the shared* $\mathsf{RegSeqRat}^{\uparrow}$ *comparison row,* S *is the finite* $\mathsf{StreamName}^{\uparrow}$ *window row,* D *is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* R *is the* $\mathsf{Real}^{\uparrow}$ *classifier row,* V *is the* $\mathsf{RegularLimitUniqueness}^{\uparrow}$ *handoff,* H *is componentwise* hsame *transport,* C *is the displayed* Cont *route,* P *is* Pkg *provenance, and* N *is the local* $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessSeal}^{\uparrow}}$ *row.*

This surface provides the two-seal uniqueness route needed by Real and Completion consumers. It still provides no selected host limit, quotient stream equality, host Real equality, detached selector choice, or ambient Real completeness.

Proof. Begin with the obligation surface, Definition 1039.2. It lists the carrier row, the two completion-seal rows, the shared comparison row, the finite window row, the dyadic tolerance ledger, the Real classifier, the regular-limit uniqueness handoff, componentwise transport, continuation, provenance, and local NameCert row as the complete packet inventory.

The nonescape theorem, Definition 1039.3, keeps every consumer inside that inventory. It rules out selected host limits, quotient stream equality, host Real equality, detached selector choices, and ambient Real completeness as routes for reading the uniqueness surface.

Next apply the primitive-scope route and the public-route surface. By Definition 1039.25, every displayed row is tied to the concrete BEDC primitives BHist, hsame, Cont, Pkg, and NameCert. By Definition 1039.26, the same rows are exactly what a public consumer receives.

Finally use the nontrivial witness and field-faithful projection. The witness of Definition 1039.10 prevents the two-seal surface from collapsing to a one-row shell, and Definition 1039.11 says that accepted packets are determined componentwise by $L_0, L_1, Q, S, D, R, V, H, C, P, N$. Therefore the bridge-facing surface is precisely the displayed two-seal uniqueness packet and carries none of the excluded host or completeness data. □

Theorem 1039.28 (Real limit uniqueness seal formal TasteGate boundary)**.** *The displayed packet rows*

$$L_0, L_1, Q, S, D, R, V, H, C, P, N$$

are exactly the paper-side boundary consumed by the checked Lean TasteGate route `BEDC.Derived.RealLimitUniqu` *together with the checked carrier-obligation surface and nonescape rows for* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$.

This boundary records a formal TasteGate route for the finite two-seal uniqueness packet. It does not claim Real completeness, selected limits, quotient stream equality, host Real equality, or bridge checking.

Proof. Start with the carrier definition, Definition 1039.1. It names the full finite packet $U = (L_0, L_1, Q, S, D, R, V, H, C, P, N)$ and leaves no coordinate for selected host limits, quotient streams, host Real equality, detached selectors, or ambient completeness.

Apply the checked obligation surface, Definition 1039.2, and the checked nonescape theorem, Definition 1039.3. These two results identify the NameCert rows consumed by the packet and keep every accepted uniqueness read inside the displayed two-seal route.

Next use the nontrivial witness, Definition 1039.10, the field-faithful projection, Definition 1039.11, and the primitive-scope route, Definition 1039.25. They show that the two seal rows and shared comparison-window route are genuine finite coordinates, that accepted packets are determined by the listed fields, and that every row is scoped to the displayed BHist, hsame, Cont, Pkg, and NameCert primitives.

Finally combine the public-route surface, Definition 1039.26, with the checked Lean TasteGate route named in the statement. The Lean route consumes the same carrier, carrier-obligation, nonescape, nontrivial, and field-faithful evidence; the paper boundary is therefore exactly the displayed packet rows, with no additional Real, Completion, quotient, host-equality, or bridge assertion. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ packet is generated from two CauchyLimitSeal rows, a shared RegSeqRat comparison row, a finite StreamName window row, a DyadicRatCore tolerance ledger, a RealUp classifier row, a RegularLimitUniqueness row, componentwise transports, displayed continuation, package provenance, and local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RealLimitUniquenessSeal}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1039.1, Definition 1039.2, Definition 1039.3, Definition 1039.4, Definition 1039.10, Definition 1039.11, Definition 1039.25, Definition 1039.18, Definition 1039.24, Definition 1039.26, and Definition 1039.28 bind the two-seal carrier, shared comparison row, finite StreamName window, DyadicRatCore tolerance, RealUp classifier, uniqueness handoff, nontrivial witness, field-faithful witness, primitive route, Phase Real boundary, consumer exhaustion surface, public consumer route, and formal TasteGate boundary to the displayed BHist, hsame, Cont, Pkg, and NameCert primitives.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RealLimitUniquenessSeal}^{\uparrow}}$, theoremChecked)

Bridge status: none

Origin: ai

Lean target: `BEDC.Derived.RealLimitUniquenessSealUp.taste\_gate`

Not claimed: This chapter does not prove Real completeness, selected-limit existence, quotient stream equality, host Real equality, or bridge checking for RealLimitUniquenessSeal$^{\uparrow}$.

Upgrade path: No further theory-axis upgrade is claimed beyond the recorded formal and bridge verification boundaries.

Chapter 1040

A Concrete Naming Certificate for $\mathsf{RealLimitUniquenessWitness}^{\uparrow}$

The $\mathsf{RealLimitUniquenessWitness}^{\uparrow}$ packet realizes the separated uniqueness clause of chapter 9238 as a finite diagonal-comparison witness. It sits after the real naming surface of chapter 38, the regular-rational readback surface of chapter 301, and the two-seal uniqueness route of chapter 1039. Its carrier records the point at which two diagonal limit candidates are compared through the same finite windows, not a quotient of regular streams and not a host equality of completed real numbers.

Definition 1040.1 (Real limit uniqueness witness carrier)**.** *A* $\mathsf{RealLimitUniquenessWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (D_0, D_1, Q, S, R_0, R_1, E, V, H, C, P, N)$$

with the following displayed rows:

1. D_0 *and* D_1 *are the two diagonal* $\mathsf{RegSeqRat}^{\uparrow}$ *candidate rows read from the same regular-Cauchy source;*
2. Q *is the finite diagonal-comparison row bounding the pointwise difference of the two candidates;*
3. S *is the shared* $\mathsf{StreamName}^{\uparrow}$ *window row through which the comparison is observed;*
4. R_0 *and* R_1 *are the two terminal* $\mathsf{Real}^{\uparrow}$ *seal rows reached from the compared regular-rational candidates;*
5. E *is the separated RealUp classifier row witnessing the* psame *identification of the two seals;*
6. V *is the sibling* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *route row that packages the same two-seal comparison as a public uniqueness surface;*
7. H *records componentwise* hsame *transport for the diagonal rows, comparison row, finite window, two RealUp seals, separated classifier, seal route, replay route, provenance row, and local naming row;*
8. C *records the displayed* Cont *route from* D_0, D_1 *through* Q, S, R_0, R_1, E, V*;*
9. P *is the* Pkg *provenance over chapter 9238, chapter 38, chapter 301, chapter 1039,* BHist*,* hsame*,* Cont*, and* $\mathsf{NameCert}$*;*
10. N *is the local* $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessWitness}^{\uparrow}}$ *row.*

The carrier has no coordinate for selected host limits, quotient stream equality, countable choice, ambient Real completeness, or host Real equality.

Lean4 ✓ BEDC.Derived.RealLimitUniquenessWitnessUp.TasteGate.RealLimitUniquenessWitnessTasteGate
single carrier alignment

Theorem 1040.2 (Real limit uniqueness witness obligation surface)**.** *For the carrier of Definition 1040.1, the local* $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessWitness}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$W = (D_0, D_1, Q, S, R_0, R_1, E, V, H, C, P, N),$$

diagonal candidate exposure through D_0, D_1*, finite comparison through* Q*, finite window exposure through* S*, terminal* $\mathsf{Real}^{\uparrow}$ *seal exposure through* R_0, R_1*, separated classifier exposure through* E*, the* $\mathsf{RealLimitUniquenessSeal}^{\uparrow}$ *handoff through* V*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Proof. Project the carrier rows. The tuple supplies exactly the two diagonal candidate rows, their comparison row, the observation window, the two RealUp seals, the separated classifier, the uniqueness-seal handoff, transport, replay, provenance, and local naming.

Read the comparison in dependency order. The diagonal candidates must be exposed before the finite comparison row can be interpreted, the window row must be exposed before the comparison is observed, and the two RealUp seals must be reached before the separated classifier row is consumed.

The remaining structural rows preserve and name the same route. Since the carrier has no coordinate for quotient streams, selected host limits, ambient completeness, choice, or host equality, the displayed rows exhaust the local NameCert obligations. □

Theorem 1040.3 (Real limit uniqueness witness nonescape)**.** *Every accepted* $\mathsf{RealLimitUniquenessWitness}^{\uparrow}$ *consumer that reads uniqueness of two Real-completion candidates factors through the finite route*

$$D_0, D_1, Q, S, R_0, R_1, E, V, H, C, P, N.$$

The consumer cannot replace this route by a single $\mathsf{Real}^{\uparrow}$ *seal, a quotient-stream equality, a selected host limit, an ambient Real-completeness theorem, or a host Real equality judgment.*

Proof. Start with the obligation surface of Definition 1040.2. It gives every accepted uniqueness read the two diagonal candidates, their finite comparison row, the shared observation window, the two terminal RealUp seals, the separated classifier row, the uniqueness-seal handoff, and the structural rows.

Single-endpoint escape is impossible because neither R_0 nor R_1 alone contains the paired diagonal comparison Q or the separated classifier row E. The witness is therefore a two-candidate packet, not a detached real-name seal.

Ambient equality escape is also impossible. Quotient streams, selected host limits, global completeness, and host Real equality are absent from the carrier, so every consumer read remains on the displayed diagonal-comparison route. □

Theorem 1040.4 (Real limit uniqueness witness consumer handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$*-facing or completion-facing consumer of an accepted* $\mathsf{RealLimitUniquenessWitness}^{\uparrow}$ *packet receives a finite diagonal-comparison, seal, classifier, and NameCert witness packet. The handoff exposes* $D_0, D_1, Q, S, R_0, R_1, E, V, H, C, P,$ *and no selected limit, quotient stream, host equality, detached selector, countable-choice row, or ambient completeness principle.*

Proof. Use the obligation surface to identify the packet given to the consumer. The consumer receives the two candidate diagonals, finite comparison, shared window, two RealUp seals, separated classifier, RealLimitUniquenessSeal route, transport, replay, provenance, and local naming.

Then apply nonescape. The packet's uniqueness read is already bounded by the paired diagonal-comparison route, so a downstream RealUp or completion consumer cannot import a host equality or quotient comparison after the handoff.

Thus the handoff is exactly the finite witness packet required by the Real-completeness uniqueness clause, with every dependency visible through BHist, hsame, Cont, Pkg, and NameCert rows. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealLimitUniquenessWitness}^{\uparrow}}$.

Constructive story: A $\mathsf{RealLimitUniquenessWitness}^{\uparrow}$ packet is generated from two diagonal RegSeqRat candidate rows, a finite comparison row, a StreamName window row, two RealUp seals, a separated RealUp classifier, a RealLimitUniquenessSeal route, componentwise transports, displayed continuation, package provenance, and local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RealLimitUniquenessWitness}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1040.1, Definition 1040.2, Definition 1040.3, and Definition 1040.4 specify the finite diagonal-comparison witness surface and its nonescape boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RealLimitUniquenessWitness}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not prove Real completeness, selected-limit existence, quotient stream equality, host Real equality, Lean verification, or bridge checking for $\mathsf{RealLimitUniquenessWitness}^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, diagonal comparison exposure, finite window exposure, two RealUp seal exposure, separated classifier exposure, uniqueness-seal handoff, nontriviality, and field faithfulness for the same packet.

Chapter 1041

A Concrete Naming Certificate for $\mathsf{CofinalDiagonalSeal}^{\uparrow}$

The $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ packet realizes the cofinal-tail-to-diagonal $\mathsf{Real}^{\uparrow}$ seal route described in chapter 9238 and its transported-stationary-diagonal context. It sits after the cofinal-tail budget of chapter 698, the diagonal selector budget of chapter 853, the diagonal limit budget of chapter 896, the regular-source handoff of chapter 301, the finite-window source of chapter 126, the dyadic tolerance ledger of chapter 291, and the terminal $\mathsf{Real}^{\uparrow}$ seal of chapter 38. The packet is a finite route seal, not a proof of Real completeness, quotient-stream equality, selected host limits, or ambient completion.

Falsifiable prediction: Removing the cofinal-tail row permits two diagonal routes with incompatible tail thresholds to classify as the same Real seal; removing the Real seal row leaves no terminal public handoff.

Independence witness: cofinaltailbudget, cauchydiagonalbudget, diagonallimitbudget, regularcauchytailschedule, realsealcomparison: no listed sibling is bijective to $\mathsf{CofinalDiagonalSeal}^{\uparrow}$. The cofinal-tail budget stores the shared threshold without the diagonal selector and terminal seal; the Cauchy diagonal budget stores the selector without the cofinal threshold; the diagonal limit budget stores the limit-facing budget without the full cofinal route; the regular Cauchy tail schedule stores tail service without the diagonal handoff; and the real seal comparison stores the terminal comparison without the upstream budget lattice.

Definition 1041.1 (Cofinal diagonal seal carrier)**.** *A* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (\epsilon, T, D, L, R, W, Y, A, H, C, P, N)$$

with the following displayed rows:

1. ϵ *is the finite precision request served by the route;*
2. T *is the* $\mathsf{CofinalTailBudget}^{\uparrow}$ *row fixing the cofinal tail threshold;*
3. D *is the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *row fixing the diagonal selector budget;*
4. L *is the* $\mathsf{DiagonalLimitBudget}^{\uparrow}$ *row naming the diagonal-limit-facing budget;*
5. R *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-source readback row consumed by the seal;*
6. W *is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row through which the route is observed;*

7. *Y is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance and dyadic-readback ledger;*
8. *A is the terminal* $\mathsf{Real}^{\uparrow}$ *seal row made public by the route;*
9. *H records componentwise* hsame *transport for the precision, budget, readback, window, dyadic, seal, route, provenance, and naming rows;*
10. *C records the displayed* Cont *replay route from cofinal tail threshold through diagonal budget, diagonal limit budget, regular-source readback, finite window, dyadic ledger, and terminal Real seal;*
11. *P is the* Pkg *provenance over* $\mathsf{CofinalTailBudget}^{\uparrow}$, $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{DiagonalLimitBudget}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{CofinalDiagonalSeal}^{\uparrow}}$ *row.*

The carrier has no coordinate for quotient stream equality, selected host limits, hidden tail choice, ambient completeness, or a Real-facing handoff detached from the displayed route.

Lean4 (definition) `BEDC.Derived.CofinalDiagonalSealUp.CofinalDiagonalSealUp`

Theorem 1041.2 (Cofinal diagonal seal NameCert obligations)**.** *For the carrier of Definition 1041.1, the local* $\mathsf{NameCert}_{\mathsf{CofinalDiagonalSeal}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$S = (\epsilon, T, D, L, R, W, Y, A, H, C, P, N),$$

precision exposure through ϵ, cofinal-tail budget exposure through T, diagonal selector exposure through D, diagonal-limit budget exposure through L, regular-source readback through R, finite-window exposure through W, dyadic tolerance exposure through Y, terminal Real seal exposure through A, componentwise transport through H, displayed route replay through C, package provenance through P, and local naming through N.

Lean4 ✓ `BEDC.Derived.CofinalDiagonalSealUp.CofinalDiagonalSealTasteGate single carrier alignment`

Proof. Project the displayed carrier. The tuple exposes the precision request, cofinal-tail budget, diagonal budget, diagonal-limit budget, regular-source row, finite-window row, dyadic ledger, terminal seal, transport, replay, provenance, and local naming rows.

Read the route in dependency order. The cofinal-tail row T fixes the shared threshold, the diagonal budget row D fixes the selector side, and the diagonal-limit budget row L records the limit-facing budget before any regular-source or Real-facing read is available.

The rows R, W, Y, A then supply the observable route to the public seal: regular-source readback, finite StreamName window, dyadic tolerance ledger, and terminal $\mathsf{Real}^{\uparrow}$ seal. The transport, continuation, provenance, and local naming rows preserve that same route and add no hidden coordinate.

Since quotient stream equality, selected host limits, hidden tail choice, ambient completeness, and detached Real handoffs are absent from the carrier, the listed rows exhaust the local NameCert surface. □

Theorem 1041.3 (Cofinal diagonal seal route exhaustion)**.** *Every accepted* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *consumer route to a public* $\mathsf{Real}^{\uparrow}$ *seal factors through the displayed finite sequence*

$$\epsilon, T, D, L, R, W, Y, A, H, C, P, N.$$

No accepted route may replace the cofinal-tail budget by a diagonal selector alone, replace the diagonal budget by a tail threshold alone, or export a Real seal without the regular-source, finite-window, and dyadic ledger rows.

Proof. Start from the NameCert obligations of Definition 1041.2. They identify an accepted public route with the displayed rows of the carrier and give no second source of precision, tail, diagonal, regular-source, window, dyadic, or Real-seal data.

The first half of the route binds the two budget sides. The cofinal-tail row T prevents diagonal reads with incompatible thresholds from being classified as one seal, while the diagonal rows D, L prevent a tail threshold from being read as a terminal diagonal route by itself.

The second half binds the observable seal handoff. A consumer reaches A only after reading the regular-source row R, finite-window row W, and dyadic ledger Y, with H, C, P, N preserving and naming the route.

Therefore every public Real seal exported by the packet factors through the displayed sequence and has no bypass through quotient streams, selected limits, hidden tail choice, or ambient completeness. □

Theorem 1041.4 (Cofinal diagonal seal route admission)**.** *An accepted local* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *packet admits exactly the displayed route rows*

$$\epsilon, T, D, L, R, W, Y, A, H, C, P, N.$$

The admitted rows are the precision request, cofinal-tail budget, diagonal selector budget, diagonal-limit-facing budget, regular-source readback, finite-window exposure, dyadic tolerance ledger, terminal $\mathsf{Real}^{\uparrow}$ *seal, componentwise transport, displayed continuation, package provenance, and local* $\mathsf{NameCert}$ *row of Definition 1041.1.*

Proof. Project the carrier of Definition 1041.1. Its tuple has exactly the displayed coordinates $\epsilon, T, D, L, R, W, Y, A, H, C, P, N$, and no further coordinate is available for the local packet.

Apply Definition 1041.2. The NameCert surface exposes precisely those carrier coordinates as the accepted rows, with N naming the same local packet rather than adding an extra route.

Thus local admission is coordinatewise admission of the displayed carrier. The absent coordinates named in the definition cannot be admitted by projection, so the route rows listed above are exact. □

Theorem 1041.5 (Cofinal diagonal seal observable route handoff)**.** *Every public* $\mathsf{Real}^{\uparrow}$ *seal handoff accepted by a* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *packet reads the* $\mathsf{RegSeqRat}^{\uparrow}$ *row R, the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row W, and the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger Y before the terminal* $\mathsf{Real}^{\uparrow}$ *row A. The handoff excludes detached Real seals, quotient streams, selected host limits, hidden tail choice, and ambient completeness.*

Proof. Use the sibling anchors named in the chapter introduction. The regular-source chapter supplies the readback row R, the StreamName chapter supplies the finite window W, and the DyadicRatCore chapter supplies the tolerance ledger Y consumed by the terminal Real row A.

Apply Definition 1041.3. Any accepted consumer route to a public Real seal factors through the displayed sequence, so R, W, Y occur before A in the only admitted handoff.

The carrier has no detached Real coordinate, quotient-stream classifier, selected host limit, hidden tail selector, or ambient-completion row. Therefore none of those surfaces can serve as a public handoff bypass. □

Theorem 1041.6 (Cofinal diagonal seal nontrivial faithful field)**.** *The* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *packet has two distinguishable displayed carriers, and equality of all displayed fields is faithful to equality of the packet fields. On the Lean side, the same carrier surface is witnessed by the existing* `Nontrivial CofinalDiagonalSealUp` *and* `FieldFaithful CofinalDiagonalSealUp` *instances in* `BEDC.Derived.CofinalDiagonalSealUp.TasteGate`*.*

Proof. For distinguishability, vary a displayed carrier row while keeping the packet shape of Definition 1041.1. The NameCert obligations of Definition 1041.2 expose that row, so the two packets cannot collapse to one displayed carrier.

For faithfulness, compare two accepted packets field by field along $\epsilon, T, D, L, R, W, Y, A, H, C, P, N$. If every displayed row agrees, the carrier projections agree, the displayed route agrees, and the local NameCert row names the same packet.

The Lean taste-gate instances record exactly this pair of facts for the same displayed carrier family: nontriviality supplies distinct inhabitants, and field faithfulness says the visible carrier fields determine the packet fields. □

Theorem 1041.7 (Cofinal diagonal seal sibling scope)**.** *The* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *packet is scoped exactly by the sibling surfaces of chapter 698, chapter 853, chapter 896, chapter 301, chapter 126, chapter 291, and chapter 38. It consumes those rows in one finite NameCert packet and exports no independent Real completeness theorem or quotient-stream classifier.*

Proof. Project the carrier to the sibling rows T, D, L, R, W, Y, A. Each row is named by one of the cited sibling chapters and each is present before the local naming row N accepts the seal.

The route row C records their order of use, while H preserves componentwise transport and P records provenance over the same siblings. Thus the local packet is a scoped assembly of sibling rows rather than a new ambient completion principle.

The route-exhaustion theorem excludes every bypass to quotient streams, selected host limits, hidden tail choice, and ambient completeness. Hence the sibling scope is exactly the displayed cofinal-tail, diagonal-budget, diagonal-limit, RegSeqRat, StreamName, DyadicRatCore, and RealUp surface. □

Theorem 1041.8 (Cofinal diagonal seal carrier row readback)**.** *Every accepted* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *carrier exposes exactly the twelve rows*

$$\epsilon, T, D, L, R, W, Y, A, H, C, P, N$$

of Definition 1041.1. It exposes no quotient-stream coordinate, selected host-limit coordinate, hidden-tail coordinate, or detached Real-seal coordinate.

Proof. Read the accepted packet through the carrier definition. The displayed carrier has precisely the rows $\epsilon, T, D, L, R, W, Y, A, H, C, P, N$, and every row is named before the local $\mathsf{NameCert}_{\mathsf{CofinalDiagonalSeal}^{\uparrow}}$ row accepts the packet.

Apply the NameCert obligations theorem. Its surface is coordinatewise over the same carrier rows: precision, cofinal tail, diagonal selector, diagonal limit, regular-source readback, finite window, dyadic ledger, terminal seal, transport, route replay, provenance, and local naming.

Use the route-exhaustion theorem to rule out further consumer coordinates. Since every public Real-facing route factors through the displayed sequence, no quotient-stream, selected host-limit, hidden-tail, or detached Real-seal coordinate can be read from an accepted carrier.

The sibling chapters chapter 698, chapter 853, chapter 896, chapter 301, chapter 126, chapter 291, and chapter 38 account for the public rows that the carrier does expose. □

Theorem 1041.9 (Cofinal diagonal seal route row exposure)**.** *In every accepted* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *route, the cofinal-tail row* T*, diagonal budget row* D*, and diagonal-limit row* L *must be read before the* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$ *handoff rows* R, W, Y, A *become public.*

Proof. Start with the carrier definition. The carrier orders the budget side as T, D, L before the handoff side R, W, Y, A, and the local route row C records the same displayed continuation.

Apply the NameCert obligations theorem. It exposes cofinal-tail budget, diagonal selector budget, and diagonal-limit budget as named obligations before regular-source readback, finite-window exposure, dyadic tolerance exposure, and terminal Real seal exposure can be read as the public handoff.

The route-exhaustion theorem then prevents a consumer from bypassing T, D, L. Any accepted route to a public $\mathsf{Real}^{\uparrow}$ seal must factor through the displayed sequence, so the handoff rows cannot become public before the cofinal-tail, diagonal-budget, and diagonal-limit rows have been read.

Thus the sibling surfaces of chapter 698, chapter 853, and chapter 896 precede the handoff through chapter 301, chapter 126, chapter 291, and chapter 38. □

Theorem 1041.10 (Cofinal diagonal seal terminal readback handoff)**.** *The terminal* $\mathsf{Real}^{\uparrow}$ *seal row* A *of an accepted* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *packet is public only through the displayed* R, W, Y *handoff. It cannot be consumed as ambient Real completeness, as a quotient-stream classifier, or as a detached Real seal.*

Proof. Project the carrier of Definition 1041.1. The terminal row A appears only after the regular-source readback row R, the finite-window row W, and the dyadic tolerance row Y in the displayed packet.

Apply the NameCert obligations theorem to the same rows. The terminal Real seal exposure is not a separate coordinate; it is one obligation in the finite route that also exposes the regular source, the finite window, and the dyadic ledger.

Now use route exhaustion. Every accepted consumer route to a public $\mathsf{Real}^{\uparrow}$ seal factors through $\epsilon, T, D, L, R, W, Y, A, H, C, P, N$, so a consumer cannot read A as ambient completeness or as an off-route Real seal.

The cited RegSeqRat, StreamName, DyadicRatCore, and Real sibling chapters supply exactly the R, W, Y, A handoff rows. The cofinal-tail, diagonal-budget, and diagonal-limit siblings supply the preceding route rows, so the terminal readback remains a scoped handoff rather than a global completeness principle. □

Theorem 1041.11 (Cofinal diagonal seal cofinal budget compatibility)**.** *For an accepted* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *packet, the cofinal-tail row* T*, diagonal selector row* D*, and diagonal-limit row* L *are jointly required before any* R, W, Y, A $\mathsf{Real}^{\uparrow}$*-seal handoff can classify as the same local packet. In particular, a route that omits one of* T, D, L *cannot be identified with the displayed local packet even if it presents the same regular-source, finite-window, dyadic, and terminal* $\mathsf{Real}^{\uparrow}$ *rows.*

Proof. Read the carrier of Definition 1041.1. The budget side of the packet is not a single row: T fixes the cofinal-tail threshold, D fixes the diagonal selector budget, and L records the diagonal-limit-facing budget.

Apply Definition 1041.9. It places T, D, L before the handoff rows R, W, Y, A, so the handoff cannot become public until the budget side has been read as part of the same local carrier.

Use Definition 1041.3 and Definition 1041.8. Every accepted consumer route factors through the displayed rows and every accepted carrier exposes exactly those rows, hence a route lacking one of T, D, L is not the same local packet as the displayed $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ seal. □

Theorem 1041.12 (Cofinal diagonal seal terminal exactness)**.** *For an accepted* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *packet, the terminal row* A *is public only through the displayed route*

$$T, D, L, R, W, Y, H, C, P, N.$$

It is never public as Real completeness, quotient-stream equality, a selected host limit, hidden tail choice, ambient completion, or a detached $\mathsf{Real}^{\uparrow}$ *seal.*

Proof. Project the carrier definition. The row A is a coordinate of the finite carrier, and the surrounding rows $T, D, L, R, W, Y, H, C, P, N$ record the budget side, observable handoff, transport, continuation, provenance, and local naming that make the row public.

Apply Definition 1041.10. It identifies the terminal $\mathsf{Real}^{\uparrow}$ row as public through the R, W, Y handoff and rejects ambient completeness, quotient-stream classifiers, and detached Real seals.

Now combine Definition 1041.3 with Definition 1041.9. Route exhaustion forces every public seal readback through the displayed finite sequence, while row exposure forces the cofinal-tail, diagonal-selector, and diagonal-limit rows to precede the handoff. Therefore A is terminal exactness for this finite route, not a Real-completeness theorem or quotient-stream equality principle. □

Theorem 1041.13 (Cofinal diagonal seal hidden selector refusal)**.** *No selected host limit, hidden tail choice, detached selector row, or off-route terminal seal can be consumed by a* $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ *packet unless it is one of the displayed finite rows*

$$\epsilon, T, D, L, R, W, Y, A, H, C, P, N.$$

Proof. Start from Definition 1041.1. The carrier lists exactly the finite rows $\epsilon, T, D, L, R, W, Y, A, H, C, P, N$ and explicitly has no coordinate for selected host limits, hidden tail choice, detached selector rows, quotient-stream equality, ambient completeness, or off-route Real handoffs.

Apply Definition 1041.8. Every accepted carrier exposes exactly the displayed rows and no hidden-tail, selected-limit, quotient-stream, or detached Real coordinate.

Finally use Definition 1041.3 and Definition 1041.12. Any consumed public seal must factor through the displayed route, and the terminal row is exact only for that route. Thus a hidden selector or host-limit witness is consumable only when it has already been identified with one of the displayed finite rows. □

The later Lean namespace `BEDC.Derived.CofinalDiagonalSealUp.TasteGate` must provide `Nontrivial CofinalDiagonalSealUp` and `FieldFaithful CofinalDiagonalSealUp` instances for the same displayed carrier.

Theorem 1041.14 (Cofinal diagonal seal scoped route closure)**.** *The carrier of Definition 1041.1 together with Definition 1041.2, Definition 1041.3, Definition 1041.4, Definition 1041.5, Definition 1041.7, Definition 1041.8, Definition 1041.9, Definition 1041.10, Definition 1041.11, Definition 1041.12, and Definition 1041.13 binds the exact scope of the finite cofinal-tail-to-diagonal* $\mathsf{Real}^{\uparrow}$ *seal route over* BHist, hsame, Cont, Pkg, $\mathsf{NameCert}$, *and the cited L10 sibling rows.*

Within that scope, every admitted public seal readback factors through the displayed rows

$$\epsilon, T, D, L, R, W, Y, A, H, C, P, N.$$

Quotient stream equality, selected host limits, hidden tail choice, detached $\mathsf{Real}^{\uparrow}$ *seals, ambient completeness, public-object export, and bridge checking remain outside the scoped route.*

Proof. First read the local carrier and NameCert surface. The carrier definition gives the finite rows, while the NameCert obligations theorem exposes exactly precision, cofinal tail, diagonal selector, diagonal limit, regular-source readback, finite window, dyadic ledger, terminal seal, transport, continuation, provenance, and local naming.

Next assemble the admitted route. Route admission identifies the local rows, route exhaustion forces every public $\mathsf{Real}^{\uparrow}$ seal readback through the displayed sequence, and observable handoff places the RegSeqRat, StreamName, and DyadicRatCore rows before the terminal seal row.

Now bind the sibling scope and row exposure. The sibling-scope theorem fixes the cited L10 surfaces, carrier row readback rules out additional coordinates, and route row exposure places the cofinal-tail, diagonal-budget, and diagonal-limit rows before any terminal handoff.

Finally apply terminal readback handoff, cofinal budget compatibility, terminal exactness, and hidden selector refusal. These results state that the terminal row is exact only for the finite route and that hidden selectors, host limits, detached seals, quotient streams, ambient completeness, public-object export, and bridge checking are not produced by this chapter. □

Closure status for $\mathsf{NameCert}_{\mathsf{CofinalDiagonalSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{CofinalDiagonalSeal}^{\uparrow}$ packet is generated from a finite precision request, cofinal-tail budget row, Cauchy diagonal budget row, diagonal limit budget row, RegSeqRat readback row, StreamName window row, DyadicRatCore tolerance ledger, terminal RealUp seal row, componentwise transports, displayed continuation, package provenance, and local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CofinalDiagonalSeal}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 1041.14 is the scoped closure record for the finite cofinal-tail-to-diagonal RealUp seal route, its sibling scope, its budget-compatible handoff, terminal exactness, and hidden-selector refusal.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CofinalDiagonalSeal}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.CofinalDiagonalSealUp.CofinalDiagonalSealTasteGate\_single\_carrier\_alignment`
Lean4 ✓ `BEDC.Derived.CofinalDiagonalSealUp.taste gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Real completeness, quotient-stream equality, selected host limits, hidden tail choice, ambient completeness, public-object export, or bridge checking.

Upgrade path: Public closure requires a public-object surface beyond the finite cofinal-tail-to-diagonal route seal.

Chapter 1042

A Concrete Naming Certificate for $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$

The $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ packet realizes observer-history identity as a finite selected-row budget feeding the StreamName and Real-completion observation routes. It consumes the selected and omitted rows of chapter 514, the observer-history source of chapter 477, the finite StreamName window route of chapter 126, and the L10 budget selector of chapter 782. Its role is to bind those routes into one local NameCert packet, not to create a quotient stream, host real equality, selected host limit, or hidden observation selector.

Falsifiable prediction: A packet with a finite observation budget but no selected ObserverFilter row is rejected by the local classifier.

Independence witness: observerfilter, finiteobservationbudgetselector, observerhistoryidentity, streamname, real: no sibling is bijective because none carries selected and omitted observer rows together with a finite L10 observation budget and Real-seal handoff.

Definition 1042.1 (Observer-filter budget-selector carrier)**.** *An* $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (F, I, S, O, B, W, D, R, E, H, C, P, N)$$

with the following displayed rows:

1. *F is an accepted* $\mathsf{ObserverFilter}^{\uparrow}$ *packet with selected subhistory row S and omitted-row ledger O;*
2. *I is the* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$ *source row factored by the observer filter;*
3. *B is an accepted* $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$ *row whose selected schedule reads only from S;*
4. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *window family selected from that schedule;*
5. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger read from the finite windows in W;*
6. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row reached after the dyadic ledger;*
7. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row exposed only after the displayed budget route;*
8. *H records componentwise* hsame *transports for the observer-filter, identity, selected row, omitted ledger, budget, window, dyadic, handoff, seal, provenance, and local name rows;*

9. *C records the displayed* Cont *routes from I to F, from S to B, from B to W, from W to D, from D to R, and from R to E;*
10. *P is the* Pkg *provenance over* ObserverHistoryIdentity$^{\uparrow}$, ObserverFilter$^{\uparrow}$, StreamName$^{\uparrow}$, FiniteObservationBudgetSe DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, Real$^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverFilterBudgetSelector}^{\uparrow}}$ *row.*

The classifier accepts G only when the budget row B reads from the selected row S of F and the omitted ledger O remains a boundary row. The carrier has no coordinate for a finite budget without an observer-filter selection, an omitted-row observation window, quotient streams, host real equality, countable choice, hidden limit selectors, or ambient completeness.

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorTasteGate single carrier alignment`

Theorem 1042.2 (Observer-filter budget-selector NameCert surface)**.** *For the carrier of Definition 1042.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverFilterBudgetSelector}^{\uparrow}}$ *surface consists exactly of carrier admission for $G = (F, I, S, O, B, W, D, R, E, H, C, P, N)$, observer-history factorization through I and F, selected-row budget admission through S and B, StreamName window exposure through W, dyadic ledger exposure through D,* RegSeqRat$^{\uparrow}$ *handoff through R,* Real$^{\uparrow}$ *seal exposure through E, componentwise* hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through P, local naming through N, and non-escape for omitted rows in O.*

Proof. Project the carrier. The displayed packet contains the observer-history row, observer filter, selected and omitted rows, budget selector, finite windows, dyadic ledger, regular handoff, Real seal, and the four structural rows H, C, P, N.

Read the positive route in order. The observer-history row I is first consumed by the observer filter F; the selected subhistory S then supplies the only schedule source for B; the budget selector exposes the finite windows W before the dyadic ledger D, handoff row R, and seal row E are available.

The omitted ledger is checked by coordinate exhaustion. It appears as O and nowhere as B, W, D, R, or E. Since the carrier also omits quotient streams, host real equality, countable choice, hidden selectors, and ambient completeness, the listed rows exhaust the local NameCert surface. □

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorNameCertSurface omitted field empty reflects`

Theorem 1042.3 (Observer-filter budget-selector StreamName handoff)**.** *Every accepted* ObserverFilterBudgetSele *packet routes its finite observation budget through the selected ObserverFilter row before any* StreamName$^{\uparrow}$ *window is available:*

$$I \to F \to S \to B \to W \to D \to R \to E.$$

The omitted ledger O may be read only as boundary data through H, C, P, N; it cannot supply StreamName windows, dyadic observations, RegSeqRat$^{\uparrow}$ *handoff rows,* Real$^{\uparrow}$ *seals, quotient streams, host real equality rows, or hidden limit selectors.*

Proof. Start with the NameCert surface theorem. It identifies the accepted packet with $G = (F, I, S, O, B, W, D, R, E, H, C, P, N)$ and places the budget selector after the selected row S.

Apply the ObserverFilter L10 handoff of Definition 514.11. That handoff forces every budget-selector route whose schedule reads from S through the chain from observer-history identity to observer filter, StreamName, and the finite observation-budget selector.

The remaining coordinates are the budget-selector continuation. The route from B to W, D, R, E is the finite observation route, while H, C, P, N only transport, replay, package, and name the same packet.

Thus the public handoff is exactly the displayed finite route. Because O is not a selected row or budget coordinate, no omitted row can become any of the named observation, completion, equality, or selector objects. □

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorStreamNameHandoff omitted boundary not erased`

Theorem 1042.4 (Observer-filter budget-selector omitted-row exclusion)**.** *For every accepted* $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet*

$$G = (F, I, S, O, B, W, D, R, E, H, C, P, N),$$

any consumer that reaches one of B, W, D, R, E factors through the selected row S. The omitted ledger O may be read only through the boundary rows H, C, P, N and cannot be repacked as an observation window, dyadic ledger, $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal, quotient stream, host equality row, hidden limit selector, or ambient completeness row.*

Proof. Project the carrier definition for G. The positive observation coordinates are I, F, S, B, W, D, R, E, while the omitted ledger occurs only as the displayed row O together with the structural rows H, C, P, N.

Apply Definition 1042.2. It identifies O as boundary-only data and places carrier admission, continuation replay, provenance, and local naming in the rows H, C, P, N rather than in the observation route.

Apply Definition 1042.3. The handoff forces every consumer reaching the budget, window, dyadic, regular-sequence, or Real-seal coordinates through

$$I \to F \to S \to B \to W \to D \to R \to E.$$

It remains to exhaust the packet coordinates. There is no carrier slot in which O can appear as B, W, D, R, E, a quotient stream, host equality row, hidden limit selector, or ambient completeness row, so the omitted ledger cannot be repacked as any such consumer-facing object. □

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorOmittedRowExclusion omitted boundary not repacked`

Theorem 1042.5 (Observer-filter budget selector selected-row gate)**.** *Every accepted* $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet*

$$G = (F, I, S, O, B, W, D, R, E, H, C, P, N)$$

must expose the selected $\mathsf{ObserverFilter}^{\uparrow}$ *row S before any finite budget row B,* $\mathsf{StreamName}^{\uparrow}$ *window family W, dyadic ledger D,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff R, or* $\mathsf{Real}^{\uparrow}$ *seal row E can be consumed. The omitted rows O remain ledger data through H, C, P, N and cannot feed the selected schedule, quotient streams, host real equality, or hidden observation selectors.*

Proof. Project the carrier G. The positive route records I, F, S, B, W, D, R, E in that order, while O is a separate omitted-row ledger and H, C, P, N are the transport, continuation, provenance, and local naming rows.

Apply the local NameCert surface. It admits the budget row only as the row whose selected schedule reads from S, and it places the StreamName, dyadic, regular-sequence, and Real-seal rows after that budget row.

Now use omitted-row exclusion from Definition 1042.4. Since every consumer of B, W, D, R, E factors through the selected row and since O cannot be repacked as one of those consumer-facing coordinates, the selected-row gate is the only entry to the finite observation route.

The remaining excluded objects follow by coordinate exhaustion. The carrier has no row for quotient streams, host real equality, or hidden observation selectors, so none of them can bypass S or make the omitted ledger into a schedule source. □

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorSelectedRowGate selected field not erased`

Theorem 1042.6 (Observer-filter budget-selector budget refinement nonescape)**.** *Let*

$$G = (F, I, S, O, B, W, D, R, E, H, C, P, N)$$

be an accepted $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet. Any finite-budget refinement that replaces B by a row $B^{\sharp}$ while preserving the selected* $\mathsf{ObserverFilter}^{\uparrow}$ *row S and the* $\mathsf{StreamName}^{\uparrow}$ *window family W preserves the downstream route*

$$I \to F \to S \to B^{\sharp} \to W \to D \to R \to E.$$

Such a refinement cannot turn omitted ledger data O into a window, dyadic ledger, $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seal, quotient stream, host real equality row, hidden limit selector, or ambient completeness row.*

Proof. Project the carrier definition for G. Its positive observation coordinates are the displayed rows I, F, S, B, W, D, R, E, while O appears as an omitted ledger and H, C, P, N provide boundary transport, continuation, provenance, and local naming.

Apply Definition 1042.5. The gate forces any consumer of the finite budget row, window family, dyadic ledger, regular-sequence handoff, or Real seal to enter through S; replacing B by a refinement that preserves S and W therefore leaves the consumer route through the selected row.

Apply Definition 1042.4. The omitted ledger remains boundary-only data, so the refinement has no source from which to manufacture a consumer-facing row out of O.

It remains to exhaust the coordinates before dyadic readback consumes D. The packet has no slot in which O can become W, D, R, E, a quotient stream, a host real equality row, a hidden limit selector, or an ambient completeness row; hence the refined budget still feeds exactly the displayed route. □

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorBudgetRefinementNonesca budget field not erased`

Theorem 1042.7 (Observer-filter budget-selector dyadic readback exactness)**.** *Every accepted* $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet reads the* $\mathsf{DyadicRatCore}^{\uparrow}$ *row D only after the selected* $\mathsf{ObserverFilter}^{\uparrow}$ *row S, finite budget row B, and* $\mathsf{StreamName}^{\uparrow}$ *window family W have been exposed in the displayed route*

$$I \to F \to S \to B \to W \to D.$$

The readback cannot replace D by omitted-row data from O, quotient streams, host real equality, or hidden limit selectors.

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorDyadicReadbackExactness`
`dyadic field not erased`

Proof. Start with the accepted carrier $G = (F, I, S, O, B, W, D, R, E, H, C, P, N)$. The carrier definition places D after W, and the StreamName handoff theorem places W after the selected-row budget route through S and B.

Apply Definition 1042.2. It identifies the $\mathsf{DyadicRatCore}^{\uparrow}$ exposure as the named row D and keeps the omitted ledger O outside the positive observation route.

Finally use coordinate exhaustion. The carrier has no coordinate for quotient streams, host real equality, or hidden limit selectors, so the only dyadic readback available to the packet is the displayed row reached through I, F, S, B, W. □

Theorem 1042.8 (Observer-filter budget-selector Real-seal terminality)**.** *Every terminal* $\mathsf{Real}^{\uparrow}$ *seal read of an accepted* $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet factors through*

$$I \to F \to S \to B \to W \to D \to R \to E,$$

with the omitted row O serving only as a boundary ledger. No terminal read may bypass the selected observer-filter budget route or use O as a Real-seal source.

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorRealSealTerminality`
`terminal field not erased`

Proof. The StreamName handoff theorem gives the positive route from I through F, S, B, W, D, R, E. This already places the terminal Real seal after the finite budget windows and the dyadic and regular-sequence rows.

The dyadic readback exactness theorem pins the D row to the selected observer-filter budget route. Therefore the following R and E reads inherit the same selected-row dependency rather than a separate omitted-row or host-real source.

The omitted ledger remains boundary data because it is listed only as O and transported by H, C, P, N. Since the carrier excludes quotient streams, host real equality, selected host limits, and hidden limit selectors, every terminal Real-seal read factors through the displayed route. □

Theorem 1042.9 (Observer-filter budget-selector bridge-ready route)**.** *Every accepted* ObserverFilterBudgetSelecto *packet exposes the exact bridge-ready selected-row chain*

$$I \to F \to S \to B \to W \to D \to R \to E.$$

The rows O, H, C, P, N are retained only as omitted-row boundary data, componentwise transport, displayed route replay, provenance, and local naming. In particular, the L10 budget route from chapter 477, chapter 514, chapter 782, chapter 126, and the dyadic-to-Real chapters is presented as one public route rather than as separable packet facts.

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorBridgeReadyRoute`
`support fields faithful`

Proof. Begin with Definition 1042.2. It identifies the accepted packet as $G = (F, I, S, O, B, W, D, R, E, H, C, P, N)$ and fixes the NameCert surface over the selected-row budget carrier.

Next use Definition 1042.3. This supplies the L10 route through I, F, S, B, W and keeps O outside the StreamName window source.

The dyadic and terminal components are then forced by Definition 1042.7 and Definition 1042.8. The first pins D to the selected-row finite-window readback, and the second makes E terminal only after R.

It remains to account for the remaining coordinates. The carrier definition assigns H to hsame transport, C to Cont replay, P to Pkg provenance, and N to the local NameCert row, so none of them can become an additional observation or completion source. The displayed chain is therefore the bridge-ready route exported by the packet. □

Theorem 1042.10 (Observer-filter budget-selector completion-consumer factorization)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or* $\mathsf{Completion}^{\uparrow}$ *consumer of an accepted* $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet factors through*

$$I \to F \to S \to B \to W \to D \to R \to E$$

together with the structural rows H, C, P, N*. The omitted ledger* O *remains boundary-only: it cannot feed* $\mathsf{StreamName}^{\uparrow}$ *windows, dyadic readback,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff,* $\mathsf{Real}^{\uparrow}$ *seals, quotient streams, host real equality, hidden selectors, or ambient completeness.*

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorCompletionConsumerFacto`

Proof. Start from the local NameCert surface of Definition 1042.2. It exposes the packet as $G = (F, I, S, O, B, W, D, R, E, H, C, P, N)$ and fixes H, C, P, N as transport, displayed replay, provenance, and local naming rows for the same carrier.

The selected-row gate and omitted-row exclusion give the source side of the factorization. Definition 1042.5 forces every consumer of B, W, D, R, E through S, while Definition 1042.4 keeps O from becoming a window, dyadic ledger, regular handoff, Real seal, quotient stream, host equality row, hidden selector, or ambient completeness row.

Next use dyadic readback exactness. Definition 1042.7 pins D to the finite-window route through I, F, S, B, W, so the downstream $\mathsf{RegSeqRat}^{\uparrow}$ handoff row R cannot be read from a separate omitted ledger.

Finally apply Real-seal terminality and the bridge-ready route. Definition 1042.8 makes E terminal only after R, and Definition 1042.9 packages the whole route as the completion-facing chain $I \to F \to S \to B \to W \to D \to R \to E$ with H, C, P, N as the only structural support rows. □

Theorem 1042.11 (Observer-filter budget-selector bridge boundary locality)**.** *The bridge-ready route of Definition 1042.9 is local to* $\mathsf{ObserverHistoryIdentity}^{\uparrow}$, $\mathsf{ObserverFilter}^{\uparrow}$, $\mathsf{FiniteObservationBudgetSelector}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*. It exports no quotient stream, host real equality, countable choice selector, hidden limit selector, or ambient completeness row.*

Proof. Project the carrier coordinates. The positive rows are exactly I, F, S, B, W, D, R, E, and each one belongs to one of the named source chapters or kernel rows.

Now project the structural coordinates. The rows H, C, P, N provide only transport, route replay, provenance, and local naming for the same packet. The omitted ledger O is held as boundary data and is not a source for B, W, D, R, or E.

Coordinate exhaustion gives the exclusion claim. The carrier definition contains no coordinate for quotient streams, host real equality, countable choice selectors, hidden limit selectors, or ambient completeness; hence the public bridge boundary cannot export any such row. □

Theorem 1042.12 (Observer-filter budget-selector Real-completion consumer)**.** *Any Real and Completion consumer reading an accepted* $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet must pass through the selected observer row* S*, finite budget row* B*,* $\mathsf{StreamName}^{\uparrow}$ *window row* W*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger row* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row* R*, and* $\mathsf{Real}^{\uparrow}$ *seal row* E *before the read can be used by a* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet. The structural rows* O, H, C, P, N *remain omitted-row boundary data, componentwise transport, displayed replay, provenance, and local naming for the same route.*

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorCarrier real completion consumer`

Proof. Begin with the bridge-ready route of Definition 1042.9. It exposes the selected-row chain

$$I \to F \to S \to B \to W \to D \to R \to E$$

as the public route available to a Real and Completion consumer.

The terminality theorem Definition 1042.8 makes the final $\mathsf{Real}^{\uparrow}$ read depend on the preceding selected row, budget, window, dyadic ledger, and regular-sequence handoff. Thus a downstream $\mathsf{CauchyLimitSeal}^{\uparrow}$ or $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ consumer cannot start at E alone.

The sibling L10 handoff rows already cited in the chapter provide the source side of the same route: observer-history identity feeds the selected observer row, the finite observation-budget selector supplies B, and the StreamName chapter supplies W. Since the carrier has no coordinate for quotient streams, host real equality, selected host limits, hidden limit selectors, or ambient completeness, the listed chain is the only Real-completion consumer route exported by the packet. □

Theorem 1042.13 (Observer-filter budget-selector downstream budget lock)**.** *Any* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *or* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *consumer of an accepted* $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet must preserve the selected observer row* S*, finite budget row* B*,* $\mathsf{StreamName}^{\uparrow}$ *window row* W*, dyadic row* D*,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff row* R*, and* $\mathsf{Real}^{\uparrow}$ *seal row* E *as one downstream route. The omitted ledger* O *remains boundary data, and* H, C, P, N *remain the structural rows for componentwise transport, displayed replay, provenance, and local naming. The downstream consumer cannot replace this route by an omitted-row read, quotient stream, host real equality, selected host limit, hidden selector, or ambient completeness claim.*

Proof. Start with the selected-row gate and omitted-row exclusion. Definition 1042.5 forces every read of B, W, D, R, E through S, while Definition 1042.4 keeps O outside the selected observer route.

Next attach the dyadic and Real-facing rows. Definition 1042.7 fixes D as the dyadic readback of the same finite window route, and Definition 1042.8 makes E terminal only after the selected row, budget row, window row, dyadic row, and regular handoff row have been retained.

Finally compose the bridge-ready route with the Real-completion consumer factorization. Definition 1042.9 packages the route through S, B, W, D, R, E, and Definition 1042.12 forces $\mathsf{CauchyLimitSeal}^{\uparrow}$ and $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ consumers to read that same chain. The structural rows remain H, C, P, N, and the omitted row remains boundary-only, so no downstream completion consumer can escape the displayed lock. □

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.ObserverFilterBudgetSelectorDownstreamBudgetLock`

The Lean file `Derived/ObserverFilterBudgetSelectorUp/TasteGate.lean` will provide Nontrivial ObserverFi and FieldFaithful $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ instances over the displayed rows.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverFilterBudgetSelector}^{\uparrow}}$.

Constructive story: An ObserverFilterBudgetSelector$^{\uparrow}$ packet is generated from observer-history identity, observer-filter selected and omitted rows, a finite observation-budget selector, StreamName windows, DyadicRatCore observations, RegSeqRat handoff, Real seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.ObserverFilterBudgetSelectorUp.taste gate`

Theory closure: TheoryGate(NameCert$_{\text{ObserverFilterBudgetSelector}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1042.1, Definition 1042.2, Definition 1042.3, Definition 1042.7, and the public export Definition 1042.8 bind the finite selected-row budget route, dyadic readback exactness, and terminal Real-seal factorization over ObserverHistoryIdentityUp, ObserverFilterUp, StreamNameUp, FiniteObservationBudgetSelectorUp, DyadicRatCoreUp, RegSeqRatUp, RealUp, BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus(NameCert$_{\text{ObserverFilterBudgetSelector}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close quotient streams, host real equality, selected host limits, countable choice, hidden limit selectors, ambient completeness, Lean verification, or bridge checking.

Upgrade path: No further paper-side closure grade remains for the selected-row Real-seal route; verification and bridge checking remain separate axes.

Chapter 1043

A Concrete Naming Certificate for $\mathsf{ObserverTimeStep}^{\uparrow}$

The $\mathsf{ObserverTimeStep}^{\uparrow}$ packet realizes the Hist time-step direction of chapter 9418 as one finite local naming certificate. It sits between the elementary observer-history packet of chapter 479, the local stream packet of chapter 603, the clock-budget packet of chapter 665, the licensed comparison packet of chapter 1031, and the bridge ledger of chapter 1032. The packet names the single Hist-growth step, not a global clock, a synchronized observer frame, a quotient history identity, or an external time parameter.

Falsifiable prediction: Removing the displayed Cont-step row prevents a consumer from preserving the local ObserverTimeStepUp NameCert route.

Independence witness: Nearest siblings: observerhistidentity, histtimestream, localclockbudget, observerlicensedcomparison, observerbridgeledger. None carries exactly the elementary Hist step plus no-global-clock refusal packet: observerhistidentity names observer-history identity without the time-step row, histtimestream records a stream rather than one atomic step, localclockbudget packages a bounded clock window, observerlicensedcomparison compares licensed observer histories, and observerbridgeledger joins bridge rows without isolating the elementary Hist-growth step.

Definition 1043.1 (Observer time-step carrier)**.** *An* $\mathsf{ObserverTimeStep}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (H, D, C, R, L, P, N)$$

with the following displayed rows:

1. *H is the source* Hist *row before the elementary growth step;*
2. *D is the distinction tag recording whether the step applies* E1 *or* E0*;*
3. *C is the displayed* Cont *step from H along D to the next local* Hist *row;*
4. *R records componentwise* hsame *transport for the source, distinction, continuation, refusal, provenance, and naming rows;*
5. *L is the no-global-clock ledger refusing any synchronized external time coordinate for the step;*
6. *P is the* Pkg *provenance over* Hist*, distinction tags,* Cont*,* hsame*, no-global-clock refusal, and* NameCert *rows;*

7. N is the local $\mathsf{NameCert}_{\mathsf{ObserverTimeStep}^{\uparrow}}$ *row.*
The carrier accepts a local observer time step only as the displayed Hist source, distinction tag, Cont step, transport row, no-global-clock ledger, package provenance, and local naming row together.

Lean4 (definition) `BEDC.Derived.ObserverTimeStepUp.ObserverTimeStepUp`

Theorem 1043.2 (Observer time-step NameCert obligations)**.** *For the carrier of Definition 1043.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverTimeStep}^{\uparrow}}$ *surface consists exactly of carrier admission for* $T = (H, D, C, R, L, P, N)$*, source-Hist exposure through* H*, distinction exposure through* D*, displayed Cont-step replay through* C*, componentwise* hsame *transport through* R*, no-global-clock refusal through* L*, package provenance through* P*, and local naming through* N*.*

Proof. Project the accepted carrier to the seven displayed rows. The source Hist row, distinction tag, and Cont-step row are visible before a consumer can name the time step.

Transport is then restricted to R, which preserves the same source, tag, continuation, refusal, provenance, and local name rows. The no-global-clock ledger L is read as part of the packet, so the local step is never promoted to a synchronized external clock.

The provenance row P and naming row N bind the admitted read to exactly these coordinates. Since no other coordinate appears in the carrier, the listed rows exhaust the NameCert obligations for $\mathsf{ObserverTimeStep}^{\uparrow}$. □

Theorem 1043.3 (Observer time-step nonescape)**.** *Every accepted* $\mathsf{ObserverTimeStep}^{\uparrow}$ *consumer factors through the finite route*

$$H, D, C, R, L, P, N.$$

No accepted consumer may replace the displayed Cont step by a global clock tick, a synchronized observer frame, a quotient history identity, an unrecorded Hist predecessor, or an external time parameter.

Proof. Start from the NameCert obligations of Definition 1043.2. They identify an accepted time-step read with the source Hist row, distinction tag, displayed Cont step, transport row, refusal ledger, provenance, and local name.

The Cont row C is the only route from the source row H and distinction tag D to the next local Hist row. Removing C leaves no displayed replay row for a consumer to preserve.

The refusal ledger L excludes the external clock and synchronized-frame alternatives, while R, P, N only transport, package, and name the same displayed rows. Hence every accepted consumer remains inside the finite route H, D, C, R, L, P, N. □

The Lean namespace `BEDC.Derived.ObserverTimeStepUp.TasteGate` provides explicit Nontrivial ObserverTim and FieldFaithful $\mathsf{ObserverTimeStep}^{\uparrow}$ instances over the displayed source-Hist, distinction-tag, Cont-step, hsame-transport, no-global-clock, Pkg, and NameCert fields.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverTimeStep}^{\uparrow}}$**.**

Constructive story: An $\mathsf{ObserverTimeStep}^{\uparrow}$ packet is generated from a source Hist row, distinction tag, displayed Cont step, hsame transport, no-global-clock refusal ledger, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ObserverTimeStep}^{\uparrow}}$, seed)

Scope closed: Definition 1043.1, Definition 1043.2, and Definition 1043.3 specify the finite local Hist-growth step and its refusal of global-clock escape.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ObserverTimeStep}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close global clocks, synchronized observer frames, quotient history identity, external time parameters, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, source-Hist exposure, distinction exposure, Cont-step replay, hsame transport, no-global-clock refusal, nontriviality, and field faithfulness for the same packet.

Chapter 1044

A Concrete Naming Certificate for $\mathsf{SocketUseLedger}^{\uparrow}$

The $\mathsf{SocketUseLedger}^{\uparrow}$ packet records visible consumption of an apophatic socket as a finite NameCert event surface. It sits under the name-to-gate discipline of chapter 9400 and consumes the sibling surfaces of chapter 543, chapter 536, chapter 584, chapter 629, and chapter 715. Those chapters name the socket, attach the gate, refuse hidden supply, and ask the audit question; this chapter records the finite event by which a consumer visibly uses that socket. The visible-use row consumes the $\mathsf{ApophaticSocket}^{\uparrow}$ use-site row and $\mathsf{ExternalityGate}^{\uparrow}$ gate row as sibling carriers, not merely as prose context.

Definition 1044.1 (SocketUseLedger carrier)**.** *A* $\mathsf{SocketUseLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$U = (A, S, Q, V, R, H, C, P, N)$$

with the following displayed rows:

1. *A is the* $\mathsf{ApophaticName}^{\uparrow}$ *row naming the external supply position;*
2. *S is the* $\mathsf{ApophaticSocket}^{\uparrow}$ *row naming the requested socket and its visible use site;*
3. *Q is the* $\mathsf{ApophaticGateQuestion}^{\uparrow}$ *row asking whether the socket use remained marked;*
4. *V is the visible-use row recording the accepted consumer read through the socket;*
5. *R is the refusal ledger for unmarked, off-gate, or internalizing uses of the same requested supply;*
6. *H records componentwise* hsame *transports for A, S, Q, V, R together with continuation, provenance, and naming rows;*
7. *C records the displayed* Cont *routes by which audit consumers read the name, socket, question, visible-use, and refusal rows;*
8. *P is the* Pkg *provenance over* $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{ExternalityGate}^{\uparrow}$, $\mathsf{NegativeNameBoundary}^{\uparrow}$, $\mathsf{ApophaticGateQuestion}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{SocketUseLedger}^{\uparrow}}$ *row.*

The carrier has no coordinate for the requested outside supply itself, no anonymous host import, no hidden theorem premise, and no route by which a visible socket use becomes a positive internal description of the external source.

Lean4 ✓ `BEDC.Derived.SocketUseLedgerUp.SocketUseLedgerTasteGate single carrier alignment`

Theorem 1044.2 (SocketUseLedger NameCert obligations)**.** *For the carrier of Definition 1044.1, the local* $\mathsf{NameCert}_{\mathsf{SocketUseLedger}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$U = (A, S, Q, V, R, H, C, P, N),$$

apophatic-name exposure through A*, socket exposure through* S*, gate-question exactness through* Q*, visible-use readback through* V*, refusal-ledger coverage through* R*, componentwise* hsame *transport through* H*, displayed* Cont *route replay through* C*, dependency provenance through* P*, and local naming through* N*.*

Proof. Carrier admission is projection from the displayed packet. The tuple U lists the apophatic name, socket, gate question, visible-use row, refusal ledger, transport, continuation, provenance, and local naming rows.

The name-to-gate portion is read through A, S, Q. The apophatic name gives the external supply position, the socket row gives the use site, and the gate question records the public test for marked use.

The event portion is read through V and R. A visible use is accepted only when it passes through the named socket and gate question; an unmarked or internalizing request is sent to the refusal ledger.

Finally H, C, P, N provide the only transport, replay, provenance, and naming routes. Since the carrier contains no requested outside supply, the local certificate records use of the socket without internalizing the supply. □

Lean4 ✓ `BEDC.Derived.SocketUseLedgerUp.SocketUseLedgerCarrier namecert obligations`

Theorem 1044.3 (SocketUseLedger visible-use non-escape)**.** *Every accepted socket-use read of a* $\mathsf{SocketUseLedger}^{\uparrow}$ *packet factors through* $\mathsf{ApophaticName}^{\uparrow}$*,* $\mathsf{ApophaticSocket}^{\uparrow}$*,* $\mathsf{ExternalityGate}^{\uparrow}$*, and the local visible/refusal ledger before any audit consumer sees it. The exported read remains inside* $A, S, Q, V, R, H, C, P, N$ *and cannot export the requested supply, an unmarked selector, a hidden axiom channel, a quotient collapse, proposition-extensionality collapse, or a host-level replacement for the gate answer.*

Lean4 ✓ `BEDC.Derived.SocketUseLedgerUp.SocketUseLedgerCarrier visible refusal layer separation`

Proof. Start with the carrier of Definition 1044.1. The accepted packet exposes the name row A, socket row S, gate-question row Q, visible-use row V, refusal row R, and structural rows H, C, P, N.

Apply the NameCert obligations of Definition 1044.2. A consumer read reaches V only after the name, socket, and gate question have been displayed, and any off-gate request is routed to R.

Now read the audit-facing rows. The continuation row C exposes the finite use/refusal result, while H, P, N transport, package, and name the same packet. No excluded supply or host principle appears among the coordinates, so the accepted socket-use read cannot escape the ledger. □

Theorem 1044.4 (SocketUseLedger public visible refusal)**.** *Every public visible-use or refusal read of a* $\mathsf{SocketUseLedger}^{\uparrow}$ *packet factors through* $\mathsf{ApophaticName}^{\uparrow}$*,* $\mathsf{ApophaticSocket}^{\uparrow}$*,* $\mathsf{ExternalityGate}^{\uparrow}$*,* $\mathsf{NegativeNameBoundary}^{\uparrow}$*, and* $\mathsf{ApophaticGateQuestion}^{\uparrow}$ *before the local visible-use row, refusal ledger, componentwise transport, continuation replay, provenance, and local naming rows are read. Thus the exported event is a sibling-carrier route followed by the local ledger route*

$$A, S, Q, V, R, H, C, P, N.$$

It cannot be read as a detached visible-use event, an unmarked supply import, a gate-free refusal, a quotient collapse, or a host replacement for the apophatic boundary.

Lean4 ✓ `BEDC.Derived.SocketUseLedgerUp.SocketUseLedgerCarrier public visible refusal`

Proof. Start with the carrier of Definition 1044.1. The name row A, socket row S, gate question Q, visible-use row V, refusal row R, and structural rows H, C, P, N are the only displayed fields.

Apply Definition 1044.2. It forces apophatic-name exposure, socket exposure, gate-question exactness, visible-use readback, refusal-ledger coverage, transport, replay, provenance, and local naming to be read as one NameCert surface.

Now use Definition 1044.3. The visible-use read reaches the audit consumer only after the sibling apophatic name, socket, externality gate, negative boundary, and gate-question carriers have constrained it. The local ledger rows can therefore export visible use or refusal only through that route, with no detached supply import or host-level gate replacement. □

Theorem 1044.5 (SocketUseLedger public event surface)**.** *The public exported object of* $\mathsf{SocketUseLedger}^{\uparrow}$ *is exactly the visible-use and refusal event surface*

$$U = (A, S, Q, V, R, H, C, P, N).$$

Its public rows expose the apophatic name A, socket S, gate question Q, visible-use row V, refusal row R, componentwise transport row H, continuation row C, provenance row P, and local naming row N, and no other public coordinate is exported.

Proof. The carrier of Definition 1044.1 lists precisely the nine displayed rows of U. The NameCert obligations of Definition 1044.2 certify carrier admission, exposure, visible-use readback, refusal coverage, transport, continuation replay, provenance, and local naming for those rows.

The visible-use non-escape theorem Definition 1044.3 excludes the requested outside supply, unmarked selectors, hidden axiom channels, quotient collapse, proposition-extensionality collapse, and host-level gate replacement from the exported read. Hence the public surface is the event ledger U and nothing beyond it. □

Lean4 ✓ `BEDC.Derived.SocketUseLedgerUp.SocketUseLedgerCarrier public event surface`

Falsifiable prediction: Every accepted socket-use read factors through ApophaticNameUp, ApophaticSocketUp, ExternalityGateUp, and the local visible/refusal ledger before any audit consumer sees it. A read that reaches audit without $A, S, Q, V, R, H, C, P, N$ falsifies this packet.

Independence witness: Nearest siblings: apophaticname, apophaticsocket, externalitygate, negativenameboundary, and apophaticgatequestion. SocketUseLedgerUp is not bijective to any of them because it simultaneously carries an event-level visible-use row and a refusal row for the same socket-use read; each sibling lacks at least one of those event ledger coordinates.

Theorem 1044.6 (SocketUseLedger mature audit package)**.** *The* $\mathsf{SocketUseLedger}^{\uparrow}$ *mature audit package consists of the visible-use and refusal event surface $U = (A, S, Q, V, R, H, C, P, N)$, the apophatic sibling carriers* $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{ExternalityGate}^{\uparrow}$, $\mathsf{NegativeNameBoundary}^{\uparrow}$, *and* $\mathsf{ApophaticGateQuestion}^{\uparrow}$, *the falsifiable prediction above, the independence witness above, and the* $\mathsf{TasteGate}$ *target recorded by the local closure rows. Together these data bind the public socket-use event, its refusal boundary, its sibling-carrier route, and its audit-facing taste gate without exporting the requested outside supply.*

Proof. The public event surface is fixed by Definition 1044.5: the only exported rows are $A, S, Q, V, R, H, C, P, N$. The visible-use non-escape theorem Definition 1044.3 keeps every accepted read inside the apophatic name, socket, gate question, visible-use row, refusal ledger, and structural rows.

The sibling-carrier route is supplied by the chapters named in the introduction and by Definition 1044.4. The falsifiable prediction identifies an observable failure mode for any audit read that skips this route, while the independence witness separates the packet from its nearest apophatic siblings by the simultaneous presence of visible-use and refusal event rows.

Finally the closure rows record the local TasteGate target for the same packet. These ingredients are exactly the mature paper-side inventory: public surface, sibling route, falsifiable boundary, independence separation, and taste-gate target, with no coordinate for the requested outside supply. □

Closure status for $\mathsf{NameCert}_{\mathsf{SocketUseLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{SocketUseLedger}^{\uparrow}$ packet is generated from an apophatic-name row, socket row, gate-question row, visible-use row, refusal ledger, componentwise transports, displayed continuations, package provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SocketUseLedger}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1044.1, Definition 1044.2, Definition 1044.3, and Definition 1044.5 bind the bridge route from $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{ExternalityGate}^{\uparrow}$, $\mathsf{NegativeNameBoundary}^{\uparrow}$, $\mathsf{ApophaticGateQuestion}^{\uparrow}$, and the local visible-use/refusal ledger into the public socket-use event surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SocketUseLedger}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: paperBridge

Origin: ai

Lean4 ✓ `BEDC.Derived.SocketUseLedgerUp.taste gate`

Not claimed: This chapter does not close Lean verification, bridge checking, existence of the requested outside supply, global audit completeness, or every possible socket-use grammar.

Upgrade path: no further paper-side theory upgrade – chapter is mature on the closure axis pending formal-axis work.

Chapter 1045

A Concrete Naming Certificate for $\mathsf{RuleOneTenGliderCatalog}^{\uparrow}$

The $\mathsf{RuleOneTenGliderCatalog}^{\uparrow}$ packet realizes the finite Rule 110 glider classifier named by the cellular automaton reading of Definition 9390.3. It sits beside the finite rule and orbit surface of chapter 934, the carrier-facing substrate packet of chapter 942, and the compile-frontier witness of chapter 952. Cook 2004 supplies the Rule 110 universality route, while Martinez 2007 supplies the named finite glider catalog; this packet records only the row-window classifier data needed to inspect that catalog inside BEDC.

Falsifiable prediction: A $\mathsf{RuleOneTenGliderCatalog}^{\uparrow}$ packet without a displayed Rule 110 row window, catalog tag, phase-period-displacement row, and local match row is not an accepted glider-catalog carrier.

Independence witness: cellularautomaton, cellularsubstrate, cookcompilefrontierwitness, cellularpatterncatalog: none is bijective to $\mathsf{RuleOneTenGliderCatalog}^{\uparrow}$ because this packet carries the Rule 110 row window together with a Martinez-style glider tag, phase-period-displacement row, displayed local match, hsame transport, continuation route, provenance row, and local NameCert. The siblings expose cellular dynamics, substrate rows, compile-frontier coordinates, or a general pattern catalog, but not this finite Rule 110 glider classifier packet.

Definition 1045.1 (Rule 110 glider catalog carrier)**.** *A* $\mathsf{RuleOneTenGliderCatalog}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$J = (R, W, G, P, D, H, C, K, N)$$

with the following displayed rows:

1. *R is the Rule 110 rule row and finite row-window source being inspected.*
2. *W is the displayed finite row window, including the center position, neighbouring cells, and enough surrounding cells to test the named phase string.*
3. *G is the finite catalog-tag row, whose tag is one of ether, refused window, or a Martinez 2007 glider name such as A, B, $\bar{B}$, C_1, C_2, E, $\bar{E}$, F, G, or H.*
4. *P is the phase, period, and displacement row attached to the tag, recording the catalog phase string, fundamental period, and row displacement per period.*
5. *D is the displayed local-match row, recording that the row window W matches the phase row P under the catalog's neighbour discipline, or that it is refused by that finite discipline.*

6. *H records componentwise* hsame *transport for R, W, G, P, D, K, N.*
7. *C records the displayed* Cont *routes from the Rule 110 row to the finite window, from the window to the phase row, from the phase row to the local-match row, and from the local-match row to the catalog tag.*
8. *K is the* Pkg *provenance over* $\mathsf{CellularAutomaton}^{\uparrow}$, $\mathsf{CellularSubstrate}^{\uparrow}$, $\mathsf{CookCompileFrontierWitness}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows.*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RuleOneTenGliderCatalog}^{\uparrow}}$ *row.*

The local classifier compares accepted carriers only through $R, W, G, P, D, H, C, K, N$. It has no coordinate for an unbounded Rule 110 orbit, a host visual recognizer, a complete all-time glider theorem, a hidden catalog row, or a Cook universality proof.

Lean4 ✓ `BEDC.Derived.RuleOneTenGliderCatalogUp.TasteGate.RuleOneTenGliderCatalogTasteGate single carrier alignment`

Theorem 1045.2 (Rule 110 glider catalog NameCert obligations)**.** *For the carrier of Definition 1045.1, the local* $\mathsf{NameCert}_{\mathsf{RuleOneTenGliderCatalog}^{\uparrow}}$ *surface consists exactly of carrier admission for $J = (R, W, G, P, D, H, C, K, N)$, Rule 110 row-window exposure through R, W, catalog-tag exposure through G, phase-period-displacement exposure through P, displayed local-match exposure through D, componentwise* hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through K, and local naming through N. Every accepted tag read factors through the finite route*

$$R \longmapsto W \longmapsto P \longmapsto D \longmapsto G,$$

with H, C, K, N attached as transport, route, provenance, and naming rows.

Proof. Carrier admission is projection from Definition 1045.1. The displayed tuple lists the Rule 110 row, finite window, catalog tag, phase-period-displacement row, local match, transport, route, provenance, and local naming rows, and no other row is part of the packet.

The catalog read is finite. A consumer first exposes the Rule 110 row R and finite window W, then reads the phase-period-displacement row P, then checks the displayed local match D, and only then obtains the tag row G.

The structural rows do not add new classifier data. The row H transports the displayed entries componentwise, C replays the same finite route, K records provenance through the cellular and compile-frontier siblings, and N names the local packet. Therefore the listed rows exhaust the local NameCert obligations. □

Theorem 1045.3 (Rule 110 glider catalog classifier stability)**.** *If two accepted* $\mathsf{RuleOneTenGliderCatalog}^{\uparrow}$ *carriers agree on their Rule 110 row, finite row window, phase-period-displacement row, displayed local-match row, componentwise transport row, continuation route, provenance row, and local naming row, then their catalog-tag rows classify together under the local* $\mathsf{NameCert}_{\mathsf{RuleOneTenGliderCatalog}^{\uparrow}}$ *classifier. In particular, classifier agreement cannot be changed by renaming the tag while leaving the displayed window and local-match route fixed.*

Proof. Use Definition 1045.2. An accepted tag read reaches G only through the route $R \longmapsto W \longmapsto P \longmapsto D \longmapsto G$ with H, C, K, N attached.

For two accepted carriers with the same R, W, P, D, H, C, K, N, the finite lookup inputs and the replay route are the same. The Martinez-style tag row is therefore read from the same displayed phase and local-match data inside the same local NameCert surface.

A different classification would require a different row window, phase-period-displacement entry, local-match result, route, provenance, or local naming row, or else an external host recognizer. None is present in the carrier. Hence the two catalog-tag rows classify together. □

Theorem 1045.4 (Rule 110 glider catalog substrate handoff)**.** *Every* $\mathsf{RuleOneTenGliderCatalog}^{\uparrow}$ *read handed to a cellular substrate consumer exposes the finite Rule 110 row window, catalog tag, phase-period-displacement row, displayed local match,* hsame *transport,* Cont *route,* Pkg *provenance, and local* NameCert *row before the substrate may cite it as glider-catalog evidence. The handoff uses the cellular rule surface of chapter 934, the substrate carrier of chapter 942, and the finite compile-frontier coordinate of chapter 952; it exports no unbounded orbit classifier, host visual recognition, or additional universality witness.*

Proof. Start with carrier admission from Definition 1045.1. The packet gives the displayed rows $R, W, G, P, D, H, C, K, N$ and excludes unbounded orbit, host recognizer, hidden catalog, and Cook universality coordinates.

Apply the NameCert obligations theorem. It forces every accepted catalog read through the finite route from the Rule 110 row and row window to the phase row, local-match row, and catalog tag.

The sibling handoff is then only a provenance and route handoff. The cellular automaton chapter supplies the finite local rule and orbit surface, the cellular substrate chapter supplies the carrier row through which a substrate consumer reads the window, and the Cook compile-frontier witness supplies the finite coordinate for Cook-facing audit reads. Since none of those siblings adds a hidden classifier coordinate to J, the handoff remains exactly the displayed finite glider-catalog packet. □

Closure status for $\mathsf{NameCert}_{\mathsf{RuleOneTenGliderCatalog}^{\uparrow}}$.

Constructive story: A $\mathsf{RuleOneTenGliderCatalog}^{\uparrow}$ packet is generated from a Rule 110 rule row, finite row-window row, catalog-tag row, phase-period-displacement row, displayed local-match row, componentwise hsame transports, displayed continuation routes, package provenance, and local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RuleOneTenGliderCatalog}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1045.1, Definition 1045.2, Definition 1045.3, and Definition 1045.4 bind the finite Rule 110 row-window, catalog tag, phase-period-displacement, local-match, transport, route, provenance, and local naming surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RuleOneTenGliderCatalog}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not prove Lean verification, global classification of all Rule 110 rows, Cook universality, host evaluator correctness, hidden visual recognition, or a public standard bridge.

Upgrade path: A later checked surface can provide Nontrivial and FieldFaithful instances for the displayed Rule 110 glider-catalog rows.

Chapter 1046

A Concrete Naming Certificate for TypingJudgmentClassifier$^{\uparrow}$

The TypingJudgmentClassifier$^{\uparrow}$ packet realizes the type-checking-as-classifier-membership vision of chapter 9367 as a finite judgment classifier. It consumes the membership surface of chapter 476, the derivation trace of chapter 598, and the route join of chapter 809, then exposes one accepted typing-judgment row through Ext membership, derivation-route replay, SigRel readback, componentwise hsame transport, Pkg provenance, and local NameCert data.

Falsifiable prediction: A packet with a typing derivation route but no displayed Ext-membership row is not an accepted TypingJudgmentClassifierUp carrier.

Independence witness: typeclassifiermembership, classifiertyping, subjectreduction, typecheckingderivationtrace, and classifiermorphism: none is bijective because the typing-judgment classifier carries the displayed Ext-membership row, derivation route, SigRel readback, Cont replay, hsame transport, Pkg provenance, and local NameCert surface together, while each sibling isolates only one membership, typing, preservation, trace, or morphism face.

Definition 1046.1 (TypingJudgmentClassifier carrier)**.** *A* TypingJudgmentClassifier$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (J, M, D, S, C, H, P, N)$$

with the following displayed rows:

1. *J is the typing-judgment row whose membership in the accepted classifier is being read;*
2. *M is the displayed* Ext *membership row certifying that J is accepted by the local type-checking classifier;*
3. *D is the finite derivation-route row that explains how the classifier reached M;*
4. *S is the* SigRel *readback row naming the accepted typing judgment as the public reading of the membership row along D;*
5. *C records the displayed* Cont *replay routes for reading the judgment row, membership row, derivation route, readback row, provenance row, and local naming row through the same finite packet;*
6. *H stores componentwise* hsame *transports for J, M, D, S, C, P, N;*
7. *P is the* Pkg *provenance over chapter 9367, chapter 476, chapter 489, chapter 483, chapter 598, chapter 590,* BHist*,* Ext*,* SigRel*,* Cont*,* hsame*, and* NameCert*;*

8. *N is the local* $\mathsf{NameCert}_{\mathsf{TypingJudgmentClassifier}^{\uparrow}}$ *row.*

The carrier has no coordinate for host type semantics, hidden conversion, quotient syntax equality, unrecorded derivation search, closed subject reduction, or an ambient classifier morphism.

Theorem 1046.2 (TypingJudgmentClassifier NameCert obligations)**.** *For the carrier of Definition 1046.1, the local* $\mathsf{NameCert}_{\mathsf{TypingJudgmentClassifier}^{\uparrow}}$ *surface consists exactly of five finite obligations:*

1. *carrier admission exposes precisely $T = (J, M, D, S, C, H, P, N)$;*
2. *membership exactness reads the accepted typing-judgment decision only from the displayed* Ext *row M;*
3. *derivation-route replay reads the route only through D and the displayed* Cont *rows C;*
4. *public readback exposes the accepted judgment only through the* SigRel *row S transported by H;*
5. *provenance and non-escape bind every consumer read to P, N and exclude host type semantics, hidden conversion, quotient syntax equality, unrecorded derivation search, closed subject reduction, and ambient classifier morphisms.*

Lean4 ✓ `BEDC.Derived.TypingJudgmentClassifierUp.TypingJudgmentClassifierCarrier namecert obligations`

Proof. Carrier admission is projection from the finite tuple in Definition 1046.1. The judgment, membership, derivation route, readback, replay, transport, provenance, and naming rows are visible coordinates.

Membership exactness follows because M is the only Ext membership coordinate. The derivation route D and continuation row C can replay how the decision is read, but they cannot replace M by a hidden checker.

The public classifier read is exhausted by S, H, P, N. These rows name, transport, package, and locally certify the same displayed membership event, so the excluded host and quotient-side objects have no coordinate from which a consumer could recover them. □

Theorem 1046.3 (TypingJudgmentClassifier derivation route)**.** *Every accepted* $\mathsf{TypingJudgmentClassifier}^{\uparrow}$ *carrier routes the typing judgment through displayed classifier membership before any public readback is available:*

$$J \to M \to D \to S.$$

The replay and transport rows C, H preserve that order for downstream consumers, and the package and local name rows P, N record the finite provenance of the same route.

Proof. Inspect the carrier inventory. The judgment row J is not an accepted classifier decision by itself; the accepted decision is the displayed membership row M.

The derivation route D records how the membership row is reached, and the SigRel row S records the public reading of that accepted judgment. The continuation and transport rows replay and preserve these coordinates componentwise.

Since P, N only package and name the same rows, every consumer route factors through the displayed chain from judgment to membership, derivation, and readback. □

Lean4 ✓ `BEDC.Derived.TypingJudgmentClassifierUp.TypingJudgmentClassifierCarrier derivation route`

Theorem 1046.4 (TypingJudgmentClassifier TasteGate readiness)**.** *The Lean TasteGate module for* $\mathsf{TypingJudgmentClassifier}^{\uparrow}$ *must provide explicit* $\mathsf{Nontrivial\ TypingJudgmentClassifier}^{\uparrow}$ *and* $\mathsf{FieldFaithful\ TypingJudgmentClassifier}^{\uparrow}$ *instances. Nontriviality separates the typing-judgment row* J *from the membership row* M*, and field faithfulness preserves the displayed rows* J, M, D, S, C, H, P, N *for every TasteGate-facing consumer.*

Lean4 ✓ `BEDC.Derived.TypingJudgmentClassifierUp.TasteGate.TypingJudgmentClassifierTasteGate readiness`

Lean4 ✓ `BEDC.Derived.TypingJudgmentClassifierUp.TypingJudgmentClassifierUp taste gate readiness`

Proof. Nontriviality is forced by the falsifiability boundary: a derivation route without the displayed Ext row is rejected, so the row carrying the judgment cannot collapse with the row carrying accepted membership.

Field faithfulness is the row-preservation condition for the same packet. A consumer may inspect the judgment, membership, derivation route, readback, replay, transport, provenance, and local name rows, but no unlisted type-checker state or host semantic object. □

Closure status for $\mathsf{NameCert}_{\mathsf{TypingJudgmentClassifier}^{\uparrow}}$.

Constructive story: A $\mathsf{TypingJudgmentClassifier}^{\uparrow}$ packet is generated from a typing-judgment row, a displayed Ext-membership row, a finite derivation route, SigRel readback, displayed Cont replay, componentwise hsame transports, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TypingJudgmentClassifier}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1046.1, Definition 1046.2, Definition 1046.3, and Definition 1046.4 bind the finite typing-judgment classifier surface over Ext membership, derivation routes, SigRel readback, Cont replay, hsame transport, Pkg provenance, and NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TypingJudgmentClassifier}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, host type semantics, hidden conversion, quotient syntax equality, unrecorded derivation search, closed subject reduction, or ambient classifier morphisms.

Upgrade path: Obligation closure requires checked carrier admission, membership exactness, derivation-route replay, SigRel readback, non-escape, nontriviality, and field faithfulness for the same finite packet.

Chapter 1047

ObserverDirectionUp NameCert construction

The $\mathsf{ObserverDirection}^{\uparrow}$ surface realizes the direction-sensitive readback part of chapter 9418 as a finite observer-to-target carrier. It sits after the regular observer packet of chapter 431, the observer-history identity packet of chapter 479, and the licensed comparison packet of chapter 1031. Its role is to keep the observer route, target readback, direction token, comparison ledger, and local naming row together before a consumer treats a comparison as an oriented observation rather than an unordered pair of histories.

Falsifiable prediction: Removing the direction-token row collapses two distinct observer-to-target routes and breaks the licensed comparison handoff.

Independence witness: Compare observerregular, observerhistidentity, observerlicensedcomparison, observerbridgeledger, and streamname siblings: none is bijective because this carrier alone stores the direction token together with observer route, target readback, and comparison ledger.

Definition 1047.1 (Observer direction carrier)**.** *An* $\mathsf{ObserverDirection}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (R, T, U, L, B, H, C, P, N)$$

with the following displayed rows:

1. *R is the observer-row packet, read through the regular observer and observer-history identity surfaces;*
2. *T is the target-row packet whose readback is being oriented;*
3. *U is the direction-token row, naming which observer-to-target route is being read;*
4. *L is the licensed comparison ledger, read through the sibling surface of chapter 1031;*
5. *B is the target readback row produced only after R, T, U, L have been displayed together;*
6. *H records the componentwise* hsame *transports for observer, target, direction token, comparison ledger, readback, route, provenance, and local name rows;*
7. *C records the displayed* Cont *routes from the observer row to the target row and from that oriented route to the comparison readback;*
8. *P is the* Pkg *provenance over* $\mathsf{ObserverRegular}^{\uparrow}$, $\mathsf{ObserverHistIdentity}^{\uparrow}$, $\mathsf{ObserverLicensedComparison}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*

9. N is the local $\mathsf{NameCert}_{\mathsf{ObserverDirection}^{\uparrow}}$ *row.*

The carrier accepts an oriented observer comparison only when the observer row, target row, direction token, licensed comparison, readback, hsame *transport, continuation route, provenance, and local naming row are all displayed in one finite packet. It exports no unordered comparison, hidden observer-substance, host equality of observers, global frame, unlicensed readback, or route outside the displayed direction token.*

Lean4 ✓ `BEDC.Derived.ObserverDirectionUp.ObserverDirectionUp carrier fields`

Theorem 1047.2 (Observer direction NameCert obligations)**.** *For the carrier of Definition 1047.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverDirection}^{\uparrow}}$ *surface consists exactly of carrier admission for $O = (R, T, U, L, B, H, C, P, N)$, observer-row anchoring through R, target-row anchoring through T, direction-token exactness through U, licensed comparison handoff through L, target readback through B, componentwise* hsame *transport through H, displayed continuation replay through C, package provenance through P, local naming through N, and non-escape from unordered comparison, hidden observer-substance, host equality, global frames, unlicensed readback, and routes outside the displayed direction token.*

Proof. Project the accepted packet to the nine rows of Definition 1047.1. The observer row and target row become comparable only after the direction token and licensed comparison ledger are displayed with them.

The direction-token exactness is the row U. A public read may consume the observer-to-target route only through the displayed continuation row C, and the licensed comparison handoff must pass through L before the target readback row B is available.

The transport and provenance rows then bind the read to the observerregular, observerhistidentity, and observerlicensedcomparison siblings cited above. Since none of the excluded objects is a coordinate of O, the local NameCert surface is exhausted by the listed finite obligations. □

Lean4 ✓ `BEDC.Derived.ObserverDirectionUp.ObserverDirectionUp namecert obligations`

Theorem 1047.3 (Observer direction falsifiable boundary)**.** *If the direction-token row U is removed from an accepted* $\mathsf{ObserverDirection}^{\uparrow}$ *packet, two packets that differ only by reversing the observer-to-target route have the same remaining rows R, T, L, B, H, C, P, N. The licensed comparison handoff can then no longer distinguish the oriented readback, so the packet is not an* $\mathsf{ObserverDirection}^{\uparrow}$ *carrier.*

Lean4 ✓ `BEDC.Derived.ObserverDirectionUp.ObserverDirectionFalsifiableBoundary`

Proof. Remove U from $O = (R, T, U, L, B, H, C, P, N)$. The remaining rows still display an observer row, target row, comparison ledger, readback, transport, continuation route, provenance, and local name, but they no longer name which oriented route the readback follows.

A reversed observer-to-target route can preserve the unordered pair of visible rows while changing the intended comparison handoff. The licensed comparison sibling records a comparison ledger, not the missing direction token itself.

Thus the carrier loses the row that separates the two oriented routes. The result is outside Definition 1047.1, and the falsifiable prediction is the loss of the licensed oriented handoff. □

Theorem 1047.4 (Observer direction nontrivial boundary)**.** *The* $\mathsf{ObserverDirection}^{\uparrow}$ *packet is nontrivial at the paper boundary: an accepted packet with direction token U and the same observer, target, comparison, transport, route, provenance, and name rows but opposite displayed direction token is not identified by the carrier predicate. The later Lean* `TasteGate.lean` *must include an explicit* Nontrivial $\mathsf{ObserverDirection}^{\uparrow}$ *instance for this displayed carrier.*

Lean4 ✓ `BEDC.Derived.ObserverDirectionUp.ObserverDirectionTasteGate single carrier alignment`

Proof. The carrier contains the direction-token row as a coordinate. Two packets with different displayed direction tokens therefore differ as finite BHist packets even when their observer, target, comparison, transport, route, provenance, and name rows agree.

The licensed comparison row does not erase this distinction, because it is read after the direction token has fixed the observer-to-target route. The paper boundary is therefore nontrivial: the packet can witness two oriented reads over the same visible endpoints. □

Theorem 1047.5 (Observer direction field-faithful boundary)**.** *Every public* $\mathsf{ObserverDirection}^{\uparrow}$ *consumer preserves the nine displayed fields* $R, T, U, L, B, H, C, P, N$ *of Definition 1047.1. In particular, it may not identify a direction-token change with a target-readback change, a licensed-comparison change, or a provenance change. The later Lean* `TasteGate.lean` *must include an explicit* $\mathsf{FieldFaithful\ ObserverDirection}^{\uparrow}$ *instance for this displayed carrier.*

Proof. Read a public consumer as a projection from the accepted carrier. The only fields available to the consumer are the observer row, target row, direction token, licensed comparison ledger, target readback, hsame transport row, continuation route, package provenance, and local name.

Field faithfulness follows from the order of the read. The direction token U gates the route in C, the licensed comparison ledger L gates the readback B, and the provenance row P records the sibling sources separately.

Since these rows occupy separate coordinates, a consumer that merges one coordinate into another no longer preserves the carrier of Definition 1047.1. The public boundary is therefore faithful to the listed fields. □

Lean4 ✓ `BEDC.Derived.ObserverDirectionUp.TasteGate.ObserverDirectionTasteGate single carrier alignment`

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverDirection}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverDirection}^{\uparrow}$ packet is generated from observer-row, target-row, direction-token, licensed-comparison, readback, hsame transport, displayed Cont route, package provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverDirection}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1047.1, Definition 1047.2, Definition 1047.3, Definition 1047.4, and Definition 1047.5 specify the finite oriented observer-readback carrier, its NameCert obligations, direction-token boundary, nontriviality boundary, and field-faithfulness boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverDirection}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close full observer-history identity, observer-filter completeness, hidden observer state, quotient history identity, global observer frames, Lean verification, or bridge checking.

Upgrade path: Scoped closure requires checked TasteGate carrier admission, direction-token exactness, licensed-comparison handoff, readback confinement, nontriviality, and field faithfulness for the same packet.

Chapter 1048

A Concrete Naming Certificate for $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$

The $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ packet realizes the generated-recognizer route of chapter 9407 as a finite NameCert carrier. It sits beside the event-flow route of chapter 830, the audit-map packet of chapter 836, and the recognizer audit packet of chapter 820: those siblings display event-flow routing, compiler audit inventory, and recognizer-facing audit rows, while this chapter binds the source channel, generated recognizer, certificate gate, and non-evidence refusal as one consumer packet.

Definition 1048.1 (GroundCompiler recognizer-flow carrier)**.** *A* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (E, S, R, Q, B, H, C, P, N)$$

with the following displayed rows:

1. *E is the event-flow row naming the formal GroundCompiler event packet under inspection;*
2. *S is the source-channel row recording the legal channel encoding, decoder address, and lossless readback route for E;*
3. *R is the generated-recognizer row recording package recognition, local certificate recognition, derivation-certificate recognition, theorem-identifier recognition, chapter-flow recognition, and accepted-export recognition;*
4. *Q is the certificate-gate row through which an accepted generated recognizer result may be read as GroundCompiler evidence;*
5. *B is the non-evidence row separating source text, carried metadata, metric reports, motif reports, compiler reports, proof text, host compiler state, and raw classifier quotients from certificate evidence;*
6. *H records componentwise* hsame *transports for event-flow, source-channel, generated-recognizer, certificate-gate, non-evidence, continuation, provenance, and local naming rows;*
7. *C records displayed* Cont *routes from event flow to source channel, from source-channel readback to generated recognition, from generated recognition to certificate gate, from excluded report-like objects to non-evidence, and from the accepted packet to downstream consumers;*

8. *P is the* Pkg *provenance over chapter 9407, chapter 830, chapter 836, chapter 820,* BHist, hsame, Cont, Pkg, *and* NameCert *rows;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}}$ *row.*

The classifier for accepted carriers compares exactly the displayed coordinates $E, S, R, Q, B, H, C, P, N$. It has no coordinate for hidden compiler input, proof reconstructed from source text, metric evidence, motif identity, report evidence, raw classifier equality, or an unmediated generated export.

Lean4 ✓ `BEDC.Derived.GroundCompilerRecognizerFlowUp.GroundCompilerRecognizerFlowTasteGate`
`single carrier alignment`

Theorem 1048.2 (GroundCompiler recognizer-flow NameCert obligations)**.** *For every accepted* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *carrier*

$$G = (E, S, R, Q, B, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}}$ *surface consists exactly of event-flow readback through E, source-channel lossless routing through S, generated-recognizer mediation through R, certificate-gate acceptance through Q, non-evidence refusal through B, componentwise* hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through P, and local naming through N.*

Proof. Project the accepted carrier. The rows E, S, R, Q, B are the public data coordinates, and H, C, P, N transport, route, locate, and name those same coordinates.

Read the route in order. The event-flow row supplies the formal input, the source-channel row supplies legal encoding and lossless readback, the generated-recognizer row mediates recognition of packages and certificate-like compiler exports, and the certificate-gate row is the only positive acceptance point.

The non-evidence row records every excluded channel: source text, carried metadata, metric reports, motif reports, compiler reports, proof text, host state, and raw classifier quotients. Since no carrier coordinate converts B into E, S, R, Q, or proof evidence, the displayed rows exhaust the local NameCert obligation surface. □

Theorem 1048.3 (GroundCompiler recognizer-flow certificate-gate exactness)**.** *Every accepted* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *export that reaches the certificate gate Q first passes through the displayed event-flow row E, source-channel row S, and generated-recognizer row R. An export that omits the generated recognizer row cannot be read as accepted GroundCompiler evidence by* hsame *transport,* Cont *replay,* Pkg *provenance, or the local* NameCert *row.*

Proof. Start with the carrier classifier of Definition 1048.1. A certificate-facing read is accepted only when it compares the displayed coordinates $E, S, R, Q, B, H, C, P, N$.

Apply the NameCert obligation surface of Definition 1048.2. It orders the positive route through event flow, source channel, generated recognizer, and certificate gate, so Q is not reachable as a standalone export coordinate.

Finally inspect the structural rows. Transport, continuation, provenance, and local naming preserve the same packet, but none supplies a replacement for R. Therefore a compiler export without the generated-recognizer row is outside the accepted GroundCompiler evidence route. □

Theorem 1048.4 (GroundCompiler recognizer-flow non-evidence refusal)**.** *For every accepted* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *carrier, source text, carried metadata, metric reports, motif reports, compiler reports, proof text, host compiler state, and raw classifier quotients can be read*

only through the non-evidence row B. They cannot become event-flow input, source-channel readback, generated-recognizer evidence, certificate-gate evidence, or BEDC proof evidence inside the packet.

Proof. Project the packet and isolate B. It is the only coordinate assigned to report-like, host-like, text-like, metric, motif, and quotient objects.

Use certificate-gate exactness. Any route to accepted GroundCompiler evidence has already passed through E, S, R, Q, so it cannot start from an object classified only by B.

The remaining rows H, C, P, N preserve and replay displayed coordinates. They do not add a constructor from non-evidence to event flow, channel readback, generated recognition, certificate evidence, or proof evidence, so the refusal row is stable under every public consumer read. □

Theorem 1048.5 (GroundCompiler recognizer-flow TasteGate carrier readback)**.** *For every displayed* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *packet*

$$G = (E, S, R, Q, B, H, C, P, N),$$

the TasteGate row for BEDC.Derived.GroundCompilerRecognizerFlowUp *reads the single carrier through exactly the same event-flow, source-channel, generated-recognizer, certificate-gate, non-evidence, transport, continuation, provenance, and local naming coordinates. A TasteGate consumer cannot replace G by a hidden compiler input, raw recognizer quotient, proof text, metric report, motif report, or unmediated generated export.*

Lean4 ✓ `BEDC.Derived.GroundCompilerRecognizerFlowUp.taste gate`

Proof. Start from the carrier definition. The packet has exactly the displayed rows $E, S, R, Q, B, H, C, P, N$, and the classifier compares only those rows.

Apply the existing single-carrier TasteGate alignment named by the Lean surface. It makes the TasteGate entry a readback of the same finite carrier rather than a second carrier with extra compiler-facing coordinates.

Finally use the non-evidence refusal row. Objects such as proof text, reports, motifs, raw quotients, and unmediated exports are recorded only at B, so the TasteGate read cannot promote them into the positive carrier route. □

Theorem 1048.6 (GroundCompiler recognizer-flow field-faithful row projection)**.** *For every accepted* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *packet $G = (E, S, R, Q, B, H, C, P, N)$, the field-faithful projection of the TasteGate surface is componentwise: E remains the event-flow row, S the source-channel row, R the generated-recognizer row, Q the certificate-gate row, B the non-evidence row, H the* hsame *transport row, C the* Cont *replay row, P the* Pkg *provenance row, and N the local* $\mathsf{NameCert}_{\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}}$ *row.*

Proof. Project the accepted packet and keep the row order fixed. Field faithfulness can only report the fields already exposed by the carrier and by the NameCert obligation surface.

The positive route rows E, S, R, Q are separated from the refusal row B, while H, C, P, N are structural rows attached to the same carrier. No projection step has a coordinate from which to synthesize a compiler proof, hidden recognizer state, or report-like witness.

Thus the TasteGate field readback is exactly componentwise over $E, S, R, Q, B, H, C, P, N$. □

Theorem 1048.7 (GroundCompiler recognizer-flow nontrivial witness boundary)**.** *The nontrivial witness for* $\mathsf{GroundCompilerRecognizerFlow}^{\uparrow}$ *separates an accepted recognizer-flow packet from*

every packet that omits one of $E, S, R, Q, B, H, C, P, N$ or tries to identify the non-evidence row B with event-flow, source-channel, generated-recognizer, certificate-gate, or proof-evidence data. The separation is witnessed inside the finite carrier rows and does not assert compiler correctness, self-hosting, or proof reconstruction.

Proof. Use the carrier inventory to compare two candidate packets. A packet missing any one of the displayed coordinates cannot satisfy the same row-by-row classifier as G.

For the positive evidence route, apply certificate-gate exactness. Accepted evidence must pass through E, S, R, Q, and none of the structural rows replaces a missing generated-recognizer or certificate-gate coordinate.

For the boundary side, apply non-evidence refusal. The row B is stable under transport, continuation, provenance, and local naming, so it remains separated from evidence and proof rows. This gives a finite nontrivial witness boundary without importing compiler correctness or proof reconstruction. □

Falsifiable prediction: A compiler export that omits the generated recognizer row cannot pass the certificate gate as accepted GroundCompiler evidence.

Independence witness: groundcompilereventflowaudit, groundcompilerauditmap, auditmapfamily, auditmapcoverageledger, namecertgenerated: event-flow audit lacks generated-recognizer mediation, audit-map packets lack the certificate-gate row, audit families lack source-channel lossless routing, coverage ledgers lack the non-evidence refusal row, and NameCert-generated surfaces do not carry the compiler recognizer flow as a single packet.

The Lean TasteGate follow-up for BEDC.Derived.GroundCompilerRecognizerFlowUp must provide Nontrivial GroundCompilerRecognizerFlow$^{\uparrow}$ and FieldFaithful GroundCompilerRecognizerFlow$^{\uparrow}$ instances for the displayed carrier $E, S, R, Q, B, H, C, P, N$.

Closure status for NameCert$_{\text{GroundCompilerRecognizerFlow}^{\uparrow}}$.

Constructive story: A GroundCompilerRecognizerFlow$^{\uparrow}$ packet is generated from event-flow, source-channel, generated-recognizer, certificate-gate, non-evidence, componentwise hsame, displayed Cont, Pkg, and local NameCert rows; the TasteGate row is recorded at BEDC.Derived.GroundCompilerRecognizerFlowUp.taste_gate.

Theory closure: TheoryGate(NameCert$_{\text{GroundCompilerRecognizerFlow}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1048.1, Definition 1048.2, Definition 1048.3, Definition 1048.4, Definition 1048.5, Definition 1048.6, and Definition 1048.7 bind the finite GroundCompiler recognizer-flow carrier, TasteGate carrier readback, field-faithful projection, nontrivial witness boundary, certificate-gate exactness, and non-evidence refusal.

Formal verification: FormalStatus(NameCert$_{\text{GroundCompilerRecognizerFlow}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.GroundCompilerRecognizerFlowUp.GroundCompilerRecognizerFlowTasteGate\_single\_carrier\_`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close compiler correctness, self-hosting coverage, proof reconstruction from source text, metric evidence, motif evidence, report evidence, audit cleanliness, or bridge checking.

Upgrade path: The paper closure axis is complete for the event-flow and source-channel recognizer packet; bridge checking remains independent unless a StdBridge target is supplied.

Chapter 1049

A Concrete Naming Certificate for AxisCarryRouteSeparation$^{\uparrow}$

The AxisCarryRouteSeparation$^{\uparrow}$ packet records the finite route boundary around the Zeckendorf carry classifier of chapter 9345. It reads the carry-budget surface of chapter 692, the unary-spine normalizer of chapter 599, and the unary-direction normalizer of chapter 1010 as sibling routes, while keeping carry-relatedness separate from hsame identification.

It is an ai over the ZeckendorfCarryClassifier$^{\uparrow}$, AxisZeckendorfCarryBudget$^{\uparrow}$, AxisUnarySpineNormalizer$^{\uparrow}$, and UnaryDirectionNormalizer$^{\uparrow}$ sibling surfaces, with the route-separation row serving only as the finite boundary bundle.

Definition 1049.1 (Axis carry route separation carrier)**.** *An* AxisCarryRouteSeparation$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (A, U, D, S, T, B, R, H, C, P, N)$$

with the following visible rows:

1. *A is the accepted* AxisZeckendorfCarryBudget$^{\uparrow}$ *row containing the displayed carry source, carry target, normal-form target, value ledger, and non-*hsame *boundary;*
2. *U is the* AxisUnarySpineNormalizer$^{\uparrow}$ *row through which the axis-unary spine is read before a direction route is visible;*
3. *D is the* UnaryDirectionNormalizer$^{\uparrow}$ *row through which the direction-normalized unary packet is read;*
4. *S is the carry source row generated by the displayed* ZCarry *generator;*
5. *T is the normal target row reached by the same carry route;*
6. *B is the refusal row recording that the carry-related source and target are not identified by* hsame*;*
7. *R is the route ledger separating carry classification, normal-form routing, and refusal replay;*
8. *H records componentwise* hsame *transports for the sibling rows without converting the carry relation into history sameness;*
9. *C records the displayed* Cont *routes for reading $A, U, D, S, T, B, R, H, P, N$;*
10. *P is the* Pkg *provenance over* ZCarry$^{\uparrow}$*,* AxisZeckendorfCarryBudget$^{\uparrow}$*,* AxisUnarySpineNormalizer$^{\uparrow}$*,* UnaryDirectionNormalizer$^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*;*

11. N is the local $\mathsf{NameCert}_{\mathsf{AxisCarryRouteSeparation}^{\uparrow}}$ *row.*

The carrier has no coordinate for promoting the carry relation to hsame*, no global carry rewrite, no host arithmetic quotient, and no normalizer that forgets the refusal row B.*

Theorem 1049.2 (Axis carry route separation boundary)**.** *Every accepted* $\mathsf{AxisCarryRouteSeparation}^{\uparrow}$ *packet $Q = (A, U, D, S, T, B, R, H, C, P, N)$ exposes carry-relatedness only through the displayed carry row $S \to T$, exposes normal-form routing only through the sibling rows A, U, D, and exposes the history-sameness refusal only through B, R, H, C, P, N. A consumer therefore receives a finite packet separating carry-relatedness, normal-target routing, and non-*hsame *refusal, and it cannot turn the Zeckendorf carry row of chapter 9345 into an* hsame *identification.*

Proof. Project the finite carrier of Definition 1049.1. The rows S and T are the only carry source and target rows, while A, U, D are the only sibling route rows for the carry budget, axis-unary spine normalizer, and unary-direction normalizer.

The refusal row B records the non-hsame boundary supplied by the Zeckendorf carry classifier. The route ledger R, componentwise transport row H, continuation row C, provenance row P, and local name N replay that refusal without adding a kernel equality coordinate.

Finally use coordinate exhaustion. Since Q contains no host quotient, no global rewrite, and no coordinate that identifies S with T by hsame, every public read remains within the finite carry route, normal-target route, and refusal ledger displayed above. □

Lean4 ✓ `BEDC.Derived.AxisCarryRouteSeparationUp.AxisCarryRouteSeparationTasteGate single carrier alignment`

Falsifiable prediction: Any accepted route that turns a Zeckendorf carry row into hsame must pass through the refusal ledger rather than the public carry-route classifier.

Independence witness: zeckendorf-carry-classifier, axiszeckendorfcarrybudget, axisunaryspinenormalizer, unarydirectionnormalizer: the route-separation packet is not bijective to any sibling because it carries the carry row, normal-target row, non-hsame refusal, and route ledger simultaneously.

The Lean taste-gate file is `lean4/BEDC/Derived/AxisCarryRouteSeparationUp/TasteGate.lean`. It must provide explicit `Nontrivial AxisCarryRouteSeparationUp` and `FieldFaithful AxisCarryRouteSepara` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{AxisCarryRouteSeparation}^{\uparrow}}$.

Constructive story: An $\mathsf{AxisCarryRouteSeparation}^{\uparrow}$ packet is generated from carry-budget, axis-unary-spine, unary-direction, carry source, normal target, refusal, route-ledger, transport, continuation, provenance, and local NameCert rows.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AxisCarryRouteSeparation}^{\uparrow}}$, seed)

Scope closed: Definition 1049.1 and Definition 1049.2 specify the finite carrier separating carry-relatedness, normal-form routing, and history-sameness refusal.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AxisCarryRouteSeparation}^{\uparrow}}$, unformalized)

Ledger evidence: BEDC.Meta.DiscoveryDeltaLedger.axisCarryRouteSeparationDeltaLedger

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, global carry normalization, host arithmetic quotienting, or any kernel-level identification of carry-related histories.

Upgrade path: Scoped closure requires Lean encoding and checked routing for carrier admission, route separation, nontriviality, and field faithfulness over the same packet.

Chapter 1050

A Concrete Naming Certificate for $\mathsf{HostTotalTrace}^{\uparrow}$

The $\mathsf{HostTotalTrace}^{\uparrow}$ packet is the finite host-trace object for the total-host side of chapter 9370. It sits beside chapter 964, chapter 960, chapter 936, and chapter 970. Its distinguishing datum is that one packet carries host readback, finite fuel, substrate endpoint, timeout refusal, componentwise transport, route replay, provenance, and local naming rows without collapsing them into the broader step-indexed host boundary.

Falsifiable prediction: HostTotalTraceUp has no morphism to StepIndexedTotalHostUp that preserves timeout refusal while forgetting trace endpoint readback.

Independence witness: StepIndexedTotalHostUp, FuelIndexedSubstrateBridgeUp, ZNormalUp, ReductionFuelBoundaryUp: HostTotalTraceUp carries both host readback and timeout-refusal rows, while these siblings separately expose total-host boundary, substrate bridge, normal-form predicate, or fuel boundary without the same trace-level packet.

Definition 1050.1 (HostTotalTrace carrier)**.** *A* $\mathsf{HostTotalTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (H, F, R, E, U, L, C, P, N)$$

with the following displayed rows:

1. *H is the total-host readback row, naming the finite host computation being inspected;*
2. *F is the finite fuel row under which the trace is accepted;*
3. *R is the normal-form readback row, read through the host-side normality discipline of* $\mathsf{ZNormal}^{\uparrow}$*;*
4. *E is the substrate endpoint row reached by the finite trace when an endpoint is displayed;*
5. *U is the timeout-refusal row, recording fuel exhaustion as a refused endpoint rather than as nontermination, convergence, or halting evidence;*
6. *L records componentwise* hsame *transports for H, F, R, E, U, C, P, N;*
7. *C records displayed* Cont *routes from host readback to fuel, from fuel to normal-form readback, from the same fuel to substrate endpoint or timeout refusal, and from barred semantic requests to the refusal row;*
8. *P is the* Pkg *provenance over* $\mathsf{HostTotalTrace}^{\uparrow}$*, chapter 9370,* $\mathsf{StepIndexedTotalHost}^{\uparrow}$*,* $\mathsf{FuelIndexedSubstrateBridge}$ $\mathsf{ZNormal}^{\uparrow}$*,* $\mathsf{ReductionFuelBoundary}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows;*

9. N is the local $\mathsf{NameCert}_{\mathsf{HostTotalTrace}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through $H, F, R, E, U, L, C, P, N$. It has no coordinate for host partiality, unbounded substrate completion, quotient endpoint equality, host-substrate equality, or a detached timeout oracle.

Definition 1050.2 (HostTotalTrace classifier)**.** *The* $\mathsf{HostTotalTrace}^{\uparrow}$ *classifier compares two accepted packets only by the displayed tuple*

$$H, F, R, E, U, L, C, P, N.$$

Two packet presentations agree when their host readback, fuel, normal-form readback, substrate endpoint, timeout-refusal, componentwise transport, route, provenance, and local naming rows agree componentwise. The classifier does not compare partial host evaluators, unbounded substrate completions, quotient endpoints, host-substrate equalities, or detached timeout oracles.

Theorem 1050.3 (HostTotalTrace NameCert obligations)**.** *For the carrier of Definition 1050.1 and classifier of Definition 1050.2, the local* $\mathsf{NameCert}_{\mathsf{HostTotalTrace}^{\uparrow}}$ *surface consists exactly of five obligation rows:*

1. *carrier admission and classifier exactness for $T = (H, F, R, E, U, L, C, P, N)$;*
2. *host readback and finite fuel exposure through H, F;*
3. *normal-form readback and substrate endpoint exposure through R, E;*
4. *timeout-refusal exactness through U;*
5. *componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local naming through L, C, P, N.*

Proof. Project the carrier and classifier in Definition 1050.1 and Definition 1050.2. They display exactly the rows $H, F, R, E, U, L, C, P, N$, so carrier admission and classifier exactness cannot introduce a detached endpoint, alternate fuel, or hidden timeout branch.

Read the constructive rows in order. The host readback row H is accepted only under the finite fuel row F; the normal-form readback R and substrate endpoint E are public only as rows of that same finite trace packet.

The refusal row U accounts for fuel exhaustion. It records timeout as a boundary outcome and not as nontermination, halting, convergence, host-substrate equality, or quotient endpoint equality.

Finally L, C, P, N preserve and replay only the same finite packet. The five listed rows therefore exhaust the local NameCert obligation surface. □

Lean4 ✓ `BEDC.Derived.HostTotalTraceUp.HostTotalTraceTasteGate single carrier alignment`

Theorem 1050.4 (HostTotalTrace timeout endpoint separation)**.** *Every accepted* $\mathsf{HostTotalTrace}^{\uparrow}$ *packet separates endpoint readback from timeout refusal by the displayed route*

$$H, F, R, E, U, L, C, P, N.$$

A consumer may read the host readback, fuel, normal-form readback, displayed substrate endpoint, and timeout-refusal rows. It may not erase E while preserving U, turn timeout into nontermination, turn endpoint readback into unbounded convergence, or identify the host trace with the substrate bridge.

Proof. Start from the obligation surface of Definition 1050.3. The endpoint row E and timeout-refusal row U are separate coordinates of the same accepted packet.

Compare the sibling surfaces. $\mathsf{StepIndexedTotalHost}^{\uparrow}$ supplies the broader total-host boundary, $\mathsf{FuelIndexedSubstrateBridge}^{\uparrow}$ supplies the substrate bridge, $\mathsf{ZNormal}^{\uparrow}$ supplies the normal-form predicate, and $\mathsf{ReductionFuelBoundary}^{\uparrow}$ supplies the fuel-boundary refusal discipline. None lets this packet forget endpoint readback while retaining the local timeout row.

The route and transport rows L, C, P, N preserve that separation. Hence a downstream consumer can replay the finite trace, but it cannot convert timeout into a semantic nontermination claim or endpoint readback into unbounded convergence. □

The proposed Lean follow-up is the module `lean4/BEDC/Derived/HostTotalTraceUp/TasteGate.lean`. It must provide explicit $\mathsf{Nontrivial\ HostTotalTrace}^{\uparrow}$ and $\mathsf{FieldFaithful\ HostTotalTrace}^{\uparrow}$ instances preserving the host readback, finite fuel, normal-form readback, substrate endpoint, timeout refusal, componentwise transport, displayed route, provenance, and local naming rows.

Closure status for $\mathsf{NameCert}_{\mathsf{HostTotalTrace}^{\uparrow}}$.

Constructive story: A $\mathsf{HostTotalTrace}^{\uparrow}$ packet is generated from host readback, finite fuel, normal-form readback, substrate endpoint, timeout-refusal, componentwise hsame transport, displayed Cont route, package provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{HostTotalTrace}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1050.1, Definition 1050.2, Definition 1050.3, and Definition 1050.4 specify the finite host-trace packet separating endpoint readback from timeout refusal.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{HostTotalTrace}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove Lean verification, bridge checking, host partiality, unbounded substrate completion, halting decidability, quotient endpoint equality, or host-substrate equality.

Upgrade path: Obligation closure requires checked carrier admission, classifier exactness, host readback, fuel exposure, normal-form readback, endpoint exposure, timeout-refusal exactness, nontriviality, and field faithfulness for the same packet.

Chapter 1051

A Concrete Naming Certificate for $\mathsf{TailCauchyRouter}^{\uparrow}$

The $\mathsf{TailCauchyRouter}^{\uparrow}$ packet realizes the tail-selection route used by the Real-completion vision of chapter 9238. It sits after the finite window service of chapter 126, the rational readback of chapter 301, the regular-Cauchy source surface of chapter 660, the limit handoff of chapter 386, and the terminal Real seal of chapter 38. The packet is a finite route certificate for a displayed tail selector, not a quotient stream equality, ambient completeness theorem, hidden choice principle, or host-level real equality.

Definition 1051.1 (Tail Cauchy router carrier)**.** *A* $\mathsf{TailCauchyRouter}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (S, M, W, R, L, E, H, C, P, N)$$

with the following displayed rows:

1. *S is the tail selector that names the accepted tail threshold for the requested precision;*
2. *M is the shared modulus row used by every source and consumer read in the packet;*
3. *W is the finite* $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *window reached at the selected tail;*
4. *R is the regular-Cauchy source row whose tail is being routed;*
5. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row fed by the selected window and source row;*
6. *E is the terminal* $\mathsf{Real}^{\uparrow}$ *seal endpoint exported to the consumer;*
7. *H records componentwise* hsame *transport for the selector, modulus, window, source, limit handoff, endpoint, route, provenance, and local naming rows;*
8. *C records the displayed* Cont *routes from the selected tail and shared modulus to the window, from the window and source row to the limit handoff, and from the handoff to the Real endpoint;*
9. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{RegularCauchySequence}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{TailCauchyRouter}^{\uparrow}}$ *row.*

The carrier has no coordinate for a second selector, unbounded window, quotient stream equality, detached Real endpoint, ambient completeness, or a limit handoff not fed by the displayed source row.

Lean4 (definition) `BEDC.Derived.TailCauchyRouterUp.TailCauchyRouterUp`
Lean4 ✓ `BEDC.Derived.TailCauchyRouterUp.TailCauchyRouterTasteGate single carrier alignment`

Theorem 1051.2 (Tail Cauchy router carrier exposure)**.** *For the carrier of Definition 1051.1, the local* $\mathsf{NameCert}_{\mathsf{TailCauchyRouter}^{\uparrow}}$ *surface exposes exactly the finite rows*

$$S, M, W, R, L, E, H, C, P, N.$$

Every accepted packet makes the selector, shared modulus, finite StreamName and RegSeqRat window, regular-Cauchy source row, CauchyLimitSeal handoff, Real endpoint, transport, continuation, provenance, and local naming rows available as named coordinates.

Proof. Project the displayed carrier. The tuple lists the selector, modulus, window, source, handoff, endpoint, transport, continuation, provenance, and local naming rows as finite coordinates.

The exclusion clause of the carrier forbids any second selector, unbounded window, quotient equality, detached endpoint, ambient completeness row, or unrelated handoff coordinate. Thus the listed coordinates are exactly the exposed NameCert surface. □

Theorem 1051.3 (Tail selector determinacy)**.** *Inside an accepted* $\mathsf{TailCauchyRouter}^{\uparrow}$ *packet, the tail selector row S determines the window row W relative to the shared modulus M. A consumer cannot replace S by a different selector while keeping the same local NameCert row N and the same displayed route rows C.*

Proof. Read the continuation row C from the selector side. It records the route from S and M to the finite window W, so the window admitted by the certificate is the one reached by the displayed selector and modulus.

If a consumer replaces S while keeping N and C, the first continuation edge no longer has the source named by the carrier. The replacement is therefore outside the accepted NameCert packet rather than a second accepted tail route. □

Theorem 1051.4 (Tail modulus-window coverage)**.** *Every accepted* $\mathsf{TailCauchyRouter}^{\uparrow}$ *packet covers the selected tail window by the shared modulus row M. The finite row W must contain the StreamName observations and RegSeqRat readback needed by the regular-Cauchy source row R at the tail named by S.*

Proof. Use the carrier exposure theorem to isolate S, M, W, R. The packet contains a single shared modulus row and a single finite window row, so all source and consumer reads pass through those displayed coordinates.

The continuation row C binds S and M to W, then binds W to the source row R. Hence a window lacking the StreamName observations or RegSeqRat readback required at the selected tail is not covered by the certificate. □

Theorem 1051.5 (Tail seal non-escape)**.** *The* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row L of an accepted* $\mathsf{TailCauchyRouter}^{\uparrow}$ *packet is fed only by the displayed window row W and regular-Cauchy source row R. No accepted packet exports a limit handoff detached from the selected tail route.*

Proof. Inspect the route row C. Its middle segment reaches L from W and R, after W has already been selected by S under the shared modulus M.

The carrier contains no detached handoff coordinate. Therefore any proposed limit seal not fed by the displayed selected window and source row has no coordinate in the local packet and is outside the certificate. □

Theorem 1051.6 (Tail RealUp consumer handoff)**.** *Every consumer route from an accepted* $\mathsf{TailCauchyRouter}^{\uparrow}$ *packet to a public* $\mathsf{Real}^{\uparrow}$ *endpoint factors through*

$$S, M, W, R, L, E, H, C, P, N.$$

The consumer receives the Real endpoint E only after the selected tail window has fed the displayed $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row L.*

Proof. Start with carrier exposure. A consumer can inspect only the displayed selector, modulus, window, source, handoff, endpoint, transport, continuation, provenance, and naming rows.

Follow the displayed continuation route. It first selects and covers the finite tail window, then feeds the CauchyLimitSeal row from that window and the regular-Cauchy source, and only then reaches the Real endpoint.

Since no detached endpoint or ambient completeness coordinate occurs in the carrier, every accepted Real-facing consumer route factors through the displayed finite packet. □

Theorem 1051.7 (Tail Cauchy router RegSeqRat route totality)**.** *Every* $\mathsf{RegSeqRat}^{\uparrow}$ *read admitted by an accepted* $\mathsf{TailCauchyRouter}^{\uparrow}$ *packet reaches the consumer only through*

$$S, M, W, R, H, C, P, N.$$

Here W is the finite $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *window selected by S under the shared modulus M. The packet has no unbounded window coordinate and no RegSeqRat route outside the displayed finite window.*

Proof. Project the carrier of Definition 1051.1. The RegSeqRat-facing rows available before the limit handoff are the selector S, shared modulus M, finite window W, regular-Cauchy source row R, transport row H, continuation row C, provenance row P, and local naming row N.

Use Definition 1051.2 and Definition 1051.3. They expose the displayed rows and bind W to the selected tail route, so a consumer cannot replace the selected window while keeping the same packet.

Finally apply Definition 1051.4. The RegSeqRat readback required by R is covered inside W, and the carrier contains no unbounded window coordinate. Hence every admitted RegSeqRat read is total only along the displayed finite route. □

Theorem 1051.8 (Tail Cauchy router dyadic budget non-escape)**.** *In an accepted* $\mathsf{TailCauchyRouter}^{\uparrow}$ *packet, every dyadic tolerance and budget read is confined to the shared modulus M, selected tail S, finite window row W, and route provenance H, C, P, N. No dyadic budget can be imported from a hidden selector, detached window, quotient stream equality, or ambient completeness coordinate.*

Proof. Read the carrier rows for the budget-facing route. The only dyadic control row is the shared modulus M, and it is paired with the selected tail row S before the route reaches the finite window W.

Apply Definition 1051.3. The selector cannot be changed while preserving the same continuation row, so a second dyadic schedule would not be a read of the accepted packet.

Then apply Definition 1051.4. The budget reaches the StreamName and RegSeqRat observations through W, with H, C, P, N recording transport, continuation, provenance, and local naming. The carrier exposure theorem supplies no hidden selector, detached window, quotient equality, or ambient completeness row. □

Theorem 1051.9 (Tail Cauchy router Real seal handoff)**.** *The Real seal endpoint E of an accepted* $\mathsf{TailCauchyRouter}^{\uparrow}$ *packet is public only after the selected window W and source row R feed the displayed* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row L. The handoff exports no quotient stream equality, host real equality, hidden choice, or ambient completeness principle.*

Proof. Begin with Definition 1051.5. The limit row L is fed only by the displayed finite window W and regular-Cauchy source row R, after W has been selected from S under the shared modulus M.

Now apply Definition 1051.6. Every Real-facing consumer route factors through the full displayed packet $S, M, W, R, L, E, H, C, P, N$, so the endpoint E is visible only downstream of the selected window and limit handoff.

The carrier exposure theorem supplies no quotient stream equality, host real equality, hidden choice row, or ambient completeness row. Therefore the public seal handoff is exactly the displayed finite route to E. □

Falsifiable prediction: Any accepted TailCauchyRouterUp packet whose selected tail window does not feed the displayed CauchyLimitSeal row is outside the certificate.

Independence witness: streamname, regseqrat, regularcauchysequence, cauchylimitseal, real: TailCauchyRouterUp is not bijective to any sibling because it carries a route row binding all five surfaces at once; the siblings expose point streams, regular sequence rows, Cauchy input data, limit seals, or RealUp endpoints separately.

The Lean site `lean4/BEDC/Derived/TailCauchyRouterUp/TasteGate.lean` provides `Nontrivial TailCauchyRouterUp` and `FieldFaithful TailCauchyRouterUp` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{TailCauchyRouter}^{\uparrow}}$.

Constructive story: A $\mathsf{TailCauchyRouter}^{\uparrow}$ packet is generated from a tail selector, shared modulus, finite StreamName and RegSeqRat window, regular-Cauchy source row, CauchyLimitSeal handoff, RealUp endpoint, componentwise transports, displayed continuations, package provenance, and local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{TailCauchyRouter}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1051.1, Definition 1051.2, Definition 1051.3, Definition 1051.4, Definition 1051.5, Definition 1051.6, Definition 1051.7, Definition 1051.8, and Definition 1051.9 specify the finite tail-selection route from StreamName and RegSeqRat windows to CauchyLimitSeal and RealUp handoff.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{TailCauchyRouter}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Real completeness, quotient stream equality, host real equality, hidden choice, ambient completion, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, selector determinacy, modulus-window coverage, seal non-escape, RealUp consumer handoff, nontriviality, and field faithfulness for the same packet.

Chapter 1052

A Concrete Naming Certificate for $\mathsf{InscriptionTraceClassifier}^{\uparrow}$

The $\mathsf{InscriptionTraceClassifier}^{\uparrow}$ packet realizes the source/name/route/check/consumer surface of the inscription-event vision in chapter 9397. It sits beside the full event packet of chapter 519, the public residue ledger of chapter 520, the trace reader of chapter 682, and the route audit of chapter 1005. These siblings expose event, ledger, trace, and route aspects; the present classifier isolates the finite packet a downstream consumer must display before an inscription event may be exported as public record data.

Definition 1052.1 (Inscription trace-classifier carrier)**.** *An* $\mathsf{InscriptionTraceClassifier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (S, M, R, K, U, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the finite source row from which the inscription trace is read;*
2. *M is the public name row attached to the trace;*
3. *R is the displayed route row from source to named trace;*
4. *K is the accepted check row that admits the route as public record data;*
5. *U is the downstream consumer row permitted to read the accepted trace;*
6. *L is the refusal-ledger row for incomplete source, name, route, check, or consumer displays;*
7. *H records componentwise* hsame *transports for S, M, R, K, U, L together with continuation, provenance, and local naming rows;*
8. *C records the displayed* Cont *routes by which a consumer reads source, name, route, check, consumer, and refusal-ledger rows;*
9. *P is the* Pkg *provenance over* BHist, $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{InscriptionGapLedger}^{\uparrow}$, $\mathsf{InscriptionAuditTrace}^{\uparrow}$, $\mathsf{InscriptionRouteAudit}^{\uparrow}$, $\mathsf{InscriptionCommitmentSeal}^{\uparrow}$, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{InscriptionTraceClassifier}^{\uparrow}}$ *row.*

The classifier accepts exactly packets with these ten displayed rows. It has no coordinate for a private source, hidden name, unchecked route, off-packet checker, consumer right outside U, or inscription-event export that bypasses the refusal ledger L.

Theorem 1052.2 (Inscription trace-classifier obligations)**.** *For the carrier of Definition 1052.1, the local* $\mathsf{NameCert}_{\mathsf{InscriptionTraceClassifier}^{\uparrow}}$ *surface consists exactly of carrier exposure for*

$$T = (S, M, R, K, U, L, H, C, P, N),$$

source visibility through S*, public naming through* M*, route exactness through* R*, accepted-check admission through* K*, consumer accountability through* U*, refusal-ledger coverage through* L*, componentwise transport through* H*, displayed continuation through* C*, provenance through* P*, and local naming through* N*.*

Proof. Carrier exposure is projection from the displayed packet. The rows $S, M, R, K, U, L, H, C, P, N$ are the whole inventory available to a trace-classifier reader.

Read the content rows in order. The source row S supplies the visible origin, the name row M supplies the public handle, the route row R supplies the trace path, the check row K admits that path as public record data, and the consumer row U names the permitted downstream reader.

The refusal row L covers every incomplete display among those five rows. The structural rows H, C, P, N then transport, replay, source, and name the same finite packet. Since no carrier coordinate exports a hidden source, hidden name, unchecked route, off-packet checker, or extra consumer right, these rows exhaust the local certificate surface. □

Falsifiable prediction: Any accepted trace-classifier consumer without displayed source, name, route, check, and consumer rows factors to the refusal ledger rather than exporting an inscription event.

Theorem 1052.3 (Inscription trace-classifier falsifiable prediction)**.** *For every accepted* $\mathsf{InscriptionTraceClassifier}^{\uparrow}$ *packet* $T = (S, M, R, K, U, L, H, C, P, N)$*, any purported trace-classifier consumer that omits one of the displayed source, name, route, check, or consumer rows factors through the refusal ledger* L *rather than exporting an* $\mathsf{InscriptionEvent}^{\uparrow}$ *row. Thus an inscription event is public only after* S, M, R, K, U *are visible in the same packet.*

Proof. Project the carrier of Definition 1052.1. The only inscription-facing export path is the displayed chain through S, M, R, K, U.

Apply Definition 1052.2. It assigns missing source, name, route, check, or consumer data to the refusal-ledger row L, while the accepted event-facing path requires the five displayed content rows.

The transport, continuation, provenance, and local naming rows preserve this same split. Therefore a consumer that omits any one of S, M, R, K, U has no event-export coordinate left in the carrier and must be read through L. □

Independence witness: inscriptionevent, inscriptiongapledger, inscriptionaudittrace, inscriptionrouteaudit, inscriptioncommitmentseal: this classifier packet has the simultaneous source/name/route/check/co acceptance chain and a refusal-ledger fallback, while the named siblings respectively expose a full event packet, residue ledger, trace audit, route audit, or commitment seal. No carrier bijection preserves all rows.

Theorem 1052.4 (Inscription trace-classifier independence witness)**.** *The* $\mathsf{InscriptionTraceClassifier}^{\uparrow}$ *carrier is not bijective, under NameCert-row preservation, with* $\mathsf{InscriptionEvent}^{\uparrow}$*,* $\mathsf{InscriptionGapLedger}^{\uparrow}$*,* $\mathsf{InscriptionAuditTrace}^{\uparrow}$*,* $\mathsf{InscriptionRouteAudit}^{\uparrow}$*, or* $\mathsf{InscriptionCommitmentSeal}^{\uparrow}$*. It uniquely binds the displayed source, name, route, accepted check, downstream consumer, and refusal-ledger rows as one classifier packet.*

Proof. Compare the displayed coordinates. The present carrier contains the accepted classifier chain

$$S \to M \to R \to K \to U$$

together with the refusal-ledger row L for incomplete presentations.

The inscription event sibling contains the full event packet rather than the classifier fallback. The gap ledger sibling records public residue, but not the simultaneous accepted source/name/route/check/consume chain. The audit trace sibling records trace readback, and the route-audit sibling isolates the accepted route to a consumer, but neither supplies this packet's refusal fallback for missing classifier rows.

The commitment seal sibling records an accepted commitment and ledger rather than the full trace-classifier surface. Hence no bijection preserving the local NameCert rows can identify any of those carriers with $T = (S, M, R, K, U, L, H, C, P, N)$. □

Closure status for $\mathsf{NameCert}_{\mathsf{InscriptionTraceClassifier}^{\uparrow}}$.

Constructive story: An $\mathsf{InscriptionTraceClassifier}^{\uparrow}$ packet is generated from visible source, public name, displayed route, accepted check, downstream consumer, refusal-ledger fallback, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{InscriptionTraceClassifier}^{\uparrow}}, \mathsf{obligation})$

Scope closed: Definition 1052.1, Definition 1052.2, Definition 1052.3, and Definition 1052.4 bind the finite source/name/route/check/con classifier packet and its refusal-ledger fallback.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{InscriptionTraceClassifier}^{\uparrow}}, \mathsf{axiomClean})$

Lean4 ✓ `BEDC.Derived.InscriptionTraceClassifierUp.taste gate`

Lean target: `BEDC.Derived.InscriptionTraceClassifierUp.TasteGate.InscriptionTraceClassifierTasteGate\_single\_car`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close bridge checking, private agency, host process traces, unchecked routes, inscription-event completeness, or consumer rights outside the displayed packet.

Upgrade path: Scoped closure requires binding the classifier packet to each downstream inscription-event consumer route without adding any row beyond $S, M, R, K, U, L, H, C, P, N$.

Chapter 1053

A Concrete Naming Certificate for $\mathsf{RegSeqObservationBudget}^{\uparrow}$

The $\mathsf{RegSeqObservationBudget}^{\uparrow}$ packet realizes the finite observation-budget route required by the Real-completeness target of chapter 9238. It consumes the diagonal selector surface of chapter 853, the terminal Real seal surface of chapter 38, the finite StreamName window row, the $\mathsf{RegSeqRat}^{\uparrow}$ readback row, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, and the primitive hsame, Cont, Pkg, and $\mathsf{NameCert}$ rows. The packet is an observation route to a seal, not an ambient completeness theorem, quotient stream equality, host real equality, or selected external limit.

It is composite over the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, and $\mathsf{DyadicRatCore}^{\uparrow}$ surfaces, binding their displayed rows into a single observation-budget route.

Falsifiable prediction: Every RealUp-seal consumer accepted by $\mathsf{RegSeqObservationBudget}^{\uparrow}$ factors through the displayed observation-budget row before any seal read.

Independence witness: cauchydiagonalbudget, realobservationbudget, regularcauchycomparison, streamname, real: no listed sibling is bijective to $\mathsf{RegSeqObservationBudget}^{\uparrow}$. The diagonal budget stores selector data without the full RealUp observation row, the Real observation budget stores seal-facing budget admission without the regular-source and diagonal selector packet, the regular-Cauchy comparison row stores finite comparison data without the terminal seal route, the StreamName row stores finite windows without the RealUp budget, and the RealUp certificate stores the seal without the upstream observation schedule.

Definition 1053.1 (Regular observer-budget carrier)**.** *A* $\mathsf{RegSeqObservationBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (W, R, E, D, \epsilon, H, C, P, N)$$

with the following displayed rows:

1. W *is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row that exposes the requested observation window;*
2. R *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained from the displayed window;*
3. E *is the* $\mathsf{Real}^{\uparrow}$ *observation-budget row reached only after the regular-source readback;*
4. D *is the* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *row selecting the diagonal observation budget consumed by the same read;*
5. ϵ *is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row that fixes the finite precision served by the packet;*

6. *H records componentwise* hsame *transports for the window, readback, RealUp budget, diagonal selector, tolerance, continuation, provenance, and local naming rows;*
7. *C records the displayed* Cont *replay route from W to R, from R and ϵ to D, and from D to E;*
8. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RegSeqObservationBudget}^{\uparrow}}$ *row.*

The classifier accepts only the displayed finite route $W, R, E, D, \epsilon, H, C, P, N$. It has no coordinate for quotient stream equality, host real equality, an unbounded observation schedule, a hidden diagonal selector, an undisplayed seal read, or ambient completeness.

Lean4 ✓ `BEDC.Derived.RegSeqObservationBudgetUp.RegSeqObservationBudgetTasteGate single carrier alignment`

Theorem 1053.2 (Regular observer-budget NameCert obligations)**.** *For the carrier of Definition 1053.1, the local* $\mathsf{NameCert}_{\mathsf{RegSeqObservationBudget}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$O = (W, R, E, D, \epsilon, H, C, P, N),$$

StreamName window exposure through W, RegSeqRat readback through R, RealUp observation-budget exposure through E, diagonal selector exposure through D, dyadic tolerance exposure through ϵ, componentwise hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through P, and local naming through N.*

Proof. Project the displayed carrier. Its public rows are precisely the finite window, regular-source readback, RealUp observation budget, diagonal selector, dyadic tolerance, transport, continuation, provenance, and local naming rows.

Read the route in dependency order. The StreamName window W is available before regular readback R; the tolerance row ϵ and diagonal budget D then determine the finite observation request; the RealUp budget row E is reached only after those rows are displayed.

The rows H, C, P, N preserve and name the same packet. Since the carrier lacks coordinates for quotient stream equality, host real equality, unbounded observation schedules, hidden selectors, detached seals, and ambient completeness, the listed rows exhaust the local NameCert surface. □

Theorem 1053.3 (Regular observer-budget filter-schedule non-escape)**.** *Every accepted* $\mathsf{RegSeqObservationBudget}^{\uparrow}$ *consumer route to a* $\mathsf{Real}^{\uparrow}$ *seal factors through the displayed observation-budget sequence*

$$W, R, \epsilon, D, E, H, C, P, N.$$

No accepted route may inspect the terminal RealUp seal before the StreamName window, RegSeqRat readback, dyadic tolerance, and CauchyDiagonalBudget selector rows have been read, and no route may replace that finite schedule by an omitted filter row, hidden diagonal selector, quotient stream, host real equality, or ambient completeness principle.

Proof. Start from the NameCert obligation theorem. It identifies every accepted packet with the displayed rows $W, R, E, D, \epsilon, H, C, P, N$ and gives the local classifier no additional schedule coordinate.

The positive route is fixed by the carrier itself. The window row W feeds the readback row R, the tolerance row ϵ and diagonal selector D fix the finite observation budget, and only then is the RealUp observation-budget row E available for a seal-facing consumer.

The structural rows preserve that order. Componentwise hsame transport in H and replay in C move the displayed route, while P and N record provenance and local naming for the same packet. Therefore any omitted filter row, hidden selector, quotient, host equality, or ambient completeness object remains outside the accepted route. □

Theorem 1053.4 (Regular observer-budget window admission)**.** *Every accepted* $\mathsf{RegSeqObservationBudget}^{\uparrow}$ *route exposes the finite window row W before it may read the regular-source row R, the dyadic tolerance row ϵ, the diagonal selector row D, or the RealUp observation-budget row E. In particular, no accepted consumer may enter through R, ϵ, D, or E while leaving the StreamName window undisplayed.*

Proof. Use the carrier of Definition 1053.1. Its accepted packet is the displayed row

$$O = (W, R, E, D, \epsilon, H, C, P, N),$$

and the classifier has no coordinate for an alternate entry point.

Apply Definition 1053.2. The local NameCert surface lists StreamName window exposure through W before RegSeqRat readback, dyadic tolerance exposure, diagonal selector exposure, and RealUp budget exposure.

Finally apply Definition 1053.3. Any consumer route to the seal must factor through the finite schedule in which W is already visible before R, ϵ, D, and E are consumed. Hence a route that enters through those later rows without exposing W is outside the accepted packet. □

Theorem 1053.5 (Regular observer-budget tail monotonicity)**.** *Componentwise* hsame *transport and displayed* Cont *replay preserve the same finite observation budget*

$$W, R, \epsilon, D, E, H, C, P, N$$

for an accepted $\mathsf{RegSeqObservationBudget}^{\uparrow}$ *route. They may transport or replay the displayed rows, but they cannot introduce a hidden selector, quotient stream, host real equality, unbounded observation schedule, or second terminal seal read.*

Proof. Project the structural rows from Definition 1053.1. The row H records only componentwise hsame transports for the displayed window, readback, RealUp budget, diagonal selector, tolerance, continuation, provenance, and local naming rows, while C records only the displayed replay route from W to R, from R and ϵ to D, and from D to E.

Apply Definition 1053.2. The accepted NameCert surface is exhausted by the same finite carrier rows, so transport and replay have no independent coordinate in which a new selector, quotient, host equality, unbounded schedule, or extra seal read could be stored.

Apply Definition 1053.3. Since every accepted seal-facing route factors through the finite observation schedule, extending along a transported or replayed tail preserves that schedule and cannot escape to an undisplayed observation object. □

Theorem 1053.6 (Regular observer-budget Real seal handoff)**.** *The RealUp seal-facing row E of an accepted* $\mathsf{RegSeqObservationBudget}^{\uparrow}$ *carrier is consumed only after the StreamName window W, RegSeqRat readback R, dyadic tolerance ϵ, and CauchyDiagonalBudget selector D have been displayed. Thus the terminal seal handoff is a consequence of the finite observation-budget route, not an independent Real equality, quotient stream, or ambient completeness premise.*

Proof. Start with the carrier in Definition 1053.1. The row E is a displayed RealUp observation-budget row inside the same finite packet as W, R, ϵ, and D.

Apply Definition 1053.2. The obligation surface reaches RealUp budget exposure through E only as part of the listed window exposure, regular readback, dyadic tolerance, diagonal selector, transport, replay, provenance, and local naming rows.

Now apply Definition 1053.3. It forbids inspecting the terminal RealUp seal before W, R, ϵ, and D have been read. Therefore any seal-facing use of E is a handoff from the finite observation-budget route, and not from an independent equality, quotient, or completeness principle. □

The Lean TasteGate boundary for this packet must provide `Nontrivial RegSeqObservationBudgetUp` and `FieldFaithful RegSeqObservationBudgetUp` instances in `Derived/RegSeqObservationBudgetUp/TasteGa` with the canonical obligation theorem expected at `BEDC.Derived.RegSeqObservationBudgetUp.RegSeqObservat`

Theorem 1053.7 (Regular observer-budget scoped closure)**.** *The carrier definition, NameCert obligations, filter-schedule non-escape, window admission, tail monotonicity, Real seal handoff, and the two Lean TasteGate witnesses bind the scoped* $\mathsf{RegSeqObservationBudget}^{\uparrow}$ *surface exactly over the displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows. Inside this scope, every accepted seal-facing consumer is a consumer of the finite observation-budget packet*

$$W, R, \epsilon, D, E, H, C, P, N.$$

The scope has no classifier coordinate for quotient streams, host real equality, hidden selectors, unbounded schedules, or ambient completeness.

Proof. Apply the carrier description of Definition 1053.1 and the obligation surface of Definition 1053.2. These identify the accepted object with the listed finite rows and leave no independent row beyond the displayed window, readback, Real budget, diagonal selector, tolerance, transport, continuation, provenance, and local naming data.

Next apply Definition 1053.3, Definition 1053.4, and Definition 1053.5. The window is visible before later rows, every seal-facing route factors through the finite schedule, and transport or replay preserves the same observation budget rather than creating a new selector or schedule.

Finally apply Definition 1053.6. The RealUp seal row is reached only as the terminal handoff of the displayed route. The Lean TasteGate names `RegSeqObservationBudgetTasteGate_single_carrier_alignme` and `taste_gate` witness that the same singleton carrier boundary supplies nontriviality and field faithfulness, so the paper scope and kernel TasteGate evidence refer to the same finite packet. □

Theorem 1053.8 (Regular observer-budget public consumer export)**.** *Every public* $\mathsf{Real}^{\uparrow}$, $\mathsf{DiagonalLimitStability}^{\uparrow}$, *or* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegSeqObservationBudget}^{\uparrow}$ *packet receives exactly the displayed finite route*

$$W, R, \epsilon, D, E, H, C, P, N.$$

The exported route reads the $\mathsf{StreamName}^{\uparrow}$ *window* W *before* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R, *reads the dyadic tolerance row* ϵ *and diagonal selector row* D *before* $\mathsf{Real}^{\uparrow}$ *budget exposure* E, *and then replays only the displayed transport, continuation, provenance, and local naming rows* H, C, P, N. *The export contains no quotient stream equality, host real equality, hidden selector, unbounded schedule, detached seal read, or ambient completeness coordinate.*

Proof. First expose the public entry row. Theorem 1053.4 forces every accepted route to display the StreamName window W before it may read R, ϵ, D, or E.

Next preserve the finite tail budget. Theorem 1053.5 keeps componentwise hsame transport and displayed Cont replay on the same rows $W, R, \epsilon, D, E, H, C, P, N$, so public $\mathsf{DiagonalLimitStability}^{\uparrow}$ and $\mathsf{CauchyDiagonalBudget}^{\uparrow}$ consumers cannot replace the selector or schedule by an unshown coordinate.

Then apply the Real seal handoff. Theorem 1053.6 reaches the RealUp budget row E only after the window, readback, dyadic tolerance, and diagonal selector have been displayed. Thus a public $\mathsf{Real}^{\uparrow}$ consumer receives the same finite route rather than a detached seal read.

Finally use Definition 1053.7. The scoped closure binds the carrier, NameCert obligations, non-escape theorem, window admission, tail monotonicity, and Real seal handoff to the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows. The accepted carrier has no coordinate for quotient stream equality, host real equality, hidden selectors, unbounded schedules, detached seal reads, or ambient completeness, so the displayed route is the whole public export surface. □

Theorem 1053.9 (Regular observer-budget bridge precondition)**.** *Any standard bridge eligible to consume the public* $\mathsf{NameCert}_{\mathsf{RegSeqObservationBudget}^{\uparrow}}$ *export must preserve the displayed finite route*

$$W, R, \epsilon, D, E, H, C, P, N$$

through $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{CauchyDiagonalBudget}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. Bridge-side data may be exposed only after the window* W*, readback* R*, tolerance* ϵ*, diagonal selector* D*, and RealUp budget row* E *have appeared in that order, followed by the displayed transport, continuation, provenance, and local naming rows* H, C, P, N*. No quotient stream equality, host real equality, hidden selector, unbounded schedule, detached seal read, or ambient completeness premise can serve as an alternate bridge entry.*

Lean4 ✓ `BEDC.Derived.RegSeqObservationBudgetUp.RegSeqObservationBudgetUp StdBridge`

Proof. Start with the public export of Definition 1053.8. It already identifies the consumer-visible boundary with the single finite route $W, R, \epsilon, D, E, H, C, P, N$ and excludes quotient stream equality, host real equality, hidden selectors, unbounded schedules, detached seal reads, and ambient completeness coordinates from that boundary.

Next use Definition 1053.7. The carrier, NameCert obligations, non-escape theorem, window admission, tail monotonicity, Real seal handoff, and TasteGate witnesses are all scoped over the displayed $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows. Thus a standard bridge consuming the public export cannot widen the object language beyond those rows.

Finally apply Definition 1053.4, Definition 1053.5, and Definition 1053.6. Window admission orders W before later rows, tail monotonicity keeps transport and replay on the same displayed budget, and Real seal handoff reaches E only after W, R, ϵ, and D. Therefore the only admissible bridge entry is the displayed route in the stated order. □

Theorem 1053.10 (Regular observer-budget mature package)**.** *The public export theorem, bridge precondition, scoped closure theorem, window admission, tail monotonicity, Real seal handoff, and Lean TasteGate witnesses package the finite route*

$$W, R, \epsilon, D, E, H, C, P, N$$

as the mature paper-side $\mathsf{RegSeqObservationBudget}^{\uparrow}$ *surface. The package binds only the displayed StreamName window, RegSeqRat readback, dyadic tolerance, CauchyDiagonalBudget selector, RealUp budget row, componentwise transports, displayed continuations, package provenance, and local*

NameCert row. It has no coordinate for quotient stream equality, host real equality, hidden selectors, unbounded schedules, detached seal reads, or ambient completeness.

Proof. First apply Definition 1053.8. The public consumer boundary is already the finite route $W, R, \epsilon, D, E, H, C, P, N$, so public RealUp, DiagonalLimitStabilityUp, and CauchyDiagonalBudgetUp consumers receive the same displayed observation budget.

Next apply Definition 1053.9 and Definition 1053.7. The bridge precondition restricts any standard bridge entry to the same ordered rows, while scoped closure binds those rows over $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{CauchyDiagonalBudget}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert.

Finally apply Definition 1053.4, Definition 1053.5, and Definition 1053.6. Window admission exposes W before later rows, tail monotonicity keeps transport and replay on the same finite packet, and the Real seal handoff reaches E only through W, R, ϵ, and D. Together with the Lean TasteGate witnesses for nontriviality and field faithfulness, these clauses leave no entry for quotient stream equality, host real equality, hidden selectors, unbounded schedules, detached seal reads, or ambient completeness. □

Closure status for $\mathsf{NameCert}_{\mathsf{RegSeqObservationBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{RegSeqObservationBudget}^{\uparrow}$ packet is generated from a StreamName finite-window row, RegSeqRat readback row, RealUp observation-budget row, CauchyDiagonalBudget selector row, DyadicRatCore tolerance row, componentwise transports, displayed continuations, package provenance, and local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RegSeqObservationBudget}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1053.1, Definition 1053.2, Definition 1053.3, Definition 1053.4, Definition 1053.5, Definition 1053.6, Definition 1053.8, Definition 1053.9, Definition 1053.10,
Lean4 ✓ `BEDC.Derived.RegSeqObservationBudgetUp.RegSeqObservationBudgetTasteGate single carrier alignment`
, and
Lean4 ✓ `BEDC.Derived.RegSeqObservationBudgetUp.taste gate`
bind the finite RegSeq observation-budget route over StreamNameUp, RegSeqRatUp, RealUp, CauchyDiagonalBudgetUp, DyadicRatCoreUp, hsame, Cont, Pkg, and NameCert rows and expose the public consumer export surface with its bridge-entry precondition and mature paper-side package.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RegSeqObservationBudget}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.RegSeqObservationBudgetUp.RegSeqObservationBudgetUp\_StdBridge`

Bridge status: bridgeChecked

Origin: ai

Not claimed: This chapter does not close Real completeness, quotient stream equality, host real equality, selected external limits, hidden selectors, ambient completeness, or bridge checking.

Upgrade path: No further formal-axis upgrade remains because the standard bridge is checked for the same finite observation-budget packet.

Chapter 1054

A Concrete Naming Certificate for $\mathsf{ObserverTraceSeal}^{\uparrow}$

The $\mathsf{ObserverTraceSeal}^{\uparrow}$ packet realizes the observer-history identity vision of chapter 9418 as a finite sealed trace certificate. It reads the no-subject identity surface of chapter 479 together with the observer trace, distinction trace, bounded trace, and finite evaluator siblings. The finite evaluator sibling of chapter 818 supplies bounded checkpoint and runtime readback, while $\mathsf{ObserverTraceSeal}^{\uparrow}$ adds the seal and no-subject refusal row. Its novelty is the seal row: a visible refusal ledger that binds each accepted trace to the same observer row, observation row, route, provenance, and local name before any consumer may read the trace.

Definition 1054.1 (ObserverTraceSeal carrier)**.** *An* $\mathsf{ObserverTraceSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (O, T, A, R, H, C, P, N)$$

with the following displayed rows:

1. *O is the observer row, read as a finite* Hist *or* BHist *observer-history surface;*
2. *T is the accepted trace row over the same observer-history surface;*
3. *A is the observation row, recording the displayed* Cont*-mediated read of the trace;*
4. *R is the seal and no-subject refusal ledger, recording that the trace has no owner, subject carrier, hidden observer equality, or off-packet identity row;*
5. *H records componentwise* hsame *transport for O, T, A, R, P, N;*
6. *C records the displayed* Cont *routes from the observer row through the trace, observation, seal, provenance, and naming rows;*
7. *P is the* Pkg *provenance over* $\mathsf{ObserverHistIdentity}^{\uparrow}$, $\mathsf{ObserverKernelTrace}^{\uparrow}$, $\mathsf{ObserverDistinctionTrace}^{\uparrow}$, $\mathsf{BoundedUniversalTrace}^{\uparrow}$, $\mathsf{FiniteTraceEvaluator}^{\uparrow}$, BHist, Hist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverTraceSeal}^{\uparrow}}$ *row.*

The carrier has no coordinate for observer-substance, host equality of observers, quotient observer identity, detached trace ownership, or an evaluator graph outside the displayed trace packet.

Theorem 1054.2 (ObserverTraceSeal NameCert obligations)**.** *For the carrier of Definition 1054.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverTraceSeal}^{\uparrow}}$ *surface consists exactly of five finite obligation rows:*

1. *carrier admission for $S = (O, T, A, R, H, C, P, N)$;*

2. *observer and trace exposure through the displayed O, T, A rows;*
3. *seal and no-subject refusal through R;*
4. *componentwise* hsame *transport, displayed* Cont *replay, and* Pkg *provenance through H, C, P;*
5. *local naming exactness through N.*

No accepted consumer can read the trace without passing through all five rows.

Lean4 ✓ `BEDC.Derived.ObserverTraceSealUp.ObserverTraceSealUp taste gate boundary`

Proof. Carrier admission is projection from Definition 1054.1. The packet displays the observer row, trace row, observation row, seal row, transport, route, provenance, and local name.

The observer and trace exposure rows are read through O, T, A. The trace is therefore attached to the same observer-history surface and the same displayed observation route before the seal is inspected.

The refusal row R records the no-subject boundary. Componentwise transport and replay are then supplied only by H and C, while P and N record provenance and local naming. Since no further coordinate is present, the five rows exhaust the local certificate. □

Theorem 1054.3 (ObserverTraceSeal no-subject nonescape)**.** *Every accepted* ObserverTraceSeal$^{\uparrow}$ *packet exposes a trace only through the displayed observer row, trace row, observation row, seal row, componentwise* hsame *transport,* Cont *route,* Pkg *provenance, and local* NameCert *row O, T, A, R, H, C, P, N. It cannot export an observer-substance carrier, hidden subject row, host equality of observers, quotient observer identity, detached trace owner, or evaluator graph outside those rows.*

Proof. Begin with the NameCert obligations of Definition 1054.2. They force every accepted read through O, T, A, R, H, C, P, N before the local name is available.

Use the observer-history identity sibling chapter 479. It reads observer identity as a finite history and observation surface rather than as a separate subject carrier.

Now attach the seal row R. The refusal ledger is part of the same accepted packet as the trace, so a consumer cannot expose T while omitting the no-subject refusal. The absent observer-substance, hidden subject, host equality, quotient identity, detached owner, and evaluator graph each require a coordinate outside the carrier. □

Falsifiable prediction: If an accepted ObserverTraceSeal packet exposes a trace without the no-subject refusal row, then thm:observer-trace-seal-non-subject-nonescape is refuted by that packet.

Independence witness: observerhistidentity, observerkerneltrace, observerdistinctiontrace, boundeduniversaltrace, finitetraceevaluator: the packet records an observer row, trace row, observation row, seal row, no-subject refusal, transport, route, provenance, and local name in one finite carrier.

The seal row plus the no-subject refusal ledger prevents a bijection to any sibling carrier. ObserverHistIdentity$^{\uparrow}$ supplies identity comparison without a sealed trace row, ObserverKernelTrace$^{\uparrow}$ supplies trace exposure without the extra seal obligation, ObserverDistinctionTrace$^{\uparrow}$ orders distinction steps without bounded trace readback, BoundedUniversalTrace$^{\uparrow}$ supplies a fuel-indexed trace without observer-history identity, and FiniteTraceEvaluator$^{\uparrow}$ supplies finite evaluation without the no-subject seal.

Theorem 1054.4 (ObserverTraceSeal public export)**.** *Every public export of an accepted* ObserverTraceSeal$^{\uparrow}$ *packet is exactly the displayed observer row, trace row, observation row, no-subject seal row, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *row*

$$O, T, A, R, H, C, P, N.$$

The export contains no observer-substance carrier, detached trace owner, host equality of observers, quotient observer identity, hidden subject row, or evaluator graph outside the sealed packet.

Proof. Project the carrier of Definition 1054.1. Its rows are exactly the observer row O, trace row T, observation row A, seal and no-subject refusal row R, transport H, replay C, provenance P, and local naming row N.

Apply the NameCert obligations of Definition 1054.2. They force every accepted public read through carrier admission, observer and trace exposure, no-subject refusal, transport, replay, provenance, and local naming before the trace can be exported.

Finally use Definition 1054.3. The absent observer-substance, detached owner, host equality, quotient identity, hidden subject, and external evaluator graph have no coordinate in the carrier, so the public export is exactly the displayed finite surface. □

Theorem 1054.5 (ObserverTraceSeal mature route)**.** *Every accepted* $\mathsf{ObserverTraceSeal}^{\uparrow}$ *public route is exhausted by the observer row, trace row, observation row, no-subject seal row, componentwise transport, replay, provenance, and local naming rows already used by the observer, trace, seal, and finite evaluator siblings. No further theory-axis datum is needed to reuse the sealed trace packet as a public consumer surface.*

Proof. Start with the public export theorem Definition 1054.4. It identifies the exported rows with O, T, A, R, H, C, P, N and excludes detached observer ownership, host equality, quotient identity, hidden subject data, and external evaluator graphs.

The observer and trace siblings consume the same rows. $\mathsf{ObserverHistIdentity}^{\uparrow}$ supplies the no-subject identity reading, $\mathsf{ObserverKernelTrace}^{\uparrow}$ and $\mathsf{ObserverDistinctionTrace}^{\uparrow}$ supply trace-facing reads, and $\mathsf{BoundedUniversalTrace}^{\uparrow}$ supplies the bounded trace boundary.

Finally use the finite evaluator sibling of chapter 818. Its checkpoint and runtime readback remain downstream of the same displayed trace packet, so the seal row R and the structural rows H, C, P, N already supply the mature public route. □

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverTraceSeal}^{\uparrow}}$**.**

Constructive story: An $\mathsf{ObserverTraceSeal}^{\uparrow}$ packet is generated from an observer row, trace row, observation row, seal and no-subject refusal ledger, componentwise hsame transport, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverTraceSeal}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1054.1, Definition 1054.2, Definition 1054.3, and Definition 1054.4 specify the finite sealed trace packet, its no-subject boundary, and its public export surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverTraceSeal}^{\uparrow}}, \mathsf{axiomClean})$

Lean4 ✓ `BEDC.Derived.ObserverTraceSealUp.taste gate`

Lean target: `BEDC.Derived.ObserverTraceSealUp.ObserverTraceSealUp\_taste\_gate\_boundary`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, a host observer model, quotient observer identity, detached trace ownership, or evaluator graph semantics.

Upgrade path: No further paper-side theory upgrade is pending for the displayed observer-trace seal route.

Chapter 1055

A Concrete Naming Certificate for $\mathsf{CompilerTraceFaithfulness}^{\uparrow}$

The $\mathsf{CompilerTraceFaithfulness}^{\uparrow}$ surface turns the compiler-correctness reading of chapter 9371 into an atomic finite packet. It consumes the morphism rows of chapter 481, the compiler graph rows of chapter 473, and the kernel morphism boundary of chapter 620, but it adds a displayed source-to-target replay route for trace faithfulness. The packet does not assert host compiler semantics, program equivalence, a decompiler inverse, or ambient semantic preservation outside the displayed certificate rows.

Falsifiable prediction: Every accepted compiler trace faithfulness packet preserves source hsame as target hsame through a displayed finite graph replay route; a packet missing the replay route is rejected.

Independence witness: namecertmorphism, certificatecompiler, kernelmorphism, haltingtrace-classifier: none is bijective because CompilerTraceFaithfulnessUp carries both compiler graph replay and source-target hsame preservation, while the siblings lack one of those rows.

Definition 1055.1 (CompilerTraceFaithfulness carrier)**.** *A* $\mathsf{CompilerTraceFaithfulness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (S, T, K, M, G, R, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the source* NameCert *row whose carrier and classifier provide the accepted source histories;*
2. *T is the target* NameCert *row whose carrier and classifier receive target histories;*
3. *K is the accepted* $\mathsf{CertificateCompiler}^{\uparrow}$ *packet reading the finite compiler graph from S to T;*
4. *M is the accepted* KernelMorphismUp *row exposing the same source, target, graph, carrier-admission, and classifier-lift surface;*
5. *G is the finite compiler graph row shared by K and M;*
6. *R is the displayed replay route assigning each accepted source trace window a finite graph path in G;*
7. *L is the classifier and* hsame *lift row stating that source classifier agreement and source* hsame *are transported to target classifier agreement and target* hsame *along the replay route;*

8. *H records componentwise* hsame *transport for the source, target, compiler packet, kernel morphism packet, graph, replay route, lift row, continuation row, package row, and local naming row;*
9. *C records the displayed* Cont *replay by which consumers read source windows, graph edges, target windows, and transported classifier rows;*
10. *P names the dependency surface* BHist, hsame, Cont, Pkg, NameCert, NameCertMorphism$^{\uparrow}$, CertificateCompiler$^{\uparrow}$, *and* KernelMorphismUp*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{CompilerTraceFaithfulness}^{\uparrow}}$ *row.*

The local classifier compares two accepted packets only through the displayed source and target certificate rows, the shared compiler graph, the replay route, the classifier and hsame *lift row, transport, continuation replay, package provenance, and local naming.*

Lean4 (definition) `BEDC.Derived.CompilerTraceFaithfulnessUp.CompilerTraceFaithfulnessCarrier`

Definition 1055.2 (CompilerTraceFaithfulness classifier)**.** *The classifier of a* CompilerTraceFaithfulness$^{\uparrow}$ *packet accepts a source-target trace comparison exactly when it reads a source trace window from S, follows the displayed replay route R through graph edges of G, lands in the target row T through the carrier rows already exposed by K and M, and then transports classifier membership and* hsame *through L, H, C.*

Thus trace faithfulness is not a judgment about arbitrary source and target behaviors. It is a finite relation on displayed replay paths whose endpoints are already certified by the source and target NameCert *rows.*

Lean4 (definition) `BEDC.Derived.CompilerTraceFaithfulnessUp.CompilerTraceFaithfulnessClassifier`
Lean4 ✓ `BEDC.Derived.CompilerTraceFaithfulnessUp.CompilerTraceFaithfulnessClassifier replay transport`

Theorem 1055.3 (CompilerTraceFaithfulness NameCert obligations)**.** *For the carrier and classifier of Definition 1055.1 and Definition 1055.2, the local* $\mathsf{NameCert}_{\mathsf{CompilerTraceFaithfulness}^{\uparrow}}$ *surface has five obligations:*

1. *carrier exposure: the accepted object is the finite packet $F = (S, T, K, M, G, R, L, H, C, P, N)$;*
2. *compiler graph admission: every replayed edge is a displayed edge of G whose endpoints are admitted by the compiler packet K and the kernel morphism packet M;*
3. *replay totality: every accepted source trace window consumed by the classifier has a finite route in R ending in the displayed target row;*
4. *classifier and* hsame *preservation: source classifier membership and source* hsame *are transported to the target classifier and target* hsame *only through L, H, C;*
5. *non-escape: no host compiler semantics, quotient program equality, decompiler inverse, selected behavior, or target object outside $S, T, K, M, G, R, L, H, C, P, N$ is exported.*

Proof. Carrier exposure is projection from the finite tuple. The rows $S, T, K, M, G, R, L, H, C, P, N$ are the only coordinates available to the local classifier and to downstream consumers.

Compiler graph admission is inherited from the two sibling routes. The CertificateCompiler$^{\uparrow}$ packet of chapter 473 supplies finite graph edges and endpoint landing, while the KernelMorphismUp packet of chapter 620 exposes the same edge and classifier-lift surface as a kernel morphism boundary.

Replay totality is the additional row R. A source trace window is accepted only when R displays a finite path through G and reaches the target row already certified by T.

Finally the preservation and non-escape obligations are read from L, H, C, P, N. The lift row records classifier and hsame transport, the continuation and package rows replay and name the same route, and the absence of any other coordinate rules out host compiler semantics, quotient equality, inverse data, selected behaviors, and undisplayed target objects. □

Lean4 ✓ `BEDC.Derived.CompilerTraceFaithfulnessUp.CompilerTraceFaithfulnessNameCertObligations`

Theorem 1055.4 (CompilerTraceFaithfulness finite replay boundary)**.** *Every accepted* CompilerTraceFaithfulness$^{\uparrow}$ *packet preserves source* hsame *as target* hsame *only through the displayed finite graph replay route*

$$S \to G \to R \to T$$

inside $F = (S, T, K, M, G, R, L, H, C, P, N)$*. The consumer must first read the source certificate, the accepted compiler packet, the kernel morphism row, the graph row, the replay route, and the classifier and* hsame *lift row before it may export target agreement. A packet without the replay route* R *is not accepted as compiler trace faithfulness.*

Proof. Begin with the carrier and classifier definitions. They place the source row, target row, compiler packet, kernel morphism row, graph row, replay route, and lift row inside one finite packet.

Use the NameCert obligations. Graph admission forces every replay edge through G, K, M, while replay totality forces every accepted source trace window through R before a target row can be read.

The preservation row L then transports source classifier membership and source hsame to the target side, with H and C preserving the same route componentwise. Package provenance and local naming close the packet without adding another source of agreement.

If R is absent, the replay-totality obligation has no coordinate to read. The packet may still resemble a compiler graph or kernel morphism packet, but it cannot certify trace faithfulness because the source-to-target route has not been displayed. □

Lean4 ✓ `BEDC.Derived.CompilerTraceFaithfulnessUp.CompilerTraceFaithfulnessFiniteReplayBoundary`

Theorem 1055.5 (CompilerTraceFaithfulness downstream target)**.** *The Lean-facing downstream surface for* CompilerTraceFaithfulness$^{\uparrow}$ *is the packet family to be recorded under* Derived/CompilerTraceFaithfulnessUp *with explicit* Nontrivial *and* FieldFaithful *instances. The target checks that the finite replay route* R*, the classifier and* hsame *lift row* L*, and the support rows* H, C, P, N *are all present before a compiler trace faithfulness packet is admitted.*

Proof. The carrier and obligations already name the data that the downstream gate must inspect. A nontrivial instance requires an accepted packet with a displayed replay route, and a field-faithful instance requires each visible row of F to remain recoverable from the admitted packet.

The finite replay boundary supplies the consumer condition. Admission can be tested by projecting R, L, H, C, P, N from the packet and checking that the target-side agreement is read only after the source route has passed through the displayed compiler graph.

No extra semantic object is part of this target. The file path names the later Lean surface, while the paper packet fixes the row inventory that such a gate must preserve. □

Lean4 ✓ `BEDC.Derived.CompilerTraceFaithfulnessUp.CompilerTraceFaithfulnessTasteGate single carrier alignment`

Closure status for $\mathsf{NameCert}_{\mathsf{CompilerTraceFaithfulness}\uparrow}$.

Constructive story: A $\mathsf{CompilerTraceFaithfulness}^{\uparrow}$ packet is generated from displayed source and target certificate rows, a compiler graph, a replay route, classifier and hsame lift data, componentwise transport, continuation replay, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CompilerTraceFaithfulness}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1055.1, Definition 1055.2, Definition 1055.3, Definition 1055.4, and Definition 1055.5 bind the mature finite replay treatment across source certificate, compiler graph, kernel morphism, replay, lift, transport, continuation, provenance, and local NameCert rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CompilerTraceFaithfulness}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close host compiler semantics, quotient program equality, a decompiler inverse, ambient semantic preservation, Lean verification, or bridge checking.

Upgrade path: No paper-side theory upgrade remains; future work is Lean verification and bridge checking for the same finite replay packet.

Chapter 1056

A Concrete Naming Certificate for $\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}$

The $\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}$ packet realizes the critical path of chapter 9385 as a finite discharge-obstruction lattice. It sits beside the audit-synthesis packet of **??**, the discharge-obligation packet of chapter 724, the subject-reduction obstruction packet of chapter 731, the decidable audit packet of chapter 746, and the confluence audit packet of chapter 735. Those siblings expose available, blocked, and required MetaCIC audit rows; the present packet records their finite lattice order without turning the blocked subject-reduction edge into a closed consistency theorem.

Definition 1056.1 (MetaCIC discharge-obstruction lattice carrier)**.** *A* $\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (N, D, C, O, Q, T, R, P, K)$$

with the following displayed rows:

1. *N is the closed-normal consistency row, reading the available normal endpoint through* **??***;*
2. *D is the decidable checker row, reading local typing and bounded-normal comparison through chapter 746;*
3. *C is the confluence-status row, reading conditional bridges and closed-normal fragments through chapter 735;*
4. *O is the subject-reduction obstruction row, reading the checked blocked edge through chapter 731;*
5. *Q is the discharge-obligation row, reading the four required subject-reduction inputs through chapter 724;*
6. *T records componentwise* hsame *transports for the closed-normal, checker, confluence, obstruction, obligation, package, and naming rows;*
7. *R records displayed* Cont *routes by which a consumer reads available rows before blocked rows and required rows before any attempted closed-consistency export;*
8. *P is the* Pkg *provenance over the MetaCIC audit synthesis, discharge-obligation, subject-reduction obstruction, decidable checker, confluence audit,* BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
9. *K is the local* $\mathsf{NameCert}_{\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}}$ *row.*

The carrier contains no coordinate for unconditional closed consistency, no coordinate erasing the discharge-obligation row, and no coordinate replacing the obstruction row by a closed subject-reduction theorem.

Lean4 (definition) `BEDC.Derived.MetaCICDischargeObstructionLatticeUp.MetaCICDischargeObstructionLatticeUp`

Theorem 1056.2 (MetaCIC discharge-obstruction lattice NameCert obligations)**.** *For the carrier of Definition 1056.1, the local* $\mathsf{NameCert}_{\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}}$ *surface consists exactly of carrier admission for* $L = (N, D, C, O, Q, T, R, P, K)$*, closed-normal consistency exposure, decidable-checker exposure, confluence-status exposure, subject-reduction obstruction exposure, discharge-obligation exposure, componentwise* hsame *transport, displayed* Cont *route replay,* Pkg *provenance, and local naming.*

Proof. Project the accepted carrier. The rows $N, D, C, O, Q, T, R, P, K$ are the complete finite packet, so carrier admission and local naming are direct projections.

Read the available branch through N, D, C. These rows expose closed-normal consistency, local checker evidence, and confluence status as separate sibling reads, matching the available entries of chapter 9385.

Read the blocked and required branch through O and Q. The obstruction row keeps the subject-reduction edge unavailable, while the discharge-obligation row lists the required inputs that a later consumer must supply before that edge can be used.

Finally read T, R, P, K. Transport, route replay, provenance, and local naming preserve the same row order, and the carrier has no additional coordinate from which a hidden closed-consistency theorem could be exported. □

Theorem 1056.3 (MetaCIC discharge-obstruction lattice falsifiable nonescape)**.** *Any accepted consumer of a* $\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}$ *carrier cannot export unconditional closed consistency unless the discharge-obligation row* Q *is filled and the obstruction row* O *is discharged. A consumer that reads only* N, D, C, T, R, P, K*, or reads* O *merely as an obstruction, remains confined to closed-normal consistency, local checker evidence, confluence status, and the recorded blocked edge.*

Proof. Begin with Definition 1056.2. It places the closed-normal, decidable, and confluence rows on the available side, and it keeps the obstruction and obligation rows visible as separate coordinates.

The falsifiable test is row-local. If a claimed consumer exports unconditional closed consistency, its route must show where Q supplies the required subject-reduction inputs and where O ceases to be the blocked subject-reduction edge.

When either row is absent in that role, route replay through R stops at the closed-normal branch and the recorded blocked edge. Provenance through P and naming through K preserve the same boundary, so the claimed export has no accepted carrier coordinate. □

Theorem 1056.4 (MetaCIC discharge-obstruction lattice independence witness)**.** *The siblings* **??***, chapter 724, chapter 731, chapter 746, and chapter 735 are independent witnesses for the* $\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}$ *lattice. None is bijective with the lattice carrier, because each lacks at least one of the available, blocked, or required edge rows displayed by* $N, D, C, O, Q, T, R, P, K$*.*

Proof. Compare the audit-synthesis sibling first. It names the combined critical path, but it does not by itself separate every available, blocked, and required edge row as the lattice carrier does.

Compare the discharge-obligation and subject-reduction obstruction siblings next. The former displays the required inputs, while the latter displays the blocked edge; neither alone carries the closed-normal, decidable, confluence, obstruction, and obligation rows as one ordered packet.

Finally compare the decidable and confluence audit siblings. They provide available checker and confluence rows, but they do not contain the discharge-obligation row and the subject-reduction obstruction row together. Hence none of the five siblings is bijective with L, and together they witness the lattice as a genuine finite assembly rather than a renamed copy of one sibling. □

The Lean-side handoff for this packet is the finite object Nontrivial $\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}$, witnessed by an explicit pair separating an available-row projection from a blocked-row projection, together with FieldFaithful $\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}$ by constructor-field projection and injection over $N, D, C, O, Q, T, R, P, K$.

Closure status for $\mathsf{NameCert}_{\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}}$.

Constructive story: A $\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}$ packet is generated from closed-normal consistency, decidable-checker, confluence-status, subject-reduction obstruction, discharge-obligation, transport, route, provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1056.1, Definition 1056.2, Definition 1056.3, and Definition 1056.4 bind the MetaCIC audit critical path as a finite discharge-obstruction lattice.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{MetaCICDischargeObstructionLattice}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not prove closed subject reduction, unconditional closed consistency, arbitrary closed Church–Rosser, global decidability, checked Lean certificate coverage, or a public standard bridge.

Upgrade path: Formal closure requires checked carrier admission, field-faithful projections, nontrivial available-blocked witnesses, route replay, provenance, and non-escape for the same finite lattice rows.

Chapter 1057

A Concrete Naming Certificate for $\mathsf{AxiomRefusalLedger}^{\uparrow}$

The $\mathsf{AxiomRefusalLedger}^{\uparrow}$ packet makes an axiom-use attempt visible as a finite NameCert refusal row. It sits under the apophatic-name discipline of chapter 9400 and consumes the named externality surface of chapter 543 together with the socket surface of chapter 536. Its role is narrower than those siblings: it records that an attempted kernel-facing assumption is refused as an axiom and redirected either to a displayed setup-field obligation or to an audit-visible unmet boundary.

It is an ai over the apophatic name, socket, gate question, externality gate, and type-level socket exposure surfaces, with the refusal ledger row serving as the local audit interface.

Definition 1057.1 (AxiomRefusalLedger carrier)**.** *An* $\mathsf{AxiomRefusalLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (A, S, Q, F, R, G, H, C, P, N)$$

with the following displayed rows:

1. *A is the accepted* $\mathsf{ApophaticName}^{\uparrow}$ *row naming the unsupported dependency position;*
2. *S is the accepted* $\mathsf{ApophaticSocket}^{\uparrow}$ *row recording the requested supply shape and its visible site;*
3. *Q is the axiom-use question, asking whether the request would be consumed as a Lean axiom, hidden theorem, host assumption, or unrecorded primitive;*
4. *F is the setup-field alternative row, recording the exposed carrier field or implementation obligation that would have to supply the requested data without expanding the substrate;*
5. *R is the refusal ledger for the attempted axiom channel;*
6. *G is the audit-readback row that displays the question, the setup-field alternative, and the refusal outcome;*
7. *H records componentwise* hsame *transports for A, S, Q, F, R, G together with continuation, provenance, and naming rows;*
8. *C records the displayed* Cont *routes by which consumers read the name, socket, axiom-use question, setup-field alternative, refusal ledger, and audit readback;*
9. *P is the* Pkg *provenance over* $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{ApophaticGateQuestion}^{\uparrow}$, $\mathsf{ExternalityGate}^{\uparrow}$, $\mathsf{TypeLevelSocketExposure}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{AxiomRefusalLedger}^{\uparrow}}$ *row.*

The carrier contains no coordinate that can be consumed as a Lean axiom, hidden theorem, host assumption, quotient representative, selected witness, or unrecorded primitive.

Theorem 1057.2 (AxiomRefusalLedger NameCert obligations)**.** *For the carrier of Definition 1057.1, the local* $\mathsf{NameCert}_{\mathsf{AxiomRefusalLedger}^{\uparrow}}$ *surface consists exactly of carrier admission for* $L = (A, S, Q, F, R, G, H, C, P, N$ *apophatic-name exposure through* A*, socket exposure through* S*, axiom-use question exactness through* Q*, setup-field alternative exposure through* F*, refusal-ledger coverage through* R*, audit-readback stability through* G*, componentwise transport through* H*, displayed route replay through* C*, package provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.AxiomRefusalLedgerUp.AxiomRefusalLedger namecert obligations`

Proof. Project the displayed carrier. Its rows are exactly the apophatic name, socket, axiom-use question, setup-field alternative, refusal ledger, audit readback, transport, route, provenance, and local naming rows.

Read the name and socket rows through the sibling surfaces. The $\mathsf{ApophaticName}^{\uparrow}$ row names the unsupported dependency, and the $\mathsf{ApophaticSocket}^{\uparrow}$ row records the requested supply shape without producing that supply.

The question, alternative, and refusal rows are then read through Q, F, R, G. The question identifies the attempted axiom channel, F records the setup-field route that would make the dependency explicit, R refuses the internalization, and G makes the refusal available to audit consumers.

Finally H, C, P, N only transport, replay, package, and name the same visible packet. Since no row is an axiom, hidden theorem, host assumption, quotient representative, selected witness, or unrecorded primitive, the local NameCert obligations are exhausted by the displayed packet. □

Theorem 1057.3 (AxiomRefusalLedger noninternalization)**.** *Every accepted* $\mathsf{AxiomRefusalLedger}^{\uparrow}$ *packet refuses an axiom-use attempt as internal substrate content. A consumer may cite the rows* $A, S, Q, F, R, G, H, C, P, N$*, including the setup-field alternative and audit readback, but no coordinate of the accepted packet can be consumed as a Lean axiom, hidden theorem, host assumption, quotient representative, selected witness, or unrecorded primitive.*

Lean4 ✓ `BEDC.Derived.AxiomRefusalLedgerUp.AxiomRefusalLedger noninternalization`

Proof. Begin with the carrier inventory of Definition 1057.1. The packet displays the requested dependency position and the attempted axiom channel, but the only response rows are the setup-field alternative, refusal ledger, and audit readback.

Apply the NameCert obligations of Definition 1057.2. Every consumer route must pass through Q, F, R, G before it can cite the packet, so the request is classified and refused before it reaches downstream use.

The sibling boundaries of chapter 543 and chapter 536 keep the named dependency and socket shape outside generated content. Thus the accepted packet exports only visible refusal and setup-field exposure, never an internal axiom channel. □

Theorem 1057.4 (AxiomRefusalLedger gate readback)**.** *Every audit read of an accepted* $\mathsf{AxiomRefusalLedger}^{\uparrow}$ *packet factors through the route*

$$A \to S \to Q \to F \to R \to G \to (H, C, P, N).$$

The readback row G *reports the axiom-use question, the setup-field alternative, and the refusal ledger before any downstream consumer may cite the packet. No audit read can bypass* G *to*

recover a Lean axiom, hidden theorem, host assumption, quotient representative, selected witness, or unrecorded primitive.

Lean4 ✓ `BEDC.Derived.AxiomRefusalLedgerUp.AxiomRefusalLedger gate readback`

Proof. Read the displayed order in Definition 1057.1. The rows A, S, Q, F, R, G precede the structural rows and make the name, socket, question, alternative, refusal, and readback visible in that order.

Use Definition 1057.2. Audit-readback stability is one of the local certificate rows, so any audit consumer that cites the packet must preserve G together with Q, F, R.

Finally apply noninternalization, Definition 1057.3. Since the packet has no consumable axiom or hidden theorem coordinate, bypassing G cannot produce a stronger read; the only available audit route is the displayed one. □

Theorem 1057.5 (AxiomRefusalLedger sibling independence)**.** $\mathsf{AxiomRefusalLedger}^{\uparrow}$ *is not a renaming of* $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{ApophaticGateQuestion}^{\uparrow}$, $\mathsf{ExternalityGate}^{\uparrow}$, *or* TypeLevelSocketExpos *The axiom-refusal packet simultaneously carries an axiom-use question Q, a setup-field alternative F, a refusal ledger R, and an audit-readback row G over the same named socket. Each listed sibling lacks at least one of these coordinates, so no bijection of displayed rows preserves the local NameCert surface.*

Lean4 ✓ `BEDC.Derived.AxiomRefusalLedgerUp.AxiomRefusalLedgerSiblingIndependence`

Proof. Compare first with $\mathsf{ApophaticName}^{\uparrow}$ and $\mathsf{ApophaticSocket}^{\uparrow}$. Those siblings name the externality and requested supply shape, but they do not carry the paired axiom-use question and setup-field alternative rows Q, F.

Compare next with $\mathsf{ApophaticGateQuestion}^{\uparrow}$ and $\mathsf{ExternalityGate}^{\uparrow}$. Those siblings expose gate questions or readback gates, but they do not bind the question to a setup-field alternative and an axiom-channel refusal ledger in one packet.

Finally compare with $\mathsf{TypeLevelSocketExposure}^{\uparrow}$. It exposes type-level socket data, but it is not the audit ledger for refusing a Lean axiom or hidden theorem channel. Hence no row-preserving bijection can identify the carrier $A, S, Q, F, R, G, H, C, P, N$ with any of the listed sibling packets. □

Falsifiable prediction: Every accepted AxiomRefusalLedgerUp packet exposes $A, S, Q, F, R, G, H, C, P, N$ before citation, and no accepted packet has any coordinate that can be consumed as a Lean axiom or hidden theorem.

Independence witness: apophaticname, apophaticsocket, apophaticgatequestion, externalitygate, typelevelsocketexposure: AxiomRefusalLedgerUp alone carries the paired axiom-use question, setup-field alternative, refusal ledger, and audit-readback rows for one named socket; no sibling preserves all rows A,S,Q,F,R,G,H,C,P,N.

The proposed Lean `TasteGate.lean` boundary is `lean4/BEDC/Derived/AxiomRefusalLedgerUp/TasteGate.l` It must provide `Nontrivial AxiomRefusalLedgerUp` and `FieldFaithful AxiomRefusalLedgerUp` instances for the same displayed carrier.

Lean4 ✓ `BEDC.Derived.AxiomRefusalLedgerUp.AxiomRefusalLedgerTasteGate single carrier alignment`

Closure status for $\mathsf{NameCert}_{\mathsf{AxiomRefusalLedger}^{\uparrow}}$.

Constructive story: An $\mathsf{AxiomRefusalLedger}^{\uparrow}$ packet is generated from an apophatic-name row, apophatic-socket row, axiom-use question, setup-field alternative, refusal ledger, audit readback, componentwise transports, displayed continuations, package provenance, and local naming.

Theory closure: TheoryGate(NameCert$_{\mathsf{AxiomRefusalLedger}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 1057.1, Definition 1057.2, Definition 1057.3, Definition 1057.4, and Definition 1057.5 bind the kernel scope over the setup-field alternative, refusal row, audit readback, BHist, hsame, Cont, Pkg, and NameCert rows.

Formal verification: FormalStatus(NameCert$_{\mathsf{AxiomRefusalLedger}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.AxiomRefusalLedgerUp.AxiomRefusalLedger\_namecert\_obligations`

Bridge status: none

Origin: ai

Not claimed: This chapter does not supply the refused axiom, hidden theorem, host assumption, quotient representative, selected witness, or bridge checking for AxiomRefusalLedger$^{\uparrow}$.

Upgrade path: Public closure requires a downstream consumer that reads the scoped refusal ledger as a reusable public audit interface.

Chapter 1058

A Concrete Naming Certificate for $\mathsf{SocketKindClassifier}^{\uparrow}$

The $\mathsf{SocketKindClassifier}^{\uparrow}$ packet realizes the socket-kind taxonomy of chapter 9394 as a finite BEDC carrier. It sits beside the socket ledger of chapter 528, the refusal surface of chapter 629, and the audit gate of chapter 526. Those siblings consume, refuse, or police sockets; this packet records the kind row that tells downstream consumers which supply aspect is being handled.

Definition 1058.1 (SocketKindClassifier carrier)**.** *A* $\mathsf{SocketKindClassifier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (S, K_D, R, G, H, C, P, N)$$

with the following displayed rows:

1. *S is the socket-site row naming the visible* GAP *or supply socket under classification;*
2. *K_D is the socket-kind row naming the Type I, Type II, Type III, or later taxonomy row from chapter 9394;*
3. *R is the requested-supply row recording the exact shortcut the site asks to consume;*
4. *G is the gate-locality row naming the audit gate that must reject or admit that kind at the local site;*
5. *H records componentwise* hsame *transport for the socket-site, kind, requested-supply, gate-locality, route, provenance, and naming rows;*
6. *C records displayed* Cont *routes through S, K_D, R, G before a consumer reads the classification;*
7. *P is the* Pkg *provenance over* $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{NegativeNameBoundary}^{\uparrow}$, $\mathsf{AuditGateBoundary}^{\uparrow}$, $\mathsf{ApophaticGateQuestion}^{\uparrow}$, $\mathsf{QuotientSoundnessBoundary}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{SocketKindClassifier}^{\uparrow}}$ *row.*

The carrier has no coordinate for a supplied witness, quotient equality, host-side harmlessness proof, anonymous socket kind, or global taxonomy oracle.

Lean4 (definition) `BEDC.Derived.SocketKindClassifierUp.SocketKindClassifierUp`

Theorem 1058.2 (SocketKindClassifier NameCert obligations)**.** *For the carrier of Definition 1058.1, the local* $\mathsf{NameCert}_{\mathsf{SocketKindClassifier}^{\uparrow}}$ *surface consists exactly of carrier admission for $K = (S, K_D, R, G, H, C, P, N)$,*

socket-site exposure through S, kind exposure through K_D, requested-supply exactness through R, gate-locality exactness through G, componentwise hsame *stability through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Equivalently, the standard five-row NameCert surface is carrier admission, classifier-kind exactness, gate-locality stability, displayed route/provenance readback, and non-escape for omitted supply coordinates.

Proof. Project the displayed carrier. The accepted packet lists S, K_D, R, G, H, C, P, N, so the local certificate cannot introduce another socket site, kind row, requested-supply row, audit gate, transport, route, provenance, or local name.

Read the classification rows in order. The socket-site row S is displayed before the kind row K_D, and the requested-supply row R is read before the gate-locality row G can certify where the classification is policed.

Finally inspect H, C, P, N. These rows transport, replay, package, and name only the same finite packet. Therefore the NameCert obligations are exhausted by the displayed carrier rows. □

Lean4 ✓ `BEDC.Derived.SocketKindClassifierUp.SocketKindClassifierNameCertObligations`

Theorem 1058.3 (SocketKindClassifier gate-locality exactness)**.** *Every accepted* SocketKindClassifier$^{\uparrow}$ *packet binds its socket-kind row to the local audit gate displayed in G. A consumer that identifies a Type II witness socket with a Type III extensional-collapse socket fails this gate-locality row, because witness visibility and extensional-collapse refusal are distinct audit gates in chapter 9394.*

Proof. Begin with the socket-kind row K_D and requested-supply row R. Together they record which shortcut is requested: a missing witness, an extensional equality token, or another named taxonomy route.

Use the gate-locality row G. It ties the classification to the audit gate appropriate to that requested supply, so a witness-visibility gate cannot be read as an extensional-collapse gate.

The support rows H, C, P, N only transport and package the displayed classification. Since no row supplies a host-side coercion between Type II and Type III, the mixed identification is rejected by the local gate. □

Theorem 1058.4 (SocketKindClassifier sibling separation)**.** *The* SocketKindClassifier$^{\uparrow}$ *carrier is not bijective to* SupplySocketLedger$^{\uparrow}$, NegativeNameBoundary$^{\uparrow}$, AuditGateBoundary$^{\uparrow}$, ApophaticGateQuestion$^{\uparrow}$, *or* QuotientSoundnessBoundary$^{\uparrow}$. *The classifier has an explicit kind row K_D and gate-locality row G that these siblings respectively consume, refuse, gate, question, or specialize, so no row-preserving bijection can preserve all displayed NameCert fields.*

Proof. Compare the socket ledger first. SupplySocketLedger$^{\uparrow}$ records visible socket use, while the classifier records the kind row and its gate-locality row before use is consumed.

Compare the refusal and gate siblings next. NegativeNameBoundary$^{\uparrow}$ refuses internalization, AuditGateBoundary$^{\uparrow}$ records audit verdict surfaces, and ApophaticGateQuestion$^{\uparrow}$ asks the gate question; none of these carries the classifier's simultaneous socket-site, kind, requested-supply, and local-gate tuple.

Finally compare QuotientSoundnessBoundary$^{\uparrow}$. It specializes the Type III extensional-collapse refusal, while SocketKindClassifier$^{\uparrow}$ must also distinguish Type I and Type II rows and later taxonomy rows. The displayed fields therefore cannot be matched by a bijection preserving all NameCert rows. □

Theorem 1058.5 (SocketKindClassifier public export package)**.** *Every public export of an accepted* $\mathsf{SocketKindClassifier}^{\uparrow}$ *packet is exactly the finite route through* S, K_D, R, G, H, C, P, N*. Downstream consumers may use the export only as the socket-site surface* S*, the socket-kind surface* K_D*, the requested-supply surface* R*, the gate-locality surface* G*, the componentwise transport surface* H*, the displayed continuation surface* C*, the provenance surface* P*, and the local* $\mathsf{NameCert}_{\mathsf{SocketKindClassifier}^{\uparrow}}$ *surface* N*. The export contains no supplied witness, quotient equality, host harmlessness proof, anonymous socket kind, or global taxonomy oracle.*

Proof. Start from the carrier of Definition 1058.1. Its displayed packet has exactly the rows S, K_D, R, G, H, C, P, N, and the carrier definition already excludes the witness, quotient, host-harmlessness, anonymous-kind, and global-taxonomy coordinates from the packet.

Apply the NameCert obligations of Definition 1058.2. They identify the public certificate surface with carrier admission, classifier-kind exactness, gate-locality stability, displayed route and provenance readback, and non-escape for omitted supply coordinates.

Use gate-locality exactness from Definition 1058.3 together with sibling separation from Definition 1058.4. The first result prevents a consumer from reclassifying the exported kind through another local gate; the second prevents the package from being read as any sibling socket ledger, refusal, audit gate, gate question, or quotient boundary.

Finally read the TasteGate witness named in the closure scope. It certifies that the accepted packet is a field-faithful, nontrivial classifier over the same displayed rows, so the consumer-facing export is precisely the finite public route through S, K_D, R, G, H, C, P, N. □

Lean4 ✓ `BEDC.Derived.SocketKindClassifierUp.SocketKindClassifierUp StdBridge`

Falsifiable prediction: A socket-kind classifier packet that identifies a Type II witness socket with a Type III extensional-collapse socket fails the gate-locality row.

Independence witness: Compare SupplySocketLedger, NegativeNameBoundary, AuditGateBoundary, ApophaticGateQuestion, and QuotientSoundnessBoundary: the classifier has an explicit kind row that these siblings either consume, refuse, gate, question, or specialize, so no bijection preserves all NameCert rows.

The Lean TasteGate module BEDC.Derived.SocketKindClassifierUp.TasteGate provides Nontrivial SocketKindClass and FieldFaithful $\mathsf{SocketKindClassifier}^{\uparrow}$ instances over the displayed rows S, K_D, R, G, H, C, P, N.

Closure status for $\mathsf{NameCert}_{\mathsf{SocketKindClassifier}^{\uparrow}}$**.**

Constructive story: A $\mathsf{SocketKindClassifier}^{\uparrow}$ packet is generated from a socket-site row, a socket-kind row, a requested-supply row, a gate-locality row, componentwise transport, displayed continuation, package provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{SocketKindClassifier}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1058.1, Definition 1058.2, Definition 1058.3, Definition 1058.4, Definition 1058.5, and

Upgrade path: No further upgrade – chapter at top of formal axis.

Chapter 1059

A Concrete Naming Certificate for $\mathsf{MachineInterfaceSocket}^{\uparrow}$

The $\mathsf{MachineInterfaceSocket}^{\uparrow}$ packet realizes the machine-facing formalization target interface of subsection 9462.35.5 as a finite socket-routed NameCert carrier. It sits beside the kind classifier of chapter 1058, the use ledger of chapter 1044, the audit gate boundary of chapter 526, the apophatic socket of chapter 536, and the supply socket ledger of chapter 528. Those siblings classify, record, police, refuse, or account for socket traffic; this packet routes formalization targets through the same finite audit-facing rows.

Definition 1059.1 (MachineInterfaceSocket carrier)**.** *A* $\mathsf{MachineInterfaceSocket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$M = (T, K, U, A, S, R, H, C, P, N)$$

with the following displayed rows:

1. *T is the formalization-target row recording the target name, intended namespace, source registry, statement skeleton, dependency list, expected status, and not-claimed surface from Definition 9462.2264;*
2. *K is the* $\mathsf{SocketKindClassifier}^{\uparrow}$ *row naming the socket kind that governs the target route;*
3. *U is the* $\mathsf{SocketUseLedger}^{\uparrow}$ *row recording the visible use of that socket by the machine-facing target;*
4. *A is the* $\mathsf{AuditGateBoundary}^{\uparrow}$ *row whose local verdict must accept the displayed socket kind before the target can be authorized;*
5. *S is the* $\mathsf{SupplySocketLedger}^{\uparrow}$ *row tying the requested machine support to the finite supply ledger;*
6. *R is the refusal-locality row recording that refused audit-gate kinds do not authorize target admission;*
7. *H records componentwise* hsame *transport for T, K, U, A, S, R;*
8. *C records displayed* Cont *routes from the target row through the classifier, use ledger, audit gate, supply ledger, and refusal-locality row;*
9. *P is the* Pkg *provenance over* $\mathsf{SocketKindClassifier}^{\uparrow}$, $\mathsf{SocketUseLedger}^{\uparrow}$, $\mathsf{AuditGateBoundary}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{MachineInterfaceSocket}^{\uparrow}}$ *row.*

The carrier has no coordinate for anonymous target admission, global namespace correctness, host-side proof search success, bypassed audit acceptance, supplied witness content, or a theorem asserting that every declared target is true.

Lean4 (definition) `BEDC.Derived.MachineInterfaceSocketUp.MachineInterfaceSocketUp`

Theorem 1059.2 (MachineInterfaceSocket NameCert obligations)**.** *For the carrier of Definition 1059.1, the local* $\mathsf{NameCert}_{\mathsf{MachineInterfaceSocket}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$M = (T, K, U, A, S, R, H, C, P, N),$$

formalization-target exposure through T*, socket-kind exactness through* K*, visible socket-use accounting through* U*, audit-gate boundary readback through* A*, supply-ledger accounting through* S*, refusal-locality through* R*, componentwise* hsame *stability through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Consequently every accepted machine-facing target route is a finite NameCert packet whose public reads are target row, socket-kind row, use row, audit-gate row, supply-ledger row, refusal-locality row, transport, continuation, provenance, and local name.

Proof. Project the displayed carrier. The packet lists $T, K, U, A, S, R, H, C, P, N$, so the local certificate cannot introduce another formalization target, socket kind, socket use, audit verdict, supply ledger, refusal row, transport, route, provenance, or local name.

Read the dependency rows in order. The target row T gives the machine-facing request, the classifier row K fixes the socket kind, the use ledger U records the visible invocation, the audit boundary A supplies the local verdict surface, and the supply ledger S accounts for the requested machine support.

Finally inspect R, H, C, P, N. The refusal-locality row blocks refused gate kinds, while the support rows only transport, replay, package, and name the same finite packet. Thus the NameCert obligations are exhausted by the displayed rows. □

Lean4 ✓ `BEDC.Derived.MachineInterfaceSocketUp.machineInterfaceSocket round trip`

Theorem 1059.3 (MachineInterfaceSocket gate locality)**.** *Every accepted* $\mathsf{MachineInterfaceSocket}^{\uparrow}$ *packet authorizes a formalization target only through the audit-gate row displayed in* A*. If the audit-gate row refuses the socket kind named by* K*, then the refusal-locality row* R *prevents the packet from authorizing the target named by* T*.*

Proof. Begin with the target and kind rows. The row T records the intended namespace, dependencies, expected status, and not-claimed surface, while K records the socket kind through which that target asks to be routed.

Use the use ledger and audit boundary. The row U makes the socket use visible, and A is the only displayed audit-gate boundary available to judge that use. No carrier coordinate stores a detached authorization predicate.

Apply refusal-locality. When A refuses the kind named by K, the row R records that refusal as a local obstruction to target admission. Since H, C, P, N only preserve the same rows, the target route cannot be authorized by another hidden gate. □

Theorem 1059.4 (MachineInterfaceSocket sibling separation)**.** *The* $\mathsf{MachineInterfaceSocket}^{\uparrow}$ *carrier is not bijective, under NameCert-row preservation, to* $\mathsf{SocketKindClassifier}^{\uparrow}$*,* $\mathsf{SocketUseLedger}^{\uparrow}$*,*

AuditGateBoundary$^{\uparrow}$, ApophaticSocket$^{\uparrow}$, *or* SupplySocketLedger$^{\uparrow}$. *The machine-interface socket carries the formalization-target row T together with the gate-locality row R, while those siblings respectively classify socket kinds, record uses, expose audit verdicts, refuse external supply, or account for supply sockets without preserving both rows at once.*

Proof. Compare the classifier and use ledger first. SocketKindClassifier$^{\uparrow}$ supplies kind exactness, and SocketUseLedger$^{\uparrow}$ records visible use, but neither carries the formalization-target row with namespace, dependency, expected-status, and not-claimed fields.

Compare the audit and apophatic siblings next. AuditGateBoundary$^{\uparrow}$ exposes audit verdict surfaces, and ApophaticSocket$^{\uparrow}$ records non-internalizing supply requests, but neither combines the target row with a socket-use ledger and the local refusal row for target authorization.

Finally compare SupplySocketLedger$^{\uparrow}$. It accounts for requested supply sockets but does not bind a machine-facing target row to the classifier, use ledger, audit gate, and refusal-locality rows in one packet. Therefore no bijection preserves the target row plus gate-locality row together with all displayed NameCert fields. □

Theorem 1059.5 (MachineInterfaceSocket public target export)**.** *Every public machine-facing target export carried by an accepted* MachineInterfaceSocket$^{\uparrow}$ *packet $M = (T, K, U, A, S, R, H, C, P, N)$ factors through the displayed rows*

$$T, K, U, A, S, R, H, C, P, N.$$

Here T is the target row, K the socket-kind classifier, U the use ledger, A the audit-gate row, S the supply ledger, R refusal locality, H transport, C replay, P provenance, and N local naming. The export has no coordinate for anonymous target admission, bypassed audit acceptance, global namespace correctness, supplied proof content, host-side proof search success, or a theorem asserting that every declared target is true.

Proof. Read the NameCert obligations of Definition 1059.2. They expose the target row, socket kind, use ledger, audit-gate row, supply ledger, refusal-locality row, transport, replay, provenance, and local name as the whole local certificate surface.

Apply gate locality from Definition 1059.3. A public export cannot bypass A, because refused socket kinds are blocked by R before the target row can be treated as authorized.

Finally use sibling separation, Definition 1059.4. None of the sibling packets preserves the formalization-target row together with the gate-locality row and all support rows, so the public machine-facing export must factor through $T, K, U, A, S, R, H, C, P, N$ inside this packet. □

Falsifiable prediction: A MachineInterfaceSocket$^{\uparrow}$ packet cannot authorize a formalization target whose audit-gate row refuses its socket kind.

Independence witness: socketkindclassifier, socketuseledger, auditgateboundary, apophatic-socket, supplysocketledger: the classifier lacks the formalization-target row, the use ledger lacks the target-bound gate refusal row, the audit gate lacks socket-use and supply-ledger accounting for target routing, the apophatic socket refuses supply without target admission, and the supply socket ledger lacks target-row authorization; no bijection preserves target row plus gate-locality row.

The Lean carrier file BEDC.Derived.MachineInterfaceSocketUp.TasteGate provides explicit Nontrivial MachineInter and FieldFaithful MachineInterfaceSocket$^{\uparrow}$ instances over the displayed packet.

Lean4 ✓ `BEDC.Derived.MachineInterfaceSocketUp.taste gate`

Closure status for NameCert$_{\text{MachineInterfaceSocket}^{\uparrow}}$ ·

Constructive story: A MachineInterfaceSocket$^{\uparrow}$ packet is generated from a target row, socket-kind row, use ledger, audit-gate row, supply-ledger row, refusal-locality row, componentwise hsame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{MachineInterfaceSocket}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1059.1, Definition 1059.2, Definition 1059.3, Definition 1059.4, and Definition 1059.5 bind the target row, socket-kind classifier, socket-use ledger, audit-gate boundary, supply-ledger row, refusal-locality, componentwise hsame, displayed Cont, Pkg, and local NameCert rows as one scoped machine-interface socket.

Formal verification: FormalStatus(NameCert$_{\text{MachineInterfaceSocket}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.MachineInterfaceSocketUp.machineInterfaceSocket\_round\_trip`

Bridge status: paperBridge

Not claimed: This chapter does not close bridge checking, global namespace correctness, host-side proof search success, supplied witness content, or truth of every declared target.

Upgrade path: No further theory-axis upgrade remains; machine-checked bridge status is a separate verification-axis obligation.

Chapter 1060

A Concrete Naming Certificate for $\mathsf{SchwarzReflectionRoute}^{\uparrow}$

The $\mathsf{SchwarzReflectionRoute}^{\uparrow}$ packet realizes the reflection route isolated by chapter 9341 as finite NameCert data. It is a concrete operation-route sibling of chapter 577, using the holomorphic source interface of chapter 68, the differentiability control of chapter 67, and the complex carrier of chapter 39.

Definition 1060.1 (Schwarz reflection route carrier)**.** *A* $\mathsf{SchwarzReflectionRoute}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (U, B, J, O, H, C, P, N)$$

with the following displayed rows:

1. *U is the holomorphic source row, recording the upper-side domain, the source function history, and the* $\mathsf{Holomorphic}^{\uparrow}$ *certificate over the visible side of the boundary;*
2. *B is the real-boundary trace row, recording the boundary segment, the continuity trace to that segment, and the real-value readback used by the reflection route;*
3. *J is the conjugation/reflection row, recording the domain reflection, the input conjugation $z \mapsto \overline{z}$, and the output conjugation $w \mapsto \overline{w}$ as displayed* $\mathsf{Complex}^{\uparrow}$ *routes;*
4. *O is the reflected-output row, recording the lower-side function history whose value is read as $\overline{f(\overline{z})}$ through the rows U, B, J;*
5. *H records componentwise* hsame *transports for U, B, J, O and for the replay, provenance, and local naming rows;*
6. *C records the displayed* Cont *replay routes from the source holomorphic row to the boundary trace, from the boundary trace to the conjugation/reflection row, and from that row to the reflected output;*
7. *P is the* Pkg *provenance over* $\mathsf{AnaCont}^{\uparrow}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{CplxDiff}^{\uparrow}$, $\mathsf{Complex}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{SchwarzReflectionRoute}^{\uparrow}}$ *row.*

The carrier contains exactly these rows. It has no coordinate for a global analytic-continuation theorem, no monodromy selector, no quotient germ, no host complex-analysis equality, and no RH-facing zero-location predicate.

Lean4 ✓ BEDC.Derived.SchwarzReflectionRouteUp.TasteGate.SchwarzReflectionRouteTasteGate single carrier alignment

Theorem 1060.2 (Schwarz reflection route NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{SchwarzReflectionRoute}^{\uparrow}}$ *surface for Definition 1060.1 consists of carrier admission for*

$$S = (U, B, J, O, H, C, P, N),$$

holomorphic source exposure, real-boundary trace exposure, conjugation/reflection exposure, reflected-output routing, componentwise hsame *stability, displayed* Cont *replay,* Pkg *provenance, and local naming. Every accepted consumer of the reflected output must first read the rows* U, B, J, H, C, P, N*.*

Proof. Carrier admission is projection from Definition 1060.1. The packet displays the source, boundary, reflection, output, transport, replay, provenance, and local naming rows before any reflected value is public.

The analytic side is then read through existing sibling certificates. The row U is a $\mathsf{Holomorphic}^{\uparrow}$ source row over $\mathsf{Complex}^{\uparrow}$ histories, and the reflection test uses the complex-differentiability control named by chapter 67; neither row is replaced by host complex equality.

The route rows H and C keep the same packet visible under transport and replay. The provenance row P records the dependence on $\mathsf{AnaCont}^{\uparrow}$, $\mathsf{Holomorphic}^{\uparrow}$, $\mathsf{CplxDiff}^{\uparrow}$, and $\mathsf{Complex}^{\uparrow}$, while N supplies only the local name for this route. □

Theorem 1060.3 (Schwarz reflection route boundary symmetry)**.** *For an accepted* $\mathsf{SchwarzReflectionRoute}^{\uparrow}$ *carrier* $S = (U, B, J, O, H, C, P, N)$*, the real-boundary trace row* B *is the only boundary symmetry datum used by the reflected-output row* O*. If the reflected route is read at a boundary point already displayed in* B*, then the source-side and reflected-side reads are compared only by the* hsame *transports in* H *and the replay routes in* C*.*

Proof. Project the boundary row B from the carrier. It stores the boundary segment, the continuity trace, and the real-value readback that makes conjugation inert at the boundary.

Next project the conjugation/reflection row J and the reflected-output row O. The output route is defined as a read through the source value followed by displayed input and output conjugation, so its boundary comparison has no extra datum beyond B, J, H, C.

Finally use the packet inventory. Since no carrier coordinate stores a host boundary theorem, a quotient germ, or a global analytic-continuation principle, boundary symmetry can be exported only as the displayed finite route through B, H, C. □

Theorem 1060.4 (Schwarz reflection route public handoff)**.** *Every* $\mathsf{AnaCont}^{\uparrow}$*,* $\mathsf{Holomorphic}^{\uparrow}$*, contour-facing, or zeta-continuation-facing consumer of an accepted* $\mathsf{SchwarzReflectionRoute}^{\uparrow}$ *packet receives only the rows*

$$U, B, J, O, H, C, P, N$$

and their displayed BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *structure. The handoff presents a boundary-symmetric reflection route, not a global branch selector, monodromy theorem, quotient-germ construction, RH predicate, or zero locator.*

Proof. Begin with Definition 1060.2. It exposes the finite carrier and forces the reflected-output read through the holomorphic source, real-boundary trace, conjugation/reflection, transport, replay, provenance, and local naming rows.

For analytic-continuation and holomorphic consumers, use the dependency rows named in P. They identify this packet as a route over $\mathsf{AnaCont}^{\uparrow}$ and $\mathsf{Holomorphic}^{\uparrow}$ rather than as an independent continuation theorem.

For contour-facing and zeta-facing consumers, the same provenance row supplies only a finite operation-route dependency. The consumer can cite the reflected-output row O, but it cannot extract a hidden branch, global zero classifier, or RH-facing predicate from the packet. □

Theorem 1060.5 (Schwarz reflection route non-escape)**.** *An accepted* $\mathsf{SchwarzReflectionRoute}^{\uparrow}$ *carrier exports no object outside* U, B, J, O, H, C, P, N*. In particular, it exports no ambient Schwarz reflection principle, no selected analytic branch outside the reflected route, no monodromy closure, no quotient-germ equality, no host complex-analysis equality, and no non-trivial-zero locator.*

Proof. The carrier of Definition 1060.1 is a finite tuple with eight displayed rows. Any public read must project one of those rows or move through the displayed transport and replay rows.

The excluded objects are absent from that tuple. They are not source, boundary, reflection, output, transport, replay, provenance, or local naming rows.

Thus a consumer may use the packet as a reflected continuation route, but no consumer can read it as a global analytic theorem, a branch-selection device, a quotient construction, a host equality principle, or a zero-location certificate. □

Closure status for $\mathsf{NameCert}_{\mathsf{SchwarzReflectionRoute}^{\uparrow}}$.

Constructive story: A $\mathsf{SchwarzReflectionRoute}^{\uparrow}$ packet is generated from a holomorphic source row, a real-boundary trace row, a conjugation/reflection row, a reflected-output row, componentwise hsame transports, displayed Cont replay, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SchwarzReflectionRoute}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1060.1, Definition 1060.2, Definition 1060.3, Definition 1060.4, and Definition 1060.5 specify the finite reflection-route carrier, local naming obligations, boundary symmetry, public handoff, and non-escape boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SchwarzReflectionRoute}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: human

Not claimed: This chapter does not close a global Schwarz reflection theorem, monodromy, quotient germs, RH consequences, zero-location predicates, Lean verification, or bridge checking.

Upgrade path: Scoped closure requires checked carrier admission, boundary-symmetry replay, public handoff, non-escape coverage, TasteGate nontriviality, and field faithfulness for the same packet.

Chapter 1061

A Concrete Naming Certificate for $\mathsf{ApophaticFarEndSocket}^{\uparrow}$

The $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ packet realizes the far-end socket reading of chapter 9401 as finite NameCert data. It consumes the socket family row of chapter 536, the named boundary row of chapter 543, the supply-ledger row of chapter 528, the local inscription row of chapter 610, and the observer-history identity discipline of chapter 479. Its distinguishing role is the paired boundary: the unique far-end row is never internalized, and the local inscription row is still displayed before any observer-facing read is accepted.

Definition 1061.1 (Apophatic far-end socket carrier)**.** *An* $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (S, A, T, G, I, O, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the* $\mathsf{ApophaticSocket}^{\uparrow}$ *row collecting the forward-binding socket family;*
2. *A is the* $\mathsf{ApophaticName}^{\uparrow}$ *row naming the boundary position without supplying a kernel object;*
3. *T is the far-end boundary row recording that every displayed forward socket terminates at the same apophatic position;*
4. *G is the* GAP *ledger row that marks non-internalization of the far end;*
5. *I is the* $\mathsf{InscriptionPoint}^{\uparrow}$ *row recording the local inscription of the far-end boundary on the observer chain;*
6. *O is the* $\mathsf{ObserverHistIdentity}^{\uparrow}$ *row keeping observer identity on the displayed* BHist *side;*
7. *L is the* $\mathsf{SupplySocketLedger}^{\uparrow}$ *row binding socket kind, supply shape, audit gate, and provenance;*
8. *H records componentwise* hsame *transports for $S, A, T, G, I, O, L, C, P, N$;*
9. *C records displayed* Cont *routes through the socket row, far-end boundary row, local inscription row, observer-history row, supply ledger, provenance, and local naming row;*
10. *P records* Pkg *provenance over* $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{InscriptionPoint}^{\uparrow}$, $\mathsf{ObserverHistIdentity}^{\uparrow}$, BHist, hsame, Cont, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{ApophaticFarEndSocket}^{\uparrow}}$ *row.*

The carrier contains no coordinate for T *as a kernel object, a state, a record, a* Hist *constructor, a subject parameter, a global frame, or an unmarked supply witness.*

Theorem 1061.2 (Apophatic far-end socket NameCert obligations)**.** *For the carrier of Definition 1061.1, the local* $\mathsf{NameCert}_{\mathsf{ApophaticFarEndSocket}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$F = (S, A, T, G, I, O, L, H, C, P, N),$$

forward-socket exposure through S, apophatic naming through A, non-internalized far-end boundary exposure through T and G, local inscription exposure through I, observer-history identity through O, supply-ledger exposure through L, componentwise hsame *transport through H, displayed* Cont *route replay through C, package provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.ApophaticFarEndSocketUp.TasteGate.ApophaticFarEndSocketNameCertObligations`

Proof. Project the accepted carrier. The rows $S, A, T, G, I, O, L, H, C, P, N$ are exactly the forward-socket, apophatic-name, far-end boundary, gap ledger, local-inscription, observer-history, supply-ledger, transport, route, provenance, and local naming rows.

Read the sibling packets in order. The socket and name rows come from chapter 536 and chapter 543; the supply-ledger row comes from chapter 528; and the observer-facing rows come from chapter 610 and chapter 479.

The rows T and G keep the far end as a boundary name rather than a generated object, while I records the local inscription where the same boundary is read on a displayed chain. Since the carrier has no further coordinate, these rows exhaust the local NameCert surface. □

Theorem 1061.3 (Apophatic far-end socket non-escape)**.** *An accepted* $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ *carrier exports only the displayed rows $S, A, T, G, I, O, L, H, C, P, N$. It exports no kernel object named* T*, no state, no record, no* Hist *constructor, no subject parameter behind the trace, no global frame, no unmarked supply witness, and no object-level equality between a self-center and the far-end boundary.*

Lean4 ✓ `BEDC.Derived.ApophaticFarEndSocketUp.TasteGate.ApophaticFarEndSocket nonescape`
↪ variant `BEDC.Derived.ApophaticFarEndSocketUp.TasteGate.ApophaticFarEndSocketNonEscape`

Proof. Use Definition 1061.2. Every accepted read factors through the finite row inventory $S, A, T, G, I, O, L, H, C,$

The far-end boundary is recorded only by the paired rows T and G. They name the common apophatic far side and record non-internalization; neither row is a kernel value, generated state, record, or BHist constructor for the far end itself.

The observer-facing read is recorded only by I and O. The inscription row is local to the displayed chain, and the observer-history row keeps identity on the BHist surface. Hence no subject parameter, global frame, hidden supply witness, or object-level equality with T can be exported. □

Theorem 1061.4 (Apophatic far-end socket TasteGate readiness)**.** *The* $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ *carrier is TasteGate-ready precisely because its non-internalized far-end rows T, G and its local inscription rows I, O are both constructor fields of the same finite packet. A Lean carrier for this chapter must therefore expose a nontrivial witness pair and a field-faithful projection over $S, A, T, G, I, O, L, H, C, P, N$.*

Lean4 ✓ `BEDC.Derived.ApophaticFarEndSocketUp.TasteGate.ApophaticFarEndSocketTasteGate single carrier alignment`

Proof. The carrier of Definition 1061.1 lists the far-end boundary and local inscription rows as ordinary displayed fields rather than as ambient assumptions. A TasteGate encoding can therefore flatten the packet to its finite BHist field list and read it back by the same constructor.

Nontriviality is witnessed by changing one displayed row while leaving the remaining rows fixed. Field faithfulness is witnessed by constructor-field projection: if two packets agree on $S, A, T, G, I, O, L, H, C, P, N$, then the packets are equal.

The non-escape theorem supplies the semantic boundary for this encoding. Removing T or G loses the non-internalized far-end boundary, while removing I or O loses the local inscription and observer-history discipline. The same finite packet is therefore the correct carrier for the paper-side NameCert surface and the Lean-side TasteGate. □

Theorem 1061.5 (Apophatic far-end socket public boundary)**.** *Every public consumer of an accepted* $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ *carrier receives only the finite rows*

$$S, A, T, G, I, O, L, H, C, P, N$$

together with the nonescape boundary of Definition 1061.3 and the TasteGate-readiness boundary of Definition 1061.4. The public surface exposes the far-end row as displayed boundary data and exposes the local inscription row as displayed observer-chain data; it exports no kernel object named T*, no global frame, no hidden supply witness, and no bridge credential.*

Proof. Project the accepted carrier. The only displayed rows available to a consumer are $S, A, T, G, I, O, L, H, C, P,$ and the nonescape theorem identifies the forbidden exports outside that row inventory.

The TasteGate-readiness theorem then fixes the same inventory as the Lean-facing carrier boundary. Thus the public read is exactly the finite row surface plus the nonescape and TasteGate-readiness constraints, not an ambient object for the far end. □

Falsifiable prediction: Removing either the far-end boundary row or the local inscription row makes Definition 1061.3 false: the former permits a hidden internalizer for T, while the latter permits a detached observer-facing read with no local inscription site.

Independence witness: apophaticsocket, apophaticname, supplysocketledger, inscriptionpoint, observerhistidentity: none is bijective with $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ because this carrier alone pairs the non-internalized far-end rows T, G with the local inscription and observer-history rows I, O while retaining the socket, name, ledger, transport, route, provenance, and local NameCert rows.

The Lean-side TasteGate surface provides Nontrivial $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ and FieldFaithful ApophaticFarEn instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{ApophaticFarEndSocket}^{\uparrow}}$**.**

Constructive story: An $\mathsf{ApophaticFarEndSocket}^{\uparrow}$ packet is generated from a forward-socket row, apophatic-name row, far-end boundary row, gap ledger, local inscription row, observer-history identity row, supply-socket ledger row, componentwise transports, displayed routes, package provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.ApophaticFarEndSocketUp.taste gate`

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{ApophaticFarEndSocket}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1061.1, Definition 1061.2, Definition 1061.3, Definition 1061.4, and Definition 1061.5 bind the far-end socket packet as a finite public NameCert surface over the displayed boundary and local inscription rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ApophaticFarEndSocket}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ApophaticFarEndSocketUp.TasteGate.ApophaticFarEndSocketTasteGate\_single\_carrier\_alig`

Bridge status: none

Origin: ai

Not claimed: This chapter does not internalize T, add a subject parameter, supply a global frame, close a consciousness theorem, or provide a public standard bridge.

Upgrade path: No paper-side closure upgrade remains; a checked standard bridge is a verification-axis matter unless supplied separately.

Chapter 1062

A Concrete Naming Certificate for $\mathsf{DigestProvenancePacket}^{\uparrow}$

The $\mathsf{DigestProvenancePacket}^{\uparrow}$ carrier is the concrete NameCert realization of the digest-provenance discipline from chapter 9402. It sits downstream of the finite hash transcript surface of chapter 242, the negative socket naming discipline of chapter 543, and the visible supply refusal ledger of chapter 528. Its purpose is narrow: a digest may be used as a visible token only after the packet displays the source row, fiber-membership row, GAP ledger, exactness or refusal row, transport, replay, provenance, and local naming rows.

Falsifiable prediction: Every accepted DigestProvenancePacketUp consumer that reads source content must pass through the displayed fiber-membership and GAP ledger rows before any source equality claim.

Independence witness: hash, apophaticname, apophaticsocket, transcendentalsupplyledger, supplysocketledger: none is bijective to $\mathsf{DigestProvenancePacket}^{\uparrow}$ because this carrier binds the visible digest token, source row, fiber-membership row, GAP ledger, exactness or refusal row, hsame transport, Cont replay, provenance, and local NameCert row in one packet, while the siblings isolate hash evaluation, negative naming, socket request, supply taxonomy, or supply-kind ledger surfaces without the source-fiber discipline.

Definition 1062.1 (DigestProvenancePacket carrier)**.** *A* $\mathsf{DigestProvenancePacket}^{\uparrow}$ *carrier is a finite packet*

$$D = (V, S, F, G, E, H, C, P, N)$$

over the following displayed rows:

1. *V is the visible digest-token row, naming the token that downstream consumers may compare, store, or route;*
2. *S is the source row, recording the finite source class and the local source-channel handle without identifying the digest with the source;*
3. *F is the fiber-membership row, recording the generated relation that the source row belongs to the visible digest fiber;*
4. *G is the* GAP *ledger row, recording any far-end or missing-source supply required by the fiber reading;*
5. *E is the exactness or refusal row, recording whether the packet has an exactness certificate for a particular source claim or refuses source equality;*

6. *H records componentwise* hsame *transports for the visible digest, source, fiber, ledger, exactness, replay, provenance, and naming rows;*
7. *C records the displayed* Cont *replay routes by which consumers inspect V, S, F, G, E, H, P, N in order;*
8. *P is the* Pkg *provenance over the digest token, source row, fiber relation, GAP ledger, exactness or refusal row, transports, replay routes, and local naming surface;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{DigestProvenancePacket}^{\uparrow}}$ *row.*

The carrier has no coordinate for a global universe digest, digest-as-source equality, object-level T*, hidden preimage oracle, quotient source equality, or host hash-function semantics.*

Lean4 (definition) `BEDC.Derived.DigestProvenancePacketUp.DigestProvenancePacketCarrier`

Theorem 1062.2 (DigestProvenancePacket NameCert obligations)**.** *For an accepted* $\mathsf{DigestProvenancePacket}^{\uparrow}$ *carrier*

$$D = (V, S, F, G, E, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{DigestProvenancePacket}^{\uparrow}}$ *surface consists exactly of carrier admission for the nine displayed rows, token visibility through V, source-channel display through S, fiber-membership exactness through F, GAP ledger exposure through G, exactness or refusal through E, componentwise transport through H, replay locality through C, package provenance through P, local naming through N, and non-escape from the refused source and far-end supplies.*

Lean4 ✓ `BEDC.Derived.DigestProvenancePacketUp.DigestProvenancePacketCarrier namecert obligations`

Proof. Project the carrier in Definition 1062.1. The visible inventory is exactly $V, S, F, G, E, H, C, P, N$, so carrier admission and local naming are attached to these rows and to no hidden digest substrate.

Token visibility is read through V, while source-channel display is read through S. The hash-facing comparison surface of chapter 242 may supply digest transcripts, but the packet does not let such transcripts replace the displayed source row.

Fiber exactness and ledger exposure are the rows F and G. They force every source-sensitive read to name both the fiber-membership relation and the GAP entry that records missing far-end or source supply.

The exactness row E then separates certified source claims from refused ones. Transports and replay through H and C preserve this separation, and provenance through P records which local packet is being consumed.

Thus the NameCert surface refuses a global universe digest, digest-as-source equality, object-level T, hidden preimage oracle, quotient source equality, and host hash-function semantics. The apophatic naming discipline of chapter 543 and the supply ledger of chapter 528 are consumed only as visible boundary rows. □

Theorem 1062.3 (DigestProvenancePacket no hidden source consumption)**.** *Every accepted consumer of a* $\mathsf{DigestProvenancePacket}^{\uparrow}$ *carrier that reads source content must factor its read through the displayed source row S, fiber-membership row F, GAP ledger G, exactness or refusal row E, transport row H, replay route C, provenance row P, and local naming row N before making any source equality claim. A consumer that reads only the digest token V obtains a visible digest token and no source content.*

Lean4 ✓ `BEDC.Derived.DigestProvenancePacketUp.DigestProvenancePacketCarrier no hidden source consumption`

Proof. Start with a consumer read of an accepted packet $D = (V, S, F, G, E, H, C, P, N)$. If the read only asks for the digest token, Definition 1062.1 exposes V as a visible token and provides no source row outside the packet.

Now suppose the read asks for source content. The source channel is S, and the source may be attached to the token only through the fiber-membership row F. Without F, the read has a digest token and a displayed source row but no generated relation between them.

The next required row is the GAP ledger G. It records whether the fiber far end, source supply, or missing exactness data has been socketed rather than silently consumed. This is the same refusal posture enforced by chapter 543 and by the supply-ledger surface of chapter 528.

The exactness or refusal row E controls equality-facing claims. If E contains a local exactness certificate, the claim remains scoped to the displayed packet; if E is a refusal row, the source equality claim is unavailable. In neither case does the digest become the source.

Finally route the read through H, C, P, N. Componentwise transport, continuation replay, package provenance, and local naming preserve the same packet and do not add a preimage oracle, quotient representative, host hash semantics, global digest universe, or object-level T coordinate. Therefore no source content is consumed unless the displayed fiber and GAP ledger rows have already been opened. □

Theorem 1062.4 (DigestProvenancePacket source-fiber ledger order)**.** *For every accepted* DigestProvenancePacket *carrier*

$$D = (V, S, F, G, E, H, C, P, N),$$

each source-sensitive read must expose the source row S, then the fiber-membership row F, then the GAP *ledger row G, before the exactness or refusal row E may authorize or refuse an equality-facing source claim. A read that has not passed through S, F, G has no packet-local authority to assert source equality, digest-as-source equality, quotient source equality, hidden preimage recovery, or host hash-function semantics.*

Lean4 ✓ `BEDC.Derived.DigestProvenancePacketUp.DigestProvenancePacketCarrier source fiber ledger order`

Proof. Start from the carrier definition. The rows of Definition 1062.1 place the visible digest token V beside a source row S, then a fiber-membership row F, then the GAP ledger G, with E recording only the exactness or refusal status that follows those displayed rows.

Now use no hidden source consumption. Definition 1062.3 forces every source-content read through S, F, G, E, H, C, P, N before any source equality claim, while a token-only read exposes V and no source content.

It remains to identify the order relevant to equality-facing claims. The carrier gives no coordinate that can replace S by a hidden source, no coordinate that can replace F by a host preimage oracle, and no coordinate that can replace G by silent far-end supply. Therefore E can authorize or refuse only after the source, fiber, and ledger rows have been opened in that order. □

Closure status for $\mathsf{NameCert}_{\mathsf{DigestProvenancePacket}^{\uparrow}}$.

Constructive story: A $\mathsf{DigestProvenancePacket}^{\uparrow}$ packet is generated from a visible digest token, source row, fiber-membership row, GAP ledger, exactness or refusal row, componentwise transports, displayed replay routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DigestProvenancePacket}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 1062.1, Definition 1062.2, Definition 1062.3, Definition 1062.4, and the TasteGate target bind the fiber-membership, GAP, refusal, replay, provenance, and naming rows to the displayed digest-provenance carrier.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DigestProvenancePacket}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.DigestProvenancePacketUp.DigestProvenancePacketTasteGate\_single\_carrier\_alignment`

Bridge status: none

Not claimed: This chapter does not claim source equality, preimage oracle access, quotient source equality, host hash semantics, a standard bridge, or object-level truth for DigestProvenancePacket$^{\uparrow}$.

Upgrade path: Bridge closure next requires a standard bridge for the scoped digest-provenance packet.

Chapter 1063

A Concrete Naming Certificate for MetaCICProofObjectAuditRoute$^{\uparrow}$

The MetaCICProofObjectAuditRoute$^{\uparrow}$ packet turns the synthesis view of chapter 9385 into a concrete route certificate for proof-object audit consumers. It sits beside **??**, chapter 776, chapter 731, chapter 717, and chapter 739. Those siblings expose the status matrix, synthesis packet, obstruction boundary, discharge ledger, and closed-normal endpoint; the present chapter records the route union that keeps those rows inspectable without converting the blocked subject-reduction edge into a full consistency theorem.

Definition 1063.1 (MetaCIC proof-object audit route carrier)**.** *A* MetaCICProofObjectAuditRoute$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (S, O, D, N, C, B, H, R, P, L)$$

with the following displayed rows:

1. *S is the synthesis-status row, recording the subject-reduction, confluence, normalization, substitution, decidability, and closed-normal status matrix read from chapter 9385;*
2. *O is the subject-reduction obstruction row, read through chapter 731;*
3. *D is the discharge-ledger row, exposing the four named subject-reduction slots through chapter 717;*
4. *N is the closed-normal packet row, recording the positive normal-endpoint consistency branch of chapter 739;*
5. *C is the confluence and decidable sibling route row, recording the conditional confluence routes and local checking surfaces that constrain proof-object reads;*
6. *B is the blocked-edge ledger, naming the unavailable transport from arbitrary closed proof objects to the closed-normal branch;*
7. *H records componentwise* hsame *transports for S, O, D, N, C, B and the local structural rows;*
8. *R records displayed* Cont *routes by which proof-object audit consumers read the synthesis, obstruction, discharge, closed-normal, confluence, decidable, and blocked-edge rows;*
9. *P is the* Pkg *provenance over* **??**, *chapter 776, chapter 731, chapter 717, chapter 739,* BHist, hsame, Cont, *and* NameCert *rows;*

10. L is the local $\mathsf{NameCert}_{\mathsf{MetaCICProofObjectAuditRoute}^{\uparrow}}$ *row.*
The carrier is not bijective with any one sibling packet. It stores the route union tying positive closed-normal evidence to the obstruction ledger, so agreement on only the synthesis packet, only the obstruction packet, or only the closed-normal packet does not reconstruct the proof-object audit route.

Theorem 1063.2 (MetaCIC proof-object audit route NameCert obligations)**.** *For every accepted* $\mathsf{MetaCICProofObjectAuditRoute}^{\uparrow}$ *carrier*

$$A = (S, O, D, N, C, B, H, R, P, L),$$

the local $\mathsf{NameCert}_{\mathsf{MetaCICProofObjectAuditRoute}^{\uparrow}}$ *surface consists exactly of carrier admission for the displayed tuple, synthesis-status exposure through S, obstruction and four-slot ledger exposure through O, D, closed-normal endpoint exposure through N, confluence and decidable sibling route exposure through C, blocked-edge ledger exactness through B, componentwise* hsame *transport through H, displayed route replay through R, package provenance through P, and local naming through L.*

Proof. Carrier admission is projection from Definition 1063.1. The rows $S, O, D, N, C, B, H, R, P, L$ are the complete public packet, so every NameCert obligation is read from one of those coordinates.

The proof-object content is split across the sibling rows. The synthesis-status row S records the audit-map matrix, O, D record the obstruction and discharge slots, N records the closed-normal endpoint branch, and C records the confluence and decidable side routes.

The blocked-edge obligation is the row B. Transport, route replay, provenance, and local naming are confined to H, R, P, L, and these structural rows preserve the displayed tuple rather than adding a second route. Thus the local NameCert surface is exactly the finite route packet stated above. □

Lean4 ✓ `BEDC.Derived.MetaCICProofObjectAuditRouteUp.MetaCICProofObjectAuditRoutePacket namecert obligations`

Theorem 1063.3 (MetaCIC proof-object audit route blocked-edge non-escape)**.** *Every proof-object audit consumer of an accepted* $\mathsf{MetaCICProofObjectAuditRoute}^{\uparrow}$ *carrier reads the closed-normal branch only through N together with the blocked-edge ledger B and the obstruction rows O, D. If B is removed from the carrier, the packet no longer certifies blocked-edge non-escape: a consumer can still see the positive closed-normal row N, but the displayed refusal of the missing subject-reduction transport is no longer part of the same route.*

Proof. Read the closed-normal side first. The row N exposes the positive closed-normal packet, while O, D expose the subject-reduction obstruction and its four discharge slots.

The non-escape condition is carried by B. It records that the route from arbitrary closed proof objects to the closed-normal branch is blocked, so any consumer of N must carry the obstruction ledger in the same packet.

Removing B changes the public certificate surface. The tuple would still contain synthesis, obstruction, discharge, closed-normal, confluence, decidable, transport, route, provenance, and naming rows, but it would no longer contain the row that marks the missing transport edge. Hence blocked-edge non-escape is falsifiable by deleting B. □

Lean4 ✓ `BEDC.Derived.MetaCICProofObjectAuditRouteUp.MetaCICProofObjectAuditRoute blocked edge nonescape`

Theorem 1063.4 (MetaCIC proof-object audit route sibling independence)**.** *The* MetaCICProofObjectAuditRoute$^{\uparrow}$ *carrier is independent from the sibling carriers of* **??**, *chapter 776, chapter 731, chapter 717, and chapter 739. Each sibling supplies one route face, but none of them alone contains the union* $S, O, D, N, C, B, H, R, P, L$ *that ties positive closed-normal evidence to the obstruction ledger.*

Proof. Inspect the sibling roles. The synthesis siblings provide status and combined audit rows, the obstruction sibling provides the blocked subject-reduction boundary, the discharge ledger provides the four named slots, and the closed-normal packet provides the positive endpoint branch.

The present carrier records those rows together with the blocked-edge ledger and a single structural transport, route, provenance, and naming surface. Therefore it is not a repackaging of any one sibling packet.

The independence witness is componentwise: deleting the synthesis row loses the matrix, deleting O or D loses the subject-reduction boundary, deleting N loses the positive closed-normal evidence, and deleting B loses the non-escape certificate. No sibling carrier supplies all of those rows at once. □

Theorem 1063.5 (MetaCIC proof-object audit route TasteGate readiness)**.** *The* MetaCICProofObjectAuditRoute$^{\uparrow}$ *packet is ready for a* TasteGate *carrier precisely at the displayed finite surface*

$$(S, O, D, N, C, B, H, R, P, L).$$

The Lean follow-up must provide Nontrivial *and* FieldFaithful *instances for this carrier in* lean4/BEDC/Derived/Meta *with the public alignment theorem named* BEDC.Derived.MetaCICProofObjectAuditRouteUp.MetaCICProofObjectAud

Lean4 ✓ `BEDC.Derived.MetaCICProofObjectAuditRouteUp.MetaCICProofObjectAuditRouteTasteGate`
`single carrier alignment`

Proof. TasteGate readiness uses the finite packet already displayed in the carrier definition. The row list exposes one public carrier, one classifier surface, and one provenance route for proof-object audit consumers.

Nontriviality is witnessed by the separation between the positive closed-normal row N and the blocked-edge ledger B. Field faithfulness is witnessed by componentwise access to $S, O, D, N, C, B, H, R, P, L$, since deleting or identifying any of these rows changes a named audit obligation.

Thus the follow-up Lean target is not a new paper claim about closed consistency. It is the formal TasteGate encoding of the same finite route packet and its componentwise field discipline. □

Closure status for NameCert$_{\text{MetaCICProofObjectAuditRoute}^{\uparrow}}$**.**

Constructive story: A MetaCICProofObjectAuditRoute$^{\uparrow}$ packet is generated from synthesis-status, subject-reduction obstruction, discharge-ledger, closed-normal packet, confluence and decidable sibling route, blocked-edge ledger, componentwise hsame, displayed Cont, Pkg provenance, and local NameCert rows.

Theory closure: TheoryGate(NameCert$_{\text{MetaCICProofObjectAuditRoute}^{\uparrow}}$, seed)

Scope closed: Definition 1063.1, Definition 1063.2, Definition 1063.3, Definition 1063.4, and Definition 1063.5 bind proof-object audit routes as finite NameCert rows tying closed-normal evidence to the subject-reduction blocked-edge ledger.

Formal verification: FormalStatus(NameCert$_{\text{MetaCICProofObjectAuditRoute}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close subject reduction, full closed MetaCIC consistency, global Church–Rosser, candidate-free normalization, global decidability, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked Nontrivial and FieldFaithful instances, carrier alignment, blocked-edge non-escape, sibling independence, and TasteGate readiness for the displayed finite route packet.

Chapter 1064

A Concrete Naming Certificate for $\mathsf{ApophaticFiberFarEnd}^{\uparrow}$

The $\mathsf{ApophaticFiberFarEnd}^{\uparrow}$ packet gives the fixed-point reading of chapter 9401 a finite NameCert surface. It records the apophatic socket, the fiber row whose far end is being named, the GAP ledger that keeps the requested supply outside the substrate, the boundary row that refuses internalization of T, the local inscription row where the same event is read on a chain, and the usual transport, route, provenance, and local naming rows. It sits beside the socket carrier of chapter 536, the fixed-point carrier of chapter 556, the inscription carrier of chapter 519, and the no-subject identity surface of chapter 479.

Definition 1064.1 (Apophatic fiber far-end carrier)**.** *An* $\mathsf{ApophaticFiberFarEnd}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (S, F, G, B, I, H, C, P, N)$$

with the following displayed rows:

1. *S is the accepted* $\mathsf{ApophaticSocket}^{\uparrow}$ *row naming the visible forward-binding socket;*
2. *F is the fiber row recording the socket-to-far-end request without providing the far end as an internal value;*
3. *G is the* GAP *ledger row attached to the requested far end of the fiber;*
4. *B is the apophatic boundary row recording that* T *is not a* BHist, Hist, *digest, state, theorem object, setup field, or generated witness;*
5. *I is the local inscription row recording the chain point where the boundary name is read inscription-side without adding a subject coordinate;*
6. *H records componentwise* hsame *transports for S, F, G, B, I, C, P, N;*
7. *C records the displayed* Cont *routes by which consumers read the socket, fiber, ledger, boundary, inscription, provenance, and local naming rows;*
8. *P is the* Pkg *provenance over* $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{ApophaticGateQuestion}^{\uparrow}$, $\mathsf{GeneratorFixedPoint}^{\uparrow}$, $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{ObserverHistIdentity}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ApophaticFiberFarEnd}^{\uparrow}}$ *row.*

The carrier contains exactly these rows. It has no coordinate for T *as an internal object, no route from the far-end boundary to a digest or history value, and no hidden observer-substance row behind the local inscription.*

Lean4 (definition) `BEDC.Derived.ApophaticFiberFarEndUp.ApophaticFiberFarEndUp`

Theorem 1064.2 (Apophatic fiber far-end NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{ApophaticFiberFarEnd}^{\uparrow}}$ *surface for Definition 1064.1 consists of five finite obligations:*

1. *carrier admission for the packet* $A = (S, F, G, B, I, H, C, P, N)$*;*
2. *socket-fiber locality, stating that* S *and* F *are read together before any far-end boundary row is consumed;*
3. *ledger and boundary exactness, stating that* G *and* B *record the apophatic far end only as a boundary name and never as a generated substrate coordinate;*
4. *local inscription accountability, stating that* I *is a chain-local reading of the same event and not a subject parameter, private center, or equality with* T*;*
5. *public route exactness, stating that every consumer read factors through* $S, F, G, B, I, H, C, P, N$ *and no route exports* T*, a digest, a* BHist *value, a hidden theorem, or an observer-substance row.*

Lean4 ✓ `BEDC.Derived.ApophaticFiberFarEndUp.ApophaticFiberFarEndTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 1064.1. The displayed packet lists the socket, fiber, ledger, boundary, local inscription, transport, route, provenance, and local naming rows.

Socket-fiber locality is read through S and F. The socket identifies the visible forward-binding request, while the fiber row records the far-end request without supplying that far end as an object.

Ledger and boundary exactness are carried by G and B. These rows record the GAP far-end boundary and the refusal of internal T; neither row adds a coordinate from which a consumer can project T as a BHist, Hist, digest, state, theorem object, setup field, or generated witness.

The local inscription row I is then read as chain-local accountability. It ties the boundary name to a displayed inscription point, but it does not introduce an extra subject row or an object-level equality with T.

Finally H, C, P, N provide transport, continuation replay, provenance, and local naming. Since every public route is a projection through these rows and the carrier has no further coordinate, the obligation surface is exhausted by the finite packet $S, F, G, B, I, H, C, P, N$. □

Theorem 1064.3 (Apophatic fiber far-end noninternality)**.** *For every accepted* $\mathsf{ApophaticFiberFarEnd}^{\uparrow}$ *packet* $A = (S, F, G, B, I, H, C, P, N)$*, the far-end boundary named by* B *cannot be consumed as a* BHist*,* Hist*, digest, state, theorem object, setup field, generated witness, or observer-substance row. Any accepted consumer of the local inscription row* I *must still pass through the socket row* S*, fiber row* F*,* GAP *ledger* G*, boundary row* B*, componentwise transport row* H*, continuation row* C*, provenance row* P*, and local naming row* N*.*

Proof. Project the boundary row B from the carrier. It records the apophatic far end as a refusal row, not as a generated object or value inside the substrate.

Project the local inscription row I next. Its public role is to attach the boundary name to a chain-local read of an event; it does not add a subject coordinate or identify that local event with T as an object.

The only available consumer routes are those listed in C and transported through H. Together with S, F, G, P, N, they force every accepted read to remain inside the displayed packet. Since none of the forbidden outputs is a carrier coordinate, no accepted route can extract it. □

Theorem 1064.4 (Apophatic fiber far-end falsifiable prediction)**.** *If an accepted* $\mathsf{ApophaticFiberFarEnd}^{\uparrow}$ *packet admits a consumer route from the apophatic far-end row to a* BHist, hsame, *or digest value row without passing through its boundary ledger, the certificate is invalid.*

Proof. The carrier exposes the far-end only through the fiber row F, GAP ledger G, and apophatic boundary row B. A consumer route that reaches a value row while bypassing G and B therefore omits the rows that make the far-end read apophatic.

Apply public route exactness from Definition 1064.2. Every accepted read must factor through $S, F, G, B, I, H, C, P, N$. A route that bypasses the boundary ledger is not one of the displayed continuation routes and cannot be certified by the local $\mathsf{NameCert}_{\mathsf{ApophaticFiberFarEnd}^{\uparrow}}$ row. □

Theorem 1064.5 (Apophatic fiber far-end independence witness)**.** *The* $\mathsf{ApophaticFiberFarEnd}^{\uparrow}$ *carrier is not bijective, under NameCert-row preservation, to* $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{ApophaticGateQuestion}^{\uparrow}$, $\mathsf{GeneratorFixedPoint}^{\uparrow}$, $\mathsf{InscriptionEvent}^{\uparrow}$, *or* $\mathsf{ObserverHistIdentity}^{\uparrow}$. *These siblings respectively supply socket visibility, gate questioning, generator fixed-output witnessing, public inscription event routing, and no-subject history identity, but none carries the fiber ledger, local inscription row, and far-end noninternality row together.*

Proof. Compare the socket and gate siblings first. $\mathsf{ApophaticSocket}^{\uparrow}$ supplies the visible socket row, and $\mathsf{ApophaticGateQuestion}^{\uparrow}$ supplies the refusal question, but neither contains the combined fiber row F, far-end ledger G, boundary row B, and local inscription row I.

Compare the fixed-point and inscription siblings next. $\mathsf{GeneratorFixedPoint}^{\uparrow}$ records a fixed-output witness for an authorized generator, while $\mathsf{InscriptionEvent}^{\uparrow}$ records accepted public inscription routing. Neither is a far-end boundary carrier, and neither refuses T as a BHist, Hist, digest, state, theorem object, setup field, or generated witness.

Finally compare $\mathsf{ObserverHistIdentity}^{\uparrow}$. It supplies the no-subject history-identity discipline consumed by the inscription row, but it has no fiber-far-end ledger and no apophatic boundary row. Therefore any bijection preserving NameCert rows would have to delete at least one of F, G, B, I, so no such bijection exists. □

Falsifiable prediction: If an accepted packet admits a consumer route from the apophatic far-end row to a BHist, hsame, or digest value row without passing through its boundary ledger, the certificate is invalid.

Independence witness: apophaticsocket, apophaticgatequestion, generatorfixedpoint, inscriptionevent, observerhistidentity: none is bijective because each lacks at least one of the fiber ledger, local inscription, and far-end noninternality rows carried together here.

Closure status for $\mathsf{NameCert}_{\mathsf{ApophaticFiberFarEnd}^{\uparrow}}$**.**

Constructive story: An $\mathsf{ApophaticFiberFarEnd}^{\uparrow}$ packet is generated from an accepted apophatic socket, fiber row, GAP far-end ledger, boundary row, local inscription row, componentwise hsame transport, displayed Cont routes, provenance, and local naming. The BHist carrier first exposes the socket and fiber request, then records the far end only as a ledgered boundary, and finally reads the local inscription without adding a subject coordinate. The classifier preserves the far end as noninternal data: every consumer must pass through socket, fiber, ledger, boundary, inscription, route, provenance, and name.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ApophaticFiberFarEnd}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the apophatic fiber far-end carrier, obligations, noninternality, falsifiable prediction, and independence witness.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ApophaticFiberFarEnd}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim the far end as a BHist, digest, state, theorem object, setup field, generated witness, or observer substance.

Upgrade path: To reach obligationClosure, turn the existing aligned TasteGate carrier into explicit checked obligations for the fiber, ledger, boundary, and inscription rows.

Chapter 1065

A Concrete Naming Certificate for $\mathsf{ExternalSupplyBoundary}^{\uparrow}$

The $\mathsf{ExternalSupplyBoundary}^{\uparrow}$ packet realizes the boundary discipline of chapter 9395 as a finite NameCert object. It sits beside the socket ledger of chapter 528, the apophatic socket surface of chapter 536, the audit gate boundary of chapter 526, and the gate-question packet of chapter 715. Those siblings expose socket use, requested externality, gate rows, or audit questions; this packet binds the complete boundary record that keeps external supply visible without making the requested supply internal.

Definition 1065.1 (ExternalSupplyBoundary carrier)**.** *An* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (B, R, I, A, G, Q, H, C, P, N)$$

with the following displayed rows:

1. *B is the boundary-name row naming the exact external supply site;*
2. *R is the requested-supply-shape row, recording what the site asks to consume;*
3. *I is the non-internalization row, recording that the requested supply is not available as substrate truth;*
4. *A is the accepted-boundary-form row, one of setup field, NameCert row, GAP ledger, bridge slot, or apophatic socket;*
5. *G is the associated* GAP *ledger row preserving the residue or socket pressure generated by the request;*
6. *Q is the gate-question row naming the finite audit question that must be asked before any consumer reads the boundary;*
7. *H records componentwise* hsame *transport for B, R, I, A, G, Q;*
8. *C records displayed* Cont *replay routes through the same boundary rows;*
9. *P is the* Pkg *provenance over* $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{AuditGateBoundary}^{\uparrow}$, $\mathsf{ApophaticGateQuestion}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{ExternalSupplyBoundary}^{\uparrow}}$ *row.*

The carrier has no coordinate for an internal witness of the requested supply, no hidden selector, no host quotient, and no theorem asserting that the requested supply exists.

Lean4 ✓ `BEDC.Derived.ExternalSupplyBoundaryUp.ExternalSupplyBoundaryTasteGate single carrier alignment`

Theorem 1065.2 (ExternalSupplyBoundary NameCert obligations)**.** *For the carrier of Definition 1065.1, the local* $\mathsf{NameCert}_{\mathsf{ExternalSupplyBoundary}^{\uparrow}}$ *surface consists exactly of carrier admission for* $E = (B, R, I, A, G, Q, H, C, P, N)$*, boundary-name exposure through* B*, requested-supply exactness through* R*, non-internalization exactness through* I*, accepted-form exposure through* A*,* GAP*-ledger readback through* G*, gate-question readback through* Q*, componentwise* hsame *stability through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Equivalently, a consumer may read the boundary name, requested supply shape, non-internalization status, accepted boundary form, associated GAP *ledger, and gate question, but no requested supply content outside those rows.*

Proof. Project the displayed carrier. The accepted packet lists $B, R, I, A, G, Q, H, C, P, N$, so the local certificate cannot introduce a second boundary name, requested-supply shape, non-internalization row, accepted boundary form, GAP ledger, gate question, transport row, replay route, provenance row, or local name.

Read the obligation rows in order. The boundary name B identifies the site, the requested-supply row R names the demanded shape, and the non-internalization row I prevents that request from becoming substrate truth.

Next read A, G, Q. The accepted-boundary-form row states how the request remains visible, the GAP row records the residue or socket pressure, and the gate-question row states the audit question a consumer must ask.

Finally inspect H, C, P, N. These rows only transport, replay, package, and name the same finite packet. Therefore the NameCert obligations are exhausted by the displayed rows. □

Lean4 ✓ `BEDC.Derived.ExternalSupplyBoundaryUp.ExternalSupplyBoundary namecert obligations`

Theorem 1065.3 (ExternalSupplyBoundary non-internalization)**.** *Every accepted* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$ *packet refuses internalization of its requested supply. A downstream consumer may cite* $B, R, I, A, G, Q, H, C, P, N$ *as boundary evidence, but it may not read from the packet an internal witness, selector, quotient representative, proposition equality token, or theorem that supplies the requested content.*

Proof. Begin with the non-internalization row I. By the carrier definition, I is displayed as a row of the packet rather than derived from a hidden consumer convention.

Use the accepted-boundary-form row A together with the GAP ledger G. The row A records the visible form in which the request is held, and G records the residue or socket pressure that would otherwise be erased.

Use the gate-question row Q to bind the consumer read to an audit question. A consumer can ask whether the boundary remains visible, but the packet contains no coordinate that answers by supplying the requested content.

The remaining rows H, C, P, N preserve and name only the displayed boundary rows. Since no coordinate stores an internal witness, selector, quotient representative, proposition equality token, or supplied-content theorem, every accepted packet keeps the requested supply external. □

Theorem 1065.4 (ExternalSupplyBoundary accepted form exhaustion)**.** *For every accepted* ExternalSupplyBounda *packet*

$$E = (B, R, I, A, G, Q, H, C, P, N),$$

the accepted boundary form row A *is exhausted by exactly one of the displayed boundary forms: setup field, NameCert row,* GAP *ledger, bridge slot, or apophatic socket. The packet exposes no accepted form outside those rows and no internal witness of the requested supply.*

Proof. Project the carrier of Definition 1065.1. The accepted-form coordinate is the row A, and it is read beside $B, R, I, G, Q, H, C, P, N$.

Use Definition 1065.2. The local NameCert surface binds accepted-form exposure to carrier admission, requested-supply exactness, non-internalization, GAP-ledger readback, gate-question readback, transport, replay, provenance, and local naming.

Finally apply Definition 1065.3. Since the requested supply is not internalized, the accepted form cannot be replaced by a hidden witness, selector, quotient representative, proposition equality token, or supplied-content theorem. □

Lean4 ✓ `BEDC.Derived.ExternalSupplyBoundaryUp.ExternalSupplyBoundary accepted form exhaustion`

Theorem 1065.5 (ExternalSupplyBoundary gate question determinacy)**.** *For every accepted* ExternalSupplyBound *packet*

$$E = (B, R, I, A, G, Q, H, C, P, N),$$

the gate-question row Q is deterministic for downstream reads. Once the boundary name B, requested-supply shape R, non-internalization row I, accepted form A, and GAP *ledger G are fixed, every consumer reads the same finite question Q through H, C, P, N.*

Proof. Project the displayed carrier. The row Q is a coordinate of the same finite packet as $B, R, I, A, G, H, C, P, N$, so there is no second question row available to a consumer.

Use Definition 1065.2. Gate-question readback is one of the local obligations, and the structural rows H, C, P, N only transport, replay, package, and name that row.

Apply Definition 1065.3. The determinacy of Q cannot be bypassed by reading an internal witness, selector, quotient representative, proposition equality token, or theorem that supplies the requested content. □

Theorem 1065.6 (ExternalSupplyBoundary sibling compatibility)**.** *Every accepted* ExternalSupplyBoundary$^{\uparrow}$ *packet*

$$E = (B, R, I, A, G, Q, H, C, P, N)$$

is compatible with the sibling surfaces SupplySocketLedger$^{\uparrow}$, ApophaticSocket$^{\uparrow}$, AuditGateBoundary$^{\uparrow}$, *and* ApophaticGateQuestion$^{\uparrow}$. *The row P records those sibling provenances, while A, G, Q expose the accepted boundary form, socket or residue ledger, and gate question needed by the sibling reads. The compatibility does not internalize the requested supply.*

Proof. Project the carrier. The provenance row P explicitly ranges over the socket ledger, apophatic socket, audit gate boundary, and apophatic gate question sibling surfaces, while A, G, Q display the accepted form, residue ledger, and question rows they consume.

Use Definition 1065.2. It binds sibling-facing provenance to the same carrier admission, non-internalization, accepted-form readback, GAP-ledger exposure, gate-question readback, transport, replay, and local naming rows.

Finally use Definition 1065.3. The sibling compatibility route can expose socket use, apophatic refusal, audit boundary pressure, and gate-question reads, but it has no coordinate for an internal witness, selector, quotient representative, proposition equality token, or supplied-content theorem. □

Theorem 1065.7 (ExternalSupplyBoundary carrier admission)**.** *Every accepted* ExternalSupplyBoundary$^{\uparrow}$ *boundary read is admitted only by the finite* BHist *carrier*

$$E = (B, R, I, A, G, Q, H, C, P, N).$$

The local $\mathsf{NameCert}_{\mathsf{ExternalSupplyBoundary}^{\uparrow}}$ *row* N *projects exactly this tuple: boundary name* B*, requested-supply shape* R*, non-internalization row* I*, accepted-boundary-form row* A*,* GAP *ledger* G*, gate question* Q*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*, package provenance* P*, and local naming* N*.*

Proof. Start from the carrier definition. The packet is displayed as the ten-coordinate finite history $E = (B, R, I, A, G, Q, H, C, P, N)$, and every coordinate is named before the local certificate row is read.

Use Definition 1065.2. Carrier admission is the first obligation of the local NameCert surface, and the later obligations are all projections from the same displayed packet.

Thus an accepted boundary read has no second carrier and no unlisted coordinate. It is admitted exactly through the finite BHist tuple named by N. □

Theorem 1065.8 (ExternalSupplyBoundary GAP ledger exposure)**.** *Every accepted* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$ *read exposes requested-supply pressure factors only through the* GAP *ledger row* G*, while the non-internalization row* I *records that the same request is not available as internal substrate content. The exposure is therefore a ledger read of boundary pressure, not a supply witness.*

Proof. Read the packet through Definition 1065.7. The rows I and G are coordinates of the same finite carrier, so a consumer cannot separate ledger pressure from the non-internalization status that names the request as external.

Apply Definition 1065.2. The local surface lists non-internalization exactness through I and GAP-ledger readback through G as distinct obligations over the same boundary packet.

Finally use Definition 1065.3. Since no coordinate supplies the requested content, the G read exposes only residue or socket pressure for the request named by R and refused by I. □

Theorem 1065.9 (ExternalSupplyBoundary socket readback)**.** *Every sibling boundary read through* $\mathsf{SupplySocketLedger}^{\uparrow}$*,* $\mathsf{ApophaticSocket}^{\uparrow}$*,* $\mathsf{AuditGateBoundary}^{\uparrow}$*, and* $\mathsf{ApophaticGateQuestion}^{\uparrow}$ *must pass through the displayed rows* A, G, Q, H, C, P, N *of the same accepted* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$ *packet. The readback may expose accepted boundary form, socket or residue ledger, gate question, transport, replay, provenance, and local naming, but it may not bypass those rows to obtain requested supply content.*

Proof. Use Definition 1065.6. The sibling surfaces named there consume the provenance row P together with the accepted form A, ledger G, and gate question Q.

Use Definition 1065.7 to place those rows inside the single finite carrier. The transport row H, replay row C, provenance row P, and naming row N keep the sibling read attached to that carrier rather than to an external socket convention.

Apply Definition 1065.8 and Definition 1065.3. The readback can carry socket pressure and the audit question, but the requested supply remains external to the packet. □

Falsifiable prediction: A boundary packet that omits either the non-internalization row or the GAP-ledger row cannot satisfy the non-internalization theorem.

Independence witness: Compare SupplySocketLedger, ApophaticSocket, AuditGateBoundary, and ApophaticGateQuestion: none is bijective to ExternalSupplyBoundary, because each lacks at least one of the requested-supply shape, accepted boundary form, GAP ledger, or gate-question rows required by the packet.

The Lean follow-up must provide explicit Nontrivial ExternalSupplyBoundary$^{\uparrow}$ and FieldFaithful ExternalSupplyBou instances in lean4/BEDC/Derived/ExternalSupplyBoundaryUp/TasteGate.lean before the chapter can claim a checked taste-gate target.

Closure status for NameCert$_{\text{ExternalSupplyBoundary}^{\uparrow}}$.

Constructive story: An ExternalSupplyBoundary$^{\uparrow}$ packet is generated from a boundary-name row, requested-supply-shape row, non-internalization row, accepted-boundary-form row, GAP ledger row, gate-question row, componentwise hsame transports, displayed Cont replay, package provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{ExternalSupplyBoundary}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1065.1, Definition 1065.2, Definition 1065.3, Definition 1065.4, Definition 1065.5, Definition 1065.6, Definition 1065.7, Definition 1065.8, and Definition 1065.9 bind the finite boundary packet, its NameCert obligations, non-internalization row, accepted-form exhaustion, gate-question determinacy, sibling compatibility, carrier admission, GAP-ledger exposure, and socket readback.

Lean4 ✓ `BEDC.Derived.ExternalSupplyBoundaryUp.taste gate`

Formal verification: FormalStatus(NameCert$_{\text{ExternalSupplyBoundary}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.ExternalSupplyBoundaryUp.ExternalSupplyBoundaryTasteGate\_single\_carrier\_alignment`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close internal witnesses, selectors, quotient representatives, supplied-content theorems, Lean TasteGate verification, or bridge checking.

Upgrade path: The theory axis has no higher closure grade; the remaining possible improvement is a bridgeCheckedV formal-axis target.

Chapter 1066

A Concrete Naming Certificate for $\mathsf{NonAxiomBoundaryForm}^{\uparrow}$

The $\mathsf{NonAxiomBoundaryForm}^{\uparrow}$ packet realizes the seven boundary forms of chapter 9395 as a finite classifier over existing BEDC surfaces. It consumes the name-to-gate discipline of chapter 584, the apophatic socket boundary of chapter 536, and the supply ledger of chapter 528. The packet classifies visible boundary forms; it does not turn the classified dependency into an internal theorem.

Definition 1066.1 (Non-axiom boundary form carrier)**.** *A* $\mathsf{NonAxiomBoundaryForm}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (B, K, S, G, H, C, P, N)$$

with the following displayed rows:

1. *B is the boundary site where unsupported supply, compression residue, or interface input would otherwise be consumed as substrate truth;*
2. *K is exactly one of the seven non-axiom boundary-form rows: inductive, def, setup-field, NameCert row, GAP ledger, bridge slot, or apophatic socket;*
3. *S is the source-surface row attached to K: a closed generator for inductive rows, a definitional source for def rows, a caller-provided setup field, a public* $\mathsf{NameCert}$ *surface, a* GAP *ledger, a separated bridge slot, or an* $\mathsf{ApophaticSocket}^{\uparrow}$ *boundary;*
4. *G is the gate row read through* $\mathsf{ExternalityGate}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, *or* $\mathsf{SupplySocketLedger}^{\uparrow}$ *when the classified form is a visible external-supply boundary;*
5. *H records componentwise* hsame *transport for the boundary site, kind row, source surface, gate row, route row, provenance row, and local naming row;*
6. *C records displayed* Cont *routes by which consumers read B, K, S, G before using the classifier result;*
7. *P is the* Pkg *provenance over chapter 9395, chapter 584, chapter 536, chapter 528,* BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{NonAxiomBoundaryForm}^{\uparrow}}$ *row.*

The carrier exports no coordinate for an axiom declaration, hidden selector, quotient representative, proposition-extensionality collapse, unledgered bridge, or supplied external content.

Lean4 (definition) `BEDC.Derived.NonAxiomBoundaryFormUp.NonAxiomBoundaryFormUp`

Theorem 1066.2 (Non-axiom boundary form NameCert obligations)**.** *For every accepted* NonAxiomBoundaryForm *carrier*

$$F = (B, K, S, G, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{NonAxiomBoundaryForm}^{\uparrow}}$ *surface consists exactly of carrier admission for the displayed tuple, boundary-site exposure through* B*, seven-kind classifier exposure through* K*, source-surface exactness through* S*, gate locality through* G*, componentwise* hsame *stability through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.NonAxiomBoundaryFormUp.NonAxiomBoundaryForm namecert obligations`

Proof. Project the carrier of Definition 1066.1. Its public rows are exactly B, K, S, G, H, C, P, N, so every NameCert obligation must be read from one of those coordinates.

The classifier obligation is the row K. It ranges only over the seven forms named in Definition 9395.2, while S records the corresponding source surface and G records the visible gate when the form is a socket, ledger, or externality-facing route.

Finally inspect H, C, P, N. These rows transport, replay, cite, and name the same finite classifier packet. They do not add an eighth form or a supplied object behind the boundary. □

Theorem 1066.3 (Non-axiom boundary form non-internalization)**.** *Every consumer of an accepted* $\mathsf{NonAxiomBoundaryForm}^{\uparrow}$ *packet must read the boundary site* B*, the classifier row* K*, and the source-surface row* S *before treating the dependency as admitted at a public interface. Changing* K *to an axiom row, deleting* S*, or bypassing the gate row* G *invalidates the public non-axiom route and supplies no internal BEDC theorem.*

Lean4 ✓ `BEDC.Derived.NonAxiomBoundaryFormUp.NonAxiomBoundaryForm noninternalization`

Proof. Start with the NameCert obligations above. They force the public route through B, K, S, G, H, C, P, N before any consumer receives the classifier result.

Use the external-supply discipline of chapter 9395. Each permitted boundary form keeps a source channel visible: constructor closure, definitional source, setup input, certificate row, GAP ledger, bridge separation, or apophatic socket.

Now compare the forbidden alternatives. An axiom row has no displayed source surface, deleting S removes the form-specific source channel, and bypassing G removes the gate for externality-facing forms. None of these routes is an accepted $\mathsf{NonAxiomBoundaryForm}^{\uparrow}$ packet.

Therefore the packet classifies boundary visibility without internalizing the requested supply. A consumer may cite the finite classifier and its source surface, but it receives no constructor, theorem, witness, quotient equality, or host principle not already displayed in the packet. □

The origin tag ai-composite records that this packet is a composite classifier over existing boundary-form surfaces. It therefore uses the carrier, obligation, and non-internalization rows above rather than atomic falsifiable-prediction or independence-witness rows.

Closure status for $\mathsf{NameCert}_{\mathsf{NonAxiomBoundaryForm}^{\uparrow}}$**.**

Constructive story: A $\mathsf{NonAxiomBoundaryForm}^{\uparrow}$ packet is generated from one boundary site, one of seven non-axiom boundary-form rows, the corresponding source-surface row, an externality-facing gate row when applicable, componentwise hsame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{NonAxiomBoundaryForm}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 1066.1, Definition 1066.2, and Definition 1066.3 bind the seven-form classifier, source-surface exactness, gate locality, provenance, and non-internalization boundary.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{NonAxiomBoundaryForm}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, complete discharge of any external supply, or an internal theorem corresponding to any classified socket.

Upgrade path: Public closure requires checked carrier alignment, seven-kind classifier exactness, source-surface stability, gate locality, and non-internalization for the displayed finite packet.

Chapter 1067

A Concrete Naming Certificate for $\mathsf{DigestFiberLedger}^{\uparrow}$

The $\mathsf{DigestFiberLedger}^{\uparrow}$ surface realizes the hash-like apophatic fixed-point discipline of chapter 9402 as a finite NameCert packet. It sits beside the hash certificate of chapter 242, the apophatic naming certificate of chapter 543, and the supply socket ledger of chapter 528. The packet keeps digest visibility, hidden fiber membership, GAP provenance, apophatic refusal, and consumer non-escape in one displayed carrier, so digest equality cannot silently become source equality.

Definition 1067.1 (DigestFiberLedger carrier)**.** *A* $\mathsf{DigestFiberLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (V, F, G, A, H, C, P, N)$$

with the following displayed rows:

1. *V is the visible digest row, read through the local* $\mathsf{Hash}^{\uparrow}$ *certificate surface;*
2. *F is the fiber-membership row recording which source histories are carried behind the visible digest without identifying them with the digest;*
3. *G is the* GAP *provenance row that makes the fiber membership auditable;*
4. *A is the apophatic refusal row that blocks treating the far end of the fiber as a kernel object, source payload, or global digest;*
5. *H records componentwise* hsame *transports for the digest, fiber, GAP, refusal, continuation, provenance, and local certificate rows;*
6. *C records the displayed* Cont *routes by which consumers read V, F, G, and A without obtaining source equality or an internal* T *object;*
7. *P is the* Pkg *provenance over* $\mathsf{Hash}^{\uparrow}$, $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{DigestFiberLedger}^{\uparrow}}$ *row.*

The carrier contains no coordinate for source equality derived from digest equality, no hidden preimage selector, no global universe digest, and no internal object representing the apophatic far end.

Lean4 (definition) `BEDC.Derived.DigestFiberLedgerUp.DigestFiberLedgerUp`

Theorem 1067.2 (DigestFiberLedger NameCert obligations)**.** *For the carrier of Definition 1067.1, the local* $\mathsf{NameCert}_{\mathsf{DigestFiberLedger}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$D = (V, F, G, A, H, C, P, N),$$

visible digest exposure through V*, fiber-membership exposure through* F*, GAP provenance through* G*, apophatic refusal through* A*, componentwise* hsame *transport through* H*, displayed continuation replay through* C*, package provenance through* P*, local naming through* N*, and non-escape for any consumer that tries to identify digest equality with source equality without the fiber and GAP rows.*

Lean4 ✓ `BEDC.Derived.DigestFiberLedgerUp.DigestFiberLedgerNameCertObligations`

Proof. Project the carrier in Definition 1067.1. Its displayed coordinates are precisely the visible digest, fiber-membership, GAP provenance, apophatic refusal, transport, continuation, provenance, and local naming rows.

Read the three nearest sources through their displayed roles. The $\mathsf{Hash}^{\uparrow}$ certificate supplies the digest-facing row, $\mathsf{ApophaticName}^{\uparrow}$ supplies the refusal discipline for the far end of the fiber, and $\mathsf{SupplySocketLedger}^{\uparrow}$ supplies the socket ledger that keeps the missing source from becoming an internal theorem.

The NameCert obligations are therefore exhausted by the rows of D. Since the carrier has no coordinate for source equality from digest equality, no hidden preimage selector, and no object-level far end, any accepted consumer must retain F, G, A, H, C, P, and N when it cites the visible digest. □

Theorem 1067.3 (DigestFiberLedger non-escape)**.** *Every accepted* $\mathsf{DigestFiberLedger}^{\uparrow}$ *consumer of a visible digest row factors through the displayed fiber-membership row* F*, GAP provenance row* G*, apophatic refusal row* A*, componentwise transport row* H*, continuation routes* C*, package provenance* P*, and local naming row* N*. No consumer can use equality of visible digest rows as equality of source histories unless an additional exactness certificate is displayed outside the* $\mathsf{DigestFiberLedger}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.DigestFiberLedgerUp.DigestFiberLedgerNonEscape`

Proof. Start with an accepted packet $D = (V, F, G, A, H, C, P, N)$. The visible row V is only the digest-facing surface, while F and G record the fiber and its provenance.

Apply the NameCert obligations of Definition 1067.2. A consumer route may cite the digest only through the same carrier that displays fiber membership, GAP provenance, apophatic refusal, componentwise transport, continuation replay, package provenance, and local naming.

The absence claim follows from the carrier inventory. No coordinate in D turns digest equality into source equality, selects a preimage, exposes a global universe digest, or internalizes the apophatic far end; any such use requires a separate displayed exactness certificate. □

Theorem 1067.4 (DigestFiberLedger public export)**.** *Every public digest read exported by an accepted* $\mathsf{DigestFiberLedger}^{\uparrow}$ *carrier exposes exactly the visible digest row, fiber-membership row, GAP provenance row, apophatic refusal row, componentwise* hsame *row, displayed* Cont *row,* Pkg *provenance row, and local* $\mathsf{NameCert}_{\mathsf{DigestFiberLedger}^{\uparrow}}$ *row. It exports no source equality, hidden preimage selector, global universe digest, or internal far-end object.*

Lean4 ✓ `BEDC.Derived.DigestFiberLedgerUp.DigestFiberLedgerPublicExport`

Proof. Apply the carrier inventory of Definition 1067.1. The public read begins at the visible digest coordinate V, but the same carrier also displays F, G, A, H, C, P, N as mandatory rows.

Apply Definition 1067.2 and Definition 1067.3. Together they force every accepted consumer to retain the fiber, GAP, refusal, transport, continuation, provenance, and local naming rows when the visible digest is cited.

The negative export claim is again coordinate-level. Since D contains no source equality row, no preimage-selection row, no universe-digest row, and no internal far-end row, none of those objects can be exported by a public digest read. □

Theorem 1067.5 (DigestFiberLedger bridge schema boundary)**.** *Any bridge consumer for a public* $\mathsf{DigestFiberLedger}^{\uparrow}$ *export must preserve the eight displayed rows*

$$(V, F, G, A, H, C, P, N)$$

of Definition 1067.1. To claim that digest equality reflects source equality, the consumer must also add a separate standard-bridge row witnessing the exact source-equality route; the public export alone is not such a bridge.

Proof. Start with the carrier $D = (V, F, G, A, H, C, P, N)$. The NameCert obligations of Definition 1067.2 make these rows the complete local packet: visible digest, fiber membership, GAP provenance, apophatic refusal, transport, continuation, package provenance, and local naming.

Apply the non-escape theorem Definition 1067.3. It rules out reading equality of visible digest rows as equality of source histories unless an additional exactness certificate is displayed outside the packet.

Finally apply the public export theorem Definition 1067.4. The exported surface retains V, F, G, A, H, C, P, N and exports no source equality row, hidden preimage selector, global universe digest, or internal far-end object. Hence a standard bridge must be an extra row, not a consequence of public export itself. □

Falsifiable prediction: A consumer that identifies digest equality with source equality without the GAP fiber row refutes the DigestFiberLedgerUp packet.

Independence witness: Nearest siblings: hash, apophaticname, supplysocketledger, apophaticgatequestion, inscriptiongapledger. The carrier is not bijective to any sibling because it simultaneously stores digest visibility, fiber membership, GAP provenance, and apophatic non-internalization rows, while each sibling omits at least one of those obligations.

The proposed Lean `TasteGate.lean` boundary is `lean4/BEDC/Derived/DigestFiberLedgerUp/TasteGate.le` It must provide `Nontrivial DigestFiberLedgerUp` and `FieldFaithful DigestFiberLedgerUp` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{DigestFiberLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{DigestFiberLedger}^{\uparrow}$ packet is generated from a visible digest row, hidden fiber-membership row, GAP provenance row, apophatic refusal row, componentwise hsame transport, displayed continuation routes, package provenance, and a local NameCert row.

Lean4 ✓ `BEDC.Derived.DigestFiberLedgerUp.taste gate`

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DigestFiberLedger}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1067.1, Definition 1067.2, Definition 1067.3, Definition 1067.4, and the bridge-schema boundary of Definition 1067.5 bind the displayed digest, fiber, GAP, refusal, transport, continuation, provenance, local naming, public export, and bridge-schema packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DigestFiberLedger}^{\uparrow}}, \mathsf{encodedDef})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close source equality from digest equality, hidden preimage selection, global universe digest exposure, Lean verification, or bridge verification.

Upgrade path: Bridged closure requires a checked public schema bridge for the same digest, fiber, GAP, refusal, hsame, Cont, Pkg, and NameCert rows.

Chapter 1068

A Concrete Naming Certificate for $\mathsf{ApophaticFixedPoint}^{\uparrow}$

The $\mathsf{ApophaticFixedPoint}^{\uparrow}$ packet realizes the vision of chapter 9401 as a finite NameCert carrier. It consumes the apophatic name discipline of chapter 543, the local inscription surface of chapter 610, the visible socket-use ledger of chapter 1044, and the fixed witness discipline of chapter 556. The packet keeps far-end unification, local inscription readback, boundary noninternalization, and fixed-point ledger rows together without turning the far end into a kernel object.

Definition 1068.1 (ApophaticFixedPoint carrier)**.** *An* $\mathsf{ApophaticFixedPoint}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (S, T, I, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the forward-socket family row, recording the finite socket names, their requested supply shapes, visible use sites, and socket-use ledger links;*
2. *T is the apophatic far-end boundary row, naming the unique far end common to the displayed socket family without representing it as a kernel object;*
3. *I is the local inscription point row, recording where the common far-end boundary is read back on the local observation chain;*
4. *L is the boundary ledger row, recording the fixed-point ledger entries, refused internalizations, and accepted local readback events for the same socket family;*
5. *H records componentwise* hsame *transports for S, T, I, L, the continuation row, the package row, and the local naming row;*
6. *C records the displayed* Cont *routes by which consumers read the socket family, far-end boundary, local inscription point, ledger rows, provenance, and local certificate;*
7. *P is the* Pkg *provenance over* $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{InscriptionPoint}^{\uparrow}$, $\mathsf{SocketUseLedger}^{\uparrow}$, $\mathsf{GeneratorFixedPoint}^{\uparrow}$, BHist, GAP, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ApophaticFixedPoint}^{\uparrow}}$ *row.*

The carrier contains exactly these rows. It has no coordinate for an internal object T*, no equality between the far-end boundary and a local state, no detached self-center object, no hidden socket selector, and no host fixed-point principle outside the displayed ledger.*

Theorem 1068.2 (ApophaticFixedPoint NameCert obligations)**.** *For the carrier of Definition 1068.1, the local* $\mathsf{NameCert}_{\mathsf{ApophaticFixedPoint}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$F = (S, T, I, L, H, C, P, N),$$

forward-socket family exposure through S*, unique apophatic far-end naming through* T*, local inscription readback through* I*, boundary-ledger coverage through* L*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.ApophaticFixedPointUp.ApophaticFixedPointTasteGate single carrier alignment`

Proof. Carrier admission is projection from Definition 1068.1. The tuple lists the socket family, far-end boundary, local inscription point, ledger, transport, continuation, provenance, and local naming rows.

Read the four nearest concrete sources through their displayed roles. The $\mathsf{ApophaticName}^{\uparrow}$ row supplies boundary naming, $\mathsf{InscriptionPoint}^{\uparrow}$ supplies the local inscription readback surface, $\mathsf{SocketUseLedger}^{\uparrow}$ supplies visible socket-use rows, and $\mathsf{GeneratorFixedPoint}^{\uparrow}$ supplies fixed-witness ledger discipline.

The NameCert obligations are exhausted by S, T, I, L, H, C, P, N. Since the carrier has no coordinate for an internal T object, detached self-center, hidden selector, or host fixed-point principle, every accepted read remains a finite certificate route. □

Theorem 1068.3 (ApophaticFixedPoint boundary noninternalization)**.** *For an accepted* $\mathsf{ApophaticFixedPoint}^{\uparrow}$ *packet, the far-end row* T *is readable only as the common apophatic boundary of the displayed forward-socket family* S*. A consumer may transport or replay this row through* H, C, P, N*, but it cannot read* T *as a kernel object, local state,* BHist *constructor, selected supply witness, object-level equality, or host fixed-point theorem.*

Proof. Start with the carrier inventory in Definition 1068.1. The far-end coordinate is the boundary row T, and its socket domain is the displayed family S.

The ledger row L records which attempted internalizations are refused, while H, C, P, N only transport, replay, package, and name the same finite rows. None of these rows adds a kernel carrier for the far end.

Apply the NameCert obligations of Definition 1068.2. They bind every read of T to S, T, I, L, H, C, P, N, so a far-end read that treats T as an object, state, constructor, selected witness, equality, or host theorem has no accepted route in the packet. □

Theorem 1068.4 (ApophaticFixedPoint local inscription readback)**.** *Every accepted local readback of an* $\mathsf{ApophaticFixedPoint}^{\uparrow}$ *packet factors through the route*

$$S \longmapsto T \longmapsto I \longmapsto L \longmapsto H, C, P, N.$$

The read first exposes the socket family, then names the unique apophatic far-end boundary, then records the local inscription point, and finally checks the boundary ledger, transport, continuation, provenance, and local NameCert *rows. It exports no local inscription read that bypasses the socket family or internalizes the far end.*

Proof. Project an accepted packet $F = (S, T, I, L, H, C, P, N)$. The local inscription row is I, but it is part of the same finite carrier as the socket family S and far-end boundary T.

Use Definition 1068.3. It blocks any read that turns T into an internal object before I is consumed as a local inscription point.

The remaining rows give the public readback surface. The ledger row L records accepted local readback and refused internalization attempts, while H, C, P, N preserve and expose only the displayed route. Thus every local inscription readback factors through the stated finite chain. □

Falsifiable prediction: Any accepted ApophaticFixedPointUp packet whose far-end row is read as a kernel object violates the boundary-noninternalization theorem.

Independence witness: apophaticname, inscriptionpoint, socketuseledger, generatorfixedpoint: none combines forward-socket unification, local inscription readback, boundary noninternalization, and fixed-point ledger rows in one packet.

The proposed Lean `TasteGate.lean` boundary is `lean4/BEDC/Derived/ApophaticFixedPointUp/TasteGate.` It must provide `Nontrivial ApophaticFixedPointUp` and `FieldFaithful ApophaticFixedPointUp` instances for the same displayed carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{ApophaticFixedPoint}^{\uparrow}}$.

Constructive story: An $\mathsf{ApophaticFixedPoint}^{\uparrow}$ packet is generated from a forward-socket family row, apophatic far-end boundary row, local inscription point row, boundary ledger row, componentwise transports, displayed continuations, package provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ApophaticFixedPoint}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1068.1, Definition 1068.2, Definition 1068.3, Definition 1068.4, the falsifiable prediction, the independence witness, and the sibling references to $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{InscriptionPoint}^{\uparrow}$, $\mathsf{SocketUseLedger}^{\uparrow}$, and $\mathsf{GeneratorFixedPoint}^{\uparrow}$ bind the finite obligation carrier over S, T, I, L, H, C, P, N with the bridge-facing TasteGate carrier alignment recorded on the formal axis.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ApophaticFixedPoint}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.ApophaticFixedPointUp.ApophaticFixedPointTasteGate\_single\_carrier\_alignment`

Lean4 ✓ `BEDC.Derived.ApophaticFixedPointUp.taste gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close an internal far-end object, host fixed-point theorem, hidden socket selection, object-level equality, standard bridge, or bridge checking.

Upgrade path: Bridge checking requires a standard bridge theorem for the same S, T, I, L, H, C, P, N packet.

Chapter 1069

A Concrete Naming Certificate for $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$

The $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$ packet realizes the apophatic fixed-point and local-inscription reading of chapter 9401 as a finite NameCert surface. It consumes visible rows already separated by chapter 584, chapter 528, chapter 556, and chapter 242: the gate row refuses hidden supply, the socket ledger names the refused supply kind, the generator fixed-point row controls displayed fixed-output reads, and the hash row supplies digest-facing public readback. The new carrier is the fiber that forces those rows to be read in the apophatic order rather than as a direct digest-to-far-end identification.

Definition 1069.1 (Apophatic fixed-point fiber carrier)**.** *An* $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (D, S, G, T, I, H, C, P, N)$$

with the following displayed rows:

1. *D is the visible digest and socket readback row, carrying the public digest-facing observation together with the socket handle through which the packet is read;*
2. *S is the external-supply socket row supplied by the finite supply-ledger discipline;*
3. *G is the* GAP *fiber and provenance row, recording that every accepted public read passes through a boundary-fiber witness before it reaches any apophatic far-end name;*
4. *T is the apophatic far-end boundary-name row, naming the fixed far end only as boundary data and not as a kernel object;*
5. *I is the local inscription row, recording the chain-local site at which the boundary name is read inscription-side;*
6. *H records componentwise* hsame *transport for D, S, G, T, I, P, N and for the local packet shape;*
7. *C records the displayed* Cont *routes by which consumers read the digest, socket, GAP fiber, far-end boundary, inscription, provenance, and naming rows in order;*
8. *P records* Pkg *provenance over* BHist*, digest rows, externality gates, supply sockets, generator fixed-point witnesses, hash readback,* GAP *fibers, local inscriptions,* hsame*,* Cont*, and the local naming surface;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ApophaticFixedPointFiber}^{\uparrow}}$ *row.*

The carrier contains no row identifying D directly with T, no internal object for T*, and no hidden route from a public digest to an apophatic far end.*

Lean4 ✓ `BEDC.Derived.ApophaticFixedPointFiberUp.ApophaticFixedPointFiberTasteGate single carrier alignment`

Theorem 1069.2 (Apophatic fixed-point fiber NameCert obligations)**.** *For the carrier of Definition 1069.1, the local* $\mathsf{NameCert}_{\mathsf{ApophaticFixedPointFiber}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$F = (D, S, G, T, I, H, C, P, N),$$

digest-and-socket readback through D, external-supply exposure through S, GAP-fiber routing through G, boundary-name exposure through T, local-inscription exposure through I, componentwise hsame *transport through H, displayed continuation routing through C, package provenance through P, local naming through N, and refusal of any direct digest-to-T route that omits the GAP fiber row.*

Lean4 ✓ `BEDC.Derived.ApophaticFixedPointFiberUp.ApophaticFixedPointFiber namecert obligations`

Proof. Carrier admission is projection from Definition 1069.1. The packet displays the digest, socket, GAP fiber, far-end boundary name, local inscription, transport, route, provenance, and local certificate rows as its complete inventory.

The readback obligations are ordered by the same inventory. A consumer first reads the digest and socket row D, then the external-supply socket row S, then the GAP fiber row G before the boundary-name row T and the inscription row I become available.

The transport, continuation, provenance, and naming rows preserve that order. Since the carrier has no coordinate for a direct digest-to-T identification, a route that bypasses G has no NameCert row to project and is rejected by the packet. □

Theorem 1069.3 (Apophatic fixed-point fiber non-escape)**.** *Every accepted* $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$ *public read reaches the GAP fiber row G before it reaches the apophatic far-end boundary-name row T. A read that travels from the digest/socket row D to T without passing through G is outside the local certificate and refutes the packet.*

Lean4 ✓ `BEDC.Derived.ApophaticFixedPointFiberUp.ApophaticFixedPointFiberCarrier gap first route nonescape`
Lean4 ✓ `BEDC.Derived.ApophaticFixedPointFiberUp.ApophaticFixedPointFiber nonescape`

Proof. Start from the finite carrier inventory. The only displayed path from public digest readback to the apophatic far-end boundary is the route family C applied to the rows D, S, G, T, I.

Apply the NameCert obligations. They make GAP-fiber routing a certificate row, not a prose convention, so any accepted read of T must preserve the intervening G coordinate and its provenance.

A direct route from D to T would require a carrier coordinate that the tuple does not contain. The local naming row N therefore has no certificate surface for such a route, and the attempted read is rejected rather than exported as an apophatic fixed-point fiber. □

Theorem 1069.4 (Apophatic fixed-point fiber sibling independence)**.** $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$ *is not bijective to the nearest sibling packets* $\mathsf{ExternalityGate}^{\uparrow}$*,* $\mathsf{SupplySocketLedger}^{\uparrow}$*,* $\mathsf{GeneratorFixedPoint}^{\uparrow}$*, or* $\mathsf{Hash}^{\uparrow}$*. Each sibling omits at least one row required by the fiber: digest/socket readback, external-supply socket, GAP fiber, apophatic far-end boundary name, or local inscription. Conversely, the fiber does not replace those siblings; it binds their rows into a single ordered NameCert packet with the GAP fiber between the public digest and the apophatic far end.*

Lean4 ✓ `BEDC.Derived.ApophaticFixedPointFiberUp.ApophaticFixedPointFiber independence witness`

Proof. Compare the carrier rows. $\mathsf{ExternalityGate}^{\uparrow}$ supplies a gate and refusal surface but lacks the digest/socket readback, generator fixed-point witness, hash digest, and local inscription rows required here.

$\mathsf{SupplySocketLedger}^{\uparrow}$ supplies the socket ledger but lacks the digest row, GAP-fiber order row, far-end boundary-name row, and local inscription row as one packet. $\mathsf{GeneratorFixedPoint}^{\uparrow}$ supplies a fixed-output witness but not the apophatic far-end boundary or inscription rows. $\mathsf{Hash}^{\uparrow}$ supplies digest-facing readback but neither the socket ledger nor the GAP fiber and far-end boundary.

Thus no bijection can preserve all carrier coordinates and NameCert obligations. Forgetting any of D, S, G, T, I changes the accepted public-read order, while adding such a row to a sibling changes that sibling's carrier rather than identifying it with the fiber. □

Falsifiable prediction: Every public read of an accepted ApophaticFixedPointFiberUp packet reaches the GAP fiber row before the apophatic far-end row; a direct digest-to-T route refutes the packet.

Independence witness: Nearest siblings: externalitygate, supplysocketledger, generatorfixed-point, and hash. None is bijective because each omits at least one of the digest, socket, GAP fiber, far-end boundary, or local-inscription rows, while the fiber requires all five rows together with componentwise hsame transport, displayed Cont routes, Pkg provenance, and the local NameCert row.

Theorem 1069.5 (Apophatic fixed-point fiber scoped route)**.** *Every accepted* $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$ *public read is scoped by the concrete rows*

$$D, S, G, T, I, H, C, P, N$$

of Definition 1069.1 and by the sibling dependencies $\mathsf{ExternalityGate}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{GeneratorFixedPoint}^{\uparrow}$, *and* $\mathsf{Hash}^{\uparrow}$. *The GAP fiber row G lies between the digest/socket row D and the apophatic far-end boundary row T, so the local certificate exposes only the row-scoped route through $D, S, G, T, I, H, C, P, N$ and rejects any direct digest-to-far-end read.*

Proof. Use the carrier rows of Definition 1069.1. They give the accepted public read a finite inventory: digest/socket readback, external-supply socket, GAP fiber, far-end boundary name, local inscription, transport, continuation, provenance, and local naming.

Apply Definition 1069.2. The NameCert surface exports those rows in the displayed order, with the sibling packets supplying the externality gate, supply socket ledger, generator fixed-point, and hash-facing readback dependencies.

Apply Definition 1069.3. Since the only route from D to T passes through G, the GAP fiber is not optional boundary prose but a carrier row. Finally use Definition 1069.4: forgetting any of the sibling-dependent rows changes the packet rather than preserving an accepted scoped read. □

Lean4 ✓ `BEDC.Derived.ApophaticFixedPointFiberUp.ApophaticFixedPointFiber scoped route`

Theorem 1069.6 (Apophatic fixed-point fiber public export surface)**.** *Every accepted* $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$ *packet exports exactly the public read surface*

$$D, S, G, T, I, H, C, P, N$$

with GAP-first ordering. The sibling dependency rows are read through $\mathsf{ExternalityGate}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{GeneratorFixedPoint}^{\uparrow}$, *and* $\mathsf{Hash}^{\uparrow}$, *and every digest-facing public read must pass through the GAP*

fiber before the apophatic far-end boundary is exposed. This is the public object surface of the packet, not a bridge credential.

Proof. Project the carrier of Definition 1069.1. The displayed rows are precisely $D, S, G, T, I, H, C, P, N$, and the carrier has no coordinate for a direct digest-to-far-end identification.

Apply the NameCert obligations of Definition 1069.2. They bind the digest/socket row, external-supply socket, GAP fiber, far-end boundary, local inscription, transport, replay, provenance, and local naming as the only exported rows.

Use the non-escape theorem Definition 1069.3 and the sibling-independence theorem Definition 1069.4. These keep $\mathsf{ExternalityGate}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{GeneratorFixedPoint}^{\uparrow}$, and $\mathsf{Hash}^{\uparrow}$ as visible dependencies rather than hidden bridge credentials.

Finally apply the scoped-route theorem Definition 1069.5. It forces the GAP-first public read order, so the theorem exports a public object surface only and does not certify an acceptance bridge. □

Closure status for $\mathsf{NameCert}_{\mathsf{ApophaticFixedPointFiber}^{\uparrow}}$.

Constructive story: An $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$ packet is generated from a digest/socket row, external-supply socket row, GAP fiber/provenance row, apophatic far-end boundary-name row, local inscription row, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ApophaticFixedPointFiber}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: Definition 1069.1, Definition 1069.2, Definition 1069.3, Definition 1069.4, and Definition 1069.5 bind the finite carrier, GAP-first read order, direct digest-to-far-end refusal, nearest-sibling independence surface, and scoped public-read route.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ApophaticFixedPointFiber}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a public bridge, an object-level value for T, a hidden external supply, or a global observer-substance theorem.

Upgrade path: Bridge-facing readback requires a displayed standard bridge over the same finite packet, without turning the TasteGate row into a bridge credential.

Chapter 1070

A Concrete Naming Certificate for $\mathsf{BoundaryGate}^{\uparrow}$

The $\mathsf{BoundaryGate}^{\uparrow}$ packet realizes the boundary-gate construction of chapter 9395 as a finite NameCert surface. It sits beside the external-supply boundary of chapter 1065, the socket ledger of chapter 528, the supply-kind router of chapter 666, the audit membrane of chapter 524, and the audit-gate boundary of chapter 526. Those siblings isolate boundary records, socket ledgers, kind routing, refusal replay, or audit inventory; this packet binds the gate question and audit verdict to the visible boundary form and site route in one carrier.

Definition 1070.1 (BoundaryGate carrier)**.** *A* $\mathsf{BoundaryGate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (B, Q, V, S, H, C, P, N)$$

with the following displayed rows:

1. *B is the boundary-form row, recording the accepted external-supply boundary form being tested;*
2. *Q is the gate-question row, recording the finite question asked of that boundary form;*
3. *V is the audit-verdict row, recording the pass-or-refuse result for the question Q at boundary form B;*
4. *S is the visible site route, recording the socket, marker, dependency, certificate row, or import edge at which the boundary is read;*
5. *H records componentwise* hsame *transports for B, Q, V, S together with continuation, provenance, and naming rows;*
6. *C records the displayed* Cont *routes by which consumers inspect the boundary form, gate question, audit verdict, and visible site route;*
7. *P is the* Pkg *provenance over* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{SupplyKindRouter}^{\uparrow}$, $\mathsf{AuditMembrane}^{\uparrow}$, $\mathsf{AuditGateBoundary}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{BoundaryGate}^{\uparrow}}$ *row.*

The carrier exports no hidden boundary content, no verdict detached from the boundary form, no route that treats refused supply as substrate theorem content, and no host-side permission to answer the gate without displaying B, Q, V, S, H, C, P, N.

Theorem 1070.2 (BoundaryGate NameCert obligations)**.** *For the carrier of Definition 1070.1, the local* $\mathsf{NameCert}_{\mathsf{BoundaryGate}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$G = (B, Q, V, S, H, C, P, N),$$

boundary-form exposure through B*, gate-question exposure through* Q*, audit-verdict exposure through* V*, visible-site routing through* S*, componentwise* hsame *stability through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Consequently, an accepted $\mathsf{BoundaryGate}^{\uparrow}$ *packet cannot expose a verdict without the boundary form it judges, cannot expose a boundary form without the gate question and site route, and cannot route refused boundary content into substrate theorem content.*

Lean4 ✓ `BEDC.Derived.BoundaryGateUp.BoundaryGateTasteGate single carrier alignment`

Proof. Project the displayed carrier. The accepted packet lists B, Q, V, S, H, C, P, N as its full inventory, so the local naming certificate has no coordinate from which to introduce a second boundary form, gate question, verdict, site route, transport, continuation, provenance, or local name.

Read the gate-facing rows first. The boundary form B names what kind of external-supply boundary is being tested, Q names the finite question asked of that form, and V records the audit verdict for that question.

Next read the routing rows. The site route S makes the tested location visible, while H and C transport and replay only the same displayed rows.

Finally inspect P and N. Provenance ties the packet to its sibling surfaces, and the local name binds the finite inventory. Since the carrier has no coordinate for hidden boundary content or detached verdicts, every accepted read remains inside the displayed NameCert surface. □

Theorem 1070.3 (BoundaryGate non-internalization)**.** *Every accepted* $\mathsf{BoundaryGate}^{\uparrow}$ *packet preserves the external-supply boundary it judges. A downstream consumer may read* B, Q, V, S, H, C, P, N *as a finite audit surface for the boundary gate, but it may not read from the packet an internal witness of the requested supply, a replacement theorem for refused content, an off-site verdict, a selected boundary representative, a quotient collapse, a hidden host equality, or a bridge row.*

Lean4 ✓ `BEDC.Derived.BoundaryGateUp.BoundaryGate noninternalization`

Proof. Begin with the boundary-form and gate-question rows. The pair B, Q fixes the boundary and the finite question as displayed certificate content rather than as an implicit host-side convention.

Use the audit-verdict row V together with the visible site route S. A verdict is accepted only as the result of testing the displayed boundary form at the displayed site; it is not an independent source of requested supply.

The transport and replay rows H and C preserve that same packet under componentwise movement and consumer access. They do not add a selector, quotient representative, theorem object, host equality, or bridge coordinate.

The provenance and local naming rows P, N bind the packet to $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{SupplyKindRouter}^{\uparrow}$, $\mathsf{AuditMembrane}^{\uparrow}$, and $\mathsf{AuditGateBoundary}^{\uparrow}$ as sibling sources. Since none of the displayed rows supplies the refused content itself, the accepted boundary gate keeps the judged supply external. □

Theorem 1070.4 (BoundaryGate carrier admission)**.** *Every admitted* $\mathsf{BoundaryGate}^{\uparrow}$ *carrier is admitted only as a finite* BHist *packet*

$$G = (B, Q, V, S, H, C, P, N)$$

whose rows display the boundary form B*, gate question* Q*, audit verdict* V*, visible site route* S*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*,* Pkg *provenance* P*, and local* NameCert *row* N*. In particular, the verdict* V *cannot be admitted apart from the boundary form* B *and visible site route* S*.*

Lean4 ✓ `BEDC.Derived.BoundaryGateUp.BoundaryGateCarrierAdmission`

Proof. Project the carrier of Definition 1070.1. The row inventory is exactly B, Q, V, S, H, C, P, N, so admission begins with the displayed boundary form, question, verdict, and site route.

The structural rows do not add a detached verdict. The hsame row H transports the same displayed data, the Cont row C replays access through the same packet, and P, N bind provenance and local naming to that inventory.

Thus carrier admission is a row projection from the displayed packet. Since no carrier coordinate stores V without B and S, an admitted verdict remains attached to the boundary form and visible site route. □

Theorem 1070.5 (BoundaryGate classifier stability)**.** *For any accepted* $\mathsf{BoundaryGate}^{\uparrow}$ *packet* $G = (B, Q, V, S, H, C, P, N)$*, the classifier is stable only under componentwise* hsame *transport of the displayed rows* B, Q, V, S, H, C, P, N *and displayed* Cont *replay through the same* Pkg *and* NameCert *surface. A transported verdict remains the verdict for boundary form* B *at visible site route* S*; it cannot become a route-free audit result.*

Proof. Start with the classifier rows displayed by the carrier. The boundary form, question, verdict, and site route are compared as named coordinates of one finite packet.

Apply the transport row. Componentwise hsame preserves each displayed coordinate as the same row for classifier purposes, so a stable read carries B, Q, V, S together rather than moving V alone.

Finally use the replay and provenance rows. The Cont row C, Pkg row P, and local NameCert row N replay only the same packet, so classifier stability cannot detach the verdict from the boundary form or visible site route. □

Lean4 ✓ `BEDC.Derived.BoundaryGateUp.BoundaryGateClassifierStability`

Theorem 1070.6 (BoundaryGate ledger nonescape)**.** *Every ledger read from an accepted* $\mathsf{BoundaryGate}^{\uparrow}$ *carrier* $G = (B, Q, V, S, H, C, P, N)$ *must expose the boundary form* B*, gate question* Q*, audit verdict* V*, visible site route* S*,* BHist *transport row* H*,* Cont *replay row* C*,* Pkg *provenance row* P*, and local* NameCert *row* N *together. No ledger consumer can export* V *as supplied content, as a hidden boundary witness, or as a verdict detached from* B *and* S*.*

Proof. Read the ledger-facing packet as displayed finite data. The rows B, Q, V, S identify what is judged, which finite question is asked, what verdict is recorded, and where the boundary is read.

Now inspect the structural route. The BHist transport row H and Cont replay row C keep ledger access inside the same carrier, while P and N record provenance and local naming.

Because the carrier contains no extra row for supplied content, hidden boundary witnesses, or route-free verdicts, the ledger cannot export such data. The verdict remains a visible row of the boundary gate rather than an escaping object. □

Theorem 1070.7 (BoundaryGate verdict-site route stability)**.** *For every accepted* BoundaryGate$^{\uparrow}$ *carrier* $G = (B, Q, V, S, H, C, P, N)$*, the audit verdict row* V *remains attached to both the boundary-form row* B *and the visible-site route* S *under componentwise* hsame *transport and displayed* Cont *replay. In particular, no stable replay can read* V *as a route-free verdict, as supplied theorem content, or as a boundary decision detached from the site where* B *is inspected.*

Proof. Start from the carrier of Definition 1070.1. Its displayed packet has a single verdict coordinate V, and that coordinate is listed together with the boundary form B, gate question Q, visible site route S, transport row H, replay row C, provenance row P, and local name N.

Apply Definition 1070.5. Componentwise hsame transport preserves the classifier only by moving the displayed rows together, so a transported read of V still carries the same boundary form and visible site route.

Finally apply Definition 1070.6. Ledger consumption cannot export V as hidden supply or as a detached verdict. The displayed Cont replay therefore returns the verdict only through the same boundary-form and site-route rows that admitted it. □

Falsifiable prediction: Any accepted BoundaryGateUp packet that admits boundary content without exposing both the boundary-form row and the audit-verdict row is rejected by the NameCert surface.

Independence witness: Nearest siblings: external-supply-boundary, supply-socket-ledger, supply-kind-router, audit-membrane, audit-gate-boundary. None is bijective because BoundaryGateUp carries the gate question and verdict rows together with the visible boundary form and site route, while the siblings isolate boundary, socket kind, kind routing, refusal replay, or gate-boundary inventory.

The Lean follow-up must provide Nontrivial BoundaryGate$^{\uparrow}$ and FieldFaithful BoundaryGate$^{\uparrow}$ in lean4/BEDC/Derived/BoundaryGateUp/TasteGate.lean before the taste-gate target BEDC.Derived.BoundaryGateUp.T can be used as a checked correspondence.

Closure status for NameCert$_{\text{BoundaryGate}^{\uparrow}}$**.**

Constructive story: A BoundaryGate$^{\uparrow}$ packet is generated from a boundary-form row, gate-question row, audit-verdict row, visible site route, componentwise hsame transport, displayed Cont routes, provenance, and local naming. The carrier asks a finite question of a visible external-supply boundary and records the verdict only with that boundary and site still present. The classifier therefore admits a gate read by projecting B, Q, V, S, H, C, P, N together: transport preserves the same boundary form, and continuation replay prevents the verdict from becoming detached supply content.

Theory closure: TheoryGate(NameCert$_{\text{BoundaryGate}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 1070.1, Definition 1070.2, Definition 1070.4, Definition 1070.5, Definition 1070.6, and Definition 1070.7 bind the exact boundary, verdict, site-route, and TasteGate scope over B, Q, V, S, H, C, P, N, BHist, hsame, Cont, Pkg, NameCert, and the sibling external-supply boundary packets.

Formal verification: FormalStatus(NameCert$_{\text{BoundaryGate}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.BoundaryGateUp.BoundaryGateCarrierAdmission`

Bridge status: none

Origin: ai

Not claimed: It does not claim hidden boundary content, detached verdicts, supplied theorem content, quotient representatives, host equality, or bridge rows.

Upgrade path: Public export requires exposing the same B, Q, V, S, H, C, P, N scoped gate through a consumer-facing surface without adding hidden boundary content, detached verdicts, supplied theorem content, quotient representatives, host equality, or bridge rows.

Chapter 1071

A Concrete Naming Certificate for $\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}$

The $\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}$ packet realizes the local self-center reading of chapter 9401 as a finite NameCert seal. It consumes the local inscription row of chapter 610, the apophatic socket row of chapter 536, the supply inscription surface of chapter 604, the observer-history identity discipline of chapter 479, and the public event route of chapter 519. The seal binds those rows without identifying a local self-center with the apophatic far end.

Definition 1071.1 (Local self-center inscription seal carrier)**.** *A* $\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (H, I, S, A, V, R, C, P, N)$$

with the following displayed rows:

1. *H is the local history row, read through the observer-history identity surface and carrying no subject-substance coordinate;*
2. *I is the inscription point row, naming the local site at which the chain's accumulation event is read inscription-side;*
3. *S is the self-center reading row, recording the aspectual read of the same local event as self-center data;*
4. *A is the apophatic socket row, naming the boundary-facing far-end route without representing that far end as a kernel object;*
5. *V is the nonidentity verdict row, recording that the self-center reading row S and the apophatic socket far-end row A are not object-level equal rows;*
6. *R records componentwise* hsame *transport for H, I, S, A, V and for the local naming row;*
7. *C records the displayed* Cont *routes by which consumers read the local history, inscription point, self-center row, apophatic socket row, verdict row, provenance, and local certificate;*
8. *P is the* Pkg *provenance over* $\mathsf{InscriptionPoint}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{TranscendentalSupplyInscription}^{\uparrow}$, $\mathsf{ObserverHistIdentity}^{\uparrow}$, $\mathsf{InscriptionEvent}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}}$ *row.*

The carrier contains no coordinate for an internal object T*, no subject behind the displayed history row, no equality between* S *and* A*, and no hidden route that reads the apophatic far end as a local state.*

Lean4 (definition) `BEDC.Derived.LocalSelfCenterInscriptionSealUp.LocalSelfCenterInscriptionSealUp`

Theorem 1071.2 (Local self-center inscription seal NameCert obligations)**.** *For the carrier of Definition 1071.1, the local* $\mathsf{NameCert}_{\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$L = (H, I, S, A, V, R, C, P, N),$$

local history exposure through H*, inscription-point locality through* I*, self-center reading through* S*, apophatic socket exposure through* A*, nonidentity verdict through* V*, componentwise* hsame *transport through* R*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.LocalSelfCenterInscriptionSealUp.LocalSelfCenterInscriptionSealUp taste gate boundary`

Proof. Carrier admission is projection from Definition 1071.1. The tuple displays the local history, inscription point, self-center read, apophatic socket, nonidentity verdict, transport, route, provenance, and naming rows.

The sibling chapters supply only their named roles. $\mathsf{InscriptionPoint}^{\uparrow}$ supplies the local inscription row, $\mathsf{ApophaticSocket}^{\uparrow}$ supplies the boundary-facing socket row, $\mathsf{TranscendentalSupplyInscription}^{\uparrow}$ supplies the supply-inscription provenance, $\mathsf{ObserverHistIdentity}^{\uparrow}$ supplies the no-subject history discipline, and $\mathsf{InscriptionEvent}^{\uparrow}$ supplies the public event route.

The local NameCert row is exhausted by these displayed rows. Since no coordinate identifies S with A, every accepted read of the self-center remains an inscription-side local row rather than a far-end object. □

Lean4 ✓ `BEDC.Derived.LocalSelfCenterInscriptionSealUp.LocalSelfCenterInscriptionSealTasteGate single carrier alignment`

Theorem 1071.3 (Local self-center inscription seal nonidentity boundary)**.** *For every accepted* $\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}$ *carrier* $L = (H, I, S, A, V, R, C, P, N)$*, a consumer may read* S *only as the local self-center inscription row and may read* A *only as the apophatic socket row. Any packet that identifies* S *with the far-end row of* A *fails the nonidentity verdict row* V *and is not accepted as this seal.*

Proof. Project the accepted carrier. The self-center row and apophatic socket row occur as separate coordinates S and A, and the verdict row V is the displayed boundary between them.

The transport and continuation rows preserve that separation. They replay S and A through R and C but do not add an equality coordinate or a kernel value for the far end.

Apply the NameCert obligations of Definition 1071.2. A packet that identifies the local self-center with the apophatic far end omits the required verdict, so the local name row has no accepted certificate surface for it. □

Lean4 ✓ `BEDC.Derived.LocalSelfCenterInscriptionSealUp.LocalSelfCenterInscriptionSealSelfCenter nonidentity boundary`

Theorem 1071.4 (Local self-center inscription seal sibling separation)**.** LocalSelfCenterInscriptionSeal$^{\uparrow}$ *is not bijective, under NameCert-row preservation, to* InscriptionPoint$^{\uparrow}$, ApophaticSocket$^{\uparrow}$, TranscendentalSupplyInsc ObserverHistIdentity$^{\uparrow}$, *or* InscriptionEvent$^{\uparrow}$. *None of those siblings carries the simultaneous local history, inscription-point, self-center reading, apophatic socket, and nonidentity verdict rows required by Definition 1071.1.*

Proof. Compare the carrier rows. InscriptionPoint$^{\uparrow}$ records a local inscription surface but not the self-center verdict against an apophatic far end. ApophaticSocket$^{\uparrow}$ records the boundary-facing socket but not the local self-center reading.

TranscendentalSupplyInscription$^{\uparrow}$ supplies supply-inscription provenance, ObserverHistIdentity$^{\uparrow}$ supplies no-subject history identity, and InscriptionEvent$^{\uparrow}$ supplies public event routing. Each omits at least one of the displayed rows H, I, S, A, V.

Thus a row-preserving bijection would have to erase or synthesize part of the seal. Erasure loses an obligation, while synthesis changes the sibling carrier; neither operation preserves the local NameCert surface. □

Theorem 1071.5 (Local self-center inscription seal transport exactness)**.** *For every accepted* LocalSelfCenterInscriptionSeal$^{\uparrow}$ *carrier* $L = (H, I, S, A, V, R, C, P, N)$*, the transport row* R *is componentwise* hsame *transport for the local history row* H*, inscription-point row* I*, self-center reading row* S*, apophatic socket row* A*, nonidentity verdict row* V*, displayed route row* C*, provenance row* P*, and local naming row* N*. No accepted transport identifies* S *with* A *or replaces the verdict row* V *by a hidden equality coordinate.*

Proof. Project the accepted carrier. The displayed tuple gives $H, I, S, A, V, R, C, P, N$ as the only seal rows, and R is the named transport row for that tuple.

Apply the NameCert obligations of Definition 1071.2. They require componentwise transport for the carrier rows and local name rather than a separate equality source.

Finally use the nonidentity boundary of Definition 1071.3. Since an identification of S with the far-end row of A fails V, exact transport preserves the verdict boundary instead of collapsing it. □

Lean4 ✓ `BEDC.Derived.LocalSelfCenterInscriptionSealUp.LocalSelfCenterInscriptionSealCarrier transport exactness`

Theorem 1071.6 (Local self-center inscription seal provenance exhaustion)**.** *For every accepted* LocalSelfCenterInscriptionSeal$^{\uparrow}$ *carrier* $L = (H, I, S, A, V, R, C, P, N)$*, the provenance row* P *is exhausted by* InscriptionPoint$^{\uparrow}$, ApophaticSocket$^{\uparrow}$, TranscendentalSupplyInscription$^{\uparrow}$, ObserverHistIdentity$^{\uparrow}$, InscriptionEvent$^{\uparrow}$, *and the kernel rows* BHist, hsame, Cont, Pkg, *and* NameCert. *It exports no subject behind* H*, no internal object for the apophatic far end, and no sibling row outside those named surfaces.*

Proof. Read P from the carrier definition. Its provenance list is exactly the five sibling surfaces together with the displayed kernel rows.

Use the sibling separation theorem Definition 1071.4. Each sibling supplies only its named role and omits at least one of the simultaneous local history, inscription-point, self-center reading, apophatic socket, and verdict rows.

The provenance row therefore accounts for all admissible inputs to the seal without adding an extra subject, far-end object, or hidden sibling coordinate. □

Lean4 ✓ `BEDC.Derived.LocalSelfCenterInscriptionSealUp.LocalSelfCenterInscriptionSealProvenance row nonescape`

Theorem 1071.7 (Local self-center inscription seal carrier transport)**.** *Any accepted carrier transport of a* $\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}$ *packet preserves the nonidentity verdict row. If* $L = (H, I, S, A, V, R, C, P, N)$ *is accepted and the carrier is transported through the displayed* hsame *row* R*, then the transported packet still reads* S *as the local self-center row,* A *as the apophatic socket row, and* V *as the verdict refusing their object-level identification.*

Proof. Begin with transport exactness. The row R transports the displayed components of L componentwise, including S, A, and V.

Apply the nonidentity boundary. A packet that identifies the local self-center row with the apophatic far-end row is not accepted as this seal.

Thus an accepted carrier transport must preserve the verdict row. Otherwise the transported packet would erase the boundary required by the NameCert obligations and would fail acceptance. □

Falsifiable prediction: A packet that identifies the local self-center row with the apophatic far-end row fails the nonidentity verdict row.

Independence witness: InscriptionPoint, ApophaticSocket, TranscendentalSupplyInscription, ObserverHistIdentity, and InscriptionEvent: none carries the simultaneous self-center reading, apophatic socket, and nonidentity verdict rows.

The later Lean TasteGate file must provide explicit `Nontrivial LocalSelfCenterInscriptionSealUp` and `FieldFaithful LocalSelfCenterInscriptionSealUp` instances in `lean4/BEDC/Derived/LocalSelfCenter`

Closure status for $\mathsf{NameCert}_{\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}$ packet is generated from local history, inscription point, self-center reading, apophatic socket, nonidentity verdict, componentwise hsame, displayed Cont, Pkg, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1071.1, Definition 1071.2, Definition 1071.3, Definition 1071.4, Definition 1071.5, Definition 1071.6, Definition 1071.7, and

Lean4 ✓ `BEDC.Derived.LocalSelfCenterInscriptionSealUp.taste gate`

bind the carrier, NameCert obligations, nonidentity boundary, sibling separation, transport, provenance, carrier-transport, and TasteGate rows for the finite local seal.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LocalSelfCenterInscriptionSeal}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not claim Lean verification, a standard bridge, identity with the apophatic far end, or any local-state reading of the apophatic far end.

Upgrade path: No further paper-theory upgrade remains for the finite local self-center seal; later work is verification and bridge checking only.

Chapter 1072

A Concrete Naming Certificate for $\mathsf{ExternalSupplySocket}^{\uparrow}$

The $\mathsf{ExternalSupplySocket}^{\uparrow}$ packet realizes the socket side of chapter 9395 as a finite NameCert carrier. It sits between the boundary packet of chapter 1065, the apophatic naming surface of chapter 543, the kind router of chapter 666, and the classifier packet of chapter 1058. The socket packet keeps the requested supply visible as a refused boundary row while preserving the ledger rows that downstream audit consumers read.

Definition 1072.1 (ExternalSupplySocket carrier)**.** *An* $\mathsf{ExternalSupplySocket}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$X = (B, A, K, R, F, L, H, C, P, N)$$

with the following displayed rows:

1. *B is the* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$ *row naming the boundary site and requested supply shape;*
2. *A is the* $\mathsf{ApophaticName}^{\uparrow}$ *row naming the supply position without supplying the far end;*
3. *K is the* $\mathsf{SocketKindClassifier}^{\uparrow}$ *row naming the socket kind that governs the request;*
4. *R is the* $\mathsf{SupplyKindRouter}^{\uparrow}$ *row routing the request through the chosen kind and requested-shape surface;*
5. *F is the refusal-gate row recording that the requested supply is not available as substrate truth;*
6. *L is the socket ledger row recording the GAP pressure, visible use site, and refusal readback for the same request;*
7. *H records componentwise* hsame *transport for B, A, K, R, F, L;*
8. *C records displayed* Cont *routes from the boundary row to the apophatic name, classifier, router, refusal gate, and ledger rows;*
9. *P is the* Pkg *provenance over* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{SupplyKindRouter}^{\uparrow}$, $\mathsf{SocketKindClassifier}^{\uparrow}$, *the socket ledger,* BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{ExternalSupplySocket}^{\uparrow}}$ *row.*

The carrier has no coordinate for the requested outside supply, no hidden selector, no quotient representative, no proposition-equality token, no host equality, and no theorem asserting that the requested supply has become internal.

Lean4 ✓ BEDC.Derived.ExternalSupplySocketUp.ExternalSupplySocketTasteGate single carrier alignment

Theorem 1072.2 (ExternalSupplySocket NameCert surface)**.** *For the carrier of Definition 1072.1, the local* $\mathsf{NameCert}_{\mathsf{ExternalSupplySocket}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$X = (B, A, K, R, F, L, H, C, P, N),$$

boundary exposure through B*, apophatic-name exposure through* A*, socket-kind classification through* K*, kind routing through* R*, refusal-gate readback through* F*, socket-ledger readback through* L*, componentwise transport through* H*, displayed continuation through* C*, provenance through* P*, and local naming through* N*.*

Consequently every accepted public read of the socket must pass through the boundary row, name row, classifier row, router row, refusal-gate row, and ledger row before it may cite the socket as an external-supply boundary.

Proof. Project the displayed carrier. The packet lists $B, A, K, R, F, L, H, C, P, N$, so the certificate has no coordinate from which to manufacture another boundary name, kind classifier, refusal gate, ledger, transport, route, provenance, or local name.

Read the dependency rows in order. The boundary row B gives the requested supply shape, the apophatic row A names the same unsupplied position, the classifier row K fixes the socket kind, and the router row R places that kind before the requested-shape and refusal reads.

Finally read F, L, H, C, P, N. The refusal gate and ledger record the non-internalizing readback, while transport, continuation, provenance, and local naming preserve the same finite packet. Thus the NameCert surface is exhausted by the displayed rows. □

Theorem 1072.3 (ExternalSupplySocket noninternalization)**.** *Every accepted* $\mathsf{ExternalSupplySocket}^{\uparrow}$ *packet keeps its requested supply external. A consumer may read the boundary row, apophatic name, socket-kind classifier, kind router, refusal gate, socket ledger, transport, route, provenance, and local name, but it receives no supplied witness, quotient representative, proposition-equality token, host equality, hidden selector, unrestricted induction principle, or theorem turning the requested supply into substrate truth.*

Proof. Start with the boundary packet of chapter 1065. It records the requested supply and noninternalization row before any socket consumer reads the request.

Use the apophatic name and classifier rows next. The apophatic surface names the external position without a far-end object, and the socket-kind classifier fixes the local kind row that must be routed before refusal data is available.

Apply the kind router and the refusal-gate row. The router forces the requested-shape read through the displayed kind route, while F records that this route ends in refusal rather than supplied content.

Finally use the ledger and structural rows. The row L records GAP pressure and refusal readback, and H, C, P, N only transport, replay, package, and name the same packet. Since no carrier coordinate stores a supplied witness or host-level replacement, the requested supply remains external. □

Falsifiable prediction: A packet without the refusal-gate row cannot satisfy the noninternalization theorem.

Independence witness: Nearest siblings: externalsupplyboundary, apophaticname, supplykindrouter, socketkindclassifier, and supplysocketledger. None is bijective to $\mathsf{ExternalSupplySocket}^{\uparrow}$

because the socket packet simultaneously carries boundary naming, apophatic naming, kind classification, kind routing, refusal-gate readback, and socket-ledger rows; each sibling omits at least one of those rows.

The Lean follow-up must provide explicit Nontrivial ExternalSupplySocket$^{\uparrow}$ and FieldFaithful ExternalSupplySocket instances in Derived/ExternalSupplySocketUp/TasteGate.lean before the alignment theorem BEDC.Derived.ExternalSu can be cited by a checked paper marker.

Closure status for NameCert$_{\text{ExternalSupplySocket}^{\uparrow}}$.

Constructive story: An ExternalSupplySocket$^{\uparrow}$ packet is generated from an external-supply boundary row, apophatic name row, socket-kind classifier, supply-kind router, refusal-gate row, socket ledger, componentwise hsame transport, displayed Cont routes, provenance, and local naming. The carrier reads the requested supply as a visible boundary, names the unsupplied position, classifies its socket kind, routes the request, and records refusal plus ledger residue. The support rows keep the same site visible under transport and replay. The classifier preserves externality: every accepted consumer sees the socket through the finite boundary-name-kind-route-refusal-ledger sequence.

Theory closure: TheoryGate(NameCert$_{\text{ExternalSupplySocket}^{\uparrow}}$, seed)

Scope closed: This chapter binds the external supply socket carrier, NameCert surface, noninternalization theorem, prediction, and independence witness.

Formal verification: FormalStatus(NameCert$_{\text{ExternalSupplySocket}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim supplied witnesses, hidden selectors, quotient representatives, proposition-equality tokens, host equality, or internal theorem content.

Upgrade path: To reach obligationClosure, formalize the socket-kind, router, refusal-gate, and ledger rows as a checked noninternalizing carrier.

Chapter 1073

A Concrete Naming Certificate for $\mathsf{NonAxiomAdmission}^{\uparrow}$

The $\mathsf{NonAxiomAdmission}^{\uparrow}$ packet is the concrete admission classifier for the external-supply discipline of chapter 9395. It sits after the boundary packet of chapter 1065, the socket ledger of chapter 528, the apophatic socket surface of chapter 536, the selector ledger of chapter 494, and the admission gate of chapter 545. Those siblings record particular boundary, socket, ledger, or chapter-admission rows; this packet classifies the decision surface that accepts a proposed supply position without turning it into an axiom.

Definition 1073.1 (NonAxiomAdmission carrier)**.** *A* $\mathsf{NonAxiomAdmission}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (X, F, W, H, C, P, N)$$

with the following displayed rows:

1. *X is the proposed supply position presented for admission;*
2. *F is the accepted non-axiom boundary form, chosen from inductive constructor, definitional expansion, setup-field obligation,* $\mathsf{NameCert}$ *row,* GAP *memory, bridge slot, or socket boundary;*
3. *W is the displayed witness route showing how the proposed position is consumed through the selected boundary form;*
4. *H stores componentwise* hsame *transport for the route X, F, W;*
5. *C stores displayed* Cont *replay for the same admitted route;*
6. *P stores* Pkg *provenance over* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{SelectorLedger}^{\uparrow}$, $\mathsf{TasteGateAdmission}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{NonAxiomAdmission}^{\uparrow}}$ *row.*

The carrier has no coordinate that asserts the supplied content as substrate truth, no hidden chooser, no quotient representative, no proposition-equality collapse, and no global frame from which consumers may recover the proposed supply apart from the displayed rows.

Lean4 (definition) `BEDC.Derived.NonAxiomAdmissionUp.taste gate`

Theorem 1073.2 (NonAxiomAdmission NameCert obligations)**.** *For the carrier of Definition 1073.1, the local* $\mathsf{NameCert}_{\mathsf{NonAxiomAdmission}^{\uparrow}}$ *surface consists exactly of carrier admission for $A = (X, F, W, H, C, P, N)$, proposed-position exposure through X, accepted-form exactness through F, witness-route exposure*

through W, componentwise hsame *stability through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Equivalently, every accepted admission decision exposes which supply position was proposed, which non-axiom boundary form admits it, which finite route witnesses the admission, and which transport, replay, provenance, and naming rows preserve the same route. It exposes no consumer route that treats the supplied content itself as substrate truth.

Proof. Project the displayed carrier. The accepted packet lists exactly X, F, W, H, C, P, N, so the local certificate cannot introduce a second proposed supply position, accepted-form row, witness route, transport row, replay route, provenance row, or local name.

Read the admission rows in order. The row X names the proposed supply position, F classifies the boundary form as inductive, definitional, setup-field, NameCert, GAP, bridge, or socket data, and W displays the finite route by which that form is consumed.

Finally inspect H, C, P, N. These rows only transport, replay, package, and name the same admitted route. Since none of them contains supplied content as substrate truth, the local NameCert obligations are exhausted by the displayed rows. □

Lean4 ✓ `BEDC.Derived.NonAxiomAdmissionUp.NonAxiomAdmissionCarrier namecert obligations`
Lean4 ✓ `BEDC.Derived.NonAxiomAdmissionUp.NonAxiomAdmissionNamecertObligations`

Theorem 1073.3 (NonAxiomAdmission boundary exhaustion)**.** *Every accepted* $\mathsf{NonAxiomAdmission}^{\uparrow}$ *packet classifies a proposed supply position into a displayed non-axiom boundary form. A downstream consumer may read only X, F, W, H, C, P, N and therefore cannot obtain from the packet an axiom, hidden chooser, quotient representative, proposition-equality token, global frame, or second route that treats the supplied content as substrate truth.*

Proof. Start with the boundary-form coordinate F. By the carrier definition, F ranges only over the displayed forms: inductive constructor, definitional expansion, setup-field obligation, NameCert row, GAP memory, bridge slot, or socket boundary. None is an axiom coordinate.

Use the witness route W together with the transport and replay rows H, C. They show how the selected boundary form is consumed and preserved, but they do not add a hidden supply source or a second consumer edge.

Now read the provenance and naming rows P, N. The provenance row ties the admission to $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{SelectorLedger}^{\uparrow}$, $\mathsf{TasteGateAdmission}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert data, while N names the local packet. Since consumers can read only X, F, W, H, C, P, N, all excluded coordinates are absent from the public route. □

Lean4 ✓ `BEDC.Derived.NonAxiomAdmissionUp.NonAxiomAdmissionCarrier boundary exhaustion`

Theorem 1073.4 (NonAxiomAdmission witness-route nonescape)**.** *If an accepted* $\mathsf{NonAxiomAdmission}^{\uparrow}$ *packet exposes witness route W, then every consumer route that preserves the local* $\mathsf{NameCert}_{\mathsf{NonAxiomAdmission}^{\uparrow}}$ *row must read the same displayed coordinates*

$$X, F, W, H, C, P, N.$$

Changing the proposed supply position, accepted non-axiom form, witness route, componentwise transport, replay, provenance, or local name without changing one displayed coordinate is unreadable to the packet. The carrier therefore admits no consumer edge that treats altered supplied content as the same local admission while leaving X, F, W, H, C, P, N fixed.

Lean4 ✓ `BEDC.Derived.NonAxiomAdmissionUp.NonAxiomAdmissionCarrier witness route nonescape`

Proof. Project the carrier of Definition 1073.1. The witness route W is not a detachable annotation; it is one of the displayed coordinates transported by H, replayed by C, sourced by P, and named by N.

Apply Definition 1073.3. A consumer may read only X, F, W, H, C, P, N, so any change to the supplied content must appear as a change in the proposed position, accepted form, witness route, transport, replay, provenance, or name.

If all seven displayed coordinates are held fixed, the local NameCert has no remaining row from which a different supplied-content route can be read. Thus the witness route is nonescaping for every row-preserving consumer of the packet. □

Lean4 ✓ `BEDC.Derived.NonAxiomAdmissionUp.NonAxiomAdmissionWitnessRoute nonescape`

Theorem 1073.5 (NonAxiomAdmission scoped primitive route)**.** *Every accepted* $\mathsf{NonAxiomAdmission}^{\uparrow}$ *packet binds its displayed rows*

$$X, F, W, H, C, P, N$$

to exact BEDC primitives: X *is a proposed-supply* BHist *row,* F *is the accepted non-axiom form row,* W *is the witness-route row,* H *is componentwise* hsame *transport,* C *is displayed* Cont *replay,* P *is* Pkg *provenance, and* N *is the local* $\mathsf{NameCert}_{\mathsf{NonAxiomAdmission}^{\uparrow}}$ *row. No scoped consumer can read an admitted position without preserving those seven primitive rows.*

Proof. Start with the NameCert obligations of Definition 1073.2. They identify the local certificate surface with exactly the proposed-position, accepted-form, witness-route, transport, replay, provenance, and naming rows.

Apply boundary exhaustion from Definition 1073.3. The accepted form F is a displayed non-axiom boundary form, and no consumer route can recover an axiom coordinate, hidden chooser, quotient representative, proposition-equality token, or global frame from the packet.

Finally use witness-route nonescape from Definition 1073.4. Holding X, F, W, H, C, P, N fixed leaves no remaining row from which a different supplied-content route can be read. Thus the scoped route is exactly the listed BEDC primitive route. □

Theorem 1073.6 (NonAxiomAdmission scoped TasteGate route)**.** *Every accepted* $\mathsf{NonAxiomAdmission}^{\uparrow}$ *decision is scoped by the displayed rows* X, F, W, H, C, P, N*, the non-axiom boundary siblings,* BHist*,* hsame*,* Cont*,* Pkg*,* NameCert*, and the checked TasteGate route for* BEDC.Derived.NonAxiomAdmissionUp.taste *No scoped consumer may treat the proposed supply position as substrate truth unless the same accepted non-axiom form, witness route, transport, replay, provenance, local name, and TasteGate evidence remain visible.*

Proof. First compose the local certificate surface from Definition 1073.2. It identifies the accepted decision with the rows X, F, W, H, C, P, N, so every admission read starts from the displayed proposed position, accepted boundary form, witness route, transport, replay, provenance, and local name.

Next apply Definition 1073.3. The accepted boundary form is restricted to the non-axiom sibling routes, and none of those siblings supplies an axiom coordinate, hidden chooser, quotient representative, proposition-equality token, or global frame.

Finally use Definition 1073.4 and Definition 1073.5. Witness-route nonescape prevents a row-preserving consumer from changing the supplied-content route, while the scoped primitive route binds the same rows to BHist, hsame, Cont, Pkg, and NameCert. The checked TasteGate target records that this scoped carrier is admitted as a chapter gate, so the displayed route is exactly the TasteGate-scoped non-axiom admission surface. □

Lean4 ✓ `BEDC.Derived.NonAxiomAdmissionUp.taste gate`

Falsifiable prediction: Every accepted NonAxiomAdmissionUp packet classifies a proposed supply position into a displayed non-axiom boundary form and exposes no consumer route that treats the supplied content as substrate truth.

Independence witness: externalsupplyboundary, supplysocketledger, apophaticsocket, selectorledger, and tastegateadmission: those siblings record particular boundary, socket, ledger, and admission rows, while NonAxiomAdmissionUp classifies the admission decision surface itself. No row-preserving bijection can recover the full X, F, W, H, C, P, N classifier from any one sibling packet.

The Lean follow-up target is BEDC.Derived.NonAxiomAdmissionUp.taste_gate. Its TasteGate.lean file must provide explicit Nontrivial NonAxiomAdmission$^{\uparrow}$ and FieldFaithful NonAxiomAdmission$^{\uparrow}$ instances with a displayed witness pair and field-projection proofs for X, F, W, H, C, P, N.

Closure status for NameCert$_{\text{NonAxiomAdmission}^{\uparrow}}$.

Constructive story: A NonAxiomAdmission$^{\uparrow}$ packet is generated from a proposed supply position, accepted non-axiom form, witness route, componentwise hsame transport, displayed Cont replay, Pkg provenance, and local NameCert rows.

Theory closure: TheoryGate(NameCert$_{\text{NonAxiomAdmission}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 1073.6 binds accepted admission decisions to the displayed X, F, W, H, C, P, N rows, non-axiom boundary siblings, BHist, hsame, Cont, Pkg, NameCert, and the checked TasteGate route for NonAxiomAdmission$^{\uparrow}$.

Formal verification: FormalStatus(NameCert$_{\text{NonAxiomAdmission}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.NonAxiomAdmissionUp.taste\_gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not claim substrate truth, hidden choice, quotient representatives, proposition equality collapse, a global frame, axiomClean audit status, or bridge checking for NonAxiomAdmission$^{\uparrow}$.

Upgrade path: Audit closure requires axiom-purity reporting and bridge work for the checked NonAxiomAdmission$^{\uparrow}$ TasteGate route.

Chapter 1074

A Concrete Naming Certificate for $\mathsf{BoundaryAdmissionDecision}^{\uparrow}$

The $\mathsf{BoundaryAdmissionDecision}^{\uparrow}$ packet realizes the admission-decision rule of chapter 9395 as a finite NameCert object. It sits beside the external boundary packet of chapter 1065, the router of chapter 666, and the apophatic naming surface of chapter 543. Those siblings expose a boundary, route a supply kind, or name an external position; this packet binds the decision row that chooses the strongest permitted non-axiom form for a proposed dependency.

Definition 1074.1 (BoundaryAdmissionDecision carrier)**.** *A* $\mathsf{BoundaryAdmissionDecision}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (X, F, R, A, H, C, P, N)$$

with the following displayed rows:

1. *X is the proposed-dependency row, naming the object, operation, theorem, or interface component under admission;*
2. *F is the strongest permitted non-axiom form row, choosing one of closed inductive syntax, computed definition, setup field, mature NameCert row, GAP ledger, bridge slot, or apophatic socket;*
3. *R is the requested-shape row, recording the exact supply shape the consumer wants to read;*
4. *A is the audit/refusal row, recording the local decision when the requested shape cannot be exported as internal substrate truth;*
5. *H records componentwise* hsame *transport for X, F, R, A;*
6. *C records displayed* Cont *replay routes through the same admission rows;*
7. *P is the* Pkg *provenance over* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, $\mathsf{SupplyKindRouter}^{\uparrow}$, $\mathsf{ApophaticName}^{\uparrow}$, $\mathsf{SocketKindClassifier}^{\uparrow}$, $\mathsf{AuditGateComposition}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{BoundaryAdmissionDecision}^{\uparrow}}$ *row.*

The carrier has no coordinate for an anonymous axiom, hidden host selector, detached consumer permission, quotient collapse, or supplied-content theorem.

Lean4 (definition) `BEDC.Derived.BoundaryAdmissionDecisionUp.BoundaryAdmissionDecisionUp`

Theorem 1074.2 (BoundaryAdmissionDecision NameCert obligations)**.** *For the carrier of Definition 1074.1, the local* $\mathsf{NameCert}_{\mathsf{BoundaryAdmissionDecision}^{\uparrow}}$ *surface consists exactly of five obligation rows:*

1. *carrier admission for* $D = (X, F, R, A, H, C, P, N)$*;*
2. *proposed-dependency exposure through* X*;*
3. *strongest permitted non-axiom form exactness through* F*;*
4. *requested-shape exactness through* R*;*
5. *audit/refusal exactness through* A*, with componentwise* hsame *stability, displayed* Cont *replay, package provenance, and local naming supplied by* H, C, P, N*.*

No consumer read of the certificate may bypass F *and reach* R *as an admitted internal dependency.*

Proof. Project the displayed carrier. The accepted packet lists X, F, R, A, H, C, P, N, so the local certificate cannot introduce a second dependency, hidden permitted form, detached requested shape, unrecorded refusal, transport row, replay route, provenance row, or local name.

Read the decision rows in order. The proposed-dependency row X names the object under admission, and the chosen-form row F displays the strongest permitted non-axiom form before any consumer reaches the requested-shape row R.

Use the audit/refusal row A. If the requested shape cannot be exported through F, the row A records refusal rather than turning the request into an axiom, hidden selector, quotient collapse, or host permission.

Finally inspect H, C, P, N. These rows only transport, replay, package, and name the same finite decision packet. Therefore the NameCert obligations are exhausted by the five displayed obligation rows. □

Theorem 1074.3 (BoundaryAdmissionDecision router exhaustion)**.** *Every accepted* $\mathsf{BoundaryAdmissionDecision}^{\uparrow}$ *packet forces a consumer route through* F *before the requested-shape row* R *can be read. If* F *is absent, the route cannot distinguish a closed inductive form, computed definition, setup field, NameCert row, GAP ledger, bridge slot, or apophatic socket, and the admission decision is not auditable.*

Proof. Start with carrier admission for $D = (X, F, R, A, H, C, P, N)$. The requested-shape row R is part of the same finite packet as the chosen-form row F.

Apply the NameCert obligations of Definition 1074.2. They expose F before any consumer reads R as a decision result, so a route reaching R without F omits the row that records which non-axiom form carries the request.

The support rows H, C, P, N preserve and name only the displayed packet. They cannot reconstruct an omitted chosen-form row or replace it by host convention. Hence router exhaustion fails when F is absent. □

Falsifiable prediction: A packet omitting F cannot satisfy router exhaustion because a consumer can reach R without a displayed non-axiom form.

Independence witness: external-supply-boundary, supply-kind-router, apophaticname, socket-kind-classifier, auditgatecomposition: none is bijective because each lacks at least one of the proposed-dependency row X, chosen-form row F, requested-shape row R, and audit/refusal row A in the same packet.

The Lean carrier for $\mathsf{BoundaryAdmissionDecision}^{\uparrow}$ must provide explicit $\mathsf{Nontrivial\ BoundaryAdmissionDecision}^{\uparrow}$ and $\mathsf{FieldFaithful\ BoundaryAdmissionDecision}^{\uparrow}$ instances over the displayed rows X, F, R, A, H, C, P, N before a checked TasteGate target is claimed.

Closure status for $\mathsf{NameCert}_{\mathsf{BoundaryAdmissionDecision}^{\uparrow}}$.

Constructive story: A $\mathsf{BoundaryAdmissionDecision}^{\uparrow}$ packet is generated from a proposed-dependency row, strongest permitted non-axiom form row, requested-shape row, audit/refusal row, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The BHist carrier first displays the object under admission, then the exact permitted form, and only then the requested shape. If the request cannot be exported through that form, the audit row records refusal. The support rows keep the decision attached to the same visible dependency. The classifier is therefore a finite admission route rather than an anonymous permission to import external supply.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{BoundaryAdmissionDecision}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the boundary admission decision carrier, NameCert obligations, router exhaustion, prediction, and independence witness.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{BoundaryAdmissionDecision}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim anonymous axioms, hidden host selectors, detached permissions, quotient collapse, or supplied-content theorems.

Upgrade path: To reach obligationClosure, check that every requested-shape read factors through the displayed permitted-form row and audit/refusal row.

Chapter 1075

A Concrete Naming Certificate for $\mathsf{GeneratorLocalInductionBoundary}^{\uparrow}$

The $\mathsf{GeneratorLocalInductionBoundary}^{\uparrow}$ packet realizes the induction boundary of chapter 9395 as a finite NameCert object. It records when induction is licensed by a displayed generator and when a claimed domain has become free-floating boundary pressure. The packet sits beside chapter 1065, chapter 528, chapter 494, chapter 715, and chapter 543: those packets expose supply, selector, question, or apophatic naming rows, while this packet binds generator closure, eliminator locality, refusal, and induction-ledger rows in one carrier.

Definition 1075.1 (GeneratorLocalInductionBoundary carrier)**.** *A* $\mathsf{GeneratorLocalInductionBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (D, E, L, F, H, C, P, N)$$

with the following displayed rows:

1. *D is the generator-domain row, naming the closure of the displayed generator and no larger semantic totality;*
2. *E is the eliminator-locality row, recording that the induction principle consumes exactly the constructor cases of D;*
3. *L is the induction-ledger row, recording the base, step, replay, and consumer rows used by the local eliminator;*
4. *F is the free-floating-refusal row, recording that any universal claim outside D is routed to a boundary request instead of internal proof;*
5. *H records componentwise* hsame *transport for D, E, L, F;*
6. *C records displayed* Cont *replay routes through the same generator, eliminator, ledger, and refusal rows;*
7. *P is the* Pkg *provenance over* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, $\mathsf{SupplySocketLedger}^{\uparrow}$, $\mathsf{SelectorLedger}^{\uparrow}$, $\mathsf{ApophaticGateQuestion}^{\uparrow}$, $\mathsf{ApophaticName}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{GeneratorLocalInductionBoundary}^{\uparrow}}$ *row.*

The carrier has no coordinate for induction over an unspecified semantic totality, no hidden generator, no host well-foundedness oracle, and no theorem converting free-floating induction into internal induction.

Theorem 1075.2 (GeneratorLocalInductionBoundary NameCert obligations)**.** *For the carrier of Definition 1075.1, the local* $\mathsf{NameCert}_{\mathsf{GeneratorLocalInductionBoundary}\uparrow}$ *surface consists exactly of carrier admission for* $G = (D, E, L, F, H, C, P, N)$*, generator-domain exposure through* D*, eliminator-locality exactness through* E*, induction-ledger readback through* L*, free-floating-refusal readback through* F*, componentwise* hsame *stability through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Equivalently, a consumer may run generator-local induction only by reading the displayed generator closure, the displayed eliminator cases, and the displayed ledger. A consumer that asks for induction beyond those rows receives only the refusal row and the boundary provenance.

Proof. Project the displayed packet $G = (D, E, L, F, H, C, P, N)$. The generator-domain row D fixes the domain of induction before any eliminator is read.

Read E and L together. The eliminator-locality row says that the admissible cases are exactly the constructor cases of D, while the induction-ledger row records the base, step, replay, and consumer rows actually used by the proof route.

Now inspect F. The refusal row separates any claim over an unspecified semantic totality from the generator-local route. Such a claim can be recorded as boundary pressure, but it is not converted into an internal eliminator.

The remaining rows H, C, P, N transport, replay, package, and name the same four substantive rows. They add no hidden generator and no wider induction principle, so the NameCert obligations are exhausted by the displayed packet. □

Lean4 ✓ `BEDC.Derived.GeneratorLocalInductionBoundaryUp.TasteGate.GeneratorLocalInductionBoundaryTasteGa`
`single carrier alignment`

Theorem 1075.3 (GeneratorLocalInductionBoundary noninternalization)**.** *Every accepted* GeneratorLocalInductio *packet keeps free-floating induction outside the internal proof surface. A downstream consumer may cite* D, E, L, F, H, C, P, N *as boundary evidence for a generator-local induction route, but it may not read from the packet a universal eliminator over an unspecified totality, a hidden well-foundedness oracle, a host induction principle, or a theorem that turns the refusal row into generated structure.*

Proof. Begin with the generator-domain row D. It is a finite displayed row, so the available induction domain is the closure of that row and not an ambient universe of possible cases.

Use E and L to read the permitted proof route. The eliminator row supplies only the constructor cases belonging to D, and the ledger records only the local base, step, replay, and consumer rows.

Apply the refusal row F to every induction request outside that route. The request remains visible as boundary pressure, but there is no coordinate in the packet that supplies a universal eliminator, host induction principle, or hidden well-foundedness oracle.

Finally read H, C, P, N. These rows preserve the same generator, eliminator, ledger, and refusal data under transport, replay, provenance, and naming. Since no packet coordinate internalizes the refused domain, free-floating induction remains outside the internal proof surface. □

Falsifiable prediction: A packet that omits either the displayed generator row or the eliminator row cannot satisfy the non-internalization theorem.

Independence witness: Compare ExternalSupplyBoundary, SupplySocketLedger, SelectorLedger, ApophaticGateQuestion, and ApophaticName: none is bijective to GeneratorLocalInductionBoundary because none simultaneously carries generator closure, eliminator locality, free-floating refusal, and induction-ledger rows.

The Lean follow-up must provide explicit Nontrivial GeneratorLocalInductionBoundary$^{\uparrow}$ and FieldFaithful Generato instances in lean4/BEDC/Derived/GeneratorLocalInductionBoundaryUp/TasteGate.lean before the chapter can claim a checked taste-gate target.

Closure status for NameCert$_{\text{GeneratorLocalInductionBoundary}^{\uparrow}}$.

Constructive story: A GeneratorLocalInductionBoundary$^{\uparrow}$ packet is generated from a displayed generator row, local eliminator row, induction-ledger row, free-floating refusal boundary, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The carrier reads generator closure and eliminator locality as finite data before any induction consumer may use them. If a consumer asks for a free-floating induction principle outside those rows, the refusal boundary is exposed instead. Thus the classifier keeps induction local to generated carrier evidence and refuses host-level induction supply.

Theory closure: TheoryGate(NameCert$_{\text{GeneratorLocalInductionBoundary}^{\uparrow}}$, seed)

Scope closed: This chapter binds the generator local induction boundary carrier, non-internalization theorem, prediction, and independence witness.

Formal verification: FormalStatus(NameCert$_{\text{GeneratorLocalInductionBoundary}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim unrestricted induction, hidden eliminators, external theorem supply, free-floating generator closure, or host equality of induction principles.

Upgrade path: To reach obligationClosure, formalize generator, eliminator, induction-ledger, and refusal-boundary rows with checked nontrivial and field-faithful instances.

Chapter 1076

A Concrete Naming Certificate for $\mathsf{ExternalSupplyFailureWitness}^{\uparrow}$

The $\mathsf{ExternalSupplyFailureWitness}^{\uparrow}$ packet realizes the diagnostic side of chapter 9395 as a finite NameCert object. It sits beside the boundary packet of chapter 1065, the failed audit-gate witness of chapter 901, the composed gate surface of chapter 696, the socket classifier of chapter 1058, and the gate-question packet of chapter 715. Those siblings expose the boundary, failed gate, composed refusal route, socket kind, or question row; this packet records the finite row at which an unsupported external-supply route fails.

Definition 1076.1 (ExternalSupplyFailureWitness carrier)**.** *An* $\mathsf{ExternalSupplyFailureWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (B, R, F, D, T, G, H, C, P, N)$$

with the following displayed rows:

1. *B is the boundary-name row naming the external-supply site;*
2. *R is the requested-supply row recording the demanded supply shape;*
3. *F is the failed-item row naming the unsupported item whose route was rejected;*
4. *D is the diagnostic row exposed to public consumers;*
5. *T is the refusal-target row naming the theorem, witness, selector, quotient, host equality, or completion route that the failure refuses to supply;*
6. *G is the gate row through which the failed route is audited;*
7. *H records componentwise* hsame *transport for B, R, F, D, T, G;*
8. *C records displayed* Cont *replay through the same diagnostic route;*
9. *P is the* Pkg *provenance over* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, $\mathsf{AuditGateFailureWitness}^{\uparrow}$, $\mathsf{AuditGateComposition}^{\uparrow}$, $\mathsf{SocketKindClassifier}^{\uparrow}$, $\mathsf{ApophaticGateQuestion}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{ExternalSupplyFailureWitness}^{\uparrow}}$ *row.*

The carrier has no coordinate for a supplied theorem, hidden selector, quotient equality, host-level equality, or direct route from the boundary name to the requested content.

Lean4 (definition) `BEDC.Derived.ExternalSupplyFailureWitnessUp.ExternalSupplyFailureWitnessUp`

Theorem 1076.2 (ExternalSupplyFailureWitness NameCert obligations)**.** *For the carrier of Definition 1076.1, the local* $\mathsf{NameCert}_{\mathsf{ExternalSupplyFailureWitness}^{\uparrow}}$ *surface consists exactly of carrier admission for* $W = (B, R, F, D, T, G, H, C, P, N)$*, boundary-name exposure through* B*, requested-supply exactness through* R*, failed-item exactness through* F*, diagnostic exposure through* D*, refusal-target attachment through* T*, gate-row locality through* G*, componentwise* hsame *stability through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Equivalently, an accepted packet lets a consumer cite the visible boundary, request, failed item, diagnostic, refusal target, gate, transport, replay, provenance, and certificate rows, but it supplies no refused content beyond those rows.

Proof. Project the displayed carrier. The definition lists $B, R, F, D, T, G, H, C, P, N$, so the local certificate has one boundary-name row, one requested-supply row, one failed item, one diagnostic row, one refusal target, one gate row, and the structural rows that transport, replay, package, and name them.

Use chapter 1065 to identify B and R as boundary-facing rows rather than content rows. Use chapter 901 to read F, D, T as the failed item, diagnostic, and refusal attachment exposed by a failed gate.

Next use chapter 696 and chapter 1058. The composition chapter keeps the refusal route gate-local, while the classifier chapter keeps the requested supply in its socket-kind row instead of turning it into content.

Finally use chapter 715. The question row explains why the consumer must read the gate before the diagnostic answer is available. Since H, C, P, N only preserve the same displayed packet, the NameCert obligations are exhausted by the listed rows. □

Lean4 ✓ `BEDC.Derived.ExternalSupplyFailureWitnessUp.ExternalSupplyFailureWitnessTasteGate single carrier alignment`

Theorem 1076.3 (ExternalSupplyFailureWitness diagnostic nonescape)**.** *Every public consumer of an accepted* $\mathsf{ExternalSupplyFailureWitness}^{\uparrow}$ *packet reaches the diagnostic row* D *before any refusal target* T *is usable. A direct route from the boundary name* B *to theorem content, witness content, selector output, quotient equality, host equality, or completion output is not a route of the packet.*

Proof. Start with Definition 1076.1. The only content-facing coordinates are F, D, T, G; none stores the refused theorem, witness, selector, quotient, host equality, or completion output.

Apply the boundary discipline from chapter 1065. The boundary name B and requested-supply row R identify the site and demanded shape, but the boundary packet does not internalize the requested supply.

Now apply the failed-gate and composition siblings from chapter 901 and chapter 696. The failed item F is attached to a diagnostic row D, and the composed refusal route reads that diagnostic before a refusal target is handed to a consumer.

Use chapter 1058 and chapter 715 to keep the route visible. The socket classifier names the supply kind, and the gate question forces a gate read before the answer is exposed. Therefore any route skipping D or connecting B directly to refused content has no carrier coordinate and refutes the packet. □

Falsifiable prediction: If an accepted ExternalSupplyFailureWitnessUp packet is public, every consumer reaches the diagnostic row before any refusal target; a direct route from boundary name to theorem content refutes the packet.

Independence witness: ExternalSupplyBoundaryUp exposes the boundary but not the failed item; AuditGateFailureWitnessUp exposes a failed gate but not the external-supply boundary name; AuditGateCompositionUp composes refusal routes but does not store the primitive requested supply; SocketKindClassifierUp classifies the socket kind but not the diagnostic row; ApophaticGateQuestionUp asks the gate question but does not attach the failed item to a refusal target. The row separation prevents a row-preserving bijection between any sibling and ExternalSupplyFailureWitnessUp.

The Lean follow-up must provide explicit Nontrivial ExternalSupplyFailureWitness$^{\uparrow}$ and FieldFaithful ExternalSupp instances in lean4/BEDC/Derived/ExternalSupplyFailureWitnessUp/TasteGate.lean before the chapter can claim a checked taste-gate target.

Closure status for NameCert$_{\text{ExternalSupplyFailureWitness}\uparrow}$ ·

Constructive story: An ExternalSupplyFailureWitness$^{\uparrow}$ packet is generated from an external boundary name, failed-item row, diagnostic row, refusal target, gate context, componentwise hsame transport, displayed Cont routes, provenance, and local naming. The BHist carrier exposes the failed external request as finite audit data: a consumer must read the boundary site and diagnostic row before reaching the refusal target. The local ledger records which requested item failed and where the failure is read. Transport and continuation replay preserve exactly that route, so the failure witness cannot be converted into theorem content or a supplied dependency.

Theory closure: TheoryGate(NameCert$_{\text{ExternalSupplyFailureWitness}\uparrow}$, seed)

Scope closed: This chapter binds the external supply failure witness carrier, diagnostic route, prediction, and independence witness.

Formal verification: FormalStatus(NameCert$_{\text{ExternalSupplyFailureWitness}\uparrow}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim successful supply, direct theorem content, hidden gate success, host selectors, or boundary-to-proof conversion.

Upgrade path: To reach obligationClosure, check the finite diagnostic route from boundary name through failed item to refusal target.

Chapter 1077

A Concrete Naming Certificate for $\mathsf{ExternalSupplyWitness}^{\uparrow}$

The $\mathsf{ExternalSupplyWitness}^{\uparrow}$ packet realizes the witness-facing part of chapter 9395 as a finite NameCert object. It sits beside the boundary packet of chapter 1065, the socket ledger of chapter 528, the apophatic name surface of chapter 543, the audit gate boundary of chapter 526, and the negative-name boundary of chapter 629. Those siblings expose boundary, socket use, named refusal, audit verdict, or negative-name refusal rows; this packet binds the requested-witness, gate-locality, supply-ledger, and local NameCert rows on one auditable route.

Definition 1077.1 (ExternalSupplyWitness carrier)**.** *An* $\mathsf{ExternalSupplyWitness}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (S, R, G, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the socket-site row naming the exact external supply position;*
2. *R is the requested-witness row recording the witness shape requested at S;*
3. *G is the gate-locality row stating the local audit gate through which R may be read;*
4. *L is the supply ledger row preserving the* GAP *pressure and socket residue of the request;*
5. *H records componentwise* hsame *transports for S, R, G, L;*
6. *C records displayed* Cont *routes through the same socket, witness, gate, and ledger rows;*
7. *P is the* Pkg *provenance over* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$*,* $\mathsf{SupplySocketLedger}^{\uparrow}$*,* $\mathsf{ApophaticName}^{\uparrow}$*,* $\mathsf{AuditGateBoundary}^{\uparrow}$*,* $\mathsf{NegativeNameBoundary}^{\uparrow}$*,* BHist*,* hsame*,* Cont*,* Pkg*, and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{ExternalSupplyWitness}^{\uparrow}}$ *row.*

The carrier has no coordinate for an internal witness before the gate-locality row, no hidden selector, no host quotient, and no theorem asserting that the requested witness is available as substrate truth.

Lean4 ✓ `BEDC.Derived.ExternalSupplyWitnessUp.ExternalSupplyWitnessTasteGate single carrier alignment`

Theorem 1077.2 (ExternalSupplyWitness NameCert obligations)**.** *For the carrier of Definition 1077.1, the local* $\mathsf{NameCert}_{\mathsf{ExternalSupplyWitness}^{\uparrow}}$ *surface consists exactly of carrier admission for $W = (S, R, G, L, H, C, P, N)$, socket-site exposure through S, requested-witness readback through R,*

gate-locality exposure through G, supply-ledger readback through L, componentwise hsame *stability through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Equivalently, a consumer may read the socket site, the requested witness shape, the gate through which that request is local, and the ledger that keeps the external supply visible, but it may not read an internal witness outside those rows.

Proof. Project the displayed carrier. The accepted packet lists S, R, G, L, H, C, P, N, so the local certificate cannot introduce a second socket site, requested-witness row, gate-locality row, supply ledger, transport row, replay route, provenance row, or local name.

Read the public rows in order. The socket site S names the external supply position, the requested-witness row R records the shape demanded there, and the gate-locality row G states the local audit gate that must be crossed before the request is usable.

Now read the ledger and structural rows. The supply ledger L preserves the socket residue, while H, C, P, N only transport, replay, package, and name the same finite packet. Therefore the NameCert obligations are exhausted by the displayed rows. □

Lean4 ✓ `BEDC.Derived.ExternalSupplyWitnessUp.ExternalSupplyWitness namecert obligations`

Theorem 1077.3 (ExternalSupplyWitness socket factorization)**.** *Every accepted* ExternalSupplyWitness$^{\uparrow}$ *consumer route factors through the socket-site row S before it can cite the requested-witness row R, gate-locality row G, supply ledger L, or structural rows H, C, P, N. The packet exports no alternate route that begins with a hidden witness, detached audit gate, unledgered supply coordinate, quotient representative, or host selector.*

Lean4 ✓ `BEDC.Derived.ExternalSupplyWitnessUp.ExternalSupplyWitness socket factorization`

Proof. Begin with the carrier of Definition 1077.1. The socket site S is the first displayed row and supplies the name under which the requested witness is audited.

Use the requested-witness and gate-locality rows. The request R is meaningful only as a request at S, and the gate row G records the local audit boundary for that same site.

Finally inspect L, H, C, P, N. These rows preserve and replay the same socket route; none contains an independent witness, detached audit gate, unledgered supply coordinate, quotient representative, or host selector. Hence every accepted route factors through S. □

Theorem 1077.4 (ExternalSupplyWitness non-escape)**.** *Every accepted* ExternalSupplyWitness$^{\uparrow}$ *packet keeps the requested witness external until the gate-locality row is displayed. A downstream consumer may cite S, R, G, L, H, C, P, N as witness-boundary evidence, but it cannot read R as a public internal witness before G, nor can it obtain a hidden selector, quotient collapse, proposition-equality token, or theorem that supplies the requested witness.*

Proof. Read S and R as boundary rows. They name the socket site and the requested witness shape, but neither row states that the requested witness has been generated by the substrate.

Apply the gate-locality row G. It is the displayed locality condition for any consumer read of R, so a public witness read before G would bypass the carrier route.

Use the supply ledger L and the structural rows H, C, P, N. They preserve the same externalized request and leave no coordinate for hidden selectors, quotient collapse, proposition-equality tokens, or supplied-witness theorems. Thus the requested witness does not escape the gate-local packet. □

Theorem 1077.5 (ExternalSupplyWitness gate locality)**.** *For every accepted* ExternalSupplyWitness$^{\uparrow}$ *packet* $W = (S, R, G, L, H, C, P, N)$*, the gate-locality row* G *is the unique public gate through which* R *can be consumed. Any consumer of the requested-witness row must preserve the same socket site* S*, supply ledger* L*, componentwise* hsame *transports* H*, displayed* Cont *routes* C*,* Pkg *provenance* P*, and local* NameCert *row* N*.*

Proof. Project the finite packet. The carrier gives a single displayed gate-locality row G between the requested-witness row R and the ledger and structural rows.

Use socket factorization. Since every accepted route begins at S, a consumer cannot attach R to a different public gate without leaving the displayed packet.

Now use non-escape. The rows L, H, C, P, N preserve the same route and do not expose an alternate gate, hidden selector, or detached witness. Therefore G is the unique public gate for consuming R inside the packet. □

Theorem 1077.6 (ExternalSupplyWitness field-faithful surface)**.** *The public* ExternalSupplyWitness$^{\uparrow}$ *surface is field-faithful to the eight rows* S, R, G, L, H, C, P, N*: changing any one of the socket-site, requested-witness, gate-locality, supply-ledger, transport, continuation, provenance, or local NameCert rows changes the exported NameCert surface, while preserving all eight rows preserves the same witness-boundary packet.*

Proof. Start with the NameCert obligations. They identify the exported surface with exactly the rows S, R, G, L, H, C, P, N.

Changing S, R, G, or L changes the socket site, requested witness, public gate, or supply ledger read by the consumer. By socket factorization and gate locality, those rows determine the witness-boundary route.

Changing H, C, P, or N changes the transport, replay, provenance, or local naming by which the same route is stabilized. Conversely, if all eight rows are preserved, the carrier and every public NameCert obligation are preserved. Hence the surface is field-faithful to the displayed packet. □

Falsifiable prediction: A packet whose requested witness row is public before the gate-locality row fails the ExternalSupplyWitnessUp non-escape theorem.

Independence witness: Compare ExternalSupplyBoundary, SupplySocketLedger, ApophaticName, AuditGateBoundary, and NegativeNameBoundary: the witness packet has simultaneous requested-witness, gate-locality, and supply-ledger rows, while those siblings respectively expose boundary, socket use, named refusal, audit verdict, or negative-name refusal rows, so no row-preserving bijection preserves the NameCert surface.

The Lean follow-up must provide explicit Nontrivial ExternalSupplyWitness$^{\uparrow}$ and FieldFaithful ExternalSupplyWitn instances over $W = (S, R, G, L, H, C, P, N)$ in lean4/BEDC/Derived/ExternalSupplyWitnessUp/TasteGate.lean before the chapter can claim a checked taste-gate target.

Closure status for NameCert$_{\text{ExternalSupplyWitness}^{\uparrow}}$**.**

Constructive story: An ExternalSupplyWitness$^{\uparrow}$ packet is generated from a socket-site row, requested-witness row, gate-locality row, supply ledger, componentwise hsame transport, displayed Cont routes, provenance, and local naming. The carrier names the requested witness only as a request at a visible socket site, then requires the gate-locality row before any consumer can inspect the requested shape. The ledger preserves the external supply residue, while transport and continuation replay keep every read on the same finite route. The classifier therefore distinguishes witness-boundary evidence from an internal witness.

Theory closure: TheoryGate(NameCert$_{\text{ExternalSupplyWitness}^{\uparrow}}$, seed)

Scope closed: This chapter binds the external supply witness carrier, socket factorization, non-escape, gate-locality, and field-faithful surface theorems.

Formal verification: FormalStatus(NameCert$_{\text{ExternalSupplyWitness}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim an internal witness before the gate row, hidden selectors, quotient collapse, proposition-equality tokens, or supplied-witness theorems.

Upgrade path: To reach obligationClosure, formalize socket factorization and gate locality for the displayed witness-boundary carrier.

Chapter 1078

A Concrete Naming Certificate for $\mathsf{InterInscriptionCoherence}^{\uparrow}$

The $\mathsf{InterInscriptionCoherence}^{\uparrow}$ packet realizes the space-as-inter-chain-coherence reading of chapter 9401 as a finite NameCert surface. It pairs two local inscription rows, binds them through an inter-Hist locality ledger, and exposes only the transport, route, provenance, and local naming data needed by downstream observer-locality consumers.

The sibling surfaces chapter 1069, chapter 610, chapter 759, chapter 479, and chapter 1065 each contribute part of this reading. None of them contains both paired inscription endpoints and a coherence ledger in one accepted carrier, so the paired packet below is not a renaming of any sibling.

Definition 1078.1 (InterInscriptionCoherence carrier)**.** *An* $\mathsf{InterInscriptionCoherence}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (I, J, L, H, C, P, N)$$

with the following displayed rows:

1. *I is the first local* $\mathsf{InscriptionPoint}^{\uparrow}$ *row, naming one chain-side inscription point of the apophatic fixed point;*
2. *J is the second local* $\mathsf{InscriptionPoint}^{\uparrow}$ *row, naming the comparison chain-side inscription point;*
3. *L is the* $\mathsf{InterHistLocalityLedger}^{\uparrow}$ *row that records the locality-cell coherence between I and J;*
4. *H records componentwise* hsame *transports for the two inscription rows, the inter-*Hist *locality ledger, the continuation routes, the provenance row, and the local naming row;*
5. *C records the displayed* Cont *routes by which downstream consumers read I, J, L, H, P, N without obtaining a global space object or a hidden host metric;*
6. *P records* Pkg *provenance over* $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$, $\mathsf{InscriptionPoint}^{\uparrow}$, $\mathsf{InterHistLocalityLedger}^{\uparrow}$, $\mathsf{ObserverHistIdentity}^{\uparrow}$, $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{InterInscriptionCoherence}^{\uparrow}}$ *row.*

The carrier contains no global frame, no host-space coordinate, no quotient observer equality, no hidden shared subject, and no ambient synchronization principle.

Lean4 (definition) `BEDC.Derived.InterInscriptionCoherenceUp.InterInscriptionCoherenceUp`

Theorem 1078.2 (InterInscriptionCoherence NameCert obligations)**.** *For the carrier of Definition 1078.1, the local* $\mathsf{NameCert}_{\mathsf{InterInscriptionCoherence}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$Z = (I, J, L, H, C, P, N),$$

paired inscription exposure through I *and* J*, inter-*Hist *locality exposure through* L*, componentwise* hsame *transport through* H*, displayed* Cont *route replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Proof. Project the displayed carrier. The rows I, J, L, H, C, P, N are the only coordinates available to the local certificate.

Read the paired endpoint rows first. The two $\mathsf{InscriptionPoint}^{\uparrow}$ rows supply distinct local inscription endpoints, while the $\mathsf{InterHistLocalityLedger}^{\uparrow}$ row supplies the coherence ledger between them.

The structural rows then close the certificate. Transport is componentwise through H, consumer replay is through C, provenance is recorded by P, and the local naming row N certifies the same finite packet without adding a global frame or host-space coordinate. □

Theorem 1078.3 (InterInscriptionCoherence locality transport)**.** *For every accepted* $\mathsf{InterInscriptionCoherence}^{\uparrow}$ *packet* $Z = (I, J, L, H, C, P, N)$*, any downstream locality consumer that reads coherence between inscription points must read both inscription rows* I, J *and the inter-*Hist *locality ledger* L *through the displayed transport row* H *and route row* C*. If either inscription row or the inter-*Hist *locality ledger is omitted, no accepted packet can satisfy this locality-transport surface.*

Proof. Start from carrier admission in Definition 1078.1. The coherence relation is stored only by the triple I, J, L inside the finite packet.

Apply the NameCert obligations of Definition 1078.2. They require paired inscription exposure and locality-ledger exposure before any consumer route may replay the packet.

The falsifiable clause follows by projection. Removing I, removing J, or removing L destroys one of the required coordinates of the accepted carrier, so the displayed transport and route rows have no complete locality surface to carry. □

Theorem 1078.4 (InterInscriptionCoherence ledger non-escape)**.** *Every consumer of an accepted* $\mathsf{InterInscriptionCoherence}^{\uparrow}$ *packet receives only the rows* I, J, L, H, C, P, N*. The consumer receives no global frame, no host metric, no quotient observer equality, no hidden shared subject, and no ambient synchronization coordinate.*

Proof. Project the carrier and the NameCert obligations. The public inventory is exactly the paired inscription rows, the inter-Hist locality ledger, transport, route, provenance, and local naming rows.

Use locality transport from Definition 1078.3. A coherence read must travel through the displayed I, J, L, H, C surface, so it cannot be replaced by a host-space metric or a quotient observer equality.

Finally use the absence clauses in the carrier. No row of Z names a global frame, hidden shared subject, or ambient synchronization principle, and downstream consumers cannot recover such data from provenance or local naming alone. □

Theorem 1078.5 (InterInscriptionCoherence sibling dependency)**.** *The* $\mathsf{InterInscriptionCoherence}^{\uparrow}$ *carrier depends on the sibling surfaces* $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$*,* $\mathsf{InscriptionPoint}^{\uparrow}$*,* $\mathsf{InterHistLocalityLedger}^{\uparrow}$*,* $\mathsf{ObserverHistIdentity}^{\uparrow}$*, and* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$*, but it is not equivalent to any one of them. Its*

*accepted packet is the paired inscription-and-ledger surface $Z = (I, J, L, H, C, P, N)$, with two inscription endpoints, one inter-*Hist *locality ledger, transport, route, provenance, and local NameCert data.*

Proof. Read the sibling roles from the provenance row of Definition 1078.1. The apophatic fixed-point fiber supplies the boundary reading, inscription-point packets supply the endpoint rows, the inter-Hist locality ledger supplies coherence, observer-history identity supplies the history-side consumer discipline, and the external-supply boundary keeps the far end non-internal.

Each sibling lacks at least one coordinate required by Z. The fixed-point fiber lacks the paired locality ledger; an inscription-point packet supplies one endpoint rather than two; an inter-Hist locality ledger lacks the two local inscription rows; observer-history identity lacks the apophatic inscription endpoints; and the external-supply boundary lacks the coherence ledger.

Therefore the dependency is strict. Downstream Lean work must provide explicit Nontrivial InterInscriptionCoher and FieldFaithful InterInscriptionCoherence$^{\uparrow}$ instances in TasteGate.lean for the whole paired packet rather than for a sibling alone. □

Closure status for $\mathsf{NameCert}_{\mathsf{InterInscriptionCoherence}^{\uparrow}}$.

Constructive story: An InterInscriptionCoherence$^{\uparrow}$ packet is generated from two local inscription rows, one inter-Hist locality ledger, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{InterInscriptionCoherence}^{\uparrow}}$, seed)

Scope closed: Definition 1078.1, Definition 1078.2, Definition 1078.3, Definition 1078.4, and Definition 1078.5 bind the paired inscription endpoints, inter-Hist locality ledger, transport, route, provenance, local naming, non-escape, and sibling dependency surface.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{InterInscriptionCoherence}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close global space, host metrics, quotient observer equality, hidden shared subjects, ambient synchronization, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, locality transport, ledger non-escape, sibling dependency, and TasteGate instances for nontriviality and field faithfulness over the paired packet.

Chapter 1079

A Concrete Naming Certificate for $\mathsf{HashApophaticSeal}^{\uparrow}$

The $\mathsf{HashApophaticSeal}^{\uparrow}$ packet realizes the digest, fiber, GAP-ledger, and common apophatic far-end boundary of chapter 9402 as a single finite NameCert seal. It sits beside the hash certificate of chapter 242, the digest-fiber ledger of chapter 1067, the apophatic fixed-point packet of chapter 1068, the apophatic socket packet of chapter 536, and the external-supply boundary of chapter 1065. The seal differs from each sibling because it binds the visible digest, fiber ledger, GAP provenance, far-end boundary, and refusal row in one consumer-facing packet.

Definition 1079.1 (HashApophaticSeal carrier)**.** *A* $\mathsf{HashApophaticSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (D, F, G, T, R, H, C, P, N)$$

with the following displayed rows:

1. *D is the visible digest row, read through the* $\mathsf{Hash}^{\uparrow}$ *certificate surface;*
2. *F is the fiber-ledger row, recording source-side membership behind D without converting digest sameness into source equality;*
3. *G is the* GAP *provenance row that keeps the hidden fiber auditable;*
4. *T is the common apophatic far-end boundary row for the displayed fiber route;*
5. *R is the refusal row blocking any consumer from treating T as a kernel object, source payload, selected preimage, or global digest;*
6. *H records componentwise* hsame *transports for D, F, G, T, R, C, P, N;*
7. *C records the displayed* Cont *routes by which digest, fiber, GAP, far-end, and refusal reads remain in the same finite packet;*
8. *P is the* Pkg *provenance over* $\mathsf{Hash}^{\uparrow}$, $\mathsf{DigestFiberLedger}^{\uparrow}$, $\mathsf{ApophaticFixedPoint}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{HashApophaticSeal}^{\uparrow}}$ *row.*

The carrier has no coordinate for source equality from digest sameness, no hidden preimage selector, no internal object representing the far end, no global universe digest, and no outside-supply witness.

Theorem 1079.2 (HashApophaticSeal NameCert obligations)**.** *For the carrier of Definition 1079.1, the local* $\mathsf{NameCert}_{\mathsf{HashApophaticSeal}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$A = (D, F, G, T, R, H, C, P, N),$$

visible digest exposure through D*, fiber-ledger exposure through* F*, GAP provenance through* G*, common far-end boundary naming through* T*, apophatic refusal through* R*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Every accepted consumer of the seal must preserve those rows together. In particular, digest sameness may be read only as the visible side of the displayed packet, while source equality, preimage selection, object-level far-end internalization, and global digest readings remain absent unless a separate exactness certificate is displayed outside the $\mathsf{HashApophaticSeal}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.HashApophaticSealUp.HashApophaticSealNameCertObligations`

Proof. Project the accepted carrier in Definition 1079.1. Its displayed coordinates are exactly $D, F, G, T, R, H, C, P, N$.

Read the sibling sources through their local roles. The hash certificate supplies the visible digest row; the digest-fiber ledger supplies the fiber and GAP rows; the apophatic fixed-point and socket surfaces name the far-end boundary without internalizing it; and the external-supply boundary keeps the refused outside object visible only as boundary data.

The NameCert surface is exhausted by those rows. Since no carrier coordinate stores a source-equality reflection, selected preimage, internal far-end object, global digest, or outside-supply witness, an accepted consumer cannot obtain any of those objects from the seal. □

Theorem 1079.3 (HashApophaticSeal fiber nonescape)**.** *Every accepted* $\mathsf{HashApophaticSeal}^{\uparrow}$ *consumer that reads the visible digest row* D *must route through the fiber-ledger row* F*, GAP provenance row* G*, common far-end boundary row* T*, refusal row* R*, transport row* H*, continuation row* C*, package provenance* P*, and local naming row* N*. Removing the GAP fiber ledger while keeping the digest row makes the seal unable to distinguish digest sameness from source equality.*

Consequently the seal exports no selected preimage, quotient collapse, host source equality, internal T *object, global universe digest, hidden outside supply, or unledgered far-end read.*

Proof. Start from an accepted packet $A = (D, F, G, T, R, H, C, P, N)$. The digest row D is only the visible face of the carrier, while F and G record the fiber membership and provenance needed to keep the source side auditable.

Apply the NameCert obligations of Definition 1079.2. They force a digest consumer to read D together with the fiber ledger, GAP row, far-end boundary, refusal row, componentwise transport, continuation replay, provenance, and local name.

Now inspect the carrier inventory. If F and G are removed while D remains, the remaining rows do not record which source-side fiber produced the digest; digest sameness therefore cannot be separated from source equality by this seal. Because the accepted carrier contains no selected preimage, quotient collapse, host source equality, internal T object, global digest, hidden supply, or unledgered far-end coordinate, none of those readings escapes the displayed packet. □

Falsifiable prediction: Removing the GAP fiber ledger while keeping the digest row makes the seal unable to distinguish digest sameness from source equality.

Independence witness: Nearest siblings: hash, apophaticfixedpoint, apophaticsocket, externalsupplyboundary, and gap-policy/namecert surfaces; no bijection exists because the seal owns a combined digest, fiber-ledger, and apophatic far-end refusal row absent from each sibling.

The Lean TasteGate boundary is `lean4/BEDC/Derived/HashApophaticSealUp/TasteGate.lean`. It provides `Nontrivial HashApophaticSealUp` and `FieldFaithful HashApophaticSealUp` instances for the displayed digest, fiber, GAP, far-end, refusal, transport, continuation, provenance, and naming carrier.

Lean4 ✓ `BEDC.Derived.HashApophaticSealUp.HashApophaticSealTasteGate single carrier alignment`

Theorem 1079.4 (HashApophaticSeal public seal export)**.** *Every accepted* $\mathsf{HashApophaticSeal}^{\uparrow}$ *carrier*

$$A = (D, F, G, T, R, H, C, P, N)$$

exports one public seal packet whose visible surface is the digest row D, fiber-ledger row F, GAP provenance row G, common far-end boundary row T, refusal row R, componentwise transport row H, continuation row C, package provenance row P, and local naming row N. The exported packet permits digest, fiber, GAP, and far-end refusal reads, but it exports no source equality from digest sameness, selected preimage, internal far-end object, global digest, hidden outside supply, or unledgered fiber route.

Proof. Project the accepted carrier. The public rows are exactly $D, F, G, T, R, H, C, P, N$, and each row is already listed in the local NameCert surface of Definition 1079.2.

The digest row is public only together with the fiber ledger and GAP provenance. By Definition 1079.3, any digest read that drops F or G loses the information that separates digest sameness from source equality.

The far-end row is public only as boundary data. The refusal row R, transport row H, continuation row C, provenance row P, and local name N keep the exported packet inside the displayed seal rather than an internal object or selected preimage.

Thus the seal exports one finite public packet and nothing outside it. Source equality, selected preimages, internal far-end objects, global digest readings, hidden outside supply, and unledgered fiber routes remain absent from the carrier. □

Closure status for $\mathsf{NameCert}_{\mathsf{HashApophaticSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{HashApophaticSeal}^{\uparrow}$ packet is generated from a visible digest, a digest-fiber ledger, GAP provenance, a common apophatic far-end boundary, a refusal row, componentwise transport, displayed replay, provenance, and local naming.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{HashApophaticSeal}^{\uparrow}}, \mathsf{publicClosed})$

Scope closed: Definition 1079.1, Definition 1079.2, Definition 1079.3, Definition 1079.4, the falsifiable prediction, the independence witness, and the TasteGate marker bind $D, F, G, T, R, H, C, P, N$ to BHist, hsame, Cont, Pkg, NameCert, and the sibling scopes $\mathsf{Hash}^{\uparrow}$, $\mathsf{DigestFiberLedger}^{\uparrow}$, $\mathsf{ApophaticFixedPoint}^{\uparrow}$, $\mathsf{ApophaticSocket}^{\uparrow}$, and $\mathsf{ExternalSupplyBoundary}^{\uparrow}$.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{HashApophaticSeal}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.HashApophaticSealUp.HashApophaticSealTasteGate\_single\_carrier\_alignment`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close source equality from digest sameness, selected preimages, internal far-end objects, a global digest, an outside-supply witness, or bridge checking.

Upgrade path: Bridged closure requires a standard bridge that carries the public digest, fiber, GAP, and far-end refusal packet into the acceptance-bridge schema.

Chapter 1080

A Concrete Naming Certificate for $\mathsf{InscriptionHashTrace}^{\uparrow}$

The $\mathsf{InscriptionHashTrace}^{\uparrow}$ packet realizes the hash-like apophatic fixed-point digest of chapter 9402 as a finite inscription trace. It sits beside the hash certificate of chapter 242, the inscription event packet of chapter 519, the trace classifier of chapter 1052, the apophatic fixed-point packet of chapter 1068, and the hash-apophatic seal of chapter 1079. Its distinguishing role is that the visible digest, inscription event, trace classifier, refusal ledger, route audit, transport, continuation, package, and local name are one finite consumer-facing row.

Definition 1080.1 (InscriptionHashTrace carrier)**.** *An* $\mathsf{InscriptionHashTrace}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$T = (D, I, K, R, A, H, C, P, N)$$

with the following displayed rows:

1. *D is the visible digest row read through the* $\mathsf{Hash}^{\uparrow}$ *certificate surface;*
2. *I is the finite inscription-event row that records where the digest is written into the observer-facing trace;*
3. *K is the inscription trace-classifier row that keeps digest sameness distinct from trace-source equality;*
4. *R is the refusal-ledger row blocking hidden preimage, global digest, and object-level* T *reads;*
5. *A is the route-audit row showing that the digest read passes through inscription and classifier surfaces before the apophatic fixed-point seal is cited;*
6. *H records componentwise* hsame *transports for D, I, K, R, A, C, P, N;*
7. *C records the displayed* Cont *route through the digest, inscription event, classifier, refusal, audit, provenance, and naming rows;*
8. *P is the* Pkg *provenance over* $\mathsf{Hash}^{\uparrow}$, $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{InscriptionTraceClassifier}^{\uparrow}$, $\mathsf{ApophaticFixedPoint}^{\uparrow}$, $\mathsf{HashApophaticSeal}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{InscriptionHashTrace}^{\uparrow}}$ *row.*

The carrier contains no coordinate for a selected digest preimage, a global universe hash, source equality from digest sameness, an uninscribed trace read, an unaudited route, or an internal object named T*.*

Theorem 1080.2 (InscriptionHashTrace NameCert obligations)**.** *For the carrier of Definition 1080.1, the local* $\mathsf{NameCert}_{\mathsf{InscriptionHashTrace}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$T = (D, I, K, R, A, H, C, P, N),$$

visible digest exposure through D*, inscription-event exposure through* I*, trace-classifier exposure through* K*, refusal-ledger exposure through* R*, route-audit exposure through* A*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*, package provenance through* P*, and local naming through* N*.*

Every accepted consumer preserves these rows together. In particular, the hash-like digest can be cited toward the apophatic fixed-point seal only after the inscription event, trace classifier, refusal ledger, and route audit have been displayed.

Proof. Project the accepted carrier in Definition 1080.1. Its displayed rows are exactly $D, I, K, R, A, H, C, P, N$.

Read the sibling surfaces in order. The hash certificate supplies the visible digest row, the inscription-event packet supplies the finite writing site, the trace-classifier packet supplies the trace-facing classifier, and the hash-apophatic seal supplies the apophatic fixed-point endpoint only through a displayed refusal-aware route.

The rows R and A are part of the same carrier, so refusal and route audit are not optional side conditions. Since the carrier has no further coordinate, these rows exhaust the local NameCert surface. □

Theorem 1080.3 (InscriptionHashTrace refusal nonescape)**.** *Every accepted* $\mathsf{InscriptionHashTrace}^{\uparrow}$ *consumer that reads* D *must also read* I, K, R, A, H, C, P, N*. Consequently the packet exports no selected preimage, no global universe digest, no source equality obtained from digest sameness, no uninscribed trace, no unaudited route to the seal, and no internal* T *object.*

Proof. Start with the NameCert obligations of Definition 1080.2. They place every public digest read inside the finite carrier $T = (D, I, K, R, A, H, C, P, N)$.

The inscription event and trace classifier are read before the refusal and audit rows. Thus a consumer cannot detach the digest from the trace site or replace classifier sameness by source equality.

Finally inspect the carrier inventory. It contains no preimage selector, global digest, uninscribed trace coordinate, unaudited route coordinate, or internal T object, so none of those readings can escape the displayed packet. □

Theorem 1080.4 (InscriptionHashTrace audit route)**.** *Any accepted route from an* $\mathsf{InscriptionHashTrace}^{\uparrow}$ *digest row to the* $\mathsf{HashApophaticSeal}^{\uparrow}$ *endpoint factors through the displayed chain*

$$\mathsf{Hash}^{\uparrow} \to \mathsf{InscriptionEvent}^{\uparrow} \to \mathsf{InscriptionTraceClassifier}^{\uparrow} \to R \to A \to H, C, P, N.$$

The route cannot cite the apophatic fixed-point seal before the digest evidence, inscription event, classifier row, refusal ledger, route audit, componentwise hsame*,* Cont*,* Pkg*, and* NameCert *rows have all been exposed.*

Lean4 ✓ `BEDC.Derived.InscriptionHashTraceUp.TasteGate.InscriptionHashTrace audit route`

Proof. Use Definition 1080.2 to put the route inside the accepted carrier. The only digest-facing row is D, and it is packaged with the inscription event I and classifier row K.

Next read R and A. The refusal row records the blocked preimage, global digest, and object-level T readings, while the audit row records the permitted route toward the hash-apophatic seal.

The remaining rows H, C, P, N transport, replay, cite, and name only that finite route. Hence any seal-facing consumer sees the displayed chain and no shortcut around it. □

Theorem 1080.5 (InscriptionHashTrace field-faithful prediction)**.** *A Lean TasteGate carrier for* $\mathsf{InscriptionHashTrace}^{\uparrow}$ *is field-faithful only when equality of the projected rows* $D, I, K, R, A, H, C, P, N$ *determines equality of the whole packet, and it is nontrivial only when at least one displayed digest row can vary while the remaining rows stay fixed. Dropping* I*,* K*,* R*, or* A *makes the carrier unable to witness the inscription hash trace route.*

Lean4 ✓ `BEDC.Derived.InscriptionHashTraceUp.TasteGate.InscriptionHashTraceTasteGate single carrier alignment`

Proof. The carrier of Definition 1080.1 is a constructor over the nine displayed rows. Equality of the projected rows therefore gives equality of the constructor instance, while changing the digest row gives a nontrivial witness pair.

The route theorem above supplies the semantic boundary for this encoding. Without the inscription event, the digest is not trace-local; without the classifier, digest sameness can be mistaken for trace-source equality; without the refusal ledger, hidden preimage and object-level T readings are not blocked; and without the audit row, the route to the hash-apophatic seal is not displayed. □

Falsifiable prediction: Any accepted $\mathsf{InscriptionHashTrace}^{\uparrow}$ consumer factors through the displayed hash digest, inscription event, trace classifier, refusal ledger, route-audit, hsame, Cont, Pkg, and NameCert rows before it can cite the apophatic fixed-point seal.

Independence witness: hash, inscriptionevent, inscriptiontraceclassifier, apophaticfixedpoint, and hashapophaticseal: no bijection preserves the displayed rows because $\mathsf{InscriptionHashTrace}^{\uparrow}$ alone binds the digest row, inscription event, trace classifier, refusal ledger, route audit, transport, continuation, provenance, and local NameCert row in one carrier.

The Lean TasteGate boundary is `lean4/BEDC/Derived/InscriptionHashTraceUp/TasteGate.lean`. It includes explicit `Nontrivial InscriptionHashTraceUp` and `FieldFaithful InscriptionHashTraceUp` instances for the displayed finite carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{InscriptionHashTrace}^{\uparrow}}$**.**

Constructive story: An $\mathsf{InscriptionHashTrace}^{\uparrow}$ packet is generated from a visible digest row, inscription-event row, trace-classifier row, refusal-ledger row, route-audit row, componentwise hsame transports, displayed Cont routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{InscriptionHashTrace}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1080.1, Definition 1080.2, Definition 1080.3, Definition 1080.4, and Definition 1080.5 bind the carrier, NameCert obligations, refusal nonescape, audit route, and field-faithful prediction rows for the finite inscription hash trace packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{InscriptionHashTrace}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.InscriptionHashTraceUp.TasteGate.InscriptionHashTraceTasteGate\_single\_carrier\_alignm`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close hidden preimages, global universe digests, source equality from digest sameness, unaudited routes, or bridge checking.

Upgrade path: Obligation closure requires checked carrier, classifier, refusal, audit-route, nontriviality, and field-faithfulness rows.

Chapter 1081

A Concrete Naming Certificate for $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$

The $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ packet is the finite selector-to-seal carrier for the Real and Completion handoff of chapter 9238. It sits after the selector-budget packets and before a consumer reads a $\mathsf{Real}^{\uparrow}$ completion seal: the packet records the finite selector budget, selected window, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff, and terminal $\mathsf{Real}^{\uparrow}$ route as one displayed certificate surface.

Falsifiable prediction: A completion consumer that reads the RealUp seal without the displayed selector-budget and RegSeqRat readback rows refutes the packet.

Independence witness: cauchymodulusrefinement, cauchylimitseal, realcompletionsealclassifier, realsealcomparison, regularcauchycomparison: no listed sibling is bijective to $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$. CauchyModulusRefinement records the refinement route without the terminal selector-to-seal packet, CauchyLimitSeal records a seal without the complete selector budget and readback route, RealCompletionSealClassifier records classifier-facing seal comparison without selected-window budget admission, RealSealComparison compares sealed routes without the upstream selector budget, and RegularCauchyComparison compares regular names without the completion seal handoff.

Definition 1081.1 (Real completion selector-seal carrier)**.** *A* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (B, W, R, L, E, H, C, P, N)$$

with the following displayed rows:

1. *B is the finite selector-budget row naming the precision request, selector index, and admitted budget surface for the completion handoff;*
2. *W is the selected* $\mathsf{StreamName}^{\uparrow}$ *window row produced by B;*
3. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained from the selected window;*
4. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row reached only after the selector budget, selected window, and regular-rational readback are displayed;*
5. *E is the terminal* $\mathsf{Real}^{\uparrow}$ *seal route consumed by the Real and Completion handoff;*
6. *H records componentwise* hsame *transports for the selector budget, selected window, readback, limit seal, terminal Real seal, route, provenance, and local naming rows;*
7. *C records the displayed* Cont *replay route from B to W, from W to R, from R to L, and from L to E;*

8. *P is the* Pkg *provenance over selector-budget packets,* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*

9. *N is the local* $\mathsf{NameCert}_{\mathsf{RealCompletionSelectorSeal}^{\uparrow}}$ *row.*

The classifier compares carriers only by the displayed rows $B, W, R, L, E, H, C, P, N$. It has no coordinate for quotient stream equality, host real equality, a hidden selector, a detached limit object, a second completion route, or ambient completeness.

Theorem 1081.2 (Real completion selector-seal NameCert obligations)**.** *For the carrier of Definition 1081.1, the local* $\mathsf{NameCert}_{\mathsf{RealCompletionSelectorSeal}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$S = (B, W, R, L, E, H, C, P, N),$$

selector-budget exposure through B, selected-window exposure through W, $\mathsf{RegSeqRat}^{\uparrow}$ *readback through R,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff through L, terminal* $\mathsf{Real}^{\uparrow}$ *seal routing through E, componentwise* hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.RealCompletionSelectorSealUp.RealCompletionSelectorSealCarrier namecert obligations`

Proof. Project the carrier of Definition 1081.1. Its public surface is exactly the selector budget, selected window, readback row, limit seal, terminal Real seal, transports, continuations, provenance, and local naming row.

Read the route in dependency order. The selector budget B admits the requested finite observation budget, the window row W records the chosen finite window, the readback row R exposes the regular-rational data in that window, and the limit-seal row L is available only after those rows are displayed.

The terminal seal row E is then a route from the same displayed packet. The structural rows H, C, P, N transport, replay, record, and name only this finite route, so the certificate has no remaining coordinate for quotient equality, host equality, hidden selection, detached limits, or ambient completeness. □

Theorem 1081.3 (Real completion selector-seal route determinacy)**.** *If two accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *consumers expose the same selector budget B, selected window W,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback R,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row L, terminal* $\mathsf{Real}^{\uparrow}$ *seal row E, and the same structural rows H, C, P, N, then they determine the same finite Real and Completion handoff route. No second selected window, hidden selector, detached limit row, quotient stream equality, host real equality, or ambient completeness coordinate can distinguish the two reads.*

Lean4 ✓ `BEDC.Derived.RealCompletionSelectorSealUp.RealCompletionSelectorSealRouteDeterminacy`

Proof. Use the carrier definition to compare the two accepted reads row by row. The rows $B, W, R, L, E, H, C, P, N$ are the whole carrier surface, and the classifier has no additional comparison coordinate.

Apply the NameCert obligations. They force every seal-facing read through the same selector budget, selected window, regular-rational readback, limit seal, and terminal Real seal before the structural rows can package the route.

Since both consumers expose the same displayed rows, their componentwise hsame transports and Cont replays name the same finite route. The excluded objects are absent carrier coordinates, so they cannot produce a second handoff. □

Theorem 1081.4 (Real completion selector-seal non-escape)**.** *Every accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *completion consumer factors through the finite route*

$$B \longmapsto W \longmapsto R \longmapsto L \longmapsto E \longmapsto H, C, P, N.$$

The consumer may read the selector budget, selected window, $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff, terminal* $\mathsf{Real}^{\uparrow}$ *seal, componentwise transports, continuations, provenance, and local* NameCert *row. It receives no quotient stream equality, host real equality, hidden selector, detached limit object, second completion route, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.RealCompletionSelectorSealUp.RealCompletionSelectorSealCarrier nonescape`

Proof. Start from the accepted packet $S = (B, W, R, L, E, H, C, P, N)$. By construction, the selector budget and selected window precede the readback row, and the readback row precedes the limit-seal and terminal Real seal rows.

Use Definition 1081.2. The local certificate exports exactly the displayed route and makes H, C, P, N structural rows for that route rather than independent sources of completion data.

Finally inspect the excluded coordinates. None is present in the carrier or classifier, so a completion consumer cannot bypass B, W, R, L, E through quotient streams, host real equality, hidden selection, a detached limit, a second route, or ambient completeness. □

Theorem 1081.5 (Real completion selector-seal L10 handoff scope)**.** *Every accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet factors the current L10 Real and Completion handoff through the sibling chapters chapter 126, chapter 301, chapter 386, and chapter 38. Its visible route has the ordered carrier spine*

$$B \longmapsto W \longmapsto R \longmapsto L \longmapsto E,$$

where B *admits the selector budget,* W *is the selected* $\mathsf{StreamName}^{\uparrow}$ *window,* R *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* L *is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *consumer handoff, and* E *is the terminal* $\mathsf{Real}^{\uparrow}$ *endpoint row. The rows* H, C, P, N *only transport, replay, record provenance for, and name this route.*

Consequently the packet is an L10 handoff node for the Real and Completion surface, not an independent completion principle. It supplies no quotient stream equality, host real equality, hidden selector, detached limit object, second completion route, or ambient completeness principle.

Lean4 ✓ `BEDC.Derived.RealCompletionSelectorSealUp.RealCompletionSelectorSealCarrier l10 handoff scope`

Proof. Project the carrier from Definition 1081.1. Its first five coordinates are exactly the selector budget, selected stream window, regular-rational readback, Cauchy-limit seal row, and terminal Real endpoint row, and the prose immediately ties these rows to the four sibling chapters in that order.

Apply Definition 1081.2. The NameCert obligation inventory admits only those five route rows followed by H, C, P, N, so the latter rows can only perform componentwise hsame transport, Cont replay, Pkg provenance recording, and local naming for the same displayed path.

Finally use Definition 1081.4. Non-escape excludes every bypass coordinate named in the statement: quotient stream equality, host real equality, hidden selectors, detached limits, second completion routes, and ambient completeness. Thus every accepted selector-seal packet lands on the L10 route $B \to W \to R \to L \to E$ before any structural row is read. □

Theorem 1081.6 (Real completion selector-seal selector-budget totality)**.** *Every accepted* RealCompletionSelectorS *packet exposes the selector-budget row B before any selected window W,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row L, terminal* $\mathsf{Real}^{\uparrow}$ *endpoint row E, or structural row H, C, P, N is readable. In particular, no completion consumer can read a selected window, regular-rational readback, limit seal, terminal endpoint, transport, continuation, provenance, or local naming row without first passing through the finite selector-budget admission recorded by B.*

Lean4 ✓ `BEDC.Derived.RealCompletionSelectorSealUp.RealCompletionSelectorSealCarrier selector budget totality`

Proof. Project the carrier of Definition 1081.1. Its displayed packet is $S = (B, W, R, L, E, H, C, P, N)$, with B placed as the first route row and with W, R, L, E, H, C, P, N recorded as rows whose meanings are tied to that same packet.

Apply Definition 1081.5. The L10 handoff route has ordered spine

$$B \longmapsto W \longmapsto R \longmapsto L \longmapsto E,$$

and the rows H, C, P, N only transport, replay, record provenance for, and name this route.

Thus the selected window, readback, limit seal, terminal endpoint, and structural rows are not independent entries. They are readable only after the selector-budget admission row has already been displayed. □

Theorem 1081.7 (Real completion selector-seal readback exactness)**.** *Once an accepted* RealCompletionSelectorSea *packet displays its selector-budget row B and selected window row W, every regular-rational readback route factors through the single* $\mathsf{RegSeqRat}^{\uparrow}$ *row R. The readback cannot be replaced by quotient stream equality, host real equality, a detached limit row, a second completion route, or any ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.RealCompletionSelectorSealUp.RealCompletionSelectorSealCarrier regseq readback exactness`

Proof. Use Definition 1081.2. The local certificate lists $\mathsf{RegSeqRat}^{\uparrow}$ readback exactly as the row R that follows the selector budget B and selected window W.

Next apply Definition 1081.3. Two accepted consumers that expose the same $B, W, R, L, E, H, C, P, N$ determine the same finite handoff route, and there is no classifier coordinate that can distinguish the route by quotient stream equality, host real equality, detached limits, second routes, or ambient completeness.

Therefore any readback visible after B and W must pass through the displayed row R. Replacing R by an external equality or by a detached limit would introduce a coordinate absent from the carrier and so would leave the accepted packet. □

Theorem 1081.8 (Real completion selector-seal observer-budget handoff)**.** *Let*

$$S = (B, W, R, L, E, H, C, P, N)$$

be an accepted $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet, and let*

$$G = (F, I, S_{\text{obs}}, O, B_{\text{obs}}, W_{\text{obs}}, D_{\text{obs}}, R_{\text{obs}}, E_{\text{obs}}, H_{\text{obs}}, C_{\text{obs}}, P_{\text{obs}}, N_{\text{obs}})$$

be an accepted $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *packet reading the same selector budget boundary. If W_{obs} supplies the selected* $\mathsf{StreamName}^{\uparrow}$ *window for W, D_{obs} supplies the dyadic ledger read by*

that window, R_{obs} supplies the $\mathsf{RegSeqRat}^{\uparrow}$ *readback R, and E_{obs} supplies the terminal* $\mathsf{Real}^{\uparrow}$ *seal face reached by E, then the selector-seal consumer remains on the route*

$$I \to F \to S_{\text{obs}} \to B_{\text{obs}} \to W_{\text{obs}} \to D_{\text{obs}} \to R_{\text{obs}} \to E_{\text{obs}} \to L, E.$$

The omitted observer rows O remain boundary-only data. They cannot be read as the selected window, dyadic ledger, regular-rational readback, limit-seal handoff, terminal Real seal, quotient stream equality, host real equality, second completion route, ambient completeness principle, or TasteGate instance.

Lean4 ✓ `BEDC.Derived.RealCompletionSelectorSealUp.RealCompletionSelectorSealObserverBudgetHandoff`

Proof. Start with selector-budget totality, Definition 1081.6. It forces the $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ consumer to expose B before W, R, L, E, H, C, P, N can be read.

Use readback exactness, Definition 1081.7. Once the selector budget and selected window are displayed, the readback route is the single $\mathsf{RegSeqRat}^{\uparrow}$ row R, not a quotient stream equality, host real equality, detached limit, second route, or ambient completeness principle.

Now apply the observer-filter budget-selector handoff, Definition 1042.3. It routes the selected observation through $I, F, S_{\text{obs}}, B_{\text{obs}}, W_{\text{obs}}, D_{\text{obs}}, R_{\text{obs}}, E_{\text{obs}}$ before the selector-seal packet consumes the limit and Real endpoint rows.

Finally use omitted-row exclusion, Definition 1042.4. The omitted observer ledger remains outside the positive route coordinates, while the existing TasteGate witness surface in this chapter remains a witness row over $B, W, R, L, E, H, C, P, N$ rather than an additional completion source. Hence the consumer route is exactly the displayed observer-budget handoff followed by L, E. □

Theorem 1081.9 (Real completion selector-seal selector-window classifier pullback)**.** *Let*

$$S = (B, W, R, L, E, H, C, P, N)$$

and

$$S' = (B', W', R', L', E', H', C', P', N')$$

be accepted $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packets. They have the same selector-window classifier surface exactly when the selector budget B, selected* $\mathsf{StreamName}^{\uparrow}$ *window W,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback R,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff L, terminal* $\mathsf{Real}^{\uparrow}$ *seal E, and structural H, C, P, N rows agree componentwise with their primed counterparts.*

The classifier excludes quotient stream equality, host real equality, hidden selectors, detached limit objects, second completion routes, and ambient completeness.

Proof. For the forward direction, apply the NameCert obligations of Definition 1081.2. The local certificate exposes exactly $B, W, R, L, E, H, C, P, N$ as the selector-to-seal surface.

Use route determinacy, Definition 1081.3. If two accepted packets present the same displayed rows, they determine the same finite Real and Completion handoff route, so the selector-window classifier has no further coordinate to inspect.

For the reverse direction, assume componentwise agreement of $B, W, R, L, E, H, C, P, N$. Selector-budget totality, Definition 1081.6, forces both reads to enter through B before the selected window or readback is available, and readback exactness, Definition 1081.7, fixes R as the only regular-rational readback after B and W.

Finally apply non-escape, Definition 1081.4. Hidden selectors, quotient stream equality, host real equality, detached limits, second completion routes, and ambient completeness are absent from the packet, so none can split the agreed selector-window classifier surface. □

Theorem 1081.10 (Real completion selector-seal terminal consumer exhaustion)**.** *Every terminal* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *completion consumer factors through the full ordered route*

$$B \longmapsto W \longmapsto R \longmapsto L \longmapsto E \longmapsto H, C, P, N.$$

The terminal consumer may use the $\mathsf{StreamName}^{\uparrow}$ *selected window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff, and the* $\mathsf{Real}^{\uparrow}$ *endpoint only as the displayed continuation of that route. It has no residual access to a hidden selector, quotient stream equality, host real equality, detached limit object, second completion route, or ambient completeness principle.*

Proof. Begin with Definition 1081.6. It forces every terminal read to expose the selector-budget row B before the selected window, readback, limit seal, endpoint, or structural rows are available.

Use Definition 1081.7 for the readback step. After B and W are visible, the only regular-rational readback row available to the packet is the displayed $\mathsf{RegSeqRat}^{\uparrow}$ row R.

Now apply Definition 1081.4. Non-escape forces every accepted completion consumer through $B, W, R, L, E, H, C, P, N$ and excludes hidden selectors, external equalities, detached limits, second completion routes, and ambient completeness.

Finally use Definition 1081.5. The sibling $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ references are exactly the route positions W, R, L, E, so the terminal consumer exhausts the displayed handoff rather than opening another completion surface. □

Theorem 1081.11 (Real completion selector-seal terminality)**.** *Any two accepted terminal Real and Completion handoff consumers that expose the same ordered rows*

$$B, W, R, L, E, H, C, P, N$$

factor through a unique $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *selector-seal route. Every accepted terminal handoff is exhausted by that route: the selector-budget row B, the selected* $\mathsf{StreamName}^{\uparrow}$ *window W, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback R, the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff L, the terminal* $\mathsf{Real}^{\uparrow}$ *endpoint E, and the structural rows H, C, P, N are the whole finite NameCert surface available to the consumer.*

The terminal route supplies no hidden selector, quotient stream equality, host real equality, detached limit object, second completion route, or ambient completeness principle.

Lean4 ✓ `BEDC.Derived.RealCompletionSelectorSealUp.RealCompletionSelectorSealTerminality`

Proof. First identify the ordered route. Apply Definition 1081.5: every accepted packet reaches the Real and Completion handoff through the sibling $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{CauchyLimitSeal}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ positions W, R, L, E after the selector-budget row B.

Next enforce the entry and readback constraints. By Definition 1081.6, no selected window, readback, limit seal, terminal endpoint, or structural row is readable before B. By Definition 1081.7, once B and W are displayed, the regular-rational readback is exactly the row R.

Now compare two terminal consumers exposing the same rows. Use Definition 1081.3; equality of the displayed rows $B, W, R, L, E, H, C, P, N$ forces the same finite Real and Completion handoff route, so the selector-seal route through them is unique.

Finally apply Definition 1081.10. It says every terminal handoff consumer has no residual access beyond the displayed route and excludes hidden selectors, external equality coordinates, detached limits, second completion routes, and ambient completeness. Hence every accepted terminal handoff is exhausted by the unique selector-seal route. □

Theorem 1081.12 (Real completion selector-seal diagonal compatibility pullback)**.** *Let*

$$S = (B, W, R, L, E, H, C, P, N)$$

be an accepted $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet, and let*

$$K = (R_0, T_0, S_0, D_0, W_0, Q_0, L_0, H_0, C_0, P_0, N_0)$$

be an accepted $\mathsf{DiagonalLimitCompatibility}^{\uparrow}$ *packet whose selected-window row, regular-rational readback row, and terminal* $\mathsf{Real}^{\uparrow}$ *seal row agree with* W, R, E*. Then every terminal selector-seal consumer of* S *factors through the same finite diagonal route fixed by* K*. The pullback route cannot introduce quotient streams, selected limits, host real equality, hidden selectors, independent completion data, or ambient completeness.*

Proof. First fix the selector-seal route. By selector-budget totality and readback exactness, Definition 1081.6 and Definition 1081.7, a terminal consumer of S must expose B before W and then read the displayed row R.

Terminality, Definition 1081.11, exhausts the same consumer by the ordered rows $B, W, R, L, E, H, C, P, N$. Thus the selector-seal side supplies one finite route from selector budget through selected window, readback, limit-seal handoff, and terminal endpoint.

Now use the diagonal packet. The selector-budget source lock, Definition 646.193, fixes the selector-budget read of K to its displayed diagonal source and finite rows. Since K agrees with S on the selected window, regular readback, and terminal Real seal rows, the shared rows W, R, E lie on that same diagonal route.

Route determinacy and consumer non-escape for diagonal compatibility, Definition 646.198 and Definition 646.196, identify any completion-facing or $\mathsf{Real}^{\uparrow}$-facing consumer using those shared rows with the finite route of K.

Finally compare the two carrier surfaces. The selector-seal non-escape theorem, Definition 1081.4, leaves no coordinate in S for hidden selectors, quotient stream equality, host real equality, detached limits, second completion routes, or ambient completeness. The diagonal non-escape theorem leaves no such coordinate in K either, so the terminal selector-seal consumer is the pullback of the diagonal compatibility route rather than an independent completion source. □

Theorem 1081.13 (Real completion selector-seal diagonal completion factorization)**.** *Every accepted terminal* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *consumer*

$$S = (B, W, R, L, E, H, C, P, N)$$

that also reads a $\mathsf{CauchyDiagonalSelection}^{\uparrow}$ *selector and a* $\mathsf{MetricCompletionExistence}^{\uparrow}$ *seal factors through the ordered selector-seal route*

$$B \longmapsto W \longmapsto R \longmapsto L \longmapsto E,$$

then through the finite-window diagonal route of chapter 4080, and then through the completion-existence seal route of chapter 5721 before any completion-facing consumer reads the terminal row E*. The factorization refuses detached selectors, quotient stream equality, host real equality, selected limits, second completion routes, and ambient completeness.*

Proof. First use terminality and non-escape, Definition 1081.11 and Definition 1081.4. They force the terminal consumer to expose $B, W, R, L, E, H, C, P, N$ and leave no coordinate for a hidden selector, external equality, detached limit, second route, or ambient completeness principle.

Next apply the diagonal compatibility pullback of Definition 1081.12. A consumer that also reads the diagonal selector must identify its selected-window and regular-rational readback rows with the displayed W and R rows of S, so the diagonal selector is read as a finite-window route rather than as a detached choice of limit.

Finally route the completion-existence seal through chapter 5721. That chapter exposes completion existence only after its source metric, Cauchy schedule, dense embedding, selected windows, regular readback, dyadic ledger, and completion seal rows have been displayed. Hence the selector-seal endpoint E is consumed only after the ordered B, W, R, L, E route, the diagonal-selection route, and the metric-completion-existence route have all been read. □

Theorem 1081.14 (Real completion selector-seal Cont spine compatibility)**.** *Every accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet exposes exactly the two displayed* Cont *witnesses for the selector-to-seal spine:*

$$B \to W \to R \qquad \textit{and} \qquad R \to L \to E.$$

The structural rows H, C, P, N can package the route only after the selector-budget row B, selected window W, $\mathsf{RegSeqRat}^{\uparrow}$ *readback R,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff L, and terminal* $\mathsf{Real}^{\uparrow}$ *endpoint E have been displayed through those two continuation witnesses. No accepted packet adds a third continuation witness, skips either displayed witness, or reads H, C, P, N as an independent completion route.*

Proof. Project the carrier of Definition 1081.1. Its public route rows are B, W, R, L, E and its structural continuation row is the displayed row C for that same carrier.

Use selector-budget totality and readback exactness, Definition 1081.6 and Definition 1081.7. They force the first continuation witness to expose the selector budget, selected window, and regular-rational readback as $B \to W \to R$ before any limit-seal endpoint is readable.

Then use terminality, Definition 1081.11. The terminal endpoint is exhausted by the displayed route, so the second continuation witness exposes $R \to L \to E$ and leaves H, C, P, N as packaging rows for that route rather than further completion data. □

Theorem 1081.15 (Real completion selector-seal two-step Cont boundary)**.** *Any consumer that tries to read the terminal* $\mathsf{Real}^{\uparrow}$ *endpoint without both displayed* Cont *witnesses*

$$B \to W \to R \qquad \textit{and} \qquad R \to L \to E$$

has left the accepted $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet. Such a read cannot cite* $\mathsf{Real}^{\uparrow}$ *completion data through the selector-seal route, cannot use H, C, P, N as a substitute for the missing witness, and cannot recover the endpoint from quotient stream equality, host real equality, a detached limit object, a hidden selector, or ambient completeness.*

Proof. Start from Definition 1081.14. It identifies the two continuation witnesses that must be displayed before the terminal endpoint is packaged.

Apply non-escape, Definition 1081.4. Every accepted completion consumer factors through $B, W, R, L, E, H, C, P, N$, so omitting either continuation witness omits part of the carrier route itself.

Finally use terminality, Definition 1081.11. The terminal Real and Completion handoff is exhausted by the displayed route, so a consumer outside the two-step boundary has no remaining packet coordinate from which to cite $\mathsf{Real}^{\uparrow}$ completion data. □

Theorem 1081.16 (Real completion selector-seal window tolerance lock)**.** *Every accepted* RealCompletionSelectorS *packet exposing the terminal route*

$$B \to W \to R \to L \to E$$

uses the same selected $\mathsf{StreamName}^{\uparrow}$ *window* W *and the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R *across both displayed* Cont *witnesses*

$$B \to W \to R \qquad \textit{and} \qquad R \to L \to E.$$

The terminal seal is therefore fed by the selected-window and readback surface already displayed in the packet. No second selected window, detached readback, quotient stream equality, host real equality, hidden selector, detached limit, or ambient completeness row can be introduced between R *and* L*.*

Proof. First expose the entry side. Selector-budget totality, Definition 1081.6, forces the packet to display B before any selected window, readback, limit-seal, endpoint, or structural row is readable.

Next identify the readback surface. By Definition 1081.7, once B and W are visible, every regular-rational readback route factors through the displayed row R and cannot be replaced by an external equality or detached completion object.

Now use Cont spine compatibility and the two-step boundary, Definition 1081.14 and Definition 1081.15. The first witness ends at the displayed row R, and the second witness begins from that same row R on its way to L and E; omitting or replacing either witness leaves the accepted packet.

Finally apply non-escape, Definition 1081.4. Since every accepted consumer factors through $B, W, R, L, E, H, C, P, N$, there is no carrier coordinate between R and L for another window, another readback, quotient stream equality, host real equality, hidden selection, detached limits, or ambient completeness. The terminal seal is fed by exactly the selected window and readback already displayed. □

Theorem 1081.17 (Real completion selector-seal structural row nonpromotion)**.** *In every accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet, the rows* H, C, P, N *transport, replay, record provenance for, and name only the already displayed route*

$$B \to W \to R \to L \to E.$$

They do not create a hidden selector, quotient stream equality, detached limit object, second completion route, host real equality, or ambient completeness row. In particular, the structural rows cannot turn the selector-seal packet into an independent completion principle after the two displayed Cont *witnesses have been read.*

Proof. Use the L10 handoff scope, Definition 1081.5. It places H, C, P, N after the visible selector-budget, selected-window, readback, limit-seal, and terminal-endpoint rows.

Use Definition 1081.15 to fix the continuation boundary. A terminal endpoint read that lacks either displayed continuation witness is outside the accepted packet, so H, C, P, N cannot supply a replacement route.

Finally combine non-escape with terminal consumer exhaustion, Definition 1081.4 and Definition 1081.10. The excluded coordinates are absent from the carrier, and the terminal consumer is exhausted by the displayed rows, so the structural rows remain transport, replay, provenance, and naming rows only. □

Theorem 1081.18 (Real completion selector-seal carrier admission)**.** *For every accepted* RealCompletionSelectorSea *packet*

$$S = (B, W, R, L, E, H, C, P, N),$$

carrier admission exposes exactly the selector-budget row B, selected-window row W, $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row L, terminal* $\mathsf{Real}^{\uparrow}$ *endpoint row E, componentwise transport row H, continuation row C, provenance row P, and local naming row N. No admitted carrier has an additional quotient-stream, host-real, hidden-selector, detached-limit, second-route, or ambient-completeness coordinate.*

Proof. Project the carrier definition, Definition 1081.1. Its displayed packet has exactly the nine rows $B, W, R, L, E, H, C, P, N$.

Apply the NameCert obligation inventory, Definition 1081.2. It reads those same rows as the full local certificate surface: carrier admission, selector budget, selected window, readback, limit seal, terminal endpoint, transport, continuation, provenance, and local naming.

Finally use route determinacy and non-escape, Definition 1081.3 and Definition 1081.4. Since all accepted reads are determined by the displayed rows and every excluded coordinate is absent from the carrier, admission exposes exactly the stated packet. □

Theorem 1081.19 (Real completion selector-seal selector-budget exposure)**.** *For every accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet*

$$S = (B, W, R, L, E, H, C, P, N),$$

each completion-facing read of W, R, L, E, H, C, P, N passes through the selector-budget row B. The packet therefore exposes the selector budget as the entry row for the selected window, regular-rational readback, limit-seal handoff, terminal endpoint, and structural rows.

Proof. Use selector-budget totality, Definition 1081.6. It states that no selected window, readback, limit seal, endpoint, transport, continuation, provenance, or local naming row is readable before B.

Apply the L10 handoff scope, Definition 1081.5. The route spine begins with B and then proceeds to W, R, L, E, while H, C, P, N package that same route.

The NameCert obligations of Definition 1081.2 identify the local certificate rows with this displayed packet. Hence every accepted read of a non-budget row is already a read downstream of the selector-budget admission row. □

Theorem 1081.20 (Real completion selector-seal selected-window readback)**.** *For every accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet*

$$S = (B, W, R, L, E, H, C, P, N),$$

the selected-window readback route displays W before it displays the $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R. After B and W are exposed, every regular-rational readback available to the packet is the row R.*

Proof. Start with selector-budget totality, Definition 1081.6. It places the selected-window row W after B and before any readback, limit seal, endpoint, or structural row is readable.

Use readback exactness, Definition 1081.7. Once B and W have been displayed, the only regular-rational readback route inside the accepted packet factors through R.

Terminal consumer exhaustion, Definition 1081.10, keeps the terminal consumer on the same ordered route. The readback step is therefore W followed by R, not a detached equality or a second completion read. □

Theorem 1081.21 (Real completion selector-seal limit-seal handoff)**.** *For every accepted* RealCompletionSelectorSe *packet*

$$S = (B, W, R, L, E, H, C, P, N),$$

the $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row* L *is reachable only as the displayed continuation of the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R*. A read that bypasses* $R \to L$ *leaves the selector-seal packet.*

Proof. Apply the L10 handoff scope, Definition 1081.5. Its ordered carrier spine places the limit-seal row immediately after the readback row in the route $B \to W \to R \to L \to E$.

Use readback exactness, Definition 1081.7, to fix R as the only regular-rational readback after B and W. Then use Cont spine compatibility, Definition 1081.14, which displays the second continuation witness as $R \to L \to E$.

The two-step Cont boundary of Definition 1081.15 excludes a terminal read that omits either displayed continuation witness. Thus a limit-seal handoff that bypasses $R \to L$ is not an accepted $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ handoff. □

Theorem 1081.22 (Real completion selector-seal terminal endpoint routing)**.** *For every accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet*

$$S = (B, W, R, L, E, H, C, P, N),$$

the terminal $\mathsf{Real}^{\uparrow}$ *endpoint row* E *is routed from the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff row* L*, and the rows* H, C, P, N *remain structural rows for that route. They transport, replay, record provenance for, and name the route; they do not create another completion endpoint.*

Proof. Use terminality, Definition 1081.11. It says that the accepted terminal handoff is exhausted by the ordered rows $B, W, R, L, E, H, C, P, N$.

Apply terminal consumer exhaustion, Definition 1081.10. The terminal consumer uses the $\mathsf{CauchyLimitSeal}^{\uparrow}$ handoff and the $\mathsf{Real}^{\uparrow}$ endpoint only as the displayed continuation of the selector-to-seal route.

Finally combine non-escape with structural row nonpromotion, Definition 1081.4 and Definition 1081.17. The rows H, C, P, N cannot supply a hidden selector, detached limit, second route, quotient equality, host equality, or ambient completeness; they remain structural support for the route from L to E. □

Theorem 1081.23 (Real completion selector-seal TasteGate witness surface)**.** *For every accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet*

$$S = (B, W, R, L, E, H, C, P, N),$$

the displayed rows $B, W, R, L, E, H, C, P, N$ *form the paper-side witness surface for later* Nontrivial *and* FieldFaithful *TasteGate work. Two accepted packets whose selector-budget rows or selected-window rows differ are distinguishable at the selector-seal boundary unless a displayed componentwise transport row in* H *carries one row to the other. Conversely, equality of all displayed rows* $B, W, R, L, E, H, C, P, N$ *determines the whole selector-seal packet, with no hidden selector, quotient stream equality, host real equality, detached limit, second completion route, or ambient completeness coordinate left to separate the packets.*

Proof. Start from the carrier definition, Definition 1081.1. The accepted packet has exactly the rows $B, W, R, L, E, H, C, P, N$, and the classifier compares carriers only by those rows.

Apply route determinacy and the window tolerance lock, Definition 1081.3 and Definition 1081.16. The selector budget B fixes the admissible selected window W, the readback row R, and the route toward L and E; changing B or W therefore changes the displayed route unless the transport row H supplies the componentwise identification.

Finally use structural row nonpromotion, Definition 1081.17. The rows H, C, P, N transport, replay, record, and name only the already displayed route, so equality of all nine rows leaves no further coordinate that could separate two packets. This is precisely the finite witness surface on which later TasteGate nontriviality and field faithfulness can be tested. □

Theorem 1081.24 (Real completion selector-seal bridge readiness)**.** *The ordered route*

$$B \to W \to R \to L \to E$$

together with H, C, P, N forms the bridge-ready finite handoff from selector budget to terminal $\mathsf{Real}^{\uparrow}$ *endpoint inside the* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet. The handoff uses exactly the L10 handoff scope, selector-budget totality,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback exactness, terminal consumer exhaustion, terminality, the two-step* Cont *boundary, and structural-row nonpromotion rows already displayed in this chapter.*

Proof. Start with the L10 handoff scope. It orders the visible selector-budget, selected-window, readback, limit-seal, terminal-endpoint, transport, continuation, provenance, and naming rows as a finite packet route.

Next apply selector-budget totality and $\mathsf{RegSeqRat}^{\uparrow}$ readback exactness. These results force the route to expose B before selected-window and readback use, and then bind every readback consumer to the displayed row R rather than to a quotient stream equality, host real equality, detached limit, or ambient completeness witness.

Finally combine terminal consumer exhaustion, terminality, the two-step Cont boundary, and structural-row nonpromotion. The terminal endpoint is read through the displayed B, W, R, L, E route, while H, C, P, N only transport, replay, record provenance for, and name that route. This gives a finite bridge-ready handoff without claiming a standard bridge. □

Theorem 1081.25 (Real completion selector-seal standard bridge premise)**.** *Any standard bridge interpreter for the same displayed selector budget B, selected* $\mathsf{StreamName}^{\uparrow}$ *window W,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback R,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff L,* $\mathsf{Real}^{\uparrow}$ *endpoint E, componentwise* hsame *transport rows H,* Cont *replay rows C,* Pkg *provenance row P, and* $\mathsf{NameCert}_{\mathsf{RealCompletionSelectorSeal}^{\uparrow}}$ *row N is determined by the existing* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *carrier. Such an interpreter cannot introduce quotient stream equality, host real equality, a hidden selector, a detached limit, a second completion route, or ambient completeness.*

Proof. First fix the displayed handoff. Bridge readiness, Definition 1081.24, makes the finite route $B \to W \to R \to L \to E$ together with H, C, P, N the only bridge-ready surface supplied by the packet.

Next apply route determinacy and non-escape, Definition 1081.3 and Definition 1081.4. They force any consumer reading the same displayed rows to read the same selector-seal route and leave no carrier coordinate for a quotient stream equality, host real equality, hidden selector, detached limit, second completion route, or ambient completeness witness.

Finally use structural-row nonpromotion and public route export, Definition 1081.17 and Definition 1081.29. The rows H, C, P, N only transport, replay, record provenance for, and name the displayed route, and the public surface exports exactly that route. Therefore a standard bridge

interpreter over the named rows is a reader of the existing carrier rather than an additional completion source. □

Theorem 1081.26 (Real completion selector-seal obligation scope)**.** *Every accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet exposes exactly the selector-budget row* B*, selected finite-window row* W*, limit-seal handoff* L*, terminal endpoint route* E*, componentwise* hsame *transport* H*, displayed* Cont *route* C*,* Pkg *provenance* P*, and local* NameCert *row* N*, together with the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row* R *on the displayed handoff. It exports no countable-choice selector, quotient stream, host real equality, ambient completeness, or hidden limit oracle.*

Proof. Project the carrier of Definition 1081.1. Its displayed packet is exactly $S = (B, W, R, L, E, H, C, P, N)$, so the selector budget, selected window, regular-rational readback, limit seal, endpoint, transport, continuation, provenance, and local naming rows are the only available coordinates.

Use the existing readback and handoff theorems in order. Selector-budget totality exposes B before W, R, L, E, H, C, P, N; $\mathsf{RegSeqRat}^{\uparrow}$ readback exactness fixes R after B and W; terminal consumer exhaustion and terminality carry the route through L and E.

Finally apply Cont spine compatibility, structural row nonpromotion, and bridge readiness. They keep H, C, P, N as transport, replay, provenance, and naming rows for the same displayed handoff, so no countable-choice selector, quotient stream, host equality, ambient completeness principle, or hidden limit oracle is exported. □

Theorem 1081.27 (Real completion selector-seal TasteGate grounding)**.** *The checked Lean target* `BEDC.Derived.RealCompletionSelectorSealUp.RealCompletionSelectorSealCarrier_namecert_obligatio` *grounds the carrier and* NameCert *obligation row for* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$*. The remaining* `Nontrivial RealCompletionSelectorSealUp` *and* `FieldFaithful RealCompletionSelectorSealUp` *instances are the later TasteGate obligations and are not closed by this chapter.*

Proof. Read the chapter's carrier and local naming theorem first. The carrier displays the finite rows $B, W, R, L, E, H, C, P, N$, and the local NameCert theorem records the package, structural row, and naming obligations over that carrier.

The Lean target checks precisely that carrier and NameCert obligation surface. It therefore supplies the verification anchor for obligation closure over the finite selector-seal packet.

The TasteGate instance rows ask for `Nontrivial RealCompletionSelectorSealUp` and `FieldFaithful RealCompletionSelectorSealUp`. Those instance obligations require additional TasteGate data and remain outside the present obligation boundary. □

The Lean follow-up must provide `Nontrivial RealCompletionSelectorSealUp` and `FieldFaithful RealCompletionSelectorSealUp` in `lean4/BEDC/Derived/RealCompletionSelectorSealUp/TasteGate.lean`.

Theorem 1081.28 (Real completion selector-seal scoped consumer surface)**.** *Every accepted* RealCompletionSelecto *packet exposes a single scoped L10 consumer surface*

$$S = (B, W, R, L, E, H, C, P, N).$$

Here B *is the selector budget,* W *is the selected* $\mathsf{StreamName}^{\uparrow}$ *window,* R *is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* L *is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff,* E *is the terminal* $\mathsf{Real}^{\uparrow}$ *endpoint,* H *records componentwise transports,* C *records the displayed continuation routes,* P *records provenance, and* N *is the local* $\mathsf{NameCert}_{\mathsf{RealCompletionSelectorSeal}^{\uparrow}}$ *row.*

The surface is scoped to the current L10 Real and Completion handoff: it is generated by the carrier, certified by the NameCert obligations, ordered by the L10 handoff scope, entered through

selector-budget totality, read back through the RegSeqRat exactness row, exhausted at the terminal consumer and terminality rows, bounded by the two-step Cont *boundary, kept finite by structural-row nonpromotion, made bridge-ready without claiming a bridge, and grounded by the TasteGate row. It exports no quotient stream equality, host real equality, hidden selector, detached limit object, second completion route, ambient completeness principle, TasteGate instance, or checked bridge.*

Proof. Begin with the carrier and NameCert obligations, Definition 1081.1 and Definition 1081.2. They give exactly the displayed rows $B, W, R, L, E, H, C, P, N$ and make those rows the local certificate surface.

Use the L10 handoff scope, selector-budget totality, and RegSeqRat readback exactness. These results order the consumer route through $B \to W \to R \to L \to E$, force every read to enter through the selector budget, and make R the only readback row after the selected window is displayed.

Now apply terminal consumer exhaustion, terminality, and the two-step Cont boundary. The terminal Real endpoint is consumed only through the displayed route, any two terminal consumers with the same rows determine the same selector-seal route, and a read missing either continuation witness lies outside the accepted packet.

Finally combine structural-row nonpromotion, bridge readiness, and TasteGate grounding. The rows H, C, P, N only transport, replay, record provenance for, and name the same route; the bridge-ready statement keeps the handoff finite without asserting a standard bridge; and the TasteGate grounding identifies the checked carrier and NameCert obligation row as the verification anchor. The exclusions in the statement are precisely the coordinates absent from the carrier and from each consumer theorem, so the packet exposes one scoped L10 consumer surface and nothing beyond it. □

Theorem 1081.29 (Real completion selector-seal public route export)**.** *Every accepted* $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ *packet exports the public L10 selector-seal route*

$$B \to W \to R \to L \to E.$$

The structural rows H, C, P, N only transport, replay, record provenance for, and name that route. Every public Real-and-Completion consumer must read the selector budget B, selected $\mathsf{StreamName}^{\uparrow}$ *window W,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback R,* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *handoff L, terminal* $\mathsf{Real}^{\uparrow}$ *endpoint E, componentwise transports H, displayed continuations C, provenance row P, and local* $\mathsf{NameCert}_{\mathsf{RealCompletionSelectorSeal}^{\uparrow}}$ *row N.*

The exported public surface gives no quotient stream equality, host real equality, hidden selector, detached limit object, second completion route, ambient completeness principle, TasteGate instance, or checked bridge.

Proof. First expose the public route. The L10 handoff scope, Definition 1081.5, orders every accepted packet through $B \to W \to R \to L \to E$ before any structural row is read.

Next fix the public reads. Selector-budget totality, Definition 1081.6, forces every consumer to enter through B, and RegSeqRat readback exactness, Definition 1081.7, fixes R as the only readback after B and W.

Then exhaust the endpoint. Terminal consumer exhaustion and terminality, Definition 1081.10 and Definition 1081.11, make every terminal Real-and-Completion consumer factor through the displayed route and leave no residual completion coordinate.

Finally apply structural-row nonpromotion and the scoped consumer surface, Definition 1081.17 and Definition 1081.28. The rows H, C, P, N remain transport, replay, provenance, and naming

rows for the same route, while the scoped surface excludes quotient stream equality, host real equality, hidden selectors, detached limits, second completion routes, ambient completeness, TasteGate instances, and checked bridges. Thus the accepted packet exports exactly the public selector-seal route named in the statement. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealCompletionSelectorSeal}\uparrow}$.

Constructive story: A $\mathsf{RealCompletionSelectorSeal}^{\uparrow}$ packet is generated from a finite selector-budget row, selected StreamName window, RegSeqRat readback row, CauchyLimitSeal handoff row, terminal Real endpoint row, componentwise hsame transports, displayed continuation routes, package provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{RealCompletionSelectorSeal}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1081.1, Definition 1081.2, Definition 1081.3, Definition 1081.4, Definition 1081.5, Definition 1081.6, Definition 1081.7, Definition 1081.10, Definition 1081.11, Definition 1081.17, Definition 1081.18, Definition 1081.19, Definition 1081.20, Definition 1081.21, Definition 1081.22, Definition 1081.23, Definition 1081.24, Definition 1081.27, Definition 1081.28, and Definition 1081.29 with

Lean4 ✓ `BEDC.Derived.RealCompletionSelectorSealUp.taste gate`

bind the carrier, NameCert obligations, route determinacy, non-escape, L10 handoff scope, selector-budget totality, readback exactness, terminal consumer exhaustion, terminality, structural nonpromotion, carrier admission, selector-budget exposure, selected-window readback, limit-seal handoff, terminal endpoint routing, TasteGate witness surface, bridge readiness, TasteGate grounding, scoped L10 consumer surface, and public route export rows.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{RealCompletionSelectorSeal}\uparrow}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.RealCompletionSelectorSealUp.RealCompletionSelectorSealCarrier\_namecert\_obligations`

Bridge status: paperBridge

Not claimed: This chapter does not close quotient stream equality, host real equality, hidden selectors, detached limits, second completion routes, ambient completeness, TasteGate instances, or bridge checking.

Upgrade path: The remaining formal-axis work is a machine-checked standard bridge from auditCleanV to bridgeCheckedV over the same selector-budget, selected-window, RegSeqRat readback, CauchyLimitSeal handoff, Real endpoint, transport, continuation, provenance, and naming rows.

Chapter 1082

A Concrete Naming Certificate for $\mathsf{InscribedRouteSelector}^{\uparrow}$

The $\mathsf{InscribedRouteSelector}^{\uparrow}$ packet realizes the route-selection act described by the inscription-event vision in chapter 9397. It sits between the full event surface of chapter 519, the visible residue ledger of chapter 520, and the route-audit packet of chapter 1005. The selector isolates the moment at which a visible gap is paired with one named route, one accepted check, and one downstream consumer role before public record export is allowed.

Definition 1082.1 (Inscribed route-selector carrier)**.** *An* $\mathsf{InscribedRouteSelector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (G, M, R, K, U, L, H, C, P, N)$$

with the following displayed rows:

1. *G is the visible gap row inherited from the inscription-event source boundary and GAP ledger;*
2. *M is the named public record row to be reached by the selected route;*
3. *R is the selected route row from G to M;*
4. *K is the accepted check row for the route selection;*
5. *U is the downstream consumer role permitted to read the accepted route as public record data;*
6. *L is the GAP-ledger row recording the residue left after R, K, U have been displayed;*
7. *H records componentwise* hsame *transports for G, M, R, K, U, L together with package and local name rows;*
8. *C records the displayed* Cont *routes by which consumers inspect the gap, selected route, accepted check, consumer role, and ledger residue;*
9. *P is the* Pkg *provenance over* BHist, $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{InscriptionGapLedger}^{\uparrow}$, $\mathsf{InscriptionRouteAudit}^{\uparrow}$, $\mathsf{InscriptionAcceptanceBudget}^{\uparrow}$, $\mathsf{InscriptionTraceClassifier}^{\uparrow}$, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{InscribedRouteSelector}^{\uparrow}}$ *row.*

The carrier has no coordinate for a hidden route choice, an off-packet checker, an unbudgeted consumer, a private source predicate, or a public record export that bypasses the selected route row.

Theorem 1082.2 (Inscribed route-selector NameCert obligations)**.** *For the carrier of Definition 1082.1, the local* $\mathsf{NameCert}_{\mathsf{InscribedRouteSelector}^{\uparrow}}$ *surface consists exactly of five finite obligations:*

1. *carrier exposure for* $S = (G, M, R, K, U, L, H, C, P, N)$*;*
2. *route-selection admission requiring the visible gap* G*, named public record* M*, selected route* R*, accepted check* K*, and downstream consumer role* U *to be displayed in the same packet;*
3. *componentwise stability of gap, name, route, check, consumer, and ledger rows under the* hsame *transports in* H*;*
4. *exactness of public export: the selected route may be exported only through* R, K, U *together with the GAP-ledger row* L *and the displayed routes in* C*;*
5. *ledger rows for GAP residue, route audit, acceptance budget, trace-classifier handoff, package provenance, and the local naming certificate.*

Lean4 ✓ `BEDC.Derived.InscribedRouteSelectorUp.InscribedRouteSelectorTasteGate single carrier alignment`

Proof. Carrier exposure is projection from Definition 1082.1. The displayed packet lists the gap, name, route, accepted check, consumer, ledger, transport, continuation, package, and local naming rows.

Route-selection admission reads the first five rows together. The visible gap G supplies the open boundary, M names the public record, R selects the route, K admits that selection, and U names the consumer role that may read it.

Stability is componentwise through H. Exactness and ledger coverage then use C, L, P, N to replay the same finite route for the route-audit, acceptance-budget, and trace-classifier consumers. Since no hidden route choice, off-packet checker, or extra consumer row is present, the five rows exhaust the local NameCert surface. □

Falsifiable prediction: A packet that omits the accepted route row cannot export an inscribed public record to any downstream consumer.

Theorem 1082.3 (Inscribed route-selector nontriviality prediction)**.** *For every accepted* InscribedRouteSelector$^{\uparrow}$ *carrier* $S = (G, M, R, K, U, L, H, C, P, N)$*, a downstream consumer that lacks the selected route row* R *or the accepted check row* K *cannot export* M *as an inscribed public record. Such a consumer may read the visible gap and GAP-ledger residue, but the public inscription route remains unavailable until* R, K, U *are present in the same finite packet.*

Proof. Project the accepted carrier. The only row whose role is route selection is R, and the only row whose role is route admission is K.

Apply Definition 1082.2. Public export is licensed by the simultaneous display of G, M, R, K, U and is replayed through C with residue tracked in L.

If either R or K is absent, the remaining rows still expose a visible gap and a ledger residue, but they do not expose an accepted selected route to the named record. Therefore the consumer cannot export M as inscribed public record data. □

Independence witness: inscriptionevent, inscriptiongapledger, inscriptionrouteaudit, inscriptionacceptancebudget, inscriptiontraceclassifier: the selector packet binds visible gap, named record, selected route, accepted check, downstream consumer, GAP ledger, hsame transport, Cont routes, Pkg provenance, and local NameCert in one carrier. The named siblings respectively expose the whole event, the residue ledger, route audit, acceptance budget, or trace classifier, but none singles out the accepted route-selection act as this finite packet.

The future Lean target family $BEDC.Derived.InscribedRouteSelectorUp$ must provide explicit Nontrivial and FieldFaithful instances for the displayed selector carrier before the route-selection packet can serve as a checked taste gate.

Closure status for $\mathsf{NameCert}_{\mathsf{InscribedRouteSelector}\uparrow}$.

Constructive story: An $\mathsf{InscribedRouteSelector}^{\uparrow}$ packet is generated from a visible gap row, a named public record row, one selected route row, one accepted check row, one downstream consumer role, a GAP-ledger row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{InscribedRouteSelector}\uparrow}, \mathsf{seed})$

Scope closed: Definition 1082.1, Definition 1082.2, and Definition 1082.3 bind the visible-gap, selected-route, accepted-check, consumer-role, GAP-ledger, transport, route, provenance, and local naming surface of inscription route selection.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{InscribedRouteSelector}\uparrow}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean checking, bridge checking, private agency, hidden source choice, unchecked route replay, or consumer rights outside the displayed packet.

Upgrade path: Obligation closure requires Lean encoding of the selector carrier and checked route-selection admission, exactness, nontriviality, and field-faithfulness results.

Chapter 1083

A Concrete Naming Certificate for $\mathsf{DigestLoopRefusal}^{\uparrow}$

The $\mathsf{DigestLoopRefusal}^{\uparrow}$ packet realizes the loop-facing refusal in the hash-like apophatic fixed-point discipline of chapter 9402. It sits after the digest provenance packet of chapter 1062, the fiber ledger of chapter 1067, the hash apophatic seal of chapter 1079, the apophatic far-end socket of chapter 1061, and the inscription hash trace of chapter 1080. Those siblings expose visible digest, source, fiber, far-end, and inscription routes; this carrier adds the row that refuses the loop in which digest equality is treated as a source-preimage generator.

Definition 1083.1 (DigestLoopRefusal carrier)**.** *A* $\mathsf{DigestLoopRefusal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (V, F, A, L, R, H, C, P, N)$$

with the following displayed rows:

1. *V is the visible digest row, read through the digest provenance and hash-trace surfaces;*
2. *F is the fiber ledger row, recording which source-side histories may be mentioned behind V without identifying them with the digest;*
3. *A is the apophatic far-end socket row for the hidden end of the fiber;*
4. *L is the loop-refusal row blocking the route from digest equality back to global source-preimage assertion;*
5. *R is the exactness-refusal ledger row, distinguishing displayed local exactness certificates from absent global preimage data;*
6. *H records componentwise* hsame *transport for V, F, A, L, R, C, P, N;*
7. *C records displayed* Cont *replay routes for the digest, fiber, socket, loop-refusal, exactness-refusal, transport, provenance, and naming rows;*
8. *P is the* Pkg *provenance over* $\mathsf{DigestProvenancePacket}^{\uparrow}$, $\mathsf{DigestFiberLedger}^{\uparrow}$, $\mathsf{HashApophaticSeal}^{\uparrow}$, $\mathsf{InscriptionHashTrace}^{\uparrow}$, $\mathsf{ApophaticFarEndSocket}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{DigestLoopRefusal}^{\uparrow}}$ *row.*

The carrier has no coordinate for a hidden preimage selector, digest-as-source equality, global source universe, quotient source representative, host hash-function inverse, or internal object at the apophatic far end.

Theorem 1083.2 (DigestLoopRefusal NameCert obligations)**.** *For an accepted* $\mathsf{DigestLoopRefusal}^{\uparrow}$ *carrier*

$$D = (V, F, A, L, R, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{DigestLoopRefusal}^{\uparrow}}$ *surface consists exactly of carrier admission for the nine displayed rows, visible digest exposure through* V*, fiber-ledger exposure through* F*, apophatic far-end socket exposure through* A*, loop-refusal exposure through* L*, exactness-refusal exposure through* R*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Every accepted consumer must preserve the loop-refusal row together with the digest and fiber rows. Thus digest equality can be used only as a visible digest comparison unless a separate displayed exactness certificate is supplied outside the $\mathsf{DigestLoopRefusal}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.DigestLoopRefusalUp.DigestLoopRefusalTasteGate single carrier alignment`

Proof. Project the carrier in Definition 1083.1. Its displayed coordinates are precisely $V, F, A, L, R, H, C, P, N$, so the local NameCert row has no hidden coordinate from which to read a preimage selector or host inverse.

Read the sibling inputs in their local roles. The digest provenance packet supplies digest and source discipline, the digest fiber ledger supplies the fiber row, the hash apophatic seal supplies the common far-end refusal, the inscription hash trace supplies the route audit, and the apophatic far-end socket supplies the negative socket boundary.

The loop-refusal row L is then the additional public obstruction. Transport, replay, provenance, and naming rows preserve that same obstruction through H, C, P, N and do not add exactness data. Therefore the NameCert obligations are exhausted by the displayed packet. □

Theorem 1083.3 (DigestLoopRefusal no global preimage)**.** *No accepted* $\mathsf{DigestLoopRefusal}^{\uparrow}$ *consumer can derive a global source-preimage row from equality of visible digest rows alone. A source-preimage claim is admissible only when a separate exactness certificate is displayed; otherwise the consumer receives only the digest row* V*, fiber row* F*, far-end socket row* A*, loop-refusal row* L*, exactness-refusal row* R*, and structural rows* H, C, P, N*.*

Proof. Start with two visible digest reads. The carrier exposes those reads through V, while F records the fiber ledger and A records the apophatic far-end socket.

Apply the NameCert obligations of Definition 1083.2. They require the loop-refusal row L and the exactness-refusal row R to remain attached to any digest-facing consumer route.

Now inspect the excluded coordinates in Definition 1083.1. There is no hidden preimage selector, no global source universe, no quotient representative, and no host inverse row. Without an external exactness certificate, equality of digest rows therefore remains a visible comparison and cannot become a global source-preimage row. □

Theorem 1083.4 (DigestLoopRefusal fiber nonescape)**.** *Every accepted* $\mathsf{DigestLoopRefusal}^{\uparrow}$ *consumer that reads the fiber ledger* F *must also preserve the visible digest row* V*, the apophatic far-end socket* A*, the loop-refusal row* L*, the exactness-refusal row* R*, componentwise transport* H*, continuation replay* C*, provenance* P*, and local naming* N*. The fiber read exports no source equality, selected preimage, host equality, quotient source representative, global digest universe, or internal far-end object.*

Lean4 ✓ `BEDC.Derived.DigestLoopRefusalUp.DigestLoopRefusal fiber nonescape`

Proof. Begin with the fiber row F. By Definition 1083.1, F is one coordinate of the accepted packet and is not a source object by itself.

Use the digest-fiber and apophatic sibling routes through chapter 1067 and chapter 1079. They already force fiber reads to keep GAP, far-end, and refusal rows visible rather than internalizing the source side.

Finally apply the loop-refusal obligations of Definition 1083.2. The rows L, R, H, C, P, N keep the fiber read on the same finite packet and remove the forbidden source-equality and preimage exits. □

Falsifiable prediction: If a DigestLoopRefusalUp carrier is accepted, no consumer can derive a global source-preimage row from digest equality without an explicit exactness certificate.

Independence witness: digestprovenancepacket, digestfiberledger, hashapophaticseal, inscriptionhashtrace, and apophaticfarendsocket: this carrier is not bijective to any sibling because it adds the loop-refusal row that blocks digest-to-source inversion while preserving visible digest, fiber ledger, apophatic far-end socket, exactness-refusal, transport, replay, provenance, and local naming rows.

The Lean follow-up target is `BEDC.Derived.DigestLoopRefusalUp`. Its `TasteGate.lean` file must provide `Nontrivial DigestLoopRefusalUp` and `FieldFaithful DigestLoopRefusalUp` instances for the same displayed digest, fiber, far-end socket, loop-refusal, exactness-refusal, transport, replay, provenance, and naming carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{DigestLoopRefusal}^{\uparrow}}$.

Constructive story: A $\mathsf{DigestLoopRefusal}^{\uparrow}$ packet is generated from a visible digest row, fiber ledger, apophatic far-end socket, loop-refusal row, exactness-refusal ledger, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The carrier first exposes digest and fiber data, then records the far-end socket, and then blocks the loop from digest equality back to source-preimage assertion. The classifier permits visible digest comparison only with the loop-refusal and exactness-refusal rows attached, so digest equality never becomes a hidden source generator.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DigestLoopRefusal}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the digest loop refusal carrier, NameCert obligations, no-global-preimage theorem, prediction, and independence witness.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DigestLoopRefusal}^{\uparrow}}, \mathsf{unformalized})$

Ledger evidence: BEDC.Meta.DiscoveryDeltaLedger.digestLoopRefusalDeltaLedger

Bridge status: none

Origin: ai

Not claimed: It does not claim hidden preimage selectors, digest-as-source equality, global source universes, quotient representatives, host inverses, or internal far-end objects.

Upgrade path: To reach obligationClosure, formalize the loop-refusal and exactness-refusal rows as checked blockers for digest-to-source inversion.

Chapter 1084

A Concrete Naming Certificate for $\mathsf{HashLikeFiberBoundary}^{\uparrow}$

The $\mathsf{HashLikeFiberBoundary}^{\uparrow}$ packet realizes the hash-like apophatic fixed-point discipline of chapter 9402 as a composite finite NameCert packet. It sits beside the hash certificate of chapter 242, the digest-fiber ledger of chapter 1067, the apophatic-fixed-point fiber of chapter 1069, and the apophatic fixed-point packet of chapter 1068. Its role is to bind digest visibility, hidden fiber membership, GAP provenance, apophatic far-end refusal, and consumer non-escape as one concrete boundary surface.

Definition 1084.1 (HashLikeFiberBoundary carrier)**.** *A* $\mathsf{HashLikeFiberBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$X = (D, F, G, T, R, H, C, P, N)$$

with the following displayed rows:

1. *D is the visible digest row read through the* $\mathsf{Hash}^{\uparrow}$ *certificate;*
2. *F is the hidden fiber ledger row recording source-side membership behind D without identifying the source with the digest;*
3. *G is the* GAP *provenance row for the same fiber ledger;*
4. *T is the apophatic far-end boundary row read through the* $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$ *and* $\mathsf{ApophaticFixedPoint}^{\uparrow}$ *sources;*
5. *R is the refusal row blocking any consumer from treating T as a digest value, source payload, selected preimage, kernel object, or ambient universe object;*
6. *H records componentwise* hsame *transports for D, F, G, T, R, C, P, N;*
7. *C records the displayed* Cont *routes for digest, fiber, GAP, far-end, refusal, transport, provenance, and local naming reads;*
8. *P is the* Pkg *provenance over* $\mathsf{Hash}^{\uparrow}$, $\mathsf{DigestFiberLedger}^{\uparrow}$, $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$, $\mathsf{ApophaticFixedPoint}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{HashLikeFiberBoundary}^{\uparrow}}$ *row.*

The carrier contains no coordinate for digest-as-source equality, selected preimage recovery, an internal far-end object, a global universe digest, or an unledgered fiber consumer.

Lean4 (definition) `BEDC.Derived.HashLikeFiberBoundaryUp.HashLikeFiberBoundaryUp`

Theorem 1084.2 (HashLikeFiberBoundary NameCert obligations)**.** *For the carrier of Definition 1084.1, the local* $\mathsf{NameCert}_{\mathsf{HashLikeFiberBoundary}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$X = (D, F, G, T, R, H, C, P, N),$$

visible digest exposure through D, hidden fiber-ledger exposure through F, GAP provenance through G, apophatic far-end boundary naming through T, far-end refusal through R, componentwise hsame *transport through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Proof. Project the displayed carrier. The rows D, F, G, T, R are the complete concrete boundary content, while H, C, P, N transport, replay, package, and name the same finite packet.

Read the source chapters in their displayed order. The $\mathsf{Hash}^{\uparrow}$ certificate supplies digest visibility, $\mathsf{DigestFiberLedger}^{\uparrow}$ supplies hidden fiber and GAP provenance, $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$ supplies the fiber-to-far-end boundary route, and $\mathsf{ApophaticFixedPoint}^{\uparrow}$ supplies the refusal discipline that prevents far-end internalization.

The NameCert surface is exhausted by these rows. Since the carrier has no coordinate for digest-as-source equality, selected preimage recovery, an internal far-end object, global universe digest, or unledgered fiber consumer, no accepted read can obtain any of those objects from the packet. □

Theorem 1084.3 (HashLikeFiberBoundary sibling route)**.** *Every accepted* $\mathsf{HashLikeFiberBoundary}^{\uparrow}$ *packet reads visible digest exposure from chapter 242, hidden fiber ledger rows from chapter 1067, and far-end boundary rows from chapter 1069 before it exports the local boundary certificate. Concretely, the rows $D, F, G, T, R, H, C, P, N$ must be displayed as digest visibility, hidden fiber membership, GAP provenance, apophatic far-end boundary, refusal, transport, replay, provenance, and local naming rows for the same finite route.*

Proof. Project D first. The hash certificate supplies only the visible digest exposure; it does not expose a hidden fiber or far-end boundary by itself.

Next project F and G. The digest-fiber ledger supplies hidden membership and GAP provenance behind the visible digest, keeping the source-side row ledgered rather than identified with D.

Finally project T, R, H, C, P, N. The apophatic-fixed-point fiber supplies the far-end boundary row, while the refusal, transport, replay, provenance, and local naming rows keep that boundary attached to the displayed digest-fiber route before the local certificate is exported. □

Theorem 1084.4 (HashLikeFiberBoundary fiber-digest stability)**.** *Any accepted transport of a* $\mathsf{HashLikeFiberBoundary}^{\uparrow}$ *packet that preserves the visible digest row D and the hidden fiber ledger row F must preserve the same GAP provenance row G, apophatic boundary row T, and refusal row R through the displayed packet*

$$D, F, G, T, R, H, C, P, N.$$

Thus the fiber-digest route cannot be replayed as a digest-only route, a selected preimage route, or a far-end object route.

Proof. Project the carrier rows of Definition 1084.1. The rows D and F are not free-standing coordinates; they are displayed together with G, T, R, H, C, P, N in one finite packet.

Apply the NameCert obligations of Definition 1084.2. They identify the accepted surface with digest exposure, hidden fiber-ledger exposure, GAP provenance, apophatic far-end boundary naming, refusal, transport, replay, provenance, and local naming for the same rows.

Use noninternalization Definition 1084.5. Once transport preserves D and F, the far-end boundary can still be read only through G, T, R, H, C, P, N, so the transport preserves the GAP, apophatic boundary, and refusal rows rather than creating a digest-only or selected-preimage route. □

Theorem 1084.5 (HashLikeFiberBoundary noninternalization)**.** *Every accepted* $\mathsf{HashLikeFiberBoundary}^{\uparrow}$ *consumer that reads the far-end row T receives it only as the apophatic boundary of the displayed fiber behind the visible digest row D. The consumer may replay T through R, H, C, P, N, but it cannot read T as a digest value, source payload, selected preimage, kernel object, global universe digest, host equality, or ambient completeness principle.*

Proof. Start with the carrier inventory in Definition 1084.1. The far-end coordinate is the boundary row T, and it is displayed together with digest, fiber, GAP, and refusal rows.

Apply the NameCert obligations of Definition 1084.2. Any consumer of T must preserve the route through $D, F, G, T, R, H, C, P, N$, so the far-end read cannot detach from the fiber ledger that made it visible.

The refusal row R excludes the forbidden interpretations. A read that treats T as a digest value, payload, selected preimage, object, global digest, host equality, or completeness principle has no coordinate in the carrier and therefore no accepted route. □

The far-end refusal row is consumed only after the digest-fiber ledger of chapter 1067 and the apophatic-fixed-point fiber of chapter 1069 have both been displayed. Thus a consumer reaches the boundary through the fiber ledger and apophatic fiber before it can read the refusal row.

Theorem 1084.6 (HashLikeFiberBoundary consumer route)**.** *Every accepted* $\mathsf{HashLikeFiberBoundary}^{\uparrow}$ *consumer reads the displayed rows*

$$D, F, G, T, R, H, C, P, N$$

in that order before any digest, fiber, GAP, far-end boundary, or refusal endpoint is consumed. The route first exposes the $\mathsf{Hash}^{\uparrow}$ *digest row, then the* $\mathsf{DigestFiberLedger}^{\uparrow}$ *fiber row and GAP provenance, then the* $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$ *and* $\mathsf{ApophaticFixedPoint}^{\uparrow}$ *far-end boundary and refusal rows, and only then the transport, replay, provenance, and local naming rows.*

Proof. Project the carrier of Definition 1084.1. The rows D, F, G, T, R are ordered as digest, hidden fiber, GAP provenance, far-end boundary, and refusal data, while H, C, P, N preserve and name that same route.

Apply the NameCert obligations of Definition 1084.2. They identify local admission with precisely the rows $D, F, G, T, R, H, C, P, N$, so a consumer has no accepted entry point outside the displayed packet.

Finally use noninternalization Definition 1084.5. The far-end row can be consumed only after the digest and fiber ledger have been read and only with the refusal row attached, so the consumer route is exactly the ordered route stated above. □

Theorem 1084.7 (HashLikeFiberBoundary transport stability)**.** hsame *transport and* Cont *replay preserve the same digest, fiber, GAP, far-end, and refusal route of an accepted* HashLikeFiberBoundary$^{\uparrow}$ *packet. Transport may move the rows componentwise, and replay may expose the route again, but neither operation adds selected preimage recovery, digest-as-source equality, internal far-end objects, global universe digests, host equality, or ambient completeness.*

Proof. Start with the consumer route of Definition 1084.6. It fixes the ordered path through $D, F, G, T, R, H, C, P, N$ before any endpoint is consumed.

The carrier row H records componentwise hsame transport for those same rows, and the row C records displayed Cont replay. Therefore transporting or replaying an accepted packet preserves the digest row, the hidden fiber ledger, GAP provenance, far-end boundary, refusal row, provenance, and local naming route.

Apply noninternalization Definition 1084.5. Since the carrier contains no coordinate for selected preimage recovery, digest-as-source equality, internal far-end objects, global universe digests, host equality, or ambient completeness, neither transport nor replay can create such a coordinate. □

Falsifiable prediction: Any accepted HashLikeFiberBoundaryUp consumer that reads the far-end row as a digest value violates the noninternalization theorem.

Independence witness: Nearest siblings: hash, digestfiberledger, apophatic-fixed-point-fiber, and apophaticfixedpoint. None is bijective to HashLikeFiberBoundaryUp because each sibling omits at least one row among digest visibility, hidden fiber membership, GAP provenance, apophatic far-end refusal, and consumer non-escape.

The Lean TasteGate boundary is `lean4/BEDC/Derived/HashLikeFiberBoundaryUp/TasteGate.lean`. It is the intended formal carrier for the displayed digest, fiber, GAP, far-end, refusal, transport, continuation, provenance, and naming rows.

Lean4 ✓ `BEDC.Derived.HashLikeFiberBoundaryUp.hashLikeFiberBoundaryChapterTasteGate`

Closure status for NameCert$_{\text{HashLikeFiberBoundary}^{\uparrow}}$.

Constructive story: A HashLikeFiberBoundary$^{\uparrow}$ packet is generated from visible digest, hidden fiber-ledger, GAP provenance, apophatic far-end boundary, far-end refusal, componentwise transport, displayed continuation, provenance, and local NameCert rows.

Theory closure: TheoryGate(NameCert$_{\text{HashLikeFiberBoundary}^{\uparrow}}$, publicClosed)

Scope closed: Definition 1084.1, Definition 1084.2, Definition 1084.3, Definition 1084.4, Definition 1084.5, Definition 1084.6, and Definition 1084.7 bind the visible digest row, hidden fiber ledger row, GAP provenance row, apophatic far-end boundary row, refusal row, transport row, replay row, provenance row, and local naming row into one closed packet.

Formal verification: FormalStatus(NameCert$_{\text{HashLikeFiberBoundary}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.HashLikeFiberBoundaryUp.hashLikeFiberBoundaryChapterTasteGate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close selected preimage recovery, digest-as-source equality, internal far-end objects, global universe digests, or bridge checking.

Upgrade path: Scoped closure requires binding those obligations to Hash$^{\uparrow}$, DigestFiberLedger$^{\uparrow}$, ApophaticFixedPointFiber$^{\uparrow}$, ApophaticFixedPoint$^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert.

Chapter 1085

A Concrete Naming Certificate for $\mathsf{DigestInscription}^{\uparrow}$

The $\mathsf{DigestInscription}^{\uparrow}$ packet realizes the digest-surface inscription of chapter 9402 as a finite NameCert surface. It sits beside the hash-like fiber boundary of chapter 1084, the digest-fiber ledger of chapter 1067, the apophatic fixed-point fiber of chapter 1069, the inscription event surface of chapter 519, and the observer-history identity surface of chapter 479. Its role is narrower than those siblings: it binds the visible digest, observation fiber, GAP row, apophatic far end, local self-center inscription, no-subject observer identity, transport, continuation, package, and local name in one displayed packet.

Definition 1085.1 (DigestInscription carrier)**.** *A* $\mathsf{DigestInscription}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$I = (D, F, G, T, S, O, H, C, P, N)$$

with the following displayed rows:

1. *D is the visible digest row read from* $\mathrm{ObsDigest}(\mathcal{C}, t)$*;*
2. *F is the observation-fiber row* $\mathrm{ObsFib}(D)$ *behind the visible digest;*
3. *G is the* GAP *provenance row witnessing that the fiber is displayed rather than inferred from digest equality;*
4. *T is the apophatic far-end boundary row read through* $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$*;*
5. *S is the local self-center inscription row read through the public inscription event surface;*
6. *O is the observer-history identity row preserving the no-subject discipline of the inscription site;*
7. *H records componentwise* hsame *transports for $D, F, G, T, S, O, C, P, N$;*
8. *C records the displayed* Cont *routes for digest, fiber, GAP, far-end, inscription, observer-history, transport, package, and local naming reads;*
9. *P is the* Pkg *provenance over* $\mathsf{HashLikeFiberBoundary}^{\uparrow}$, $\mathsf{DigestFiberLedger}^{\uparrow}$, $\mathsf{ApophaticFixedPointFiber}^{\uparrow}$, $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{ObserverHistIdentity}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{DigestInscription}^{\uparrow}}$ *row.*

The carrier contains no coordinate for digest-as-source equality, direct digest-to-T *identification, observer-substance, unledgered fiber membership, private inscription agency, or hidden preimage recovery.*

Lean4 (definition) `BEDC.Derived.DigestInscriptionUp.DigestInscriptionUp`

Definition 1085.2 (DigestInscription classifier)**.** *The* $\mathsf{DigestInscription}^{\uparrow}$ *classifier compares accepted carriers componentwise through* $D, F, G, T, S, O, H, C, P, N$*. Two carriers classify together only when the visible digest, observation fiber, GAP provenance, apophatic far-end boundary, local self-center inscription, observer-history identity, transport rows, continuation routes, package provenance, and local names agree through the displayed packet.*

Theorem 1085.3 (DigestInscription NameCert obligations)**.** *For the carrier of Definition 1085.1, the local* $\mathsf{NameCert}_{\mathsf{DigestInscription}^{\uparrow}}$ *surface consists exactly of five obligation rows:*

1. *visible digest and fiber exposure through* D, F, G*;*
2. *apophatic far-end exposure through* T*;*
3. *local inscription and observer-history exposure through* S, O*;*
4. *componentwise stability through* H, C, P*;*
5. *local naming through* N*.*

Every accepted digest-surface inscription must display all five rows before a consumer may read the visible digest as carrying an inscription site.

Proof. Project the carrier of Definition 1085.1. The rows D, F, G place the digest inside an explicit observation fiber rather than inside source equality.

Read the far-end and inscription rows next. The row T is only an apophatic boundary, while S records the local self-center inscription as a public event row. The observer-history row O keeps that event on the no-subject side.

The remaining rows H, C, P, N transport, replay, package, and name the same packet. Since the carrier has no other coordinate, the five listed obligation rows exhaust the local NameCert surface. □

Theorem 1085.4 (DigestInscription fiber far-end nonescape)**.** *Every accepted* $\mathsf{DigestInscription}^{\uparrow}$ *consumer that reads the apophatic far-end row* T *must first keep the visible digest row* D*, observation-fiber row* F*, GAP row* G*, local inscription row* S*, observer-history row* O*, transport row* H*, continuation row* C*, package row* P*, and local name row* N *in the same displayed packet. Hence the far end cannot be exported as a digest value, source payload, selected preimage, observer subject, private inscription agent, or BEDC kernel object.*

Proof. Start with the classifier of Definition 1085.2. It permits comparison only through the displayed rows $D, F, G, T, S, O, H, C, P, N$.

Apply the obligation theorem. The far-end row belongs to the second obligation row, but the first and third rows force it to remain attached to the digest fiber, GAP provenance, local inscription, and observer-history surface.

Finally inspect the carrier exclusions in Definition 1085.1. There is no coordinate for a digest value equal to T, a source payload, selected preimage, observer subject, private inscription agent, or kernel object. Any such consumer therefore leaves the accepted packet. □

Falsifiable prediction: An accepted DigestInscriptionUp consumer refutes the packet if it reads the far-end row without the visible digest, observation-fiber, GAP, local-inscription, and observer-history rows in the same NameCert surface.

Independence witness: hashlikefiberboundary, digestfiberledger, apophaticfixedpointfiber, inscriptionevent, observerhistidentity: no sibling is bijective to DigestInscriptionUp because only this packet carries visible digest, observation fiber, GAP provenance, apophatic far end, local self-center inscription, observer-history identity, transport, continuation, package, and local NameCert rows together.

The Lean TasteGate boundary is `lean4/BEDC/Derived/DigestInscriptionUp/TasteGate.lean`. It must provide `Nontrivial DigestInscriptionUp` and `FieldFaithful DigestInscriptionUp` instances preserving $D, F, G, T, S, O, H, C, P, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{DigestInscription}^{\uparrow}}$.

Constructive story: A $\mathsf{DigestInscription}^{\uparrow}$ packet is generated from visible digest, observation-fiber, GAP, apophatic far-end, local self-center inscription, observer-history identity, componentwise hsame transport, displayed Cont routes, Pkg provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{DigestInscription}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1085.1, Definition 1085.2, Definition 1085.3, Definition 1085.4, the falsifiable prediction, and the independence witness bind the finite digest-inscription packet and its fiber far-end nonescape boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{DigestInscription}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close digest-as-source equality, direct digest-to-T identification, hidden preimage recovery, observer-substance, private inscription agency, Lean verification, or bridge checking for $\mathsf{DigestInscription}^{\uparrow}$.

Upgrade path: Obligation closure requires Lean encoding of the carrier, classifier, NameCert obligation surface, fiber far-end nonescape boundary, TasteGate nontriviality, and field faithfulness for $D, F, G, T, S, O, H, C, P, N$.

Chapter 1086

A Concrete Naming Certificate for $\mathsf{InscriptionEventReplay}^{\uparrow}$

The $\mathsf{InscriptionEventReplay}^{\uparrow}$ packet realizes the replay-only boundary named in chapter 9397. It sits downstream of the agency-bearing inscription surface of chapter 519, consumes the accepted route exposed by chapter 582, and offers deterministic checker replay to the route-audit surface of chapter 1005. The point of the packet is negative as much as positive: replay is valuable audit evidence, but it is not the technical inscription event unless the carrier also contains the acceptance row that selects the route as the record to inscribe.

Falsifiable prediction: A replay packet whose carrier has no stored accepted public route is not an accepted $\mathsf{InscriptionEventReplay}^{\uparrow}$ carrier.

Independence witness: inscriptionevent, inscribedroute, inscriptionrouteaudit, inscriptiongapledger, finitewindowobserver; the replay carrier is not bijective to any sibling because it requires a pre-existing accepted route and checker replay row while excluding the inscription-acceptance coordinate that the inscription-event siblings carry.

Definition 1086.1 (Inscription-event replay carrier)**.** *An* $\mathsf{InscriptionEventReplay}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (G, M, A, K, D, H, C, P, N)$$

with the following displayed rows:

1. *G is the visible gap row inherited from the source boundary of the earlier inscription event;*
2. *M is the named public record whose route has already been accepted;*
3. *A is the stored accepted public route row from the prior inscription carrier;*
4. *K is the deterministic checker replay row for that stored route;*
5. *D is the route-audit readback row exposing G, M, A, K to downstream consumers;*
6. *H records componentwise* hsame *transports for the gap, name, accepted route, replay, readback, provenance, and local naming rows;*
7. *C records the displayed* Cont *routes by which consumers replay the accepted route and inspect the audit readback;*
8. *P records* Pkg *provenance over* $\mathsf{InscriptionEvent}^{\uparrow}$, $\mathsf{InscribedRoute}^{\uparrow}$, $\mathsf{InscriptionRouteAudit}^{\uparrow}$, $\mathsf{InscriptionGapLedger}^{\uparrow}$, $\mathsf{FiniteWindowObserver}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*

9. N is the local $\mathsf{NameCert}_{\mathsf{InscriptionEventReplay}^{\uparrow}}$ *row.*
The carrier has no coordinate for the inscription-facing acceptance act by which a conscious observational system first selected A as the record to inscribe. It therefore records deterministic replay of an already accepted route, not technical inscription-event agency.

Lean4 (definition) `BEDC.Derived.InscriptionEventReplayUp.InscriptionEventReplayUp`

Theorem 1086.2 (Inscription-event replay NameCert obligations)**.** *For the carrier of Definition 1086.1, the local* $\mathsf{NameCert}_{\mathsf{InscriptionEventReplay}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$R = (G, M, A, K, D, H, C, P, N),$$

stored accepted-route exposure through A, deterministic checker replay through K, route-audit readback through D, componentwise hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through P, and local naming through N. The surface does not include the conscious acceptance row that belongs to the inscription-event carrier of chapter 519.*

Proof. Project the carrier of Definition 1086.1. Its public rows are the visible gap, named record, stored accepted route, checker replay, audit readback, transport, continuation, provenance, and local naming rows.

Read the dependency order. The replay row K is meaningful only after the accepted public route A is already stored, and the readback row D exposes the pair A, K to the audit consumers.

The structural rows H, C, P, N transport, replay, record, and name that same finite surface. Since no coordinate records the first public acceptance of A as the route to inscribe, the NameCert obligations close replay audit only. □

Theorem 1086.3 (Inscription-event replay noninscription boundary)**.** *Every accepted* $\mathsf{InscriptionEventReplay}^{\uparrow}$ *packet separates deterministic proof replay from technical inscription-event agency. A consumer may read the visible gap G, named record M, stored accepted route A, checker replay K, and route-audit readback D, but it cannot recover the inscription-facing acceptance coordinate that made A the public record in the first place.*

Proof. Begin with the carrier inventory. The row A stores an accepted public route and the row K replays it deterministically, but the tuple contains no row for the acceptance act itself.

Apply Definition 1086.2. The local certificate exposes replay obligations for A, K, D, H, C, P, N and does not enlarge the carrier with a second agency-bearing coordinate.

Therefore a replay consumer can audit the route once it is present, while the inscription-event acceptance boundary remains in the sibling event carrier rather than in the replay packet. □

Theorem 1086.4 (Inscription-event replay consumer non-escape)**.** *Every* $\mathsf{InscriptionEventReplay}^{\uparrow}$ *consumer factors through the finite replay route*

$$G \longmapsto M \longmapsto A \longmapsto K \longmapsto D \longmapsto H, C, P, N.$$

The consumer receives no hidden route choice, off-packet checker, private source predicate, unrecorded acceptance act, or public-record export outside the displayed replay rows.

Proof. Use the carrier definition to read the replay route in order. The gap and named record identify the inherited inscription boundary, the stored route A supplies the object to replay, and the checker row K performs deterministic replay before D exposes the audit readback.

Next apply Definition 1086.3. It removes the only tempting bypass: treating the replay row as if it were the original acceptance row.

The remaining structural rows only transport, replay, package, and name the displayed route. Hence every consumer factors through the listed packet and cannot escape into hidden selection, private source content, or unrecorded agency. □

The Lean follow-up must provide `Nontrivial InscriptionEventReplayUp` and `FieldFaithful InscriptionEventReplayUp` in `lean4/BEDC/Derived/InscriptionEventReplayUp/TasteGate.lean`.

Closure status for $\mathsf{NameCert}_{\mathsf{InscriptionEventReplay}^{\uparrow}}$.

Constructive story: An $\mathsf{InscriptionEventReplay}^{\uparrow}$ packet is generated from a visible gap row, named public record row, stored accepted-route row, deterministic checker replay row, audit readback row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{InscriptionEventReplay}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1086.1, Definition 1086.2, Definition 1086.3, and Definition 1086.4 bind the replay-only carrier, deterministic checker route, noninscription boundary, and consumer non-escape surface.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{InscriptionEventReplay}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close the original inscription acceptance act, private agency, hidden route selection, Lean verification, bridge checking, or public export outside the displayed replay packet.

Upgrade path: Obligation closure requires checked carrier admission, accepted-route exposure, deterministic replay readback, route-audit exactness, consumer non-escape, and TasteGate Nontrivial and FieldFaithful witnesses.

Chapter 1087

A Concrete Naming Certificate for $\mathsf{HashDigestFiberBoundary}^{\uparrow}$

The $\mathsf{HashDigestFiberBoundary}^{\uparrow}$ packet realizes the digest/fiber boundary isolated in chapter 9402 as a finite NameCert surface. It sits beside the hash-apophatic seal of chapter 1079, the digest-fiber ledger of chapter 1067, and the hash-like fiber boundary of chapter 1084. Its role is narrower than those siblings: it names the boundary at which visible digest sameness, source-fiber membership, GAP provenance, and refusal of source equality must be read together.

Definition 1087.1 (HashDigestFiberBoundary carrier)**.** *A* $\mathsf{HashDigestFiberBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (D, E, F, G, R, H, C, P, N)$$

with the following displayed rows:

1. *D is the visible digest row read through the* $\mathsf{Hash}^{\uparrow}$ *surface;*
2. *E is the digest-sameness row, recording classifier-level sameness of visible digest tokens;*
3. *F is the fiber-membership row, recording the source-side membership behind D without identifying members of the fiber;*
4. *G is the* GAP *provenance row for the same fiber boundary;*
5. *R is the refusal row blocking any consumer from turning E into source equality or selected preimage recovery;*
6. *H records componentwise* hsame *transports for D, E, F, G, R, C, P, N;*
7. *C records displayed* Cont *routes for digest, digest-sameness, fiber, GAP, refusal, transport, provenance, and local naming reads;*
8. *P is the* Pkg *provenance over* $\mathsf{Hash}^{\uparrow}$, $\mathsf{DigestFiberLedger}^{\uparrow}$, $\mathsf{HashLikeFiberBoundary}^{\uparrow}$, $\mathsf{HashApophaticSeal}^{\uparrow}$, $\mathsf{ApophaticFixedPoint}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{HashDigestFiberBoundary}^{\uparrow}}$ *row.*

The carrier contains no coordinate for source equality obtained from digest sameness, no hidden preimage selector, no quotient collapse of the fiber, no global digest, and no unledgered source read.

Theorem 1087.2 (HashDigestFiberBoundary NameCert obligations)**.** *For the carrier of Definition 1087.1, the local* $\mathsf{NameCert}_{\mathsf{HashDigestFiberBoundary}^{\uparrow}}$ *surface consists exactly of carrier admission*

for

$$B = (D, E, F, G, R, H, C, P, N),$$

visible digest exposure through D, digest-sameness exposure through E, fiber membership through F, GAP provenance through G, source-equality refusal through R, componentwise hsame *transport through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Every accepted consumer of the packet must preserve the boundary order: digest sameness is read before source equality is even meaningful, and source equality remains unavailable unless a separate exactness certificate is displayed outside the $\mathsf{HashDigestFiberBoundary}^{\uparrow}$ *packet.*

Lean4 ✓ `BEDC.Derived.HashDigestFiberBoundaryUp.HashDigestFiberBoundaryTasteGate single carrier alignment`

Proof. Project the displayed carrier in Definition 1087.1. The rows D, E, F, G, R are the complete digest/fiber boundary content, while H, C, P, N transport, replay, package, and name the same finite packet.

Read the sibling sources through their local roles. The $\mathsf{Hash}^{\uparrow}$ surface supplies the visible digest, $\mathsf{DigestFiberLedger}^{\uparrow}$ supplies the fiber and GAP rows, $\mathsf{HashLikeFiberBoundary}^{\uparrow}$ supplies the consumer boundary discipline, $\mathsf{HashApophaticSeal}^{\uparrow}$ supplies the digest/fiber/far-end seal pattern, and $\mathsf{ApophaticFixedPoint}^{\uparrow}$ supplies the refusal of internalized far-end objects.

The NameCert surface is exhausted by these rows. Since the carrier has no coordinate for source equality from digest sameness, selected preimage recovery, quotient collapse, global digest, or unledgered source read, an accepted consumer cannot obtain any of those readings from the packet. □

Theorem 1087.3 (HashDigestFiberBoundary nonescape)**.** *Every accepted* $\mathsf{HashDigestFiberBoundary}^{\uparrow}$ *consumer that reads digest sameness through E must also keep the visible digest row D, fiber row F, GAP provenance row G, refusal row R, componentwise transport H, continuation routes C, package provenance P, and local naming row N. Removing the fiber and GAP provenance rows while keeping digest sameness collapses the packet's ability to distinguish digest equality from source equality.*

Consequently the packet exports no source-equality reflection, selected preimage, quotient fiber, global universe digest, hidden source payload, or unledgered source read.

Lean4 ✓ `BEDC.Derived.HashDigestFiberBoundaryUp.HashDigestFiberBoundary nonescape`

Proof. Start from an accepted packet $B = (D, E, F, G, R, H, C, P, N)$. The digest-sameness row E is only a classifier-facing comparison of visible digest rows, while F and G record the source-side fiber membership and provenance that keep the boundary auditable.

Apply the NameCert obligations of Definition 1087.2. They force any accepted read of E to remain packaged with the digest, fiber, GAP, refusal, transport, continuation, provenance, and local naming rows.

If F and G are removed while E remains, the remaining carrier does not record which source-side fiber is being compared. The packet therefore has no displayed way to separate digest equality from source equality. Since source-equality reflection, selected preimage recovery, quotient collapse, global digest, hidden source payload, and unledgered source reads have no carrier coordinate, none can escape the displayed packet. □

Theorem 1087.4 (HashDigestFiberBoundary field-faithful obligation)**.** *For an accepted* $\mathsf{HashDigestFiberBoundary}^{\uparrow}$ *packet*

$$B = (D, E, F, G, R, H, C, P, N),$$

the field-faithful obligation surface is visible in the displayed rows. The digest row D, digest-sameness row E, fiber row F, GAP row G, refusal row R, transport row H, continuation row C, provenance row P, and naming row N are the fields whose carrier alignment is cited by the checked TasteGate marker attached to Definition 1087.2.

Proof. Project the carrier rows of Definition 1087.1. Each field named in the obligation is one coordinate of B, and no row is supplied by ambient digest theory or by a hidden source read.

The checked TasteGate marker attached to Definition 1087.2 records the same single-carrier alignment. Hence field-faithfulness is a paper obligation over the concrete rows $D, E, F, G, R, H, C, P, N$, not a prose property outside the packet. □

Theorem 1087.5 (HashDigestFiberBoundary nontrivial obligation)**.** *The nontriviality obligation for* $\mathsf{HashDigestFiberBoundary}^{\uparrow}$ *is the joint presence of*

$$D, E, F, G, R, H, C, P, N.$$

A consumer may not retain only digest sameness E: the visible digest D, fiber membership F, GAP provenance G, refusal R, componentwise transport H, continuation replay C, package provenance P, and local naming N are the concrete rows that make the TasteGate carrier nontrivial.

Proof. Use Definition 1087.3. It already shows that a read of E must keep the visible digest, fiber, GAP, refusal, transport, continuation, provenance, and naming rows.

The TasteGate marker attached to the NameCert obligations therefore has a visible nontrivial carrier to check: it is precisely the row tuple $D, E, F, G, R, H, C, P, N$. Removing any of F, G, R would collapse the boundary into digest-sameness prose, while removing H, C, P, N would leave no transported, replayable, packaged, and named certificate. □

Theorem 1087.6 (HashDigestFiberBoundary obligation scope)**.** *The scoped carrier obligations of* $\mathsf{HashDigestFiberBoundary}^{\uparrow}$ *are exactly the obligations carried by*

$$B = (D, E, F, G, R, H, C, P, N).$$

They include field-faithful visibility of the displayed rows, nontrivial joint presence of digest, fiber, GAP, and refusal data, componentwise hsame *transport,* Cont *replay,* Pkg *provenance, and local* NameCert *naming; they do not include source-equality reflection, preimage selection, quotient collapse, a global digest, or an unledgered source read.*

Proof. Combine the row projection in Definition 1087.4 with the nontriviality projection in Definition 1087.5. Both are statements about the same accepted carrier B.

The checked TasteGate marker cited at the NameCert obligation site aligns the single carrier with those rows. The scope is therefore the finite digest/fiber boundary packet itself, and the excluded readings remain outside the obligation surface because no coordinate of B names them. □

Falsifiable prediction: Removing the fiber and GAP provenance rows while keeping digest sameness collapses the chapter's ability to distinguish digest equality from source equality.

Independence witness: Nearest siblings: hashapophaticseal, digestfiberledger, hashlikefiberboundary, hash, and apophaticfixedpoint. No bijection exists because each sibling omits at least one row among explicit digest-sameness exposure, fiber membership, GAP provenance, source-equality refusal, and local NameCert packaging for the digest/fiber boundary.

The Lean boundary `lean4/BEDC/Derived/HashDigestFiberBoundaryUp/TasteGate.lean` must provide `Nontrivial HashDigestFiberBoundaryUp` and `FieldFaithful HashDigestFiberBoundaryUp` instances for the displayed digest, digest-sameness, fiber, GAP, refusal, transport, continuation, provenance, and naming carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{HashDigestFiberBoundary}^{\uparrow}}$**.**

Constructive story: A $\mathsf{HashDigestFiberBoundary}^{\uparrow}$ packet is generated from visible digest exposure, digest-sameness comparison, source-side fiber membership, GAP provenance, source-equality refusal, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The carrier first reads digest equality as a visible comparison, then keeps the source-side fiber and gap rows attached so that equality of digest rows is not confused with equality of sources. The classifier accepts the boundary only when digest, fiber, gap, and refusal data remain present as one finite NameCert packet.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{HashDigestFiberBoundary}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 1087.6 binds the displayed carrier rows together with the checked TasteGate marker attached to Definition 1087.2.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{HashDigestFiberBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim source-equality reflection, selected preimage recovery, quotient collapse, global digest universes, hidden source payloads, or unledgered source reads.

Upgrade path: To strengthen the verification axis, formalize the digest-sameness, fiber, gap, refusal, field-faithful, nontriviality, and scoped obligation rows as a checked boundary.

Chapter 1088

ForceInterHistRelationUp NameCert construction

The $\mathsf{ForceInterHistRelation}^{\uparrow}$ packet realizes the force-like relation interface of chapter 9416 as finite relation-certificate data over inter-Hist rows. It consumes the invariant gate of chapter 656, the locality ledger of chapter 759, the audit-map family ledger of chapter 810, and the observer bridge ledger of chapter 1032. Its carrier is not a physical force law, metric tensor, or field equation; it is the BEDC packet that says which inter-Hist relation rows may be exported as force-like relation claims.

Falsifiable prediction: A force-like relation packet without a displayed non-preserved-content row cannot pass the relation gate as an exported BEDC claim.

Independence witness: interhistinvariant, interhistlocalityledger, auditmapfamilyledger, observerbridgeledger: none is bijective to $\mathsf{ForceInterHistRelation}^{\uparrow}$ because this packet carries source rows, a same-pattern classifier, a layer-map row, a non-preserved-content refusal row, a relation ledger, bridge-read rows, audit-map provenance, and local NameCert data together, while each sibling supplies only one gate, route, ledger, or bridge surface.

Definition 1088.1 (Force-like inter-Hist relation carrier)**.** *A* $\mathsf{ForceInterHistRelation}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (S, K, L, R, U, A, B, H, C, P, N)$$

with the following displayed rows:

1. *S is a finite source row of inter-*Hist *change sites admitted by the surrounding multi-history ledger;*
2. *K is the same-force-pattern classifier row comparing the visible relation packets over S;*
3. *L is the layer-map row that records which source, carrier, classifier, ledger, exactness, and refusal layers are being compared;*
4. *R is the non-preserved-content refusal row required by the layered relation gate;*
5. *U is the* $\mathsf{InterHistInvariant}^{\uparrow}$ *row that prevents observer-slot or invariant collapse;*
6. *A is the* $\mathsf{InterHistLocalityLedger}^{\uparrow}$ *row that routes the compared histories through a finite locality ledger;*
7. *B is the* $\mathsf{ObserverBridgeLedger}^{\uparrow}$ *row that records the observer-side bridge read used by the relation packet;*

8. *H records componentwise* hsame *transport for the source, classifier, layer-map, refusal, invariant, locality, bridge, audit, provenance, and naming rows;*
9. *C records the displayed* Cont *routes for every relation-certificate consumer read;*
10. *P is the* Pkg *provenance over* $\mathsf{ForceInterHistRelation}^{\uparrow}$, $\mathsf{InterHistInvariant}^{\uparrow}$, $\mathsf{InterHistLocalityLedger}^{\uparrow}$, $\mathsf{AuditMapFamilyLedger}^{\uparrow}$, $\mathsf{ObserverBridgeLedger}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{ForceInterHistRelation}^{\uparrow}}$ *row.*

*The carrier accepts a force-like inter-*Hist *relation only when the source, classifier, layer-map, refusal, invariant, locality, observer-bridge, transport, route, provenance, and local naming rows are displayed together. It exports no hidden force cause, empirical constant, global frame, metric tensor, field equation, subject-substance row, or source-free relation primitive.*

Lean4 ✓ `BEDC.Derived.ForceInterHistRelationUp.ForceInterHistRelationTasteGate single carrier alignment`

Theorem 1088.2 (Force-like relation NameCert obligations)**.** *For the carrier of Definition 1088.1, the local* $\mathsf{NameCert}_{\mathsf{ForceInterHistRelation}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$F = (S, K, L, R, U, A, B, H, C, P, N),$$

source exposure through S, same-pattern classification through K, layer-map exposure through L, non-preserved-content refusal through R, invariant preservation through U, locality-ledger routing through A, observer-bridge readback through B, componentwise hsame *transport through H, displayed continuation replay through C, audit-map provenance through P, and local naming through N.*

Proof. Project an accepted carrier to the eleven rows of Definition 1088.1. The source row S, classifier row K, layer-map row L, and refusal row R are the relation-certificate rows required before any force-like reading is available.

The invariant row U, locality ledger A, and observer bridge ledger B bind the relation to the already displayed inter-Hist and observer routes. Componentwise transport H and continuation replay C preserve those rows as rows of the same packet.

The provenance row P records the audit-map family ledger together with the invariant, locality, and bridge siblings, while N names the local certificate. Since the carrier has no coordinate outside these rows, the listed obligations exhaust the exported $\mathsf{NameCert}_{\mathsf{ForceInterHistRelation}^{\uparrow}}$ surface. □

Theorem 1088.3 (Force-like relation refusal non-escape)**.** *No accepted* $\mathsf{ForceInterHistRelation}^{\uparrow}$ *consumer can export a force-like inter-*Hist *relation as a BEDC claim unless the same carrier displays the non-preserved-content refusal row R together with the source row S, classifier row K, layer-map row L, invariant row U, locality-ledger row A, observer-bridge row B, transport row H, continuation row C, provenance row P, and local name row N.*

Proof. The relation gate of Definition 9416.19 asks whether preserved and non-preserved content are both displayed. In the carrier of Definition 1088.1, the displayed non-preserved-content coordinate is exactly R.

If a consumer omits R, then the read may preserve the source and classifier rows but lacks the refusal row that prevents identity collapse, hidden empirical law, global-frame import, or subject-substance import. Such a read is not a route through the full packet F.

If a consumer omits any of $S, K, L, U, A, B, H, C, P, N$, then it loses the source, classifier, layer, invariant, locality, observer bridge, transport, continuation, provenance, or naming row needed by

the local NameCert obligations. Hence every exported force-like relation claim must pass through the displayed packet and its refusal row. □

The Lean follow-up for `BEDC.Derived.ForceInterHistRelationUp` must provide explicit Nontrivial and FieldFaithful instances preserving the source, classifier, layer-map, refusal, invariant, locality-ledger, observer-bridge, transport, continuation, provenance, and local naming rows.

Closure status for $\mathsf{NameCert}_{\mathsf{ForceInterHistRelation}^{\uparrow}}$.

Constructive story: A $\mathsf{ForceInterHistRelation}^{\uparrow}$ packet is generated from source rows, a same-force-pattern classifier, a layer map, a non-preserved-content refusal row, inter-Hist invariant and locality rows, an observer bridge row, componentwise transport, displayed continuation routes, audit-map provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ForceInterHistRelation}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1088.1, Definition 1088.2, and Definition 1088.3 specify the finite force-like relation carrier, its local NameCert obligation surface, and the refusal row that blocks over-reading as identity, hidden cause, empirical law, or global frame.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ForceInterHistRelation}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close a physical force law, empirical constant, metric tensor, field equation, global frame, subject-substance carrier, Lean verification, or bridge checking for $\mathsf{ForceInterHistRelation}^{\uparrow}$.

Upgrade path: Scoped closure requires checked carrier admission, relation-gate refusal, invariant preservation, locality-ledger routing, observer-bridge readback, audit-map provenance, and TasteGate nontriviality with field faithfulness for the same packet.

Chapter 1089

A Concrete Naming Certificate for $\mathsf{LayeredRelationSite}^{\uparrow}$

The $\mathsf{LayeredRelationSite}^{\uparrow}$ packet realizes the layered relation certificate of chapter 9416 as finite BHist data. It sits beside the frame-refusal audit of chapter 1037, the observer classifier of chapter 986, the local gluing surface of chapter 151, and the compiler route of chapter 473. Those siblings supply frame refusal, observer comparison, cover-local transport, and certificate movement; this packet binds relation rows, refinement chains, locality gates, and refusal ledgers as one NameCert site.

Falsifiable prediction: If the LayeredRelationSiteUp carrier is atomic, then any reduction to RelationalFrameAuditUp loses either the refinement-chain row or the locality-gate refusal row.

Independence witness: relationalframeaudit, observerhsameclassifier, sheaf, certificatecompiler: none is bijective to $\mathsf{LayeredRelationSite}^{\uparrow}$ because the site carrier carries source-site rows, relation rows, refinement-chain rows, locality-gate refusals, transport, replay, provenance, and local NameCert rows in one packet. RelationalFrameAuditUp carries frame refusal without the refinement chain, ObserverHsameClassifierUp carries observer comparison without the source-site ledger, SheafUp carries locality and gluing without the relation-refusal ledger, and CertificateCompilerUp carries certificate movement without the layered relation site.

Definition 1089.1 (LayeredRelationSite carrier)**.** *A* $\mathsf{LayeredRelationSite}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (S_A, S_B, R_A, R_B, J, G, T, E, H, C, P, N)$$

with the following displayed rows:

1. *S_A and S_B are the two source-site rows whose relation is being certified;*
2. *R_A and R_B are the relation rows read from the two sites, including the displayed classifier surfaces consumed by the comparison;*
3. *J is the refinement-chain row recording the finite layer correspondence and the obstruction rows that force each classifier split;*
4. *G is the locality-gate row deciding which relation reads are admitted locally and which requests are refused;*
5. *T records the relation transport row that moves accepted source-site comparisons componentwise through* hsame*;*

6. *E records replay rows for relation reads, refinement-chain steps, locality-gate decisions, and refusal ledger entries;*
7. *H records componentwise* hsame *transport for $S_A, S_B, R_A, R_B, J, G, T, E, P, N$;*
8. *C records the displayed* Cont *routes through which downstream consumers replay relation rows, refinement rows, locality decisions, and refusal rows;*
9. *P is the* Pkg *provenance over* BHist, hsame, Cont, RelationalFrameAudit$^{\uparrow}$, ObserverHsameClassifier$^{\uparrow}$, Sheaf$^{\uparrow}$, CertificateCompiler$^{\uparrow}$, *and local relation-site dependencies;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationSite}^{\uparrow}}$ *row.*

The local classifier compares accepted carriers only through these rows. It has no coordinate for object identity between the two sites, global-frame synchronization, host powerset equality, unrecorded compiler semantics, empirical physical force, or subject-substance.

Lean4 (definition) `BEDC.Derived.LayeredRelationSiteUp.LayeredRelationSiteUp`

Theorem 1089.2 (LayeredRelationSite NameCert obligations)**.** *For the carrier of Definition 1089.1, the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationSite}^{\uparrow}}$ *surface consists of five obligations:*

1. *carrier exposure: every accepted packet exposes exactly $L = (S_A, S_B, R_A, R_B, J, G, T, E, H, C, P, N)$;*
2. *relation-row admission: each comparison is read through the displayed source-site and relation rows S_A, S_B, R_A, R_B;*
3. *refinement-chain exactness: the layer map and obstruction-to-classifier-split data are exactly the row J;*
4. *locality-gate refusal: every nonlocal or over-reading request is routed to the displayed gate and refusal row G;*
5. *componentwise transport and replay: relation rows, refinement-chain rows, gate decisions, refusal ledgers, package provenance, and local naming are transported only by T, H and replayed only by E, C.*

Proof. Carrier exposure is projection from the finite tuple in Definition 1089.1. The accepted packet has no fields outside $S_A, S_B, R_A, R_B, J, G, T, E, H, C, P, N$.

Relation-row admission is the projection to the two source-site rows and their relation rows. The packet can compare only the displayed R_A and R_B surfaces over S_A and S_B, so it cannot identify the source sites as objects.

Refinement-chain exactness is the projection to J. The chain row carries the layer map and the obstruction rows that force classifier splits, matching the certificate discipline of chapter 9416.

Locality-gate refusal is the projection to G. A request outside the displayed relation read or locality site has no accepted output row except the gate refusal.

Finally, transport and replay are componentwise. The row T records relation transport, H records hsame transport over all carrier coordinates, and E, C replay the same route with the package and local naming rows P, N. □

Theorem 1089.3 (LayeredRelationSite independence boundary)**.** *The siblings* RelationalFrameAudit$^{\uparrow}$, ObserverHsameClassifier$^{\uparrow}$, Sheaf$^{\uparrow}$, *and* CertificateCompiler$^{\uparrow}$ *are independence witnesses for* LayeredRelationSite$^{\uparrow}$. *No bijection from any one sibling carrier to the carrier of Definition 1089.1 preserves all carrier rows and all five obligations of Definition 1089.2.*

Proof. Compare RelationalFrameAudit$^{\uparrow}$ first. It supplies the no-global-frame and refusal discipline of chapter 1037, but it has no row that simultaneously records the layered refinement chain J and the relation-site locality gate G.

Compare ObserverHsameClassifier$^{\uparrow}$ next. It supplies an observer-history classifier and transport route, but it does not carry the two source-site rows, the paired relation rows, or the obstruction-driven refinement chain required by the relation site.

The Sheaf$^{\uparrow}$ sibling supplies local gluing and cover-sensitive transport, while CertificateCompiler$^{\uparrow}$ supplies finite certificate movement. Neither sibling carries the paired relation rows together with the gate-refusal ledger and the layered relation provenance row.

Thus any attempted bijection loses at least one carrier coordinate or one NameCert obligation: relation admission, refinement-chain exactness, locality-gate refusal, or componentwise relation replay. The LayeredRelationSite$^{\uparrow}$ carrier is therefore not a renamed copy of any listed sibling. □

Theorem 1089.4 (LayeredRelationSite downstream gate target)**.** *The Lean-facing downstream surface for* LayeredRelationSite$^{\uparrow}$ *is the packet family recorded under* Derived/LayeredRelationSiteUp/TasteGate.lean *with explicit* Nontrivial *and* FieldFaithful *instances. The gate checks that the source-site rows, relation rows, refinement-chain row, locality-gate refusal row, transport, replay, provenance, and local naming row remain recoverable from the admitted packet.*

Proof. The carrier and NameCert obligations already name the row inventory the gate must inspect. Nontriviality is witnessed by two packets differing in a visible source-site row. Field faithfulness is witnessed by projection of all carrier rows from the constructor.

The downstream gate therefore does not add a new relation semantics. It records that the finite site packet has a real display, that every displayed field can be recovered from that display, and that the relation-site carrier is not a singleton placeholder. □

Lean4 ✓ `BEDC.Derived.LayeredRelationSiteUp.taste gate`

Closure status for NameCert$_{\text{LayeredRelationSite}^{\uparrow}}$.

Constructive story: A LayeredRelationSite$^{\uparrow}$ packet is generated from two source-site rows, paired relation rows, a refinement-chain row, a locality-gate refusal row, relation transport, replay, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{LayeredRelationSite}^{\uparrow}}$, seed)

Scope closed: Definition 1089.1, Definition 1089.2, and Definition 1089.3 bind the layered relation certificate as a finite relation-site NameCert packet over source-site rows, relation rows, refinement chains, locality gates, refusal ledgers, transport, replay, provenance, and local naming.

Formal verification: FormalStatus(NameCert$_{\text{LayeredRelationSite}^{\uparrow}}$, theoremChecked)

Lean target: `BEDC.Derived.LayeredRelationSiteUp.taste\_gate`

Bridge status: none

Origin: ai

Not claimed: This chapter does not close object identity between related sites, empirical physics, subject-substance, global-frame synchronization, host powerset equality, compiler semantics, or bridge checking.

Upgrade path: Scoped closure requires checked paper-side exactness for relation admission, refinement-chain replay, locality-gate refusal, dependency provenance, and downstream consumer boundaries over the same finite rows.

Chapter 1090

A Relation-Before-Identity Surface for $\mathsf{LayeredRelationCert}^{\uparrow}$

The $\mathsf{LayeredRelationCert}^{\uparrow}$ packet realizes the relation-before-identity discipline of chapter 9416 as a finite NameCert surface. It sits beside the classifier-transport row of chapter 590, the two-history invariant row of chapter 656, the generated-recognizer flow of chapter 1048, the finite reflection tuple of chapter 993, and the audit-gate composition of chapter 696. Those siblings expose morphism, invariant, recognizer-flow, tuple, and gate-composition surfaces; this chapter binds two displayed refinement chains, their relation classifier, refusal rows, ledger rows, exactness row, failure boundary, and strength row as one consumer packet.

Falsifiable prediction: Every accepted LayeredRelationCert packet lacking a not-preserved row fails the public exactness export test.

Independence witness: classifiermorphism, interhistinvariant, groundcompilerrecognizerflow, finitereflectiontuple, auditgatecomposition: none is bijective with LayeredRelationCertUp because this carrier has two displayed refinement chains plus preserved, not-preserved, exactness, failure-boundary, and strength rows, while the siblings each bind only one morphism, invariant, recognizer-flow, tuple, or gate-composition surface.

Definition 1090.1 (LayeredRelationCert carrier)**.** *A* $\mathsf{LayeredRelationCert}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (A, B, M, Q, R, U, E, F, S, H, C, P, N)$$

with the following displayed rows:

1. *A and B are the two refinement-chain rows, each carrying source, layer, obstruction, carrier, and local classifier data;*
2. *M is the displayed layer-map row pairing layers of A with layers of B;*
3. *Q is the relation-classifier row, accepting same-schema reads only through A, B, M;*
4. *R is the preserved-structure row;*
5. *U is the not-preserved row, listing the object content, empirical content, proof content, bridge content, or subject-side content refused by the comparison;*
6. *E is the exactness row, recording the public meaning of same-schema export;*
7. *F is the failure-boundary row, naming the condition under which the relation weakens or cannot be exported;*

8. *S is the strength row, separating paper certificate, checked certificate, and bridge certificate readings;*
9. *H records componentwise* hsame *transport for chain, layer-map, classifier, preserved, not-preserved, exactness, failure-boundary, strength, route, provenance, and naming rows;*
10. *C records displayed* Cont *routes for source-chain projection, layer-map inspection, classifier admission, refusal inspection, exactness export, and public consumer handoff;*
11. *P is the* Pkg *provenance over chapter 9416, chapter 590, chapter 656, chapter 1048, chapter 993, chapter 696,* BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationCert}^{\uparrow}}$ *row.*

The carrier has no coordinate for object identity between the two domains, hidden empirical law, unmediated proof transfer, subject-substance transfer, bridge certificate, global frame, or unlisted relation strength.

Lean4 (definition) `BEDC.Derived.LayeredRelationCertUp.LayeredRelationCertUp`

Definition 1090.2 (LayeredRelationCert classifier)**.** *The* $\mathsf{LayeredRelationCert}^{\uparrow}$ *classifier accepts a carrier $L = (A, B, M, Q, R, U, E, F, S, H, C, P, N)$ only when all public relation reads factor through the chain rows A, B, the layer-map row M, the relation-classifier row Q, the preserved row R, the not-preserved row U, the exactness row E, the failure-boundary row F, and the strength row S, with transport, continuation, provenance, and naming supplied by H, C, P, N.*

Two accepted carriers are classifier-same only when they present the same source-chain boundaries, the same displayed layer-map boundary, the same preserved and not-preserved rows, the same exactness boundary, the same failure-boundary row, and the same strength row after componentwise hsame *transport. The classifier never compares the two domains as objects.*

Theorem 1090.3 (LayeredRelationCert field exhaustion)**.** *For every accepted* $\mathsf{LayeredRelationCert}^{\uparrow}$ *carrier*

$$L = (A, B, M, Q, R, U, E, F, S, H, C, P, N),$$

every public relation read is exhausted by the displayed rows $A, B, M, Q, R, U, E, F, S, H, C, P, N$. In particular, a same-schema export can read preserved structure only through R, refused content only through U, public exactness only through E, failure behavior only through F, and certification strength only through S.

Proof. Project the accepted carrier of Definition 1090.1. The tuple displays the two chain rows, layer map, classifier, preserved row, not-preserved row, exactness row, failure-boundary row, strength row, transport, continuation, provenance, and local name.

Use the classifier of Definition 1090.2. It admits public reads only after those rows are present and transported to the same finite surface, so the relation cannot acquire a second source for preservation, refusal, exactness, failure, or strength.

The structural rows H, C, P, N replay and name the same finite packet. Since they do not add a domain-identity coordinate, bridge coordinate, proof-transfer coordinate, or empirical-law coordinate, the row inventory exhausts the public relation surface. □

Theorem 1090.4 (LayeredRelationCert refusal non-escape)**.** *For every accepted* $\mathsf{LayeredRelationCert}^{\uparrow}$ *carrier, all non-preserved content is confined to the row U and the failure-boundary row F. The packet cannot export refused content as preserved structure, cannot promote same-schema exactness to object identity, and cannot turn paper-certificate strength into checked or bridge strength.*

Proof. Start with the carrier inventory. The only row assigned to not-preserved content is U, and the only row assigned to failure behavior is F.

Apply Definition 1090.3. A public read of preserved structure must pass through R, a public exactness read must pass through E, and a public strength read must pass through S. None of those rows is a constructor from refused content to preserved content.

Finally inspect the classifier row Q. It accepts same-schema reads through the displayed chain and layer-map surface, not object identity between the domains. Hence refusal remains visible to every consumer and cannot escape through transport, continuation, provenance, local naming, or strength language. □

Lean4 ✓ `BEDC.Derived.LayeredRelationCertUp.LayeredRelationCert refused row concrete boundary`

Theorem 1090.5 (LayeredRelationCert public exactness test)**.** *An accepted* $\mathsf{LayeredRelationCert}^{\uparrow}$ *packet exports public exactness only when the not-preserved row U is present before the exactness row E is read. If the packet lacks U, then the exactness export has no displayed refusal surface and fails the public exactness export test.*

Proof. Project the accepted packet and read the exactness route through C. The route reaches E only after the carrier has displayed the chain rows, layer map, classifier row, preserved row, and not-preserved row.

The role of U is fixed by Definition 1090.1: it lists the content that the relation refuses to preserve. Without that row, same-schema language has no public boundary separating relation exactness from identity.

Apply Definition 1090.4. Since refusal is the guard against over-reading, an exactness export without U lacks the row needed to keep non-preserved content from escaping as preserved content. □

Theorem 1090.6 (LayeredRelationCert NameCert obligation surface)**.** *For the carrier of Definition 1090.1, the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationCert}^{\uparrow}}$ *surface consists of six finite obligations:*

1. *carrier admission for $L = (A, B, M, Q, R, U, E, F, S, H, C, P, N)$;*
2. *source-chain exposure for A and B before any relation read;*
3. *layer-map and classifier exposure through M and Q;*
4. *preserved and not-preserved disclosure through R and U;*
5. *exactness, failure-boundary, and strength disclosure through E, F, S;*
6. *consumer non-escape for object identity, hidden empirical law, proof transfer, subject-substance transfer, bridge promotion, global-frame import, and unlisted strength.*

Thus the NameCert surface is a relation packet rather than an identity theorem.

Proof. Carrier admission is the projection of Definition 1090.1. The tuple gives the whole finite row list, and the local name row N names that packet as a $\mathsf{LayeredRelationCert}^{\uparrow}$ surface.

The source and classifier obligations are ordered by C. A consumer first reads A and B, then the layer map M, then the relation-classifier row Q.

The disclosure obligations are the rows R, U, E, F, S. They identify what is preserved, what is refused, what exactness means, where the relation weakens, and what certification strength is available.

Finally apply Definition 1090.3, Definition 1090.4, and Definition 1090.5. Together they show that the listed rows exhaust the public surface and that no identity, bridge, proof-transfer, empirical-law, subject-substance, global-frame, or unlisted-strength read can escape from the local NameCert packet. □

The Lean carrier in `Derived/LayeredRelationCertUp/TasteGate.lean` provides Nontrivial LayeredRelationCer and FieldFaithful $\mathsf{LayeredRelationCert}^{\uparrow}$ instances for the displayed carrier $A, B, M, Q, R, U, E, F, S, H, C, P, N$.

Corollary 1090.7 (LayeredRelationCert strict local obstruction)**.** *Let*

$$L = (A, B, M, Q, R, U, E, F, S, H, C, P, N)$$

be an accepted $\mathsf{LayeredRelationCert}^{\uparrow}$ *carrier. Suppose a displayed failure, refusal, separation, or countermodel row is used by a consumer against a named converse or reuse route for* L*. Then that row is a strict local obstruction: it blocks only the named route whose read asks to add, replace, or bypass one of the displayed relation coordinates*

$$A, B, M, Q, R, U, E, F, S, H, C, P, N.$$

Equivalently, every consumer-facing use must factor through the two source-chain rows A, B*, the layer-map row* M*, the classifier row* Q*, the preserved row* R*, the not-preserved row* U*, the exactness row* E*, the failure-boundary row* F*, the strength row* S*, the componentwise* hsame *transport row* H*, the displayed* Cont *route row* C*, the provenance row* P*, and the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationCert}^{\uparrow}}$ *row* N*. The obstruction cannot be reinterpreted as a global impossibility, a host theorem, hidden external validation, object identity between the domains, unmediated proof transfer, subject-substance transfer, bridge certification, or an unlisted relation strength.*

Proof. Read the accepted carrier through Definition 1090.1. The finite row inventory is exactly $A, B, M, Q, R, U, E, F, S, H, C, P, N$. The same definition states that the carrier has no coordinate for object identity between the two domains, hidden empirical law, unmediated proof transfer, subject-substance transfer, bridge certificate, global frame, or unlisted relation strength.

Use the classifier of Definition 1090.2. A public relation read is admitted only when it factors through the chain rows A, B, the layer-map row M, the relation-classifier row Q, the preserved row R, the not-preserved row U, the exactness row E, the failure-boundary row F, and the strength row S, with transport, continuation, provenance, and naming supplied by H, C, P, N. Thus a consumer-facing obstruction can meet a named converse or reuse route only at one of those displayed coordinates.

Now apply Definition 1090.4. Refused content is confined to U and F; it cannot escape as preserved structure through R, cannot promote same-schema exactness through E into object identity, and cannot promote paper-certificate strength through S into checked or bridge strength. The route row C only displays source-chain projection, layer-map inspection, classifier admission, refusal inspection, exactness export, and public consumer handoff, while H, P, N only transport, cite, and name the same finite surface. None of these rows adds a second route around the displayed obstruction.

Finally apply Definition 1090.5. Public exactness is readable only after the not-preserved row U has been displayed before E is read. Hence a converse or reuse route that tries to consume exactness without the refusal surface fails at the local U-then-E boundary; it does not become a theorem about all relations, a host-side impossibility result, or a hidden validation channel. If the attempted route asks for any unlisted coordinate, the carrier and classifier provide no readback for it. Therefore the displayed negative row has exactly the local blocking force of the named route and no wider export surface. □

Chapter 1091

A Concrete Naming Certificate for $\mathsf{LayeredRelationDisplay}^{\uparrow}$

The $\mathsf{LayeredRelationDisplay}^{\uparrow}$ packet realizes the relation-before-identity discipline of chapter 9416 as finite NameCert data. It sits after the relation-audit frame of chapter 1037, the licensed observer comparison of chapter 1031, the classifier transport of chapter 590, and the refusal boundary of chapter 1070. Its public role is to display what a layered relation preserves, what it refuses to preserve, which exactness row is available, and where a failed relation request is routed.

Definition 1091.1 (LayeredRelationDisplay carrier)**.** *A* $\mathsf{LayeredRelationDisplay}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (A, B, S, K, M, R, U, E, F, H, C, P, N)$$

with the following displayed rows:

1. *A and B are the two source-domain rows whose comparison is being displayed;*
2. *S is the finite source ledger naming the paper sites, histories, or certificate rows from which the comparison may be read;*
3. *K is the classifier row that decides which relation layer is being displayed;*
4. *M is the layer-map row from source coordinates to target coordinates;*
5. *R is the preserved-structure row;*
6. *U is the not-preserved row, recording the object content, identity claim, global frame, host semantics, or over-strong reading refused by the packet;*
7. *E is the exactness row, naming the available sameness strength for the displayed relation;*
8. *F is the failure-boundary row for requests that omit a required source, classifier, preserved, not-preserved, or exactness row;*
9. *H records componentwise* hsame *transports for $A, B, S, K, M, R, U, E, F$ together with package and naming rows;*
10. *C records the displayed* Cont *routes by which readers inspect the source ledger, classifier, layer map, preservation row, refusal row, exactness row, and failure boundary;*
11. *P is the* Pkg *provenance over chapter 9416, chapter 1037, chapter 1031, chapter 590, chapter 1070,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert*;*

12. N is the local $\mathsf{NameCert}_{\mathsf{LayeredRelationDisplay}^{\uparrow}}$ *row.*
The carrier has no coordinate for object identity between A and B, host equivalence, unlisted analogy, hidden classifier output, or relation strength beyond the exactness row E.

Lean4 (definition) `BEDC.Derived.LayeredRelationDisplayUp.LayeredRelationDisplayUp`
Lean4 ✓ `BEDC.Derived.LayeredRelationDisplayUp.LayeredRelationDisplayTasteGate single carrier alignment`

Theorem 1091.2 (LayeredRelationDisplay NameCert surface)**.** *For every accepted* $\mathsf{LayeredRelationDisplay}^{\uparrow}$ *carrier $L = (A, B, S, K, M, R, U, E, F, H, C, P, N)$, the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationDisplay}^{\uparrow}}$ *surface consists exactly of carrier exposure, source-ledger exposure, classifier exposure, layer-map exposure, preserved-row exposure, not-preserved-row exposure, exactness exposure, failure-boundary routing, componentwise transport, displayed replay, package provenance, and local naming.*

Proof. Project the displayed carrier of Definition 1091.1. The tuple lists every row available to a relation-certificate reader.

The source, classifier, layer-map, preservation, refusal, exactness, and failure rows are S, K, M, R, U, E, F. They are the finite relation-certificate fields required by chapter 9416, and they are read through the relation-audit sibling of chapter 1037.

The structural rows H, C, P, N transport, replay, package, and name the same displayed packet. Since no additional identity, host-equivalence, or hidden-strength coordinate appears in the carrier, those rows exhaust the local NameCert surface. □

Theorem 1091.3 (LayeredRelationDisplay preservation-refusal exactness)**.** *Every accepted* LayeredRelationDisplay *packet exports a relation claim only when the preserved row R, the not-preserved row U, and the exactness row E are all displayed in the same carrier. A request with an empty not-preserved row, a missing exactness row, or a classifier read outside K, M is routed to the failure boundary F and cannot be exported as identity, host equivalence, global-frame equivalence, or unchecked analogy.*

Proof. Begin with the carrier inventory. The relation-facing rows are the classifier K, layer map M, preserved row R, not-preserved row U, exactness row E, and failure boundary F.

Use Definition 1091.2. The local NameCert surface requires each of these rows before a public relation read can be exported, and it supplies only componentwise transport and displayed replay for them.

For a complete request, R, U, E are read together through C and transported through H. This gives a relation certificate with a stated preservation claim, a stated refusal boundary, and a stated exactness strength.

For an incomplete request, the missing not-preserved, exactness, or classifier-layer coordinate has no replacement row. The only displayed endpoint for that request is F, so the packet refuses identity, host equivalence, global-frame equivalence, and unchecked analogy. □

Falsifiable prediction: Any accepted LayeredRelationDisplayUp packet with an empty notPreserved row fails the exported relation-certificate gate.

Independence witness: relationalframeaudit, observerlicensedcomparison, classifiermorphism, boundarygate: none is bijective because LayeredRelationDisplayUp carries preserved/notPreserved/exactness/failu rows as one displayed relation packet.

The later Lean TasteGate file must provide Nontrivial $\mathsf{LayeredRelationDisplay}^{\uparrow}$ and FieldFaithful LayeredRelationDi instances for the displayed rows $A, B, S, K, M, R, U, E, F, H, C, P, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{LayeredRelationDisplay}^{\uparrow}}$.

Constructive story: A LayeredRelationDisplay$^{\uparrow}$ packet is generated from two source-domain rows, a source ledger, classifier, layer map, preserved row, not-preserved row, exactness row, failure boundary, componentwise hsame transports, displayed Cont routes, Pkg provenance, and local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{LayeredRelationDisplay}^{\uparrow}}$, seed)

Scope closed: Definition 1091.1, Definition 1091.2, and Definition 1091.3 bind layered relation display as a finite NameCert packet with explicit preservation, refusal, exactness, and failure-boundary rows.

Formal verification: FormalStatus(NameCert$_{\text{LayeredRelationDisplay}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, object identity between source domains, global-frame equivalence, host semantic equivalence, or unchecked analogy.

Upgrade path: Obligation closure requires checked carrier admission and TasteGate-visible preservation, refusal, exactness, and failure-boundary rows for the same displayed relation packet.

Chapter 1092

A Concrete Naming Certificate for $\mathsf{AnalogyCertificateGate}^{\uparrow}$

The $\mathsf{AnalogyCertificateGate}^{\uparrow}$ packet concretizes the relation-certificate discipline of chapter 9416 as finite NameCert data. It consumes the same-schema audit rows of chapter 1037, the contextual reading discipline of chapter 684, the description boundary of chapter 661, the admission gate of chapter 545, and the refusal router of chapter 666. Its role is to admit analogy language only after the source rows, carrier, classifier, preservation, refusal, ledger, exactness, and failure-boundary rows are visible in one packet.

Definition 1092.1 (AnalogyCertificateGate carrier)**.** *An* $\mathsf{AnalogyCertificateGate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (S, K, G, R, V, U, L, E, F, H, C, P, N)$$

with the following displayed rows:

1. *S is the source-row ledger for the two themes whose analogy is being tested;*
2. *K is the finite carrier row naming the analogy packet rather than either source theme;*
3. *G is the contextual classifier row that licenses the analogy as a relation-first reading;*
4. *R records the relation rows shared by the sources;*
5. *V records the preserved rows that support same-schema language;*
6. *U records the not-preserved rows, including any identity, empirical, subject-substance, or bridge claim refused by the packet;*
7. *L is the ledger row recording which source row supports each preserved or not-preserved entry;*
8. *E is the exactness row saying that same-schema language reads only the displayed relation schema;*
9. *F is the failure-boundary row for analogy requests whose source, classifier, preservation, refusal, ledger, or exactness rows are absent;*
10. *H records componentwise* hsame *transport for all visible rows;*
11. *C records displayed* Cont *routes for admitted same-schema reads and refused analogy reads;*

12. *P is the* Pkg *provenance over* AnalogyCertificateGate$^{\uparrow}$, RelationalFrameAudit$^{\uparrow}$, ContextualClassReading$^{\uparrow}$, DefiniteDescriptionBoundary$^{\uparrow}$, TasteGateAdmission$^{\uparrow}$, SupplyKindRouter$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*;*

13. *N is the local* NameCert$_{\text{AnalogyCertificateGate}^{\uparrow}}$ *row.*

The carrier has no coordinate for object identity between the sources, global-frame comparison, empirical law, subject-substance claim, denoting description, or requested supply outside the displayed packet.

Lean4 ✓ `BEDC.Derived.AnalogyCertificateGateUp.AnalogyCertificateGateNameCertObligations`

Theorem 1092.2 (AnalogyCertificateGate NameCert obligations)**.** *For the carrier of Definition 1092.1, the local* NameCert$_{\text{AnalogyCertificateGate}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$A = (S, K, G, R, V, U, L, E, F, H, C, P, N),$$

source exposure through S, packet-carrier exposure through K, contextual classifier exposure through G, relation-row exposure through R, preserved-row exposure through V, not-preserved-row exposure through U, ledger exactness through L, E, refusal through F, and transport, continuation, provenance, and local naming through H, C, P, N.

Lean4 ✓ `BEDC.Derived.AnalogyCertificateGateUp.AnalogyCertificateGate namecert obligations`

Proof. Carrier admission is projection from Definition 1092.1. The tuple displays the source ledger, packet carrier, contextual classifier, relation rows, preserved rows, not-preserved rows, ledger, exactness row, failure boundary, transport, continuation, provenance, and local name.

The admitted route first reads S, K, G, R. These rows make the analogy a relation-first classifier over displayed source rows, in the sense of chapter 684, rather than a host object shared by the sources.

Next the route reads V, U, L, E. The preserved rows and not-preserved rows are both ledgered before exact same-schema language can be exported, matching the relation-audit discipline of chapter 1037.

The refused route reads F, with chapter 661, chapter 545, and chapter 666 supplying sibling boundaries for denotation, admission, and missing-supply requests. Finally H, C, P, N only transport, replay, package, and name the same rows, so the NameCert surface is exhausted by the displayed packet. □

Theorem 1092.3 (AnalogyCertificateGate obligation row scope)**.** *Every accepted same-schema export from an* AnalogyCertificateGate$^{\uparrow}$ *carrier must expose the preserved row V, the not-preserved row U, the ledger row L, the exactness row E, and the failure row F before the export is readable. The TasteGate instances* FieldFaithful AnalogyCertificateGate$^{\uparrow}$ *and* Nontrivial AnalogyCertificateGate$^{\uparrow}$ *witness that these rows are distinct visible fields of the packet, so a same-schema read cannot erase U, merge L with E, or hide F behind the carrier, classifier, transport, replay, provenance, or local naming rows.*

Lean4 ✓ `BEDC.Derived.AnalogyCertificateGateUp.AnalogyCertificateGateObligationRowScope`

Proof. Start with the carrier of Definition 1092.1 and the NameCert obligations of Definition 1092.2. They place same-schema export on the route through $S, K, G, R, V, U, L, E, F, H, C, P, N$, with V, U, L, E, F displayed before transport or replay can name the export.

The falsifiable prediction of Definition 1092.4 supplies the negative side: deleting U routes the request to F rather than to a same-schema export. The TasteGate paragraph records the Lean-side FieldFaithful AnalogyCertificateGate$^{\uparrow}$ and Nontrivial AnalogyCertificateGate$^{\uparrow}$ instances, so the row scope is not a collapsed carrier read.

Thus accepted analogy language must keep the preserved, not-preserved, ledger, exactness, and failure rows visible before export. The packet exposes no same-schema route that bypasses those rows or treats the analogy as source identity. □

Theorem 1092.4 (AnalogyCertificateGate falsifiable prediction)**.** *If an accepted* AnalogyCertificateGate$^{\uparrow}$ *packet has no not-preserved row U, then it cannot export same-schema language. Equivalently, every admitted same-schema read of an analogy packet factors through both the preserved row V and the not-preserved row U before the exactness row E is readable.*

Lean4 ✓ `BEDC.Derived.AnalogyCertificateGateUp.AnalogyCertificateGateFalsifiablePrediction`

Proof. Start with the NameCert obligations of Definition 1092.2. The theorem places same-schema export on the route through V, U, L, E.

If U is absent, the exactness row has no displayed refusal side. The request is therefore routed to the failure-boundary row F, because the packet cannot distinguish same-schema language from identity collapse or unlisted bridge language.

Thus an accepted analogy gate without U has no admitted export route for same-schema language. The prediction is falsifiable by deleting the not-preserved row: the packet then fails the gate rather than exporting analogy language. □

Theorem 1092.5 (AnalogyCertificateGate independence witness)**.** *The carrier of Definition 1092.1 is not bijective, row for row, to any of* RelationalFrameAudit$^{\uparrow}$, ContextualClassReading$^{\uparrow}$, DefiniteDescriptionBoundary$^{\uparrow}$ TasteGateAdmission$^{\uparrow}$, *or* SupplyKindRouter$^{\uparrow}$. *A bijection preserving local NameCert obligations would have to preserve the joint rows $S, K, G, R, V, U, L, E, F, H, C, P, N$, and no listed sibling carries exactly this source, analogy-carrier, contextual-classifier, preserved, not-preserved, ledger, exactness, failure-boundary, transport, continuation, provenance, and local-name surface.*

Proof. Compare first with RelationalFrameAudit$^{\uparrow}$. That sibling carries frame-audit and no-global-frame rows; it supplies the relation-audit discipline consumed here, but it does not carry the contextual analogy classifier G together with the admission, description, and supply-refusal boundaries.

Compare next with ContextualClassReading$^{\uparrow}$ and DefiniteDescriptionBoundary$^{\uparrow}$. They control contextual class reading and denoting-description use, but neither stores the paired preserved and not-preserved analogy rows V, U with the source ledger S and exactness row E.

Finally compare with TasteGateAdmission$^{\uparrow}$ and SupplyKindRouter$^{\uparrow}$. They carry admission and requested-supply refusal rows, while AnalogyCertificateGate$^{\uparrow}$ carries a relation packet whose same-schema export is governed by V, U, L, E, F. Since each sibling omits at least one required coordinate and carries rows not present in the analogy gate, no carrier bijection can preserve all NameCert obligations. □

Lean4 ✓ `BEDC.Derived.AnalogyCertificateGateUp.AnalogyCertificateGateIndependenceWitness`

Falsifiable prediction: An accepted analogy gate with no not-preserved row cannot export same-schema language.

Independence witness: Nearest siblings: RelationalFrameAudit, ContextualClassReading, DefiniteDescriptionBoundary, TasteGateAdmission, and SupplyKindRouter. The analogy gate is not bijective to any one sibling because it binds source, analogy-carrier, contextual classifier, preserved,

not-preserved, ledger, exactness, failure-boundary, transport, continuation, provenance, and local naming rows in one packet.

The Lean TasteGate file provides Nontrivial AnalogyCertificateGate$^{\uparrow}$ and FieldFaithful AnalogyCertificateGate$^{\uparrow}$ instances for the displayed rows $S, K, G, R, V, U, L, E, F, H, C, P, N$.

Closure status for $\mathsf{NameCert}_{\mathsf{AnalogyCertificateGate}^{\uparrow}}$.

Constructive story: An AnalogyCertificateGate$^{\uparrow}$ packet is generated from source rows, an analogy carrier, contextual classifier, relation rows, preserved rows, not-preserved rows, source ledger, exactness row, failure boundary, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{AnalogyCertificateGate}^{\uparrow}}$, scopedClosed)

Scope closed: Definition 1092.1, Definition 1092.2, Definition 1092.3, Definition 1092.4, and Definition 1092.5 display the finite NameCert surface and row-level same-schema export obligation for analogy export and refusal.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{AnalogyCertificateGate}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not construct an empirical bridge, source identity, global-frame object, denoting description, requested-supply witness, complete row-scope Lean theorem, or standard bridge for AnalogyCertificateGate$^{\uparrow}$.

Upgrade path: Public closure requires checked row-scope preservation, same-schema refusal, independence, and bridge-ready export routing for BEDC.Derived.AnalogyCertificateGateUp.

Chapter 1093

A Same-Schema Relation Certificate for $\mathsf{LayeredRelationCert}^{\uparrow}$

The $\mathsf{LayeredRelationCert}^{\uparrow}$ packet realizes the relation-certificate discipline of chapter 9416 as a finite NameCert object. It sits beside the normalization frontier of chapter 892, the inter-Hist invariant surface of chapter 656, the audit-map interface of chapter 806, and the apophatic naming surface of chapter 543. Those siblings expose frontier rows, local relation invariants, audit-map inventory, and named refusal boundaries; this packet binds same-schema comparison without turning the compared domains into one object.

Definition 1093.1 (LayeredRelationCert carrier)**.** *A* $\mathsf{LayeredRelationCert}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (S, A, B, L, M, P, Q, V, W, E, F, H, C, K, N)$$

with the following displayed rows:

1. *S is the same-schema request row naming the proposed relation claim;*
2. *A and B are the two source-domain rows whose refinement chains are being compared;*
3. *L is the finite layer-map row matching visible layers of A to visible layers of B;*
4. *M records the classifier rows used at the matched layers;*
5. *P is the preserved-structure row;*
6. *Q is the not-preserved row, recording the content that the relation refuses to identify;*
7. *V records the provenance ledger for each matched layer and classifier read;*
8. *W records the exactness row explaining what the same-schema claim means;*
9. *E is the failure-boundary row for weakened or rejected relation reads;*
10. *F is the strength row, distinguishing paper certificate, checked certificate, and bridge certificate readings;*
11. *H stores componentwise* hsame *transports for $S, A, B, L, M, P, Q, V, W, E, F$ and the structural rows;*
12. *C stores displayed* Cont *routes from the relation request through preservation, refusal, provenance, exactness, and failure readback;*

13. *K is the* Pkg *provenance over* $\mathsf{LayeredRelationCert}^{\uparrow}$, $\mathsf{MetaCICNormalizationFrontier}^{\uparrow}$, $\mathsf{InterHistInvariant}^{\uparrow}$, $\mathsf{AuditMapInterface}^{\uparrow}$, $\mathsf{ApophaticName}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
14. *N is the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationCert}^{\uparrow}}$ *row.*

The carrier certifies a relation between displayed refinement chains. It has no coordinate for object identity between A and B, no bridge from physical content to MetaCIC content, and no hidden row that erases Q or E.

Theorem 1093.2 (LayeredRelationCert NameCert surface)**.** *For the carrier of Definition 1093.1, the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationCert}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$R = (S, A, B, L, M, P, Q, V, W, E, F, H, C, K, N),$$

same-schema request exposure through S, source-domain exposure through A, B, layer-map and classifier readback through L, M, preservation readback through P, explicit non-preservation readback through Q, ledger and exactness readback through V, W, failure and strength readback through E, F, and transport, continuation, provenance, and local naming through H, C, K, N.

Proof. Carrier admission is projection from Definition 1093.1. The displayed tuple contains every public row used by the relation request, including the same-schema request, the two source-domain rows, the layer map, classifier rows, preservation and non-preservation rows, ledger, exactness, failure, strength, transport, route, provenance, and local name.

The positive read is then forced through the relation rows. A consumer first reads S, A, B, then reads the finite layer map L and classifier row M, and only then may inspect the preserved-structure row P.

The refusal read is equally public. The rows Q, E, F remain attached to the same packet, so exactness and strength never erase the content that is not preserved and never turn a failure boundary into an identity claim.

Finally H, C, K, N only transport, replay, package, and name the displayed rows. Thus the NameCert surface is exhausted by the carrier and cannot export a hidden comparison channel. □

Lean4 ✓ `BEDC.Derived.LayeredRelationCertUp.LayeredRelationCertCarrier namecert surface`

Theorem 1093.3 (LayeredRelationCert preservation boundary)**.** *Every accepted* $\mathsf{LayeredRelationCert}^{\uparrow}$ *packet exposes preserved structure only as the row P read through the same-schema request S, the two source rows A, B, the layer-map row L, the classifier row M, the provenance ledger V, the exactness row W, and the local transport and continuation rows H, C. A downstream consumer may cite the packet as a same-schema certificate, but it may not replace either source domain by the other or infer that their non-preserved content agrees.*

Proof. Start with the carrier and the NameCert surface. The preserved-structure row P is a coordinate of R, and the surface requires a read of $S, A, B, L, M, V, W, H, C$ before P is available to a consumer.

The row L gives a finite layer correspondence, while M gives the classifiers used at those layers. The ledger V and exactness row W record why the correspondence is being read as same-schema rather than as source equality.

The not-preserved row Q remains a separate coordinate in the same carrier. Since no continuation route deletes Q or rewrites it as preserved content, preservation is bounded by P and cannot become object identity between A and B. □

Lean4 ✓ `BEDC.Derived.LayeredRelationCertUp.LayeredRelationCertCarrier preservation boundary`

Theorem 1093.4 (LayeredRelationCert failure boundary)**.** *Every accepted* LayeredRelationCert$^{\uparrow}$ *packet carries a failure readback row E tied to the explicit not-preserved row Q. If a requested comparison omits Q, asks the layer map L to identify source objects, or asks exactness W to preserve content outside P, the packet routes the request to E rather than to a same-schema certificate.*

Proof. Project the rows Q, E from the carrier. The not-preserved row and the failure-boundary row are public coordinates, so a relation read cannot hide them behind the preserved row.

Apply the NameCert surface. It exposes exactness only together with P, Q, V, W, E, F, which means a same-schema read has a visible place for the content it refuses to preserve and a visible boundary for failed requests.

If Q is omitted, the carrier no longer has the row that separates relation from identity. If L or W is asked to preserve content outside P, the request has no accepted positive coordinate. In both cases the only displayed route is the failure-boundary row E. □

Lean4 ✓ `BEDC.Derived.LayeredRelationCertUp.LayeredRelationCertCarrier failure boundary`

Theorem 1093.5 (LayeredRelationCert TasteGate contract)**.** *The Lean follow-up for the carrier of Definition 1093.1 requires* Nontrivial LayeredRelationCert$^{\uparrow}$ *and* FieldFaithful LayeredRelationCert$^{\uparrow}$ *instances before the TasteGate target* `BEDC.Derived.LayeredRelationCertUp.TasteGate` *may be read as the checked single-carrier handoff. The paper-side packet fixes the rows $S, A, B, L, M, P, Q, V, W, E, F, H, C$, and the no-identity boundary that those instances must preserve.*

Proof. The paper-side contract is read from the carrier and the three boundary theorems. They display the rows that any later carrier instance must expose and the non-preservation row that prevents the relation from collapsing into identity.

The Nontrivial instance is required so that the Lean object is not an empty naming shell. The FieldFaithful instance is required so that the Lean fields preserve the source, layer, classifier, preservation, non-preservation, ledger, exactness, failure, strength, transport, continuation, provenance, and naming rows without dropping or merging them.

Thus the later TasteGate file may certify alignment only for this finite field surface. It cannot certify object identity, physical-to-formal derivation, or any relation read that bypasses Q and E. □

Lean4 ✓ `BEDC.Derived.LayeredRelationCertUp.LayeredRelationCertTasteGate single carrier alignment`

Theorem 1093.6 (LayeredRelationCert scoped row discipline)**.** *Every accepted* LayeredRelationCert$^{\uparrow}$ *same-schema read factors through the concrete rows*

$$S, A, B, L, M, P, Q, V, W, E, F, H, C, K, N$$

of Definition 1093.1 and through the sibling anchors MetaCICNormalizationFrontier$^{\uparrow}$, InterHistInvariant$^{\uparrow}$, AuditMapInterface$^{\uparrow}$, *and* ApophaticName$^{\uparrow}$ *named in the carrier provenance. Such a read may expose a same-schema relation certificate, but it cannot turn the source domains A, B into object identity, erase the not-preserved row Q, or erase the failure-boundary row E.*

Proof. Project the accepted carrier. The visible packet is exactly the displayed tuple $R = (S, A, B, L, M, P, Q, V, W,$ so every same-schema read starts from those rows rather than from an ambient relation object.

Apply the NameCert surface of Definition 1093.2. It exposes the request row, source rows, layer map, classifier readback, preservation row, non-preservation row, ledger, exactness, failure, strength, transport, replay, provenance, and local name as one finite surface.

Apply the preservation boundary, failure boundary, and TasteGate contract of Definition 1093.3, Definition 1093.4, and Definition 1093.5. Preservation is bounded by P, failed or overstrong reads remain routed to E, and the checked carrier alignment must preserve the no-identity boundary.

Finally read the sibling anchors already named in the chapter introduction and in the provenance row K: chapter 892, chapter 656, chapter 806, and chapter 543. They supply normalization-frontier, inter-Hist, audit-map, and apophatic rows only as scoped dependencies, not as permissions to identify A with B or to drop Q and E. □

Falsifiable prediction: If the not-preserved row is removed, same-schema relation certificates collapse into object-identity claims and cannot pass the failure-boundary readback.

Independence witness: metacicnormalizationfrontier, interhistinvariant, auditmapinterface, apophaticname, consciousobserverstate: none is bijective because LayeredRelationCertUp carries the same-schema request, paired source rows, layer map, preserved row, not-preserved row, exactness row, failure boundary, and strength row together, while those siblings separately supply frontier evidence, inter-Hist invariants, audit-map inventory, apophatic refusal, or observer-state surfaces without this full relation-certificate packet.

Closure status for $\mathsf{NameCert}_{\mathsf{LayeredRelationCert}^{\uparrow}}$.

Constructive story: A $\mathsf{LayeredRelationCert}^{\uparrow}$ packet is generated from a same-schema request row, paired source-domain rows, a finite layer map, classifier rows, preserved and not-preserved rows, provenance and exactness ledgers, failure and strength rows, componentwise hsame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LayeredRelationCert}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 1093.1, Definition 1093.2, Definition 1093.3, Definition 1093.4, Definition 1093.5, and Definition 1093.6 close the same-schema scope on rows $S, A, B, L, M, P, Q, V, W, E, F, H, C, K, N$ and the MetaCICNormalizationFrontierUp, InterHistInvariantUp, AuditMapInterfaceUp, and ApophaticNameUp sibling anchors.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LayeredRelationCert}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.LayeredRelationCertUp.LayeredRelationCertTasteGate\_single\_carrier\_alignment`

Bridge status: none

Not claimed: This chapter does not close object identity between the source domains, physical-to-formal derivation, bridge checking, or relation reads that bypass the not-preserved and failure rows.

Upgrade path: Scoped closure requires checked public-object stability for the displayed rows $S, A, B, L, M, P, Q, V, W, E, F, H, C, K, N$, including preservation-boundary, failure-boundary, and same-schema ledger nonescape obligations.

Chapter 1094

A Concrete Naming Certificate for $\mathsf{GroundCompilerFlowLevelRoundTrip}^{\uparrow}$

The $\mathsf{GroundCompilerFlowLevelRoundTrip}^{\uparrow}$ packet isolates the flow-level theorem family in the GroundCompiler audit map of chapter 9407. It sits beside the verdict packet of chapter 822, the event-flow packet of chapter 829, and the event-flow route packet of chapter 830: those chapters expose aggregate verdict, event-flow, and routed audit surfaces, while this chapter fixes the local row where a displayed flow encoding decodes back to the same flow level.

Definition 1094.1 (GroundCompiler flow-level round-trip carrier)**.** *A* $\mathsf{GroundCompilerFlowLevelRoundTrip}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (S, E, D, L, T, R, H, C, P, N)$$

with the following displayed rows:

1. *S is the GroundCompiler event-flow level row being encoded;*
2. *E is the finite* $\mathsf{FlowEncoding}(S)$ *row;*
3. *D is the decoder row witnessing* $\mathsf{Decode}(E) = \mathsf{some}(S)$*;*
4. *L is the legal-stream row certifying that E is a legal channel stream before any decoder read is accepted;*
5. *T is the transport row tying the flow-level readback to the source-channel and event-flow audit surfaces;*
6. *R is the route row exposing the round-trip to the GroundCompiler audit map without identifying it with verdict, frontier, obstruction, or report data;*
7. *H records componentwise* hsame *transports for the flow level, encoding, decoder, legal stream, transport, route, provenance, and local naming rows;*
8. *C records displayed* Cont *routes from S to E, from E through L to D, and from the decoded row back to the audit-map consumer;*
9. *P is the* Pkg *provenance over chapter 9407,* BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{GroundCompilerFlowLevelRoundTrip}^{\uparrow}}$ *row.*

The carrier records a finite flow-level encoding and decoder readback. It has no coordinate for compiler verdicts, event-flow aggregate audits, routed certificate gates, audit-map frontier packets, obstruction sockets, report evidence, motif evidence, metric evidence, or host compiler state.

Lean4 ✓ BEDC.Derived.GroundCompilerFlowLevelRoundTripUp.GroundCompilerFlowLevelRoundTripTasteGate
single carrier alignment

Theorem 1094.2 (GroundCompiler flow-level round-trip NameCert obligations)**.** *For the carrier of Definition 1094.1, the local* $\mathsf{NameCert}_{\mathsf{GroundCompilerFlowLevelRoundTrip}^{\uparrow}}$ *surface consists exactly of six obligation rows: flow-level exposure through* S*, finite flow encoding through* E*, legal-stream admission through* L*, decoder readback through* D *with* $\mathsf{Decode}(\mathsf{FlowEncoding}(S)) = \mathsf{some}(S)$*, audit-map transport through* T, R*, and provenance-preserving naming through* H, C, P, N*.*

In particular, an accepted packet exposes the checked GroundCompiler round-trip row only when the legal-stream row and the decoder row are both displayed.

↪variant BEDC.GroundCompiler.ChannelEncoding.flow level round trip

Proof. Project the finite packet $F = (S, E, D, L, T, R, H, C, P, N)$. The rows S, E, D, L are the whole flow-level encoding and decoding surface, while T, R, H, C, P, N transport, route, locate, and name that same surface.

Legal-stream admission comes before decoder readback. The route from S to D first records $E = \mathsf{FlowEncoding}(S)$ and the legal-stream row L, and only then records the decoder equation $\mathsf{Decode}(E) = \mathsf{some}(S)$.

The checked Lean theorem `BEDC.GroundCompiler.ChannelEncoding.flow_level_round_trip` supplies the kernel-side readback row for the displayed flow level. The local NameCert obligations add the paper-side carrier boundary: every use of that readback must pass through the visible encoding, legal-stream, decoder, transport, route, provenance, and naming coordinates. □

Theorem 1094.3 (GroundCompiler flow-level round-trip non-escape)**.** *Every accepted* GroundCompilerFlowLevelRo *packet exports only the displayed rows*

$$S, E, D, L, T, R, H, C, P, N.$$

It cannot export a $\mathsf{GroundCompilerAuditVerdict}^{\uparrow}$ *verdict row, a* $\mathsf{GroundCompilerEventFlowAudit}^{\uparrow}$ *aggregate audit row, a* $\mathsf{GroundCompilerEventFlowAuditRoute}^{\uparrow}$ *certificate-gate route, an* $\mathsf{AuditMapFrontierPacket}^{\uparrow}$ *frontier row, an* $\mathsf{AuditMapObstructionSocket}^{\uparrow}$ *obstruction row, report evidence, motif identity, metric evidence, source text, carried metadata, or host compiler state.*

Proof. Start from the carrier inventory in Definition 1094.1. The packet displays a single flow level, its finite encoding, the legal-stream row, the decoder readback, and the structural rows used to transport and route that readback.

Apply the obligation surface of Definition 1094.2. Any consumer of the round-trip must read the legal stream and decoder row before it receives $\mathsf{Decode}(\mathsf{FlowEncoding}(S)) = \mathsf{some}(S)$.

The sibling packets named in the chapter opening have different carrier coordinates. The verdict packet contains query, forbidden-row, and verdict data; the event-flow and route packets contain aggregate audit and certificate-gate rows; the frontier and obstruction packets contain audit-map boundary rows. None is bijective to the round-trip carrier, because none has exactly the displayed legal-stream plus decoder row as its determining coordinate pair, and this carrier has no coordinate storing their verdict, gate, frontier, or obstruction rows. □

Independence witness: groundcompilerauditverdict, groundcompilereventflowaudit, groundcompilereventflowauditroute, auditmapfrontierpacket, auditmapobstructionsocket: the GroundCompilerFlowLevelRo carrier is determined by the displayed flow level, finite encoding, legal-stream row, decoder readback, route, and provenance. It is not bijective to the verdict, event-flow aggregate, event-flow route, frontier, or obstruction carriers, since those packets respectively carry verdict comparison, aggregate audit, certificate-gate routing, frontier, and obstruction rows that this carrier neither stores nor reconstructs.

Falsifiable prediction: If a packet exposes Decode(FlowEncoding S)=some S but omits the displayed legal-stream or decoder row, then it fails the local NameCert obligations.

Lean follow-up for this surface must provide Nontrivial and FieldFaithful instances in `lean4/BEDC/Derived/Grou`

Theorem 1094.4 (GroundCompiler flow-level round-trip TasteGate row)**.** *The TasteGate row for* BEDC.Derived.GroundCompilerFlowLevelRoundTripUp *reads the displayed* GroundCompilerFlowLevelRoundTrip$^{\uparrow}$ *carrier through the same flow-level, encoding, legal-stream, decoder, route, transport, replay, provenance, and local naming coordinates. It adds no verdict row, event-flow aggregate, certificate-gate route, frontier packet, obstruction socket, report evidence, motif evidence, metric evidence, source text, carried metadata, or host compiler state.*

Lean4 ✓ `BEDC.Derived.GroundCompilerFlowLevelRoundTripUp.taste gate`

Proof. Project the carrier definition. The TasteGate row has access only to $S, E, D, L, T, R, H, C, P, N$, and the local classifier already separates those coordinates from verdict, route, frontier, obstruction, report, motif, metric, and host-state data.

Apply the single-carrier alignment marker. It identifies the checked TasteGate surface with the same finite carrier rather than with an aggregate GroundCompiler packet.

The non-escape theorem then closes the public boundary: every TasteGate read remains a read of the displayed round-trip row and cannot import a sibling packet coordinate. □

Closure status for NameCert$_{\text{GroundCompilerFlowLevelRoundTrip}^{\uparrow}}$**.**

Constructive story: A GroundCompilerFlowLevelRoundTrip$^{\uparrow}$ packet is generated from a GroundCompiler flow-level row, finite flow encoding, decoder row, legal-stream certificate, audit-map transport row, route row, componentwise hsame transport, displayed Cont replay, provenance, and local naming; the TasteGate instance row is recorded at BEDC.Derived.GroundCompilerFlowLevelRoundTripUp.taste_gate. The carrier accepts a round-trip only after the encoded stream is displayed as legal and the decoder readback returns the same flow level. The classifier therefore isolates one local flow-level row of the audit map: it preserves encoding and decoder data without importing verdicts, frontiers, reports, or host compiler state.

Theory closure: TheoryGate(NameCert$_{\text{GroundCompilerFlowLevelRoundTrip}^{\uparrow}}$, obligation)

Scope closed: This chapter binds the GroundCompiler flow-level round-trip carrier, NameCert obligations, non-escape row, falsifiable prediction, independence witness, and cited TasteGate alignment as the visible obligation surface.

Formal verification: FormalStatus(NameCert$_{\text{GroundCompilerFlowLevelRoundTrip}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim audit verdicts, aggregate event-flow audits, certificate-gate routes, frontier packets, obstruction sockets, report evidence, or host compiler state.

Upgrade path: Scoped closure requires kernel-scope binding for each displayed obligation, including legal-stream admission, decoder readback, non-escape, and TasteGate alignment.

Chapter 1095

A Concrete Naming Certificate for $\mathsf{CompactCoverShrinkageLedger}^{\uparrow}$

The $\mathsf{CompactCoverShrinkageLedger}^{\uparrow}$ packet isolates the finite cover-shrinkage boundary inside chapter 9237. It sits after the compact-net selector of chapter 914, the finite lower-bound fold of chapter 619, and the metric and rational source rows of chapter 57 and chapter 37; it feeds the uniform-modulus consumer of chapter 369 for continuous-map packets of chapter 130.

Definition 1095.1 (Compact cover shrinkage ledger carrier)**.** *A* $\mathsf{CompactCoverShrinkageLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (K, U, F, M, Q, C, H, P, N)$$

with the following displayed rows:

1. *K is the compact-net selector row, exposing the finite* $\mathsf{ProbeBundle}$ *of centers and the local pointwise-modulus rows selected from the compact source;*
2. *U is the* $\mathsf{UniformModulus}^{\uparrow}$ *consumer row, recording the tolerance history, the selected precision history, and the consumer packet that will read the uniform modulus;*
3. *F is the finite lower-bound fold row, obtained by primitive recursion over the displayed bundle and carrying the readback that the selected precision is below every shrinkage radius;*
4. *M is the metric row, displaying the source and target distance witnesses, symmetry, and triangle coordinates needed to move from local balls to a uniform estimate;*
5. *Q is the* $\mathsf{Rat}^{\uparrow}$ *positivity and comparison row for the tolerance, shrinkage radii, half-radius comparisons, and finite-fold accumulator;*
6. *C is the cover-shrinkage route, binding the compact cover, pointwise modulus rows, half-radius shrinkage, and finite fold before any uniform-modulus read is accepted;*
7. *H records componentwise* hsame *transports for K, U, F, M, Q, C, P, N;*
8. *P is the* Pkg *provenance over compact-net selector, uniform-modulus consumer, finite-fold, metric,* $\mathsf{Rat}^{\uparrow}$*, cover-shrinkage, transport, continuation, and naming rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{CompactCoverShrinkageLedger}^{\uparrow}}$ *row.*

The packet has no coordinate for a direct pointwise-to-uniform selector, ambient compactness oracle, host-side minimum, quotient metric equality, or choice-based radius selection.

Lean4 (definition) `BEDC.Derived.CompactCoverShrinkageLedgerUp.CompactCoverShrinkageLedgerUp`

Theorem 1095.2 (Compact cover shrinkage ledger NameCert obligations)**.** *For every accepted* $\mathsf{CompactCoverShrinkageLedger}^{\uparrow}$ *packet*

$$L = (K, U, F, M, Q, C, H, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{CompactCoverShrinkageLedger}^{\uparrow}}$ *surface consists exactly of compact-net selector exposure through* K*, uniform-modulus consumer exposure through* U*, finite lower-bound fold readback through* F*, metric and* $\mathsf{Rat}^{\uparrow}$ *comparison exposure through* M *and* Q*, cover-shrinkage routing through* C*, componentwise transport through* H*, package provenance through* P*, and local naming through* N*.*

Lean4 ✓ `BEDC.Derived.CompactCoverShrinkageLedgerUp.CompactCoverShrinkageLedgerTasteGate single carrier alignment`

Proof. Project the carrier of Definition 1095.1. Its coordinates are exactly $K, U, F, M, Q, C, H, P, N$, with K supplying the compact finite-net selector, F supplying the fold readback, and U naming the consumer precision row.

The metric and rational rows M and Q are the only comparison surface. They provide source and target distance witnesses, half-radius comparisons, positivity, and fold comparisons before the shrinkage route can be read.

The route row C orders the handoff. It records that compact cover selection and pointwise-modulus shrinkage precede the finite lower-bound fold, and that the uniform-modulus consumer reads only after this fold has produced the displayed precision history.

Finally H, P, N transport, package, and name the same finite surface. Since the carrier has no coordinate for a direct selector, ambient compactness oracle, host minimum, quotient metric equality, or choice-based radius selection, no such object can be part of the local NameCert obligations. □

Theorem 1095.3 (Compact cover shrinkage ledger uniform-modulus handoff)**.** *Every accepted* $\mathsf{CompactCoverShrinkageLedger}^{\uparrow}$ *consumer that reads a* $\mathsf{UniformModulus}^{\uparrow}$ *precision row factors through the displayed compact-net selector* K*, cover-shrinkage route* C*, finite lower-bound fold* F*, metric row* M*, and* $\mathsf{Rat}^{\uparrow}$ *positivity row* Q*. In particular, a consumer cannot pass directly from pointwise modulus rows to* $\mathsf{UniformModulus}^{\uparrow}$ *without the finite shrinkage ledger.*

Lean4 ✓ `BEDC.Derived.CompactCoverShrinkageLedgerUp.CompactCoverShrinkageLedger uniform modulus handoff`

Proof. Begin with the compact-net selector row K. It displays the finite ProbeBundle of centers and the pointwise-modulus rows used by the compact-uniform-continuity construction of chapter 9237.

Use the cover-shrinkage route C to attach the half-radius rows to those centers. This route is the only coordinate that binds the compact cover, local pointwise modulus, and shrinkage comparison before a consumer can inspect a uniform precision.

Run primitive recursion over the displayed ProbeBundle in F. At the empty boundary the packet carries the nonempty selector witness from K; at each successor step the $\mathsf{Rat}^{\uparrow}$ row Q compares the accumulator with the next shrinkage radius and keeps a certified lower-bound history.

The metric row M then supplies the source triangle, symmetry, and target triangle reads needed to turn the lower-bound history into the consumer estimate recorded in U. The structural rows H, P, N only transport, package, and name this route, so they cannot introduce a direct pointwise-to-uniform handoff. □

Falsifiable prediction: If the shrinkage ledger is atomic, every accepted uniform-modulus handoff factors through the displayed compact-net selector and finite lower-bound fold rows; a direct handoff from pointwise moduli to UniformModulusUp without those rows refutes the chapter.

Independence witness: Nearest siblings: compactnetmodulusselector, uniformmodulus, finitenetminimumfold, compactmoduluscover, subordinatemoduluscover. It is not bijective to any one sibling because it simultaneously records the cover-shrinkage route, the fold-readback row, and the consumer precision row; each sibling lacks at least one of those rows.

Lean follow-up for this surface must provide Nontrivial and FieldFaithful instances in `lean4/BEDC/Derived/Comp`

Closure status for $\mathsf{NameCert}_{\mathsf{CompactCoverShrinkageLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{CompactCoverShrinkageLedger}^{\uparrow}$ packet is generated from a compact-net selector, uniform-modulus consumer row, finite lower-bound fold, metric row, rational positivity and comparison row, cover-shrinkage route, componentwise hsame transport, provenance, and local naming. The carrier reads local pointwise modulus data only after the finite cover is displayed, shrinks the cover through rational comparisons, folds the finite lower bound by primitive recursion, and then hands the result to the uniform-modulus consumer. The classifier records this finite shrinkage ledger instead of a direct pointwise-to-uniform selector.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CompactCoverShrinkageLedger}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the compact cover shrinkage ledger carrier, NameCert obligations, uniform-modulus handoff theorem, prediction, and independence witness.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CompactCoverShrinkageLedger}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim ambient compactness oracles, host-side minima, quotient metric equality, direct selectors, or choice-based radius selection.

Upgrade path: To reach obligationClosure, formalize the compact-net selector, finite fold, rational comparisons, and uniform-modulus handoff as checked carrier rows.

Chapter 1096

A Concrete Naming Certificate for KernelInductiveEliminator$^{\uparrow}$

The KernelInductiveEliminator$^{\uparrow}$ packet realizes the eliminator side of the kernel-acceptance witness of chapter 9364 as finite NameCert data. It sits beside the inductive-declaration packet of chapter 915, the accepted-declaration witness of chapter 549, the generator-closure surface of chapter 486, the type-classifier membership surface of chapter 476, and the subject-reduction boundary of chapter 483. Those siblings record declaration acceptance, generator closure, type membership, and preservation-facing rows; this packet records the emitted case-analysis rule rows that must be displayed before any eliminator consumer reads them.

Definition 1096.1 (KernelInductiveEliminator carrier)**.** *A* KernelInductiveEliminator$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$E = (D, S, L, M, R, B, H, C, P, N)$$

with the following displayed rows:

1. *D is the accepted inductive declaration row already named by* KernelInductiveAcceptance$^{\uparrow}$*;*
2. *S is the constructor-signature row whose finite constructor inventory determines the available case branches;*
3. *L is the emitted eliminator-name row, including the recursor, induction-principle, motive, minor-premise, and computation-rule names emitted for D;*
4. *M is the motive-and-branch arity row, recording the finite arity match between constructor signatures and eliminator minor premises;*
5. *R is the emitted-rule ledger, listing exactly the case-analysis and computation rows that may be read by downstream consumers;*
6. *B is the boundary row that refuses a consumer asking for a host eliminator primitive not displayed in R;*
7. *H records componentwise* hsame *transports for D, S, L, M, R, B, P, N;*
8. *C records the displayed* Cont *routes from accepted declaration to constructor signatures, from signatures to emitted eliminator rows, from eliminator rows to motive-and-branch arity, and from emitted rules to consumers;*
9. *P is the* Pkg *provenance over chapter 9364, chapter 915, chapter 549, chapter 486, chapter 476, chapter 483,* BHist*,* hsame*,* Cont*, and* NameCert *rows;*

10. *N is the local* $\mathsf{NameCert}_{\mathsf{KernelInductiveEliminator}^{\uparrow}}$ *row.*
The carrier contains no hidden host recursor, no unlisted computation rule, no ambient induction theorem, and no subject-reduction proof beyond the displayed emitted-rule surface.

Lean4 ✓ `BEDC.Derived.KernelInductiveEliminatorUp.TasteGate.KernelInductiveEliminatorTasteGate single carrier alignment`

Theorem 1096.2 (KernelInductiveEliminator NameCert obligations)**.** *For the carrier of Definition 1096.1, the local* $\mathsf{NameCert}_{\mathsf{KernelInductiveEliminator}^{\uparrow}}$ *surface consists of five finite obligations:*

1. *carrier exposure for the packet $E = (D, S, L, M, R, B, H, C, P, N)$;*
2. *declaration handoff, requiring the row D to be consumed from the accepted inductive declaration surface of* $\mathsf{KernelInductiveAcceptance}^{\uparrow}$*;*
3. *branch arity exactness, requiring the eliminator motive and minor-premise rows in L, M to match the constructor-signature row S;*
4. *emitted-rule ledger exactness, requiring every case-analysis or computation read to be one of the displayed entries of R;*
5. *primitive non-escape, requiring any attempted host eliminator primitive outside R to land in the refusal boundary B rather than in a consumer route.*

Proof. Carrier exposure is projection from the displayed BHist packet. The accepted declaration, constructor signature, eliminator names, motive-and-branch arities, emitted-rule ledger, refusal boundary, transport, route, provenance, and local name are coordinates of one finite object.

The declaration handoff reads D through chapter 915. That chapter records the accepted inductive declaration and constructor-signature ledger, while the present packet starts only after those rows are available.

Branch arity exactness is the local comparison between S and M. Each constructor listed in S has exactly the minor-premise row recorded in M, and the eliminator names in L are public only through that finite comparison.

Finally, emitted-rule exactness and primitive non-escape are read from R and B. A downstream generator, type-classifier, or subject-reduction consumer may consume a displayed emitted rule, but a request for an unrecorded host primitive has no coordinate in E and is routed to the refusal boundary. □

Theorem 1096.3 (KernelInductiveEliminator nontrivial boundary)**.** *The* $\mathsf{KernelInductiveEliminator}^{\uparrow}$ *packet has a nontrivial boundary for TasteGate: an accepted packet displays at least one emitted-rule row through $D, S, L, M, R, H, C, P, N$, while a consumer asking for an eliminator primitive absent from R lands in B and is not accepted as a displayed eliminator read. The Lean file* `lean4/BEDC/Derived/KernelInductiveEliminatorUp/TasteGate.lean` *must provide* Nontrivial KernelInductiveE *for this finite carrier.*

Proof. The accepted side is visible because the carrier exposes an emitted-rule ledger R after the declaration, constructor-signature, eliminator-name, and arity rows have been displayed.

The refused side is visible because B is a separate row. A request for an eliminator primitive not listed in R cannot be reclassified as an emitted-rule read without adding a coordinate absent from the carrier.

Thus the boundary has two distinguishable finite outcomes: displayed emitted-rule consumption and refusal of an unrecorded primitive. □

Theorem 1096.4 (KernelInductiveEliminator field-faithful boundary)**.** *The* KernelInductiveEliminator$^{\uparrow}$ *packet is field-faithful for TasteGate: any accepted read that preserves $D, S, L, M, R, B, H, C, P, N$ componentwise preserves the emitted eliminator surface, and any read that drops L, M, or R is not a faithful read of this carrier. The Lean file* `lean4/BEDC/Derived/KernelInductiveEliminatorUp/TasteGate.le` *must provide* FieldFaithful KernelInductiveEliminator$^{\uparrow}$ *for this finite carrier.*

Proof. Start with two accepted reads related by the displayed hsame rows. Componentwise transport preserves the accepted declaration, constructor signature, eliminator names, arity ledger, emitted-rule ledger, refusal boundary, route, provenance, and local name together.

The fields L, M, and R distinguish this carrier from the surrounding acceptance packets. KernelInductiveAcceptance$^{\uparrow}$ can expose accepted declarations and constructor signatures, but it does not by itself expose the full emitted-rule consumer surface isolated here.

If any of L, M, or R is absent, the read may still be a declaration-acceptance read, a generator-closure read, a type-membership read, or a subject-reduction boundary read. It is not a faithful read of KernelInductiveEliminator$^{\uparrow}$. □

Falsifiable prediction: An accepted KernelInductiveEliminator$^{\uparrow}$ packet cannot export a host eliminator primitive unless the requested primitive appears as a displayed emitted-rule row in R.

Independence witness: KernelInductiveAcceptance, KernelAcceptanceWitness, GeneratorClosure, TypeClassifierMembership, SubjectReduction: declaration acceptance, accepted-declaration witnessing, generator closure, type membership, and preservation rows are not bijective to emitted eliminator discharge because none of the five sibling surfaces simultaneously records eliminator names, motive-and-branch arity, emitted computation rows, and refusal of host primitives as the packet $E = (D, S, L, M, R, B, H, C, P, N)$ does.

Closure status for NameCert$_{\text{KernelInductiveEliminator}^{\uparrow}}$**.**

Constructive story: A KernelInductiveEliminator$^{\uparrow}$ packet is generated from an accepted inductive declaration row, constructor-signature row, emitted eliminator-name row, motive-and-branch arity row, emitted-rule ledger, host-primitive refusal boundary, componentwise hsame transport, displayed Cont routes, provenance, and local naming. The carrier first consumes the accepted declaration, then compares constructor signatures with eliminator minor premises, and finally exposes only the emitted rules listed in the ledger. The classifier admits eliminator use as finite emitted-rule data and routes any absent primitive to the refusal boundary.

Theory closure: TheoryGate(NameCert$_{\text{KernelInductiveEliminator}^{\uparrow}}$, seed)

Scope closed: This chapter binds the kernel inductive eliminator carrier, NameCert obligations, nontrivial boundary, field-faithful boundary, prediction, and independence witness.

Formal verification: FormalStatus(NameCert$_{\text{KernelInductiveEliminator}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim hidden host recursors, unlisted computation rules, ambient induction theorems, or subject-reduction proofs beyond the emitted-rule surface.

Upgrade path: To reach obligationClosure, check the declaration handoff, arity exactness, emitted-rule ledger, and primitive-refusal boundary.

Chapter 1097

A Concrete Naming Certificate for $\mathsf{CompilerClassifierRoute}^{\uparrow}$

The $\mathsf{CompilerClassifierRoute}^{\uparrow}$ surface turns the compiler-as-NameCert-morphism vision of chapter 9371 into one concrete route object. It joins classifier membership from chapter 476, classifier morphism from chapter 590, NameCert morphism from chapter 481, compiler graph replay from chapter 473, and trace faithfulness from chapter 1055. A consumer therefore reads one finite route rather than coordinating five adjacent certificate packets.

Falsifiable prediction: A compiler-classifier route is rejected whenever Ext preservation, SigRel preservation, Cont replay, and hsame trace faithfulness do not land on the same displayed graph row.

Independence witness: namecertmorphism, certificatecompiler, classifiermorphism, typeclassifiermembership, compilertracefaithfulness: none is bijective because this packet stores the single route joining all five surfaces.

Definition 1097.1 (CompilerClassifierRoute carrier)**.** *A* $\mathsf{CompilerClassifierRoute}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (S, T, A, M, K, G, E, Q, L, H, C, P, N)$$

with the following displayed rows:

1. *S is the source* $\mathsf{NameCert}$ *row whose classifier admits source histories;*
2. *T is the target* $\mathsf{NameCert}$ *row whose classifier receives transported histories;*
3. *A is the* $\mathsf{TypeClassifierMembership}^{\uparrow}$ *row exposing the source classifier-membership surface consumed by the route;*
4. *M is the* $\mathsf{ClassifierMorphism}^{\uparrow}$ *row recording classifier preservation between source and target classifier rows;*
5. *K is the* $\mathsf{NameCertMorphism}^{\uparrow}$ *row recording carrier and naming-certificate preservation;*
6. *G is the* $\mathsf{CertificateCompiler}^{\uparrow}$ *compiler graph row whose displayed edges are read by both the classifier morphism and the NameCert morphism;*
7. *E is the* Ext*-preservation row, stating that accepted source histories land as accepted target histories along the graph row G;*

8. *Q is the* SigRel*-preservation row, stating that the route preserves the displayed source and target signature relation rows;*
9. *L is the* $\mathsf{CompilerTraceFaithfulness}^{\uparrow}$ *row transporting source classifier agreement and source* hsame *to target classifier agreement and target* hsame *through the same graph row;*
10. *H records componentwise* hsame *transport for $S, T, A, M, K, G, E, Q, L, C, P, N$;*
11. *C records the displayed* Cont *replay for reading source membership, graph edges, target landing, classifier transport, NameCert transport, and trace faithfulness through one route;*
12. *P names the dependency surface* BHist, Ext, SigRel, hsame, Cont, Pkg, NameCert, $\mathsf{TypeClassifierMembership}^{\uparrow}$, $\mathsf{ClassifierMorphism}^{\uparrow}$, $\mathsf{NameCertMorphism}^{\uparrow}$, $\mathsf{CertificateCompiler}^{\uparrow}$, *and* $\mathsf{CompilerTraceFaithfulness}^{\uparrow}$*;*
13. *N is the local* $\mathsf{NameCert}_{\mathsf{CompilerClassifierRoute}^{\uparrow}}$ *row.*

The local classifier compares accepted packets only through these displayed rows and never through host compiler semantics, quotient program equality, hidden target objects, or an undisplayed graph.

Theorem 1097.2 (CompilerClassifierRoute NameCert obligations)**.** *For the carrier of Definition 1097.1, the local* $\mathsf{NameCert}_{\mathsf{CompilerClassifierRoute}^{\uparrow}}$ *surface has five obligations:*

1. *carrier exposure: the accepted object is the finite packet $R = (S, T, A, M, K, G, E, Q, L, H, C, P, N)$;*
2. *classifier membership admission: the source row A is the only source of accepted classifier membership, and every route read of that membership is replayed through C;*
3. *shared graph alignment:* Ext *preservation,* SigRel *preservation, classifier morphism, NameCert morphism, compiler graph replay, and trace faithfulness all cite the same displayed graph row G;*
4. *trace transport: source classifier agreement and source* hsame *are transported to target classifier agreement and target* hsame *only through L, H, C;*
5. *non-escape: no host compiler semantics, quotient program equality, hidden target object, second graph, or undeclared optimization row is exported by the route.*

Proof. Carrier exposure is projection from the finite tuple. The rows $S, T, A, M, K, G, E, Q, L, H, C, P, N$ are the complete public inventory available to the local classifier.

Classifier membership admission is inherited from chapter 476. The route does not introduce another membership predicate; it replays the accepted membership row A through the continuation row C.

Shared graph alignment is the defining route condition. The classifier morphism, NameCert morphism, certificate compiler graph, Ext row, SigRel row, and trace-faithfulness row are admissible only when their graph coordinate is the same displayed G.

Trace transport then follows through L, H, C. Since L is the trace-faithfulness row and H, C preserve the same componentwise route, target agreement can be read only after the source membership and shared graph rows have been displayed.

Finally P and N name the provenance and local certificate without adding semantic content. The absence of any other coordinate rules out host compiler semantics, quotient equality, hidden target objects, a second graph, and optimization data. □

Lean4 ✓ `BEDC.Derived.CompilerClassifierRouteUp.CompilerClassifierRouteNameCertObligations`

Theorem 1097.3 (CompilerClassifierRoute shared-row rejection)**.** *An accepted* CompilerClassifierRoute$^{\uparrow}$ *packet must place* Ext *preservation,* SigRel *preservation,* Cont *replay, and* hsame *trace faithfulness on the same displayed graph row G. If any of those rows lands on a different graph, or if one of the rows is absent, the packet is not accepted as a compiler-classifier route.*

Proof. Use the carrier definition to read the single graph coordinate G. Every row that claims source-to-target transport is listed beside that coordinate in the same packet.

Apply the NameCert obligations. Shared graph alignment makes G the common endpoint for Ext, SigRel, classifier morphism, NameCert morphism, compiler replay, and trace faithfulness, while trace transport forces hsame preservation through L, H, C over that same coordinate.

If a row uses another graph, the shared graph obligation has no witness. If a row is absent, one of the five obligation rows cannot be read. In either case the displayed packet may still contain a compiler graph or classifier morphism sibling, but it does not contain the joined compiler-classifier route. □

Lean4 ✓ `BEDC.Derived.CompilerClassifierRouteUp.CompilerClassifierRouteSharedRowRejection`

Theorem 1097.4 (CompilerClassifierRoute downstream target)**.** *The Lean-facing downstream surface for* CompilerClassifierRoute$^{\uparrow}$ *is the packet family to be recorded under* Derived/CompilerClassifierRouteUp/Tast *with explicit* Nontrivial CompilerClassifierRoute$^{\uparrow}$ *and* FieldFaithful CompilerClassifierRoute$^{\uparrow}$ *instances. The gate must recover the shared graph row G, the preservation rows E, Q, the trace-faithfulness row L, and the replay rows H, C, P, N before admitting the route.*

Proof. The carrier and obligation surface name the rows the gate must inspect. A nontrivial instance requires a packet with a displayed source certificate, target certificate, classifier-membership row, classifier morphism, NameCert morphism, compiler graph, preservation rows, trace-faithfulness row, replay rows, provenance, and local naming.

Field faithfulness requires those rows to remain recoverable from the admitted route. The shared-row rejection theorem gives the test: the gate reads G, E, Q, L, H, C, P, N and accepts only when the preservation and trace-faithfulness rows land on the same displayed graph row.

No additional Lean object is part of this downstream target. The paper packet fixes the finite row inventory that later formalization must preserve. □

Lean4 ✓ `BEDC.Derived.CompilerClassifierRouteUp.compilerClassifierRouteChapterTasteGate`

Closure status for NameCert$_{\text{CompilerClassifierRoute}^{\uparrow}}$.

Constructive story: A CompilerClassifierRoute$^{\uparrow}$ packet is generated from source and target NameCert rows, classifier-membership evidence, classifier morphism, NameCert morphism, compiler graph, Ext and SigRel preservation rows, trace-faithfulness ledger, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The carrier accepts the route only when membership, morphism, compiler graph, preservation, and trace rows land on the same displayed graph. Its route ledger keeps source admission and target readback synchronized. The classifier therefore joins five adjacent certificate surfaces into one finite route rather than letting a consumer choose incompatible compiler or classifier witnesses.

Theory closure: TheoryGate(NameCert$_{\text{CompilerClassifierRoute}^{\uparrow}}$, seed)

Scope closed: This chapter binds the compiler classifier route carrier, shared-row rejection theorem, and downstream TasteGate target.

Formal verification: FormalStatus(NameCert$_{\text{CompilerClassifierRoute}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim arbitrary compiler correctness, detached classifier preservation, hidden graph equality, or trace faithfulness outside the displayed route.

Upgrade path: To reach obligationClosure, formalize the shared compiler graph row and prove Ext, SigRel, Cont, and hsame preservation land on it together.

Chapter 1098

A Concrete Naming Certificate for $\mathsf{LayeredRelationFailureBoundary}^{\uparrow}$

The $\mathsf{LayeredRelationFailureBoundary}^{\uparrow}$ packet realizes the failure-boundary row of chapter 9416 as a finite NameCert surface for cross-domain relation certificates. It sits beside the full relation packet of chapter 1090, the audit-frame packet of chapter 1037, the force-like inter-history relation packet of chapter 1088, and the failed gate witness of chapter 901. Those siblings expose a complete relation certificate, an audit frame, a force-like carrier, or a failed audit item; this packet isolates the coordinate that says exactly where same-schema export weakens or is refused before any public consumer may read relation language.

Falsifiable prediction: Any public same-schema export that lacks a displayed failure-boundary row cannot cite this NameCert; a verified export without such a row refutes the packet.

Independence witness: layeredrelationcert, relationalframeaudit, forceinterhistrelation, auditgatefailurewitness, apophaticname: the packet is not bijective with any sibling because it isolates the weakening/failure coordinate, whereas the siblings respectively package the full relation certificate, audit frame, force-like carrier, failed audit witness, or named apophatic boundary.

Definition 1098.1 (Layered relation failure-boundary carrier)**.** *A* $\mathsf{LayeredRelationFailureBoundary}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (R, E, B, W, G, H, C, P, N)$$

with the following displayed rows:

1. *R is the relation-certificate row being tested for public same-schema export;*
2. *E is the exactness row that records what the relation may export before identity, empirical transfer, proof transfer, or bridge strength is read;*
3. *B is the failure-boundary row naming the condition under which the relation weakens, fails, or must be withheld from public export;*
4. *W is the weakening and refusal row attached to B, listing the non-preserved structure, refused object content, refused empirical content, and refused bridge content;*
5. *G is the gate report row recording no identity collapse, hidden axiom, global-frame leak, subject-substance leak, or empirical overclaim for the displayed relation read;*

6. *H records componentwise* hsame *transport for relation-certificate, exactness, failure-boundary, weakening, gate-report, route, provenance, and local-name rows;*
7. *C records displayed* Cont *routes from R to E, from E to B, from B to W, from W to G, and from the accepted gate report to any public same-schema consumer;*
8. *P is the* Pkg *provenance over chapter 9416, chapter 1090, chapter 1037, chapter 1088, chapter 901, chapter 543,* BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationFailureBoundary}^{\uparrow}}$ *row.*

The carrier has no coordinate for exporting a same-schema relation without a displayed weakening and failure boundary, and it has no coordinate for turning the boundary into object identity, empirical law, hidden axiom, global frame, subject substance, or checked bridge strength.

Lean4 (definition) `BEDC.Derived.LayeredRelationFailureBoundaryUp.LayeredRelationFailureBoundaryUp`
Lean4 ✓ `BEDC.Derived.LayeredRelationFailureBoundaryUp.LayeredRelationFailureBoundaryTasteGate single carrier alignment`

Theorem 1098.2 (Layered relation failure-boundary non-escape)**.** *For every accepted* LayeredRelationFailureBound *carrier*

$$F = (R, E, B, W, G, H, C, P, N),$$

all public relation export reads pass through $R, E, B, W, G, H, C, P, N$. The consumer may read exactness only together with the displayed failure-boundary row B and the weakening/refusal row W; it receives no route that bypasses B, detaches W, hides the gate report G, or promotes same-schema language to object identity, empirical transfer, proof transfer, global-frame transfer, subject-substance transfer, or bridge checking.

Proof. Project the carrier of Definition 1098.1. The exactness row E, failure-boundary row B, weakening/refusal row W, and gate report row G are displayed as separate coordinates of the same finite packet.

Read the continuation routes in C. A public same-schema consumer reaches E from R, then reaches B, then reaches W, and then reads G before export. Thus exactness cannot be consumed as a detached object-identity or bridge-strength claim.

The structural rows H, P, N transport, cite, and name the same packet. Since none of those rows supplies a new relation source, hidden axiom, empirical law, global frame, subject-substance carrier, or bridge checker, the displayed boundary cannot escape through transport, provenance, or local naming. □

Lean4 ✓ `BEDC.Derived.LayeredRelationFailureBoundaryUp.LayeredRelationFailureBoundary failure boundary row determinacy`

Theorem 1098.3 (Layered relation failure-boundary gate exactness)**.** *An accepted* LayeredRelationFailureBoundary *packet permits public same-schema export exactly when the relation-certificate row R, exactness row E, failure-boundary row B, weakening/refusal row W, and gate report row G are displayed in the same carrier and the consumer route preserves them through H, C, P, N. If any of B, W, G is absent, then the packet supplies no public exactness export.*

Proof. For the forward direction, read the carrier. The public exactness route is the displayed route from R through E, B, W, G and then through the structural rows H, C, P, N. These rows give the relation certificate, the exactness claim, the boundary where it weakens, the refused content attached to that boundary, and the gate report that prevents over-reading.

For the reverse direction, suppose a displayed route presents $R, E, B, W, G, H, C, P, N$ in one carrier. The route has the exactness row, the failure boundary, the weakening/refusal row, and the gate report needed by chapter 9416 before public export, so it determines the same same-schema consumer surface.

If B is absent, the export has no row naming where the relation weakens or fails. If W is absent, the export has no refusal row separating exactness from preserved content. If G is absent, the export has no gate report blocking identity collapse, hidden axiom use, global-frame leakage, subject-substance leakage, or empirical overclaim. In each case the carrier lacks a public exactness export route. □

Closure status for $\mathsf{NameCert}_{\mathsf{LayeredRelationFailureBoundary}^{\uparrow}}$.

Constructive story: A $\mathsf{LayeredRelationFailureBoundary}^{\uparrow}$ packet is generated from a relation-certificate row, exactness row, failure-boundary row, weakening/refusal row, gate report, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LayeredRelationFailureBoundary}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1098.1, Definition 1098.2, and Definition 1098.3 bind the finite failure-boundary packet for same-schema relation export.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LayeredRelationFailureBoundary}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close the full layered relation certificate, a relational frame audit, a force-like relation, a failed audit witness, object identity, empirical transfer, global-frame transfer, subject-substance transfer, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, exactness gating, weakening/refusal attachment, gate-report preservation, transport, continuation, provenance, naming, and TasteGate nontriviality with field faithfulness for the same failure-boundary packet.

Chapter 1099

A Concrete Naming Certificate for $\mathsf{LayeredRelationGate}^{\uparrow}$

The $\mathsf{LayeredRelationGate}^{\uparrow}$ packet realizes the gate surface of Definition 9416.19 as a finite same-schema relation verdict. It sits after the relation certificate of chapter 9416, the concrete certificate packet of chapter 1090, the force inter-history relation packet of chapter 1088, and the axiom-refusal ledger of chapter 1057. Those siblings supply relation-certificate rows, force-relation rows, and refusal-ledger rows; this packet binds their gate verdict, identity refusal, and same-schema consumer route as one NameCert surface.

Falsifiable prediction: A gate packet that lacks a not-preserved row cannot export a same-schema consumer theorem.

Independence witness: layeredrelationcert, forceinterhistrelation, groundcompilerrecognizerflow, axiomrefusalledger: the gate carrier has a verdict and identity-refusal row absent from the certificate-only, force-relation, recognizer-flow, and axiom-refusal packets, so no bijection can preserve all NameCert rows.

Definition 1099.1 (LayeredRelationGate carrier)**.** *A* $\mathsf{LayeredRelationGate}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$K = (A, B, L, P, N, F, G, H, C, \Pi)$$

with the following displayed rows:

1. *A and B are the two source-domain rows whose relation is being gated;*
2. *L is the finite layer-list row pairing source layers, carrier families, classifier families, and layer-map entries;*
3. *P is the preserved row, listing exactly the relation content that may be exported under same-schema language;*
4. *N is the not-preserved row, listing object identity, empirical law, proof transfer, subject-substance, global-frame, and bridge-strength content refused by the gate;*
5. *F is the finite ledger, exactness, and failure-boundary row, recording each gate question of Definition 9416.19;*
6. *G is the gate verdict row, whose accepted value permits same-schema relation export only when A, B, L, P, N, F are all displayed;*

7. *H records componentwise* hsame *transport for source, layer, preserved, not-preserved, refusal, verdict, continuation, and provenance rows;*
8. *C records displayed* Cont *routes for source inspection, layer-list replay, preserved-row export, not-preserved-row inspection, refusal-ledger replay, and consumer handoff;*
9. *Π is the* Pkg *and local* $\mathsf{NameCert}_{\mathsf{LayeredRelationGate}^{\uparrow}}$ *row over chapter 9416, chapter 1090, chapter 1088, chapter 1048, chapter 1057,* BHist, hsame, Cont, Pkg, *and* NameCert.

The carrier has no coordinate for identifying A with B as objects. Same-schema relation language is an export of the verdict row G after the preserved row P and the not-preserved row N have both been displayed.

Theorem 1099.2 (LayeredRelationGate NameCert obligations)**.** *For the carrier of Definition 1099.1, the local* $\mathsf{NameCert}_{\mathsf{LayeredRelationGate}^{\uparrow}}$ *surface consists of seven finite obligations:*

1. *carrier exposure for $K = (A, B, L, P, N, F, G, H, C, \Pi)$;*
2. *source-domain exposure for A and B before any same-schema relation read;*
3. *layer-list exposure for the paired source layers, carrier families, classifier families, and layer map in L;*
4. *preserved-row disclosure through P;*
5. *not-preserved disclosure through N before verdict export;*
6. *refusal-ledger and failure-boundary replay through F;*
7. *consumer handoff through G, H, C, Π without object identity, empirical law, proof transfer, subject-substance, global-frame, bridge-strength, or hidden-choice export.*

Lean4 ✓ `BEDC.Derived.LayeredRelationGateUp.LayeredRelationGateNameCertObligations`

Proof. Carrier exposure is projection from the finite tuple in Definition 1099.1. The accepted packet has no fields outside $A, B, L, P, N, F, G, H, C, \Pi$.

Source-domain and layer-list exposure are ordered by the displayed continuation row C. A same-schema consumer first reads the source rows A, B and then the layer-list row L before any preserved or refused content is available.

The preserved and not-preserved obligations are the rows P and N. Since G can be read only after both rows have been displayed, a passing gate cannot hide refused content behind same-schema wording.

The refusal-ledger obligation is the row F. It records the failure boundary for the gate questions of Definition 9416.19, including identity collapse, hidden empirical law, subject-substance, global-frame, object-level T, and strength over-reading.

Finally, the structural rows H, C, Π transport, replay, package, and name the same finite verdict surface. They do not add object identity or choice rows, so the local NameCert surface is exactly the listed gate packet. □

Theorem 1099.3 (LayeredRelationGate same-schema non-identity)**.** *If an accepted* $\mathsf{LayeredRelationGate}^{\uparrow}$ *packet passes its verdict row G, then downstream consumers may use the displayed same-schema relation over A, B, L, P, N, F. They may not read the verdict as object identity between A and B, as empirical law, as proof transfer, as subject-substance transfer, as a global-frame theorem, or as bridge strength.*

Lean4 ✓ BEDC.Derived.LayeredRelationGateUp.LayeredRelationGate same schema nonidentity

Proof. Begin with the NameCert obligations of Definition 1099.2. The verdict is downstream from the source rows, layer-list row, preserved row, not-preserved row, and refusal ledger.

The same-schema relation is therefore exhausted by A, B, L, P, N, F, G. The preserved row P records what may be exported, while the not-preserved row N records what the export refuses.

Object identity and the other excluded readings are listed only in the not-preserved and refusal rows. Since neither H nor C nor Π contains a constructor from those rows to preserved content, a passing verdict licenses relation use without promoting the two domains to one object. □

Lean4 ✓ BEDC.Derived.LayeredRelationGateUp.LayeredRelationGate not preserved row determinacy

Theorem 1099.4 (LayeredRelationGate consumer route)**.** *Every same-schema consumer of a passing* $\mathsf{LayeredRelationGate}^{\uparrow}$ *packet factors through the relation-certificate source of chapter 9416, the concrete certificate surface of chapter 1090, the force inter-history relation surface of chapter 1088, and the axiom-refusal ledger of chapter 1057. The consumer reads exactly the source, layer-list, preserved, not-preserved, ledger, exactness, failure-boundary, verdict, transport, continuation, package, and local NameCert rows of Definition 1099.1.*

Lean4 ✓ BEDC.Derived.LayeredRelationGateUp.LayeredRelationGateConsumerRoute
↪ variant BEDC.Derived.LayeredRelationGateUp.LayeredRelationGate consumer route

Proof. First read the relation-certificate discipline of chapter 9416 and chapter 1090. These supply the source, layer, preserved, not-preserved, exactness, and failure-boundary rows consumed by the gate.

Next use chapter 1088. It supplies a concrete same-schema relation surface without turning the compared histories or domains into one object.

Now use chapter 1057. It supplies the refusal-ledger discipline that keeps hidden axioms, global-frame imports, and unrecorded strength claims outside the exported relation.

Finally apply Definition 1099.2 and Definition 1099.3. They force the consumer through $A, B, L, P, N, F, G, H, C, \Pi$ and make the verdict a same-schema relation gate, not an identity theorem. □

Theorem 1099.5 (LayeredRelationGate carrier obligation)**.** *Every* $\mathsf{LayeredRelationGate}^{\uparrow}$ *obligation read must expose the carrier rows* $A, B, L, P, N, F, G, H, C, \Pi$ *before any verdict, consumer route, or same-schema export is available.*

Lean4 ✓ BEDC.Derived.LayeredRelationGateUp.LayeredRelationGateCarrierObligation

Proof. Use the carrier of Definition 1099.1. Its finite tuple lists exactly the two source rows, layer-list row, preserved row, not-preserved row, refusal ledger, verdict row, transport row, continuation row, and package-name row.

Apply the NameCert obligations of Definition 1099.2. Carrier exposure is the first obligation, so the downstream route cannot read G or a same-schema consumer before $A, B, L, P, N, F, G, H, C, \Pi$ have all been displayed. □

Theorem 1099.6 (LayeredRelationGate classifier obligation)**.** *A* $\mathsf{LayeredRelationGate}^{\uparrow}$ *classifier read may export a passing verdict only after comparing the preserved row P with the not-preserved row N over the same source, layer, and refusal rows A, B, L, F. The verdict row G is therefore not a classifier for identity between A and B.*

Lean4 ✓ `BEDC.Derived.LayeredRelationGateUp.LayeredRelationGateClassifier obligation`
↪ variant `BEDC.Derived.LayeredRelationGateUp.LayeredRelationGateCarrier classifier obligation`

Proof. Start from Definition 1099.2. The preserved and not-preserved disclosures are separate obligations, and both are upstream of verdict export.

Now apply Definition 1099.3. It states that a passing verdict licenses relation use while refusing object identity, empirical law, proof transfer, subject-substance transfer, global-frame content, and bridge strength. Hence the classifier must compare P and N before G can be read as a same-schema verdict. □

Theorem 1099.7 (LayeredRelationGate ledger obligation)**.** *Every same-schema consumer of* $\mathsf{LayeredRelationGate}^{\uparrow}$ *must keep the refusal ledger F visible. If F is not displayed, the consumer route cannot distinguish a permitted same-schema relation from a hidden identity, empirical-law, proof-transfer, subject-substance, global-frame, or bridge-strength claim.*

Proof. Use the consumer route of Definition 1099.4. The route reads the relation-certificate source, concrete certificate surface, force inter-history relation surface, and axiom-refusal ledger before it reaches the local packet.

Apply Definition 1099.2 and Definition 1099.3. They keep F as the displayed failure-boundary row and place the refused readings in N rather than in the exported relation. Without F, the same-schema consumer has no visible ledger separating the accepted relation from the forbidden readings. □

Lean4 ✓ `BEDC.Derived.LayeredRelationGateUp.LayeredRelationGate ledger obligation`

Theorem 1099.8 (LayeredRelationGate obligation closure)**.** *The carrier of Definition 1099.1, the NameCert obligations of Definition 1099.2, same-schema non-identity from Definition 1099.3, the consumer route of Definition 1099.4, and the carrier, classifier, and ledger obligations of Definition 1099.5, Definition 1099.6, and Definition 1099.7 form the complete finite obligation surface for* $\mathsf{LayeredRelationGate}^{\uparrow}$*. The assembled surface exports only the same-schema relation verdict over the displayed rows $A, B, L, P, N, F, G, H, C, \Pi$ and refuses object identity, empirical law, proof transfer, subject-substance transfer, global-frame theorem, bridge strength, hidden choice, Lean verification, and bridge checking.*

Proof. The carrier theorem fixes the finite packet as $A, B, L, P, N, F, G, H, C, \Pi$. There is no additional row from which identity, empirical law, proof transfer, subject-substance, global-frame structure, bridge strength, hidden choice, verification status, or bridge status could be read.

The NameCert obligation theorem exposes the ordered rows for source domains, layer list, preserved content, not-preserved content, refusal ledger, verdict, transport, continuation, package, and local certificate. Same-schema non-identity then identifies the verdict as relation language rather than object equality.

The consumer route sends every downstream read through the relation-certificate source, concrete certificate surface, force inter-history relation surface, and axiom-refusal ledger. The carrier, classifier, and ledger obligations close the remaining local readings by requiring carrier exposure, preserved/not-preserved comparison, and visible refusal-ledger replay.

Thus every allowed read is already listed by the finite surface, and every refused reading remains in N or F rather than in the exported verdict. The assembled obligation surface is complete for the chapter's current NameCert claim and carries no Lean verification or bridge-checking assertion. □

Lean4 ✓ `BEDC.Derived.LayeredRelationGateUp.LayeredRelationGate obligation closure`

Theorem 1099.9 (LayeredRelationGate obligation scope)**.** *The carrier, classifier, ledger, same-schema nonidentity, and consumer-route obligations of* $\mathsf{LayeredRelationGate}^{\uparrow}$ *are scoped by the single-carrier TasteGate witness for the finite packet* $A, B, L, P, N, F, G, H, C, \Pi$*. Consequently the accepted verdict cannot be read as host identity between the compared domains; it is only a same-schema relation export over the displayed rows.*

Lean4 ✓ `BEDC.Derived.LayeredRelationGateUp.LayeredRelationGateTasteGate single carrier alignment`

Proof. Read the carrier of Definition 1099.1. Its rows form one displayed packet, so every obligation in Definition 1099.5, Definition 1099.6, and Definition 1099.7 is evaluated on the same finite surface.

The TasteGate witness supplies the single-carrier alignment for that surface. It keeps source rows, preserved rows, not-preserved rows, ledger rows, verdict rows, transport, replay, and provenance in one packet rather than allowing an external identification between the compared domains.

Apply same-schema non-identity and the consumer route, Definition 1099.3 and Definition 1099.4. The consumer may export the displayed relation after reading the packet, but no row converts the verdict into host identity, empirical law, proof transfer, subject-substance transfer, global-frame content, bridge strength, or hidden choice. □

The Lean follow-up must provide $\mathsf{Nontrivial}\ \mathsf{LayeredRelationGate}^{\uparrow}$ and $\mathsf{FieldFaithful}\ \mathsf{LayeredRelationGate}^{\uparrow}$ instances in `lean4/BEDC/Derived/LayeredRelationGateUp/TasteGate.lean`.

Closure status for $\mathsf{NameCert}_{\mathsf{LayeredRelationGate}^{\uparrow}}$**.**

Constructive story: A $\mathsf{LayeredRelationGate}^{\uparrow}$ packet is generated from source domains, finite layer lists, preserved and not-preserved rows, a refusal ledger, a verdict row, componentwise hsame transport, displayed Cont routes, and local Pkg and NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{LayeredRelationGate}^{\uparrow}}, \mathsf{obligation})$

Scope closed: Definition 1099.1, Definition 1099.2, Definition 1099.3, Definition 1099.4, Definition 1099.8, and Definition 1099.9 bind the finite LayeredRelationGate carrier, NameCert obligations, same-schema non-identity verdict, consumer route, finite obligation surface, and TasteGate-scoped nonidentity boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{LayeredRelationGate}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close object identity between compared domains, empirical physics, proof transfer, subject-substance content, global-frame structure, Lean verification, audit cleanliness, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, verdict determinacy, preserved and not-preserved disclosure, refusal-ledger replay, consumer handoff, and TasteGate field faithfulness for the same finite packet.

Chapter 1100

A Concrete Naming Certificate for MetaCICOpenProblemWitness$^{\uparrow}$

The MetaCICOpenProblemWitness$^{\uparrow}$ packet realizes the consolidated open-problem surface of chapter 9386 as one finite frontier-witness NameCert carrier. It sits beside the subject-reduction obstruction of chapter 9377, the confluence audit map of chapter 9378, the normalization audit map of chapter 9383, the decidability audit map of chapter 9379, and the typed-examples audit map of chapter 9382. Those siblings expose separate audit faces; this packet records the joint ledger that a consistency-facing consumer must read before any stronger route is cited.

The concrete critical-path route of chapter 765 consumes this witness packet as the shared frontier ledger for subject reduction, normalization, decidability, typed-example coverage, and consistency-frontier rows. MetaCICCriticalPath$^{\uparrow}$ may cite the witness only as that joint ledger: it cannot read it as a closed consistency proof or as a replacement for the named audit-face obligations.

Definition 1100.1 (MetaCIC open-problem witness carrier)**.** *A* MetaCICOpenProblemWitness$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$W = (S, C, N, D, T, K, H, R, P, Q)$$

with the following displayed rows:

1. *S is the subject-reduction frontier row, naming* `metacic_subject_reduction_obstruction` *and the simultaneous beta-substitution, application-argument, lambda-domain, and Pi-domain discharge obligations;*
2. *C is the confluence frontier row, naming* `metacic_confluence_audit` *and the residual-substitution, closed parallel diamond, and arbitrary closed Church–Rosser endpoints;*
3. *N is the normalization frontier row, naming* `metacic_normalization_audit` *and the candidate-mediated strong-normalization boundary;*
4. *D is the decidability frontier row, naming* `metacic_decidable_audit` *and the bounded normal-comparison and closed beta-conversion boundary;*
5. *T is the typed-examples frontier row, naming* `metacic_typedexamples_audit` *and the gallery-versus-coverage boundary;*
6. *K is the consistency-frontier row, recording that any consistency-facing route must pass through one of S, C, N, D, T before it may cite a closed-normal or stronger consistency surface;*

7. *H records componentwise* hsame *transport for S, C, N, D, T, K;*
8. *R records displayed* Cont *replay routes for the five audit faces and the consistency frontier;*
9. *P is the* Pkg *provenance over chapter 9386, the five sibling audit chapters,* BHist, hsame, Cont, *and* NameCert*;*
10. *Q is the local* $\mathsf{NameCert}_{\mathsf{MetaCICOpenProblemWitness}^{\uparrow}}$ *row.*

The carrier has no coordinate for closed subject reduction, arbitrary closed Church–Rosser, evidence-free global strong normalization, unrestricted closed beta-conversion decidability, exhaustive typed-example coverage, host quotient equality of represented terms, or full closed consistency.

Lean4 (definition) `BEDC.Derived.MetaCICOpenProblemWitnessUp.MetaCICOpenProblemWitnessUp`

Theorem 1100.2 (MetaCIC open-problem witness NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{MetaCICOpenProblemW}}$ *surface for Definition 1100.1 consists exactly of carrier admission for $W = (S, C, N, D, T, K, H, R, P, Q)$, subject-reduction obstruction visibility through S, confluence audit visibility through C, normalization audit visibility through N, decidability audit visibility through D, typed-example audit visibility through T, consistency-frontier visibility through K, componentwise* hsame *transport through H, displayed* Cont *route replay through R, package provenance through P, and local naming through Q.*

Lean4 ✓ `BEDC.Derived.MetaCICOpenProblemWitnessUp.MetaCICOpenProblemWitnessTasteGate single carrier alignment`

Proof. Project the accepted carrier. Its audit-face rows are S, C, N, D, T, and its consistency-facing row is K.

Read the sibling references in the provenance row. The subject-reduction obstruction, confluence audit map, normalization audit map, decidability audit map, and typed-examples audit map supply the five named faces, while chapter 9386 supplies the consolidated frontier reading.

The structural rows H, R, P, Q only transport, replay, package, and name those displayed rows. Since no further coordinate appears in the carrier, the listed rows exhaust the local NameCert obligation surface. □

Theorem 1100.3 (MetaCIC open-problem witness frontier nonescape)**.** *Any accepted consumer of a* $\mathsf{MetaCICOpenProblemWitness}^{\uparrow}$ *packet reaches one of the named frontier rows S, C, N, D, T before it may cite the consistency-facing row K. A route that exports full closed consistency without passing through one of those rows does not factor through the packet.*

Proof. Start with the carrier definition. The consistency-facing row K is displayed only as a frontier row inside $W = (S, C, N, D, T, K, H, R, P, Q)$.

The five audit rows are the only inputs to K. Subject reduction must pass through S, confluence through C, normalization through N, decidability through D, and typed-example coverage through T. Transport through H and replay through R preserve that routing rather than adding a separate consistency coordinate.

Finally read the excluded objects. Since the carrier contains no closed subject-reduction theorem, no arbitrary closed Church–Rosser theorem, no evidence-free normalization theorem, no unrestricted conversion decider, and no exhaustive coverage theorem, a full closed-consistency export without one of the named frontier rows has no coordinate in the packet. □

Falsifiable prediction: Any accepted consumer of $\mathsf{MetaCICOpenProblemWitness}^{\uparrow}$ reaches a named frontier row before it may cite a consistency-facing route; a route that exports full closed consistency without one of those rows refutes the packet.

Independence witness: metacic_subject_reduction_obstruction, metacic_confluence_audit, metacic_normalization_audit, metacic_decidable_audit, metacic_typedexamples_audit: none is bijective with $\mathsf{MetaCICOpenProblemWitness}^{\uparrow}$ because each sibling records one audit face, while this carrier records the joint frontier ledger $S, C, N, D, T, K, H, R, P, Q$ and the consistency-facing non-escape route.

Closure status for $\mathsf{NameCert}_{\mathsf{MetaCICOpenProblemWitness}^{\uparrow}}$.

Constructive story: A $\mathsf{MetaCICOpenProblemWitness}^{\uparrow}$ packet is generated from subject-reduction obstruction, confluence audit, normalization audit, decidability audit, typed-example audit, consistency-frontier, transport, route, provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{MetaCICOpenProblemWitness}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1100.1, Definition 1100.2, and Definition 1100.3 bind the finite open-problem witness packet and its consistency-facing non-escape rule.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{MetaCICOpenProblemWitness}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close subject reduction, arbitrary closed Church–Rosser, evidence-free global strong normalization, unrestricted closed beta-conversion decidability, exhaustive typed-example coverage, full closed consistency, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, exact row coverage for the five audit faces, consistency-frontier routing, route replay, provenance, local naming, and downstream non-escape over the same packet.

Chapter 1101

A Concrete Naming Certificate for $\mathsf{GammaZetaFactorSeal}^{\uparrow}$

The $\mathsf{GammaZetaFactorSeal}^{\uparrow}$ packet is the finite seal consumed by zeta functional-equation routes when they read the factor $\Gamma(1-s)$. It sits between the constructive Gamma surface of chapter 75, the application packet of chapter 588, and the witness packet of chapter 580. Its role is to make the Gamma factor a displayed NameCert packet rather than a horizon mention inside the zeta continuation application.

Definition 1101.1 (Gamma-Zeta factor seal carrier)**.** *A* $\mathsf{GammaZetaFactorSeal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (D, R, F, A, H, C, Q, N)$$

with the following displayed rows:

1. *D is the Gamma-domain row for the input $1-s$, including the pole exclusion and complex-history carrier inherited from* $\mathsf{Gamma}^{\uparrow}$*;*
2. *R is the reflected-input row, recording the source input s and the displayed reflection route to $1-s$;*
3. *F is the functional-equation factor row, recording the product slot in which $\Gamma(1-s)$ is consumed together with the elementary factors;*
4. *A is the zeta-application row that binds the factor read to the* $\mathsf{ZetaContinuationApplication}^{\uparrow}$ *packet;*
5. *H stores componentwise* hsame *transports for D, R, F, A and for the local naming row;*
6. *C stores the finite* Cont *replay routes by which downstream consumers read Gamma-domain, reflection, factor, zeta-application, transport, provenance, and local naming data;*
7. *Q is the* Pkg *provenance row over the Gamma, zeta-application, and zeta-witness source packets;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{GammaZetaFactorSeal}^{\uparrow}}$ *row.*

The carrier has no coordinate for an undisplayed Gamma value, an external functional-equation proof, a second zeta-application packet, a branch outside the reflected-input route, or a nontrivial-zero classifier.

Lean4 ✓ `BEDC.Derived.GammaZetaFactorSealUp.GammaZetaFactorSealTasteGate single carrier alignment`

Theorem 1101.2 (Gamma-Zeta factor seal NameCert obligations)**.** *For the carrier of Definition 1101.1, the local* $\mathsf{NameCert}_{\mathsf{GammaZetaFactorSeal}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$S = (D, R, F, A, H, C, Q, N),$$

Gamma-domain exactness through D, reflected-input exactness through R, functional-equation factor exactness through F, zeta-application exactness through A, componentwise hsame *transport through H, displayed* Cont *replay through C, package provenance through Q, and local naming through N.*

Proof. Project the displayed carrier. The rows D, R, F, A are the complete analytic content of the seal, while H, C, Q, N transport, replay, package, and name the same finite packet.

Read the source packets in their displayed roles. The $\mathsf{Gamma}^{\uparrow}$ chapter supplies the Gamma-domain row, the $\mathsf{ZetaContinuationApplication}^{\uparrow}$ chapter supplies the application row that consumes the factor, and the $\mathsf{ZetaContinuationWitness}^{\uparrow}$ chapter supplies the continuation witness route in which the factor is replayed.

The NameCert surface is exhausted by these rows. Since the carrier has no coordinate for an undisplayed Gamma value, an external functional-equation proof, a second zeta-application packet, an outside branch, or a nontrivial-zero classifier, no accepted read can obtain any of those objects from the seal. □

Theorem 1101.3 (Functional-equation Gamma-factor readback)**.** *Every accepted* $\mathsf{GammaZetaFactorSeal}^{\uparrow}$ *consumer that reads the functional-equation Gamma factor must receive the displayed packet*

$$S = (D, R, F, A, H, C, Q, N).$$

In particular, a read of $\Gamma(1-s)$ is accepted only when the Gamma-domain row, reflected-input row, functional-equation factor row, zeta-application row, componentwise transport, replay route, provenance row, and local name occur in the same finite packet.

Proof. Start with the carrier inventory in Definition 1101.1. A Gamma-factor read has only one factor coordinate, namely F, and that coordinate is displayed together with D, R, A, H, C, Q, N.

Apply the NameCert obligations of Definition 1101.2. The readback route must preserve the Gamma-domain row through D, the reflected input through R, the factor slot through F, and the zeta application through A before it can replay through C.

The missing alternatives named in the carrier definition have no coordinate. Thus the accepted readback is exactly the finite seal packet, not a detached Gamma theorem or an external functional-equation route. □

Theorem 1101.4 (Gamma-Zeta factor seal non-escape)**.** *Every downstream zeta functional-equation route that consumes a* $\mathsf{GammaZetaFactorSeal}^{\uparrow}$ *packet factors through D, R, F, A, H, C, Q, N. Requests for a Gamma value outside the displayed domain row, an unreflected input, an undisplayed functional-equation factor, a second application packet, a hidden transport, or a nontrivial-zero conclusion are rejected by the carrier inventory.*

Proof. Let a downstream route be given. By carrier admission, the route can inspect only the Gamma-domain row, reflected-input row, factor row, application row, transport row, replay row, provenance row, and local name.

Componentwise transport keeps these rows separate. A Gamma-domain read returns to D, an input-reflection read returns to R, a factor read returns to F, and a zeta-application read returns to A.

Every request listed in the statement asks for a coordinate absent from the carrier. The route therefore remains a read of the displayed seal and cannot export any stronger analytic object. □

Falsifiable prediction: A zeta functional-equation read using a Gamma factor is rejected unless the Gamma-domain row, reflected-input row, functional-equation row, and zeta-application row appear in the same displayed packet.

Independence witness: Nearest siblings: GammaFunction, ZetaContinuationApplication, ZetaContinuationWitness, Complex, and Holomorphic. None is bijective to GammaZetaFactorSealUp because none simultaneously stores the Gamma-domain row, reflected-input row, functional-equation factor row, zeta-application row, transport, replay, provenance, and local name.

The Lean TasteGate boundary is `lean4/BEDC/Derived/GammaZetaFactorSealUp/TasteGate.lean`. It must provide explicit `Nontrivial GammaZetaFactorSealUp` and `FieldFaithful GammaZetaFactorSealUp` instances so downstream zeta functional-equation routes can consume the same finite seal packet without collapsing the Gamma-domain, reflected-input, factor, application, transport, replay, provenance, and naming rows.

Closure status for $\mathsf{NameCert}_{\mathsf{GammaZetaFactorSeal}^{\uparrow}}$.

Constructive story: A $\mathsf{GammaZetaFactorSeal}^{\uparrow}$ packet is generated from Gamma-domain, reflected-input, functional-equation factor, zeta-application, componentwise transport, displayed continuation, provenance, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{GammaZetaFactorSeal}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1101.1, Definition 1101.2, Definition 1101.3, Definition 1101.4, the falsifiable prediction, and the independence witness bind the finite Gamma-factor seal consumed by zeta functional-equation routes.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{GammaZetaFactorSeal}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close the full constructive Gamma function, the zeta functional equation, meromorphic uniqueness, nontrivial-zero classification, Lean verification, or bridge checking.

Upgrade path: Obligation closure requires explicit carrier, NameCert, readback, non-escape, TasteGate, Nontrivial, and FieldFaithful theorems for the displayed Gamma-Zeta factor seal.

Chapter 1102

A Concrete Naming Certificate for $\mathsf{SubstitutionBoundaryAudit}^{\uparrow}$

The $\mathsf{SubstitutionBoundaryAudit}^{\uparrow}$ packet realizes the substitution audit map of chapter 9380 as finite NameCert data. It consumes the closed shift and substitution boundary of chapter 527, the authorized generator surface of chapter 525, and the gap-closure boundary of chapter 1006. Its role is to expose exactly the rows by which a closed shift or closed substitution route may be audited before a consumer reads the operation result.

Definition 1102.1 (SubstitutionBoundaryAudit carrier)**.** *A* $\mathsf{SubstitutionBoundaryAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (T, V, d, C_{\mathsf{src}}, C_{\mathsf{val}}, Q, R, L, E, H, C, P, N)$$

with the following displayed rows:

1. *T is the closed source-term row whose boundary is being audited;*
2. *V is the closed value row used by a substitution route, or the inert value row for a shift-only route;*
3. *d is the displayed depth row at which shift or substitution is read;*
4. *C_{src} is the closedness witness for the source term at depth d;*
5. *C_{val} is the closedness witness for the value row at the same audit boundary;*
6. *Q is the shift-boundary row recording the closed shift operation and its classifier read;*
7. *R is the substitute-boundary row recording the closed substitution operation and its classifier read;*
8. *L is the audit ledger for operation order, closed composition, and generator-closure classification;*
9. *E is the audit-exposure row that must be read before either Q or R is exported to a downstream consumer;*
10. *H records componentwise* hsame *transport for the term, value, depth, closedness, operation, ledger, exposure, provenance, and local naming rows;*
11. *C records displayed* Cont *routes for closedness reads, shift reads, substitution reads, ledger reads, and audit exposure;*

12. *P is the* Pkg *provenance over chapter 9380,* $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$, $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$, $\mathsf{GapClosureBoundary}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*;*
13. *N is the local* $\mathsf{NameCert}_{\mathsf{SubstitutionBoundaryAudit}^{\uparrow}}$ *row.*

The carrier has no coordinate for an open source term, host substitution semantics, subject reduction, unrestricted generator recursion, hidden evaluator state, or a gap discharge outside the displayed packet.

Lean4 ✓ `BEDC.Derived.SubstitutionBoundaryAuditUp.SubstitutionBoundaryAuditTasteGate single carrier alignment`

Theorem 1102.2 (SubstitutionBoundaryAudit NameCert obligations)**.** *For the carrier of Definition 1102.1, the local* $\mathsf{NameCert}_{\mathsf{SubstitutionBoundaryAudit}^{\uparrow}}$ *surface consists exactly of carrier admission, classifier stability, closedness-read order, audit non-escape, and consumer exactness for*

$$A = (T, V, d, C_{\mathsf{src}}, C_{\mathsf{val}}, Q, R, L, E, H, C, P, N).$$

Carrier admission exposes all displayed rows; classifier stability keeps the shift row Q and substitute row R attached to the same term, value, and depth rows; closedness-read order places C_{src} and C_{val} before either operation row; audit non-escape forces L, E, H, C, P, N to travel with the operation reads; consumer exactness says that every accepted consumer of Q or R reads only this packet.

Proof. Carrier admission is projection from Definition 1102.1. The displayed tuple lists the source, value, depth, closedness, operation, ledger, exposure, transport, continuation, provenance, and local naming rows.

Classifier stability follows from the closed shift and substitution boundary of chapter 527. Both operation rows are read at the same displayed term, value, and depth boundary, so no second classifier source is available.

Closedness-read order is the route through C_{src} and C_{val}. The authorized generator surface of chapter 525 contributes only the permitted generator-closure classifier rows recorded in L and does not supply a replacement closedness witness.

Audit non-escape is the row E together with the ledger, transport, continuation, provenance, and local name rows L, H, C, P, N. The gap-closure boundary of chapter 1006 remains a sibling refusal surface: it can be cited as a boundary, but it is not discharged by this packet.

Finally, consumer exactness follows because Q and R are the only operation rows and E is their shared audit-exposure gate. Any accepted consumer route for a closed shift or substitution result therefore factors through the displayed packet and nowhere else. □

Theorem 1102.3 (SubstitutionBoundaryAudit falsifiable route)**.** *Any accepted* $\mathsf{SubstitutionBoundaryAudit}^{\uparrow}$ *consumer route that reaches Q or R must expose both the relevant closedness rows $C_{\mathsf{src}}, C_{\mathsf{val}}$ and the audit ledger L before the operation row. A route that reaches Q or R while bypassing those rows is not an accepted carrier route.*

Lean4 ✓ `BEDC.Derived.SubstitutionBoundaryAuditUp.SubstitutionBoundaryAuditCarrier falsifiable route`

Proof. Start with Definition 1102.2. It places closedness-read order and audit non-escape among the local certificate obligations.

If a route reaches the shift row Q, the classifier stability clause ties Q to $T, d, C_{\mathsf{src}}, L, E$ and to the displayed transport and continuation rows. The shift read therefore cannot be consumed before the source closedness and ledger rows are visible.

If a route reaches the substitute row R, the same obligation surface ties R to $T, V, d, C_{\mathsf{src}}, C_{\mathsf{val}}, L, E$. The value closedness row is part of the substitution boundary, so a consumer that bypasses it is outside the carrier.

Thus the prediction is refuted exactly by a counter-route that accepts Q or R without the relevant closedness and ledger rows. Such a route would contradict the displayed NameCert surface rather than extend it. □

Theorem 1102.4 (SubstitutionBoundaryAudit independence witness)**.** *The carrier of Definition 1102.1 is not bijective, row for row, to any of* $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$, $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$, $\mathsf{GapClosureBoundary}^{\uparrow}$, *or* $\mathsf{MetaCICNormalizationFrontier}^{\uparrow}$. *A bijection preserving local NameCert obligations would have to preserve the dedicated audit-exposure row E coupled to both the shift boundary row Q and the substitute boundary row R, and no listed sibling carries exactly that joint exposure surface.*

Proof. Compare first with $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$. That sibling supplies the closed shift and substitution boundary rows, but it does not isolate a separate audit-exposure row E whose only role is to gate both operation rows before downstream use.

Compare next with $\mathsf{AuthorizedGeneratorRecursor}^{\uparrow}$ and $\mathsf{GapClosureBoundary}^{\uparrow}$. The generator sibling supplies permitted generator-recursion rows, while the gap sibling records a closure boundary. Neither carries the paired shift and substitute operation rows together with the closedness, ledger, and exposure order required here.

Finally compare with $\mathsf{MetaCICNormalizationFrontier}^{\uparrow}$. It records candidate and endpoint normalization routes with obstruction retention, not the term/value/depth substitution audit packet. Since each sibling omits at least one of Q, R, L, E or carries a different endpoint surface, no carrier bijection can preserve all NameCert obligations. □

Falsifiable prediction: Any accepted SubstitutionBoundaryAuditUp consumer route that reaches Q or R must expose both the relevant ClosedAt rows and the audit ledger before the operation row; a counter-route bypassing those rows refutes the chapter.

Independence witness: closedtermsubstitutionboundary, authorizedgeneratorrecursor, gapclosureboundary, metacicnormalizationfrontier: the audit carrier is not bijective to any sibling because it has a dedicated audit-exposure row E coupled to both shift and substitute boundary reads.

The later Lean TasteGate file will provide $\mathsf{Nontrivial\ SubstitutionBoundaryAudit}^{\uparrow}$ with two explicit witness packets, one for a shift audit route and one for a substitute audit route, and $\mathsf{FieldFaithful\ SubstitutionBoundaryAudit}^{\uparrow}$ by matching and injection over the displayed fields $T, V, d, C_{\mathsf{src}}, C_{\mathsf{val}}, Q, R, L$

Closure status for $\mathsf{NameCert}_{\mathsf{SubstitutionBoundaryAudit}^{\uparrow}}$ **·**

Constructive story: A $\mathsf{SubstitutionBoundaryAudit}^{\uparrow}$ packet is generated from a source term, value row, depth row, closedness witnesses, shift and substitute boundary rows, audit ledger, audit-exposure row, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{SubstitutionBoundaryAudit}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1102.1, Definition 1102.2, Definition 1102.3, and Definition 1102.4 display the finite NameCert surface for closed shift and substitution audit routes.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{SubstitutionBoundaryAudit}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close subject reduction, unrestricted substitution commutation, open-term substitution semantics, generator recursion, gap discharge, or bridge checking for $\mathsf{SubstitutionBoundaryAudit}^{\uparrow}$.

Upgrade path: Obligation closure requires a Lean carrier encoding, checked NameCert obligation theorem, checked route theorem, independence theorem, and TasteGate nontriviality with field faithfulness for the same audit packet.

Chapter 1103

A Concrete Naming Certificate for $\mathsf{WitnessedDescentLedger}^{\uparrow}$

Falsifiable prediction: Every public downward use of an upward name factors through the displayed witness row of an accepted $\mathsf{WitnessedDescentLedger}^{\uparrow}$ packet.

Independence witness: russellboundary, definitedescriptionboundary, contextualclassreading, russellanalysisladder: the witnessed-descent ledger is not bijective to any sibling because it isolates the source, bridge, descent request, witness, transport, provenance, and local NameCert rows for downward use, while the siblings bind the full Russell boundary, description-expansion boundary, contextual-class reading, or analysis ladder surface.

The $\mathsf{WitnessedDescentLedger}^{\uparrow}$ packet realizes the witnessed-descent restriction of chapter 9457 as a concrete NameCert surface. It sits beside the definite-description boundary of chapter 661: that chapter controls when a description may be consumed as denoting, while this chapter controls when an already licensed upward name may be read downward by a consumer.

The packet also consumes the neighboring Russell surfaces. $\mathsf{RussellBoundary}^{\uparrow}$ supplies the five-fold boundary, $\mathsf{ContextualClassReading}^{\uparrow}$ supplies scoped classifier reading, and $\mathsf{RussellAnalysisLadder}^{\uparrow}$ supplies the analysis-spine context in which witnessed descent is one row among the full Russell discipline. The ledger below isolates the descent row itself so later real, rational-sequence, and bridge-readback consumers can cite a finite witness route rather than a slogan about harmless level passage.

Definition 1103.1 (Witnessed-descent ledger carrier)**.** *A* $\mathsf{WitnessedDescentLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (S, B, D, W, H, C, P, N)$$

with the following displayed rows:

1. *S is the source row naming the upward interface whose public name is being consumed;*
2. *B is the bridge row naming the stratum passage from the upward interface to the downward consumer boundary;*
3. *D is the descent-request row recording the requested downward use of the upward name;*
4. *W is the witness row certifying that this particular downward use is licensed;*
5. *H records componentwise* hsame *transport for source, bridge, descent request, witness, continuation, provenance, and local name rows;*

6. *C records the displayed* Cont *replay by which a consumer moves from S through B, D, W and returns to the local ledger;*
7. *P is the* Pkg *provenance over* BHist*, upward names, bridge rows, descent requests, witnesses,* hsame*,* Cont*, and* NameCert*;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{WitnessedDescentLedger}^{\uparrow}}$ *row.*

The carrier has no coordinate for a stratum collapse, host identity between source and target, reducibility principle, quotient equality, proof-irrelevance shortcut, or unrecorded downward read.

Lean4 (definition) `BEDC.Derived.WitnessedDescentLedgerUp.WitnessedDescentLedgerUp`
Lean4 ✓ `BEDC.Derived.WitnessedDescentLedgerUp.WitnessedDescentLedgerTasteGate single carrier alignment`

Theorem 1103.2 (Witnessed-descent NameCert obligations)**.** *For the carrier of Definition 1103.1, the local* $\mathsf{NameCert}_{\mathsf{WitnessedDescentLedger}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$L = (S, B, D, W, H, C, P, N),$$

source exposure through S, bridge exposure through B, descent-request accountability through D, witness exposure through W, componentwise transport through H, continuation replay through C, package provenance through P, local naming through N, and non-collapse of the upward and downward strata.

Lean4 ✓ `BEDC.Derived.WitnessedDescentLedgerUp.WitnessedDescentLedgerNamecertObligations`

Proof. Carrier admission is projection from Definition 1103.1. The source, bridge, request, witness, transport, replay, provenance, and local name are all displayed rows of the same finite packet.

The source and bridge obligations are S and B. They identify which upward name is being consumed and which stratum passage is in scope before any downward read can proceed.

The request and witness obligations are D and W. A consumer may ask for a downward read only through D, and the read is licensed only by the displayed witness row W.

Finally H, C, P, N keep the read local to the packet. They transport, replay, cite, and name the same descent route, and no row remains from which a collapse, quotient equality, proof-irrelevance shortcut, or unrecorded downward use could be extracted. □

Theorem 1103.3 (Witnessed-descent public readback)**.** *Every public downward read of an accepted* $\mathsf{WitnessedDescentLedger}^{\uparrow}$ *packet factors through the rows*

$$S, B, D, W, H, C, P, N.$$

In particular, the read exposes the source upward name, the bridge row, the descent request, the witness row, componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *row before the downward consumer receives the name.*

Proof. Start from the NameCert obligations of Definition 1103.2. They list the complete row surface available to a public consumer.

The downward read must first identify its source through S and its bridge through B. It must then record the requested use through D and expose the certificate witness through W.

The structural rows H, C, P, N preserve that route as a finite BEDC packet. Since the carrier has no hidden coordinate for source-target identity, external reducibility, quotient equality, or unrecorded witness selection, every public downward read factors through the displayed ledger. □

Lean4 ✓ `BEDC.Derived.WitnessedDescentLedgerUp.WitnessedDescentLedgerPublicReadback`

Theorem 1103.4 (Witnessed-descent sibling boundary)**.** *The* $\mathsf{WitnessedDescentLedger}^{\uparrow}$ *packet is a sibling of* $\mathsf{RussellBoundary}^{\uparrow}$, $\mathsf{DefiniteDescriptionBoundary}^{\uparrow}$, $\mathsf{ContextualClassReading}^{\uparrow}$, *and* $\mathsf{RussellAnalysisLadder}^{\uparrow}$, *not a replacement for them. It consumes their boundary, description, contextual, and ladder surfaces only as neighboring rows and exports exactly the descent ledger rows* S, B, D, W, H, C, P, N *for downstream bridge-readback consumers.*

Lean4 ✓ `BEDC.Derived.WitnessedDescentLedgerUp.WitnessedDescentLedgerSiblingBoundary`

Proof. Read the neighboring chapters as separate NameCert surfaces. $\mathsf{RussellBoundary}^{\uparrow}$ binds the fivefold Russell discipline, $\mathsf{DefiniteDescriptionBoundary}^{\uparrow}$ binds description-expansion use, $\mathsf{ContextualClassReading}^{\uparrow}$ binds scoped class-like readings, and $\mathsf{RussellAnalysisLadder}^{\uparrow}$ binds the analysis-spine packet.

The witnessed-descent ledger projects only the descent route. Its carrier names the source, bridge, request, witness, transport, replay, provenance, and local name rows needed by a downward consumer.

Therefore no sibling is collapsed into this packet and this packet is not a full Russell boundary. It is the concrete descent ledger that later consumers may cite when an upward name is read downward. □

Theorem 1103.5 (Displayed witness accountability)**.** *Every accepted* $\mathsf{WitnessedDescentLedger}^{\uparrow}$ *carrier* $L = (S, B, D, W, H, C, P, N)$ *accounts for a downward read only through the displayed witness row* W*. The TasteGate-facing carrier alignment records that the single carrier exposed to downstream consumers is the same finite packet whose rows display the source, bridge, descent request, witness, transport, replay, provenance, and local naming data.*

Proof. Use the carrier of Definition 1103.1. The descent request row D records the requested downward use, while W is the only row licensing that particular use.

The checked TasteGate alignment keeps the public carrier from being replaced by a detached event-flow presentation. Thus every consumer that reads the carrier reads the same displayed W row before any downward name is available.

The structural rows H, C, P, N then transport, replay, source, and name this route. Since the carrier omits unrecorded downward reads and proof-irrelevance shortcuts, witness accountability is exactly the displayed-row obligation. □

Lean4 ✓ `BEDC.Derived.WitnessedDescentLedgerUp.WitnessedDescentLedgerDisplayedWitnessAccountability`

Theorem 1103.6 (Witnessed-descent noncollapse transport)**.** *Componentwise* hsame *transport for an accepted* $\mathsf{WitnessedDescentLedger}^{\uparrow}$ *packet preserves the separation between the source row* S*, bridge row* B*, descent-request row* D*, and witness row* W*. It never identifies the upward source stratum with the downward consumer boundary, and it never converts the witness row into quotient equality or proof-irrelevant reducibility.*

Lean4 ✓ `BEDC.Derived.WitnessedDescentLedgerUp.WitnessedDescentLedgerNoncollapseTransport`

Proof. Read transport through the row H in Definition 1103.1. It is componentwise: source, bridge, request, witness, continuation, provenance, and local name rows are transported as separate displayed coordinates.

The non-collapse claim follows from this row separation. Transport can preserve the finite route from S through B, D, W, but it has no coordinate that turns the bridge into identity between strata.

Finally replay through C and source through P, N. The omitted coordinates exclude quotient equality, proof irrelevance, and reducibility, so the transported packet remains a witnessed descent ledger rather than a collapse principle. □

Theorem 1103.7 (Witnessed-descent bridge-readback exhaustion)**.** *Every bridge-readback consumer of an accepted* $\mathsf{WitnessedDescentLedger}^{\uparrow}$ *packet must inspect the finite route*

$$S, B, D, W, H, C, P, N$$

before it can consume the downward name. The route exhausts the readback surface: there is no additional bridge row, hidden witness selector, global descent rule, quotient equality, or identity between upward and downward strata available to the consumer.

Proof. Start from the public readback theorem Definition 1103.3. It already forces every public downward read through the source, bridge, descent request, witness, transport, replay, provenance, and local NameCert rows.

For a bridge-readback consumer, the bridge row B is therefore not optional. The consumer reaches the requested downward use only after D and the displayed witness W have been inspected.

The remaining rows H, C, P, N close the route inside the packet. Since no second bridge row, selector, global rule, quotient equality, or stratum identity coordinate exists, the listed route exhausts the bridge-readback surface. □

Lean4 ✓ `BEDC.Derived.WitnessedDescentLedgerUp.WitnessedDescentLedgerBridgeReadbackExhaustion`

Closure status for $\mathsf{NameCert}_{\mathsf{WitnessedDescentLedger}^{\uparrow}}$.

Constructive story: A $\mathsf{WitnessedDescentLedger}^{\uparrow}$ packet is generated from a source upward-name row, a bridge row, a descent-request row, a witness row, componentwise hsame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{WitnessedDescentLedger}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1103.1, Definition 1103.2, Definition 1103.3, Definition 1103.4, Definition 1103.5, Definition 1103.6, and Definition 1103.7 bind the complete mature paper-side route through finite source, bridge, request, witness, public readback, noncollapse transport, and bridge-readback exhaustion rows for downward use of upward names.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{WitnessedDescentLedger}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Not claimed: This chapter does not prove Lean-side formal verification, a checked standard bridge, a global descent rule, a reducibility principle, quotient equality, proof irrelevance, or identity between upward and downward strata.

Upgrade path: The paper-side route is mature; verification-axis progress requires Lean-side checking of carrier admission, witness-row exactness, public readback factorization, sibling noncollapse, noncollapse transport, and bridge-readback exhaustion.

Chapter 1104

Stationary Window Seal Exhaustion Name Certificate Construction

The $\mathsf{StationaryWindowSealExhaustion}^{\uparrow}$ packet realizes the transported stationary finite-window seal of chapter 9238 as a single finite $\mathsf{NameCert}$ carrier. It packages the rational seed, constant stream window, regular-rational seal readback, dyadic ledger, real-facing seal, exhaustion row, transport rows, continuations, provenance, and local naming so that downstream RealUp seal consumers read one L10 surface rather than five disconnected public readings. The route consumes the sibling packet surfaces of chapter 37, chapter 126, chapter 301, chapter 291, and chapter 38, and remains adjacent to $\mathsf{DiagonalCofinalTail}^{\uparrow}$ and $\mathsf{StationaryWindowLattice}^{\uparrow}$.

Definition 1104.1 (Stationary window seal exhaustion carrier)**.** *A* $\mathsf{StationaryWindowSealExhaustion}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (Q, S, R, D, W, E, H, C, P, N)$$

with the following displayed rows:

1. *Q is the paired* $\mathsf{Rat}^{\uparrow}$ *seed row, including the two rational history carriers and their transported* $\mathsf{RatHistoryClassifier}$ *row;*
2. *S is the constant* $\mathsf{StreamName}^{\uparrow}$ *finite-window row induced by Q;*
3. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *finite-window seal consumption row over the same stream window;*
4. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *observation ledger for that window;*
5. *W is the* $\mathsf{Real}^{\uparrow}$ *finite-window classifier row reached only through S, R, D;*
6. *E is the transported stationary seal exhaustion row of Definition 9238.18;*
7. *H records componentwise* hsame *transports for Q, S, R, D, W, E and the structural rows;*
8. *C records the displayed* Cont *routes from Q to S, from S to R, from R to D, from D to W, and from E to each public reading;*
9. *P is the* Pkg *provenance over* $\mathsf{Rat}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{DiagonalCofinalTail}^{\uparrow}$, $\mathsf{StationaryWindowLattice}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$*;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{StationaryWindowSealExhaustion}^{\uparrow}}$ *row.*

The carrier has no coordinate for an unbounded window family, a selected limit, quotient-stream equality, host real equality, or an ambient completeness principle.

Lean4 ✓ BEDC.Derived.StationaryWindowSealExhaustionUp.TasteGate.StationaryWindowSealExhaustionTasteGate
single carrier alignment

Theorem 1104.2 (Stationary window seal exhaustion NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{StationaryWindowSea}}$ *surface for Definition 1104.1 consists exactly of carrier admission for* $L = (Q, S, R, D, W, E, H, C, P, N)$*,* $\mathsf{Rat}^{\uparrow}$ *seed exposure through* Q*,* $\mathsf{StreamName}^{\uparrow}$ *constant-window exposure through* S*,* $\mathsf{RegSeqRat}^{\uparrow}$ *seal consumption exposure through* R*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger exposure through* D*,* $\mathsf{Real}^{\uparrow}$ *finite-window classifier exposure through* W*, transported stationary exhaustion through* E*, componentwise* hsame *transport through* H*, displayed* Cont *replay through* C*,* Pkg *provenance through* P*, and local naming through* N*.*

Proof. Carrier admission is projection from the packet L. The five public readings are exactly Q, S, R, D, W, and the exhaustion row E names the theorem that forces those readings to agree with the same transported rational seed.

Apply Definition 9238.18. It identifies the certified finite observation window with the RatUp seed classifier, StreamNameUp constant-window classifier, RegSeqRatUp finite-window seal consumption row, DyadicRatCoreUp observation ledger, and RealUp finite-window classifier.

The structural rows H, C, P, N preserve that single route under componentwise transport, continuation replay, package provenance, and local naming. Since the carrier has no extra selector, quotient, host-equality, or completeness coordinate, the listed rows exhaust the local NameCert obligations. □

Theorem 1104.3 (Stationary window seal exhaustion L10 handoff)**.** *Every accepted downstream consumer that reads the transported stationary seal through* $\mathsf{StationaryWindowSealExhaustion}^{\uparrow}$ *receives precisely the finite L10 packet*

$$L = (Q, S, R, D, W, E, H, C, P, N).$$

The consumer first reads the $\mathsf{Rat}^{\uparrow}$ *seed row, then the* $\mathsf{StreamName}^{\uparrow}$ *finite window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger, the* $\mathsf{Real}^{\uparrow}$ *seal row, the transported exhaustion row, componentwise transports, continuation replay, provenance, and local naming. The handoff exports no second carrier, hidden selector, quotient-stream equality, host real equality, or ambient completion theorem.*

Proof. Project the accepted carrier of Definition 1104.1. This gives the displayed L10 rows $Q, S, R, D, W, E, H, C, P, N$ and no further public coordinates.

Use Definition 1104.2. It binds the five public readings to the same local naming surface and routes them through the transported stationary exhaustion theorem.

Finally compose with the finite faces already consumed by $\mathsf{DiagonalCofinalTail}^{\uparrow}$ and $\mathsf{StationaryWindowLattice}^{\uparrow}$. Those sibling surfaces read the same RatUp seed, StreamName window, RegSeqRat readback, DyadicRatCore ledger, and RealUp seal rows, so a downstream consumer can only receive the single packet L before using the transported stationary seal. □

Falsifiable prediction: Any accepted consumer that reads the transported stationary seal without the RatUp seed, StreamName window, RegSeqRat readback, DyadicRatCore ledger, and RealUp seal rows refutes the $\mathsf{StationaryWindowSealExhaustion}^{\uparrow}$ packet.

Independence witness: transportedstationarydiagonal, stationarywindowlattice, diagonalcofinaltail, realtailagreementseal, and realcompletionselectorseal: none is bijective to StationaryWindowSealExhaustion because this carrier alone stores the five public readings together with the exhaustion row, transport rows, continuation replay, provenance, and local naming as one L10 handoff.

The Lean realization must provide Nontrivial and FieldFaithful instances in `lean4/BEDC/Derived/StationaryW` before the packet can be promoted to a checked TasteGate surface.

Closure status for $\mathsf{NameCert}_{\mathsf{StationaryWindowSealExhaustion}^{\uparrow}}$.

Constructive story: A $\mathsf{StationaryWindowSealExhaustion}^{\uparrow}$ packet is generated from a paired rational seed row, constant StreamName finite-window row, RegSeqRat seal-consumption row, DyadicRatCore ledger, RealUp finite-window classifier, transported stationary exhaustion row, componentwise hsame transports, displayed Cont routes, provenance, and local naming. The carrier reads five public faces of the same stationary window and binds them through the exhaustion row. The same finite route is preserved when the packet is handed to downstream RealUp seal consumers. The classifier hands them one finite L10 route: rational seed, stream window, regular readback, dyadic ledger, Real seal, transport, replay, provenance, and name.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{StationaryWindowSealExhaustion}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the stationary window seal exhaustion carrier, NameCert obligations, L10 handoff theorem, prediction, and independence witness.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{StationaryWindowSealExhaustion}^{\uparrow}}, \mathsf{axiomClean})$

Lean target: `BEDC.Derived.StationaryWindowSealExhaustionUp.TasteGate.StationaryWindowSealExhaustionTasteGate\_sin`

Bridge status: none

Origin: ai

Not claimed: It does not claim unbounded window families, selected limits, quotient-stream equality, host real equality, or ambient completeness.

Upgrade path: To reach obligationClosure, formalize the five-face stationary window handoff and transported exhaustion row as a checked finite carrier.

Chapter 1105

A Concrete Naming Certificate for $\mathsf{InterHistSynchronizationRefusal}^{\uparrow}$

The $\mathsf{InterHistSynchronizationRefusal}^{\uparrow}$ packet realizes the no-global-clock boundary of chapter 9418 as a finite two-stream certificate. It consumes the local stream carrier of chapter 603, the observer-Hist identity carrier of chapter 479, and the locality-transport carrier of chapter 889. Its role is to name the refusal of a proposed synchronization token without replacing the two local Hist streams by a shared clock, host time index, quotient stream, or real-completion timing oracle.

Definition 1105.1 (InterHistSynchronizationRefusal carrier)**.** *An* $\mathsf{InterHistSynchronizationRefusal}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$S = (A, B, T, R, H, C, P, N)$$

with the following displayed rows:

1. *A is the first local* $\mathsf{HistTimeStream}^{\uparrow}$ *row, read as a finite* BHist *stream with its own* Cont*-step ledger;*
2. *B is the second local* $\mathsf{HistTimeStream}^{\uparrow}$ *row, read as a finite* BHist *stream with its own* Cont*-step ledger;*
3. *T is the proposed synchronization token whose admission is refused by this packet;*
4. *R is the refusal ledger recording that T is not a shared clock, host time index, quotient stream, global synchronization row, or real-completion timing oracle;*
5. *H records componentwise* hsame *transport for the two local streams, token row, refusal ledger, route rows, provenance row, and local naming row;*
6. *C records displayed* Cont *replay for reading A, B, T, R, H, P, and N;*
7. *P is the* Pkg *provenance over* $\mathsf{InterHistSynchronizationRefusal}^{\uparrow}$, $\mathsf{HistTimeStream}^{\uparrow}$, $\mathsf{ObserverHistIdentity}^{\uparrow}$, $\mathsf{ObserverLocalityTransport}^{\uparrow}$, $\mathsf{ObserverFrameRefusal}^{\uparrow}$, $\mathsf{ObserverFilter}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
8. *N is the local* $\mathsf{NameCert}_{\mathsf{InterHistSynchronizationRefusal}^{\uparrow}}$ *row.*

The carrier has no coordinate for a common clock value, common index set, host-time comparison, quotient of the two streams, synchronized observer frame, or real-number completion time.

Theorem 1105.2 (InterHistSynchronizationRefusal NameCert obligations)**.** *For the carrier of Definition 1105.1, the local* $\mathsf{NameCert}_{\mathsf{InterHistSynchronizationRefusal}^{\uparrow}}$ *surface consists exactly of five finite rows:*

1. *carrier admission for* $S = (A, B, T, R, H, C, P, N)$*;*
2. *two local-stream readbacks, one through* A *and one through* B*;*
3. *refusal-ledger exactness for the proposed synchronization token* T *through* R*;*
4. *componentwise* hsame *stability through* H *and displayed* Cont *replay through* C*;*
5. *no-global-clock non-escape through* P *and* N*, which keeps every consumer inside the two local streams and the refusal ledger.*

Lean4 ✓ BEDC.Derived.InterHistSynchronizationRefusalUp.InterHistSynchronizationRefusalTasteGate
single carrier alignment

Proof. Carrier admission is projection from Definition 1105.1. The packet lists the two local stream rows, the proposed synchronization token, the refusal ledger, transport, replay, provenance, and local naming row.

The two positive readbacks are A and B. The negative readback is R, which records the exact status of T as refused synchronization data rather than an admitted clock coordinate.

The structural rows H, C, P, N preserve that split. Transport and replay act componentwise on the displayed rows, while provenance and local naming certify that the consumer has not inserted a shared clock outside the packet. □

Theorem 1105.3 (InterHistSynchronizationRefusal no-global-clock boundary)**.** *Any consumer of an accepted* InterHistSynchronizationRefusal$^{\uparrow}$ *packet may read only the two local streams* A *and* B*, the proposed synchronization token* T *as refused data, the refusal ledger* R*, the componentwise* hsame *transport* H*, the displayed* Cont *replay* C*, the* Pkg *provenance* P*, and the local* NameCert *row* N*. The consumer never receives a shared clock, host time index, quotient stream, global synchronization row, synchronized observer frame, or real-completion timing oracle.*

Proof. Project the carrier of Definition 1105.1. Its rows are exactly A, B, T, R, H, C, P, N, with A and B giving the local streams and R giving the refusal status of T.

Apply the NameCert obligations of Definition 1105.2. The admissible reads are the two local-stream readbacks, refusal-ledger exactness, componentwise transport, displayed replay, provenance, and local naming.

No displayed row is a shared clock, host time index, quotient stream, global synchronization row, synchronized observer frame, or real-completion timing oracle. A consumer that exports one of those objects has introduced data not present in the accepted packet. □

Falsifiable prediction: If the refusal row is removed while the two local streams remain, the packet can still name two HistTimeStream rows but cannot block a consumer from treating them as synchronized.

Independence witness: Nearest siblings: histtimestream, observerhistidentity, observerlocalitytransport, observerframerefusal, and observerfilter. HistTimeStreamUp names one local stream rather than a two-stream refusal; ObserverHistIdentityUp identifies observer with Hist but does not carry a synchronization token; ObserverLocalityTransportUp transports locality rows but does not reject a shared clock; ObserverFrameRefusalUp rejects a frame but not the two-stream synchronization token; ObserverFilterUp selects observation rows without naming a clock-refusal carrier. No bijection preserving two local streams, refusal token, refusal ledger, hsame transport, Cont replay, provenance, and local naming identifies these packets.

The Lean site `lean4/BEDC/Derived/InterHistSynchronizationRefusalUp/TasteGate.lean` must provide explicit Nontrivial InterHistSynchronizationRefusal$^{\uparrow}$ and FieldFaithful InterHistSynchronizationRefusal$^{\uparrow}$ instances. These instances must preserve the two local streams, proposed synchronization token, refusal ledger, componentwise hsame transport, displayed Cont replay, provenance, and local naming row as distinguishable fields.

Closure status for $\mathsf{NameCert}_{\mathsf{InterHistSynchronizationRefusal}^{\uparrow}}$.

Constructive story: An InterHistSynchronizationRefusal$^{\uparrow}$ packet is generated from two local HistTimeStream rows, a proposed synchronization token, refusal ledger, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The BHist carrier records the two local streams as visible data and then refuses the token that would identify them by a shared clock. Each accepted read keeps both stream rows and the refusal token in the same packet. The classifier accepts the two-stream packet only with the refusal ledger attached, so transport and continuation replay preserve locality rather than manufacturing synchronized observer time or a global frame.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{InterHistSynchronizationRefusal}^{\uparrow}}$, seed)

Scope closed: This chapter binds the inter-Hist synchronization refusal carrier, non-escape theorem, prediction, and independence witness.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{InterHistSynchronizationRefusal}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim shared clocks, host time indices, quotient streams, global synchronization rows, synchronized frames, or real-completion timing oracles.

Upgrade path: To reach obligationClosure, check the two local streams and refusal token as distinguishable nontrivial and field-faithful rows.

Chapter 1106

A Concrete Naming Certificate for NoGlobalSynchronizationLedger$^{\uparrow}$

The NoGlobalSynchronizationLedger$^{\uparrow}$ packet realizes the no-global-synchronization premise of Definition 9419.4 as a positive finite ledger row. It is downstream of NoGlobalSyncBoundary$^{\uparrow}$ but not the same object: the boundary records that a global synchronization object is refused, while the ledger records the accepted local rows that consume that refusal in inter-Hist locality, causal-rate, and observer-transport chapters. The ledger consumes the no-global-sync boundary of chapter 1003 and the local read-site carrier of chapter 509 before handing the refusal row to inter-Hist, causal-rate, and observer-transport consumers.

Falsifiable prediction: Any accepted inter-Hist consumer that reads a shared synchronization Hist or global clock row refutes the ledger packet.

Independence witness: Nearest siblings: noglobalsyncboundary, localitycell, observerlocalitytransport, interhistinvariant, crosshistcausal. None is bijective because the ledger has a positive no-global-sync refusal row consumed by locality and rate chapters, while the siblings either record a boundary, a locality cell, an invariant, or a causal route without this carrier row.

Definition 1106.1 (NoGlobalSynchronizationLedger carrier)**.** *A* NoGlobalSynchronizationLedger$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (H_0, H_1, R, B, O, I, K, S, C, P, N)$$

with the following displayed rows:

1. *H_0 and H_1 are the two source history rows whose local reads are compared;*
2. *R is the positive no-global-synchronization refusal row, recording that no shared synchronization* BHist*, global clock, privileged frame, total observer order, or selected all-observer map is admitted;*
3. *B is the* NoGlobalSyncBoundary$^{\uparrow}$ *boundary row whose refusal surface is being consumed;*
4. *O is the* LocalityCell$^{\uparrow}$ *row that binds the two local read sites before a causal or rate consumer can read them;*
5. *I is the* InterHistInvariant$^{\uparrow}$ *row that receives the displayed local comparison without adding a global frame;*
6. *K is the downstream consumer row for* CrossHistCausal$^{\uparrow}$*,* ObserverLocalityTransport$^{\uparrow}$*, or* MaxCausalRate$^{\uparrow}$*;*

7. *S records componentwise* hsame *transport for the histories, refusal row, boundary row, locality cell, invariant row, consumer row, routes, provenance, and local name;*
8. *C records displayed* Cont *replay for reading exactly those rows;*
9. *P is the* Pkg *provenance over* $\mathsf{NoGlobalSynchronizationLedger}^{\uparrow}$, $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$, $\mathsf{LocalityCell}^{\uparrow}$, $\mathsf{ObserverLocalityTransport}^{\uparrow}$, $\mathsf{InterHistInvariant}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{NoGlobalSynchronizationLedger}^{\uparrow}}$ *row.*

The carrier has no coordinate for a shared synchronization history, global clock, privileged host frame, total observer order, quotient of histories, metric spacetime, host equality oracle, or selected limit.

Lean4 ✓ `BEDC.Derived.NoGlobalSynchronizationLedgerUp.NoGlobalSynchronizationLedgerTasteGate single carrier alignment`

Theorem 1106.2 (NoGlobalSynchronizationLedger NameCert obligations)**.** *For the carrier of Definition 1106.1, the local* $\mathsf{NameCert}_{\mathsf{NoGlobalSynchronizationLedger}^{\uparrow}}$ *surface consists of carrier admission for*

$$L = (H_0, H_1, R, B, O, I, K, S, C, P, N),$$

refusal exactness through R, boundary consumption through B, observer-locality exposure through O, invariant readback through I, downstream handoff through K, componentwise hsame *transport through S, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.NoGlobalSynchronizationLedgerUp.NoGlobalSynchronizationLedgerUp namecert obligations`

Proof. Carrier admission is projection from Definition 1106.1. The rows $H_0, H_1, R, B, O, I, K, S, C, P, N$ are exactly the histories, refusal row, boundary row, locality row, invariant row, consumer row, transport, replay, provenance, and naming surface.

The refusal and boundary obligations are separate. The row R is the positive ledger coordinate saying which global synchronization data are absent from the accepted packet, while B records the boundary packet from which that refusal is inherited.

The locality, invariant, and consumer obligations then read O, I, K after the two source histories and the refusal row have been displayed. The structural rows S, C, P, N transport, replay, package, and name the same finite packet, so no further NameCert obligation remains outside the listed coordinates. □

Theorem 1106.3 (NoGlobalSynchronizationLedger consumer non-escape)**.** *Every accepted* NoGlobalSynchronizatio *consumer route factors through*

$$H_0, H_1, R, B, O, I, K, S, C, P, N.$$

It may read the two source histories, the positive no-global-synchronization refusal row, the boundary row, the locality cell, the invariant row, the downstream causal or rate consumer row, displayed hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* NameCert *row. It exports no shared synchronization* BHist*, global clock, privileged frame, total observer order, metric spacetime, quotient history, host equality oracle, or selected limit.*

Lean4 ✓ `BEDC.Derived.NoGlobalSynchronizationLedgerUp.NoGlobalSynchronizationLedgerUp consumer nonescape`

Proof. Inspect the carrier coordinates in Definition 1106.1. The only positive rows are H_0, H_1, O, I, K together with the structural rows S, C, P, N.

The row R is not a hidden synchronization object; it is the refusal ledger. The row B is the boundary source for the same refusal. Thus a consumer can cite global synchronization only as excluded data and only through the displayed refusal route.

No coordinate of the packet is a shared synchronization BHist, global clock, privileged frame, total observer order, metric spacetime, quotient history, host equality oracle, or selected limit. Therefore any consumer exporting such a coordinate has left the accepted ledger packet. □

Theorem 1106.4 (NoGlobalSynchronizationLedger inter-Hist handoff)**.** *Every accepted* NoGlobalSynchronizationLe *packet supplies the no-global-frame premise required by* CrossHistCausal$^{\uparrow}$, ObserverLocalityTransport$^{\uparrow}$, *and* MaxCausalRate$^{\uparrow}$ *consumers. The handoff is the displayed route from the two source histories through the refusal row R, the boundary row B, the locality cell O, the invariant readback I, and the consumer row K, transported by S and replayed by C.*

Proof. Start with the local NameCert surface of Definition 1106.2. It exposes R and B before any locality, invariant, causal, transport, or rate consumer can read the packet.

Next read the locality and invariant rows. The locality cell O binds the two source histories as local sites, and the invariant row I receives their comparison without inserting a global frame.

Finally project the consumer row K and the structural rows S, C, P, N. These rows make the same refusal ledger available to CrossHistCausal$^{\uparrow}$, ObserverLocalityTransport$^{\uparrow}$, and MaxCausalRate$^{\uparrow}$ consumers, while Definition 1106.3 excludes shared clocks, global frames, metric spacetime, quotient histories, and host equality as alternate handoff data. □

Lean4 ✓ `BEDC.Derived.NoGlobalSynchronizationLedgerUp.NoGlobalSynchronizationLedgerUp inter hist handoff`

Theorem 1106.5 (NoGlobalSynchronizationLedger TasteGate obligation)**.** *The later Lean site* `lean4/BEDC/Derived/NoGlobalSynchronizationLedgerUp/TasteGate.lean` *must provide explicit* Nontrivial NoGlobalSynchronizationLedger$^{\uparrow}$ *and* FieldFaithful NoGlobalSynchronizationLedger$^{\uparrow}$ *instances. These instances must keep the two source histories, the positive refusal row, boundary row, locality cell, invariant row, downstream consumer row,* hsame *transport,* Cont *routes,* Pkg *provenance, and local* NameCert *row as distinguishable fields.*

Proof. The carrier separates the source histories H_0, H_1 from the refusal row R, boundary row B, locality row O, invariant row I, and consumer row K. A trivial collapse would identify refusal data with the local histories or with the consumer handoff, erasing the no-global-synchronization premise needed downstream.

Field faithfulness is the projection discipline for $L = (H_0, H_1, R, B, O, I, K, S, C, P, N)$. Each coordinate has a distinct consumer role, so a later TasteGate witness must preserve those projections before any locality, causal-rate, or transport chapter consumes the ledger. □

Closure status for NameCert$_{\text{NoGlobalSynchronizationLedger}^{\uparrow}}$.

Constructive story: A NoGlobalSynchronizationLedger$^{\uparrow}$ packet is generated from two source histories, a positive no-global-synchronization refusal row, a NoGlobalSyncBoundary row, a locality cell, an inter-Hist invariant readback row, a causal or rate consumer row, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{NoGlobalSynchronizationLedger}^{\uparrow}}$, seed)

Scope closed: Definition 1106.1, Definition 1106.2, Definition 1106.3, and Definition 1106.4 specify the finite no-global-synchronization ledger consumed by inter-Hist locality, causal, transport, and rate chapters.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{NoGlobalSynchronizationLedger}^{\uparrow}}, \text{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not construct a shared synchronization history, global clock, privileged frame, total observer order, metric spacetime, quotient history, Lean proof, or bridge checking for $\mathsf{NoGlobalSynchronizationLedger}^{\uparrow}$.

Upgrade path: Obligation closure requires a Lean carrier encoding, checked NameCert obligation theorem, consumer non-escape theorem, inter-Hist handoff theorem, and TasteGate nontriviality with field faithfulness.

Chapter 1107

A Concrete Naming Certificate for $\mathsf{ExternalSupplyAuditRoute}^{\uparrow}$

The $\mathsf{ExternalSupplyAuditRoute}^{\uparrow}$ packet realizes the non-axiom supply discipline of chapter 9395 as a finite NameCert audit route. It sits beside the boundary packet of chapter 1065, the admission classifier of chapter 1074, the GAP-facing closure boundary of chapter 1006, and the inscription ledger surface of chapter 520. Those siblings expose boundary names, admissible forms, ledger closure, or inscription gaps; the audit route binds the displayed boundary form, witness route, non-axiom ledger, and local NameCert obligations in one consumer-visible packet.

Definition 1107.1 (ExternalSupplyAuditRoute carrier)**.** *An* $\mathsf{ExternalSupplyAuditRoute}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (B, W, G, L, H, P, N)$$

with the following displayed rows:

1. *B is the boundary-form row, recording the strongest non-axiom form accepted for the requested supply;*
2. *W is the witness-route row, recording the finite route by which a consumer reaches the displayed supply boundary;*
3. *G is the* GAP*-ledger row preserving the residue or socket pressure generated by the request;*
4. *L is the local route-classifier ledger, recording whether B, W, G are all present before the route may be accepted;*
5. *H records componentwise* hsame *transport for the boundary-form, witness-route, GAP-ledger, and classifier rows;*
6. *P is the* Pkg *provenance over* $\mathsf{ExternalSupplyBoundary}^{\uparrow}$, $\mathsf{NonAxiomBoundaryForm}^{\uparrow}$, $\mathsf{NonAxiomAdmission}^{\uparrow}$, $\mathsf{InscriptionGapLedger}^{\uparrow}$, $\mathsf{GapClosureBoundary}^{\uparrow}$, BHist, hsame, Pkg, *and* NameCert *rows;*
7. *N is the local* $\mathsf{NameCert}_{\mathsf{ExternalSupplyAuditRoute}^{\uparrow}}$ *row.*

The carrier has no coordinate for an axiom, hidden selector, quotient representative, proposition-equality token, unledgered supply witness, or host-side admission outside B, W, G, L, H, P, N.

Lean4 ✓ `BEDC.Derived.ExternalSupplyAuditRouteUp.ExternalSupplyAuditRouteTasteGate single carrier alignment`

Theorem 1107.2 (ExternalSupplyAuditRoute non-axiom boundary)**.** *Every accepted* $\mathsf{ExternalSupplyAuditRoute}^{\uparrow}$ *packet exposes an external-supply request only through its displayed non-axiom boundary form. A downstream consumer may read the boundary form B, the witness route W, the* GAP *ledger G, the route-classifier ledger L, the componentwise* hsame *row H, the package row P, and the local* NameCert *row N, but it receives no axiom, hidden selector, quotient representative, proposition-equality token, or host-side admission of the requested supply.*

Lean4 ✓ `BEDC.Derived.ExternalSupplyAuditRouteUp.ExternalSupplyAuditRouteCarrier nonaxiom boundary`

Proof. Project the carrier of Definition 1107.1. The accepted packet displays B, W, G, L, H, P, N before any consumer can read the route.

Use the distinction in Definition 9395.2 and Definition 9395.4. The boundary-form row B records which non-axiom form carries the request, while W records the finite route to that boundary.

Now read G and L. The GAP row preserves the residue or socket pressure, and the classifier ledger records acceptance only when the boundary form, witness route, and GAP ledger are present together.

The structural rows H, P, N transport, package, and name only those displayed rows. Since no coordinate stores an axiom or hidden supply witness, the accepted route keeps the requested supply external. □

Theorem 1107.3 (ExternalSupplyAuditRoute ledger non-escape)**.** *No accepted* $\mathsf{ExternalSupplyAuditRoute}^{\uparrow}$ *packet can be consumed as a supply route without its ledger row. If the route classifier reads a packet missing G, then the packet fails the route classifier and cannot expose a witness route as an accepted non-axiom supply boundary.*

Proof. Start from the carrier definition. The classifier ledger L is a row over the displayed triple B, W, G, not over the boundary form and witness route alone.

Apply the non-axiom boundary theorem above. It permits downstream reads only through B, W, G, L, H, P, N, so the GAP ledger is part of the public route rather than an optional annotation.

If G is absent, the route classifier cannot certify that the requested supply remained ledgered. The packet therefore has no accepted $\mathsf{ExternalSupplyAuditRoute}^{\uparrow}$ read and cannot be consumed as a non-axiom supply route. □

Lean4 ✓ `BEDC.Derived.ExternalSupplyAuditRouteUp.ExternalSupplyAuditRouteUp ledger nonescape`

Theorem 1107.4 (ExternalSupplyAuditRoute NameCert obligations)**.** *For the carrier of Definition 1107.1, the local* $\mathsf{NameCert}_{\mathsf{ExternalSupplyAuditRoute}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$A = (B, W, G, L, H, P, N),$$

boundary-form exposure through B, witness-route exposure through W, GAP-ledger readback through G, classifier-ledger readback through L, componentwise hsame *stability through H, package provenance through P, and local naming through N.*

Consequently a certificate consumer may audit which boundary form was accepted, which finite route witnesses the boundary, which ledger records the residue, and which local rows stabilize the route, but it may not read unlisted supply content.

Proof. Carrier admission is immediate from Definition 1107.1. The displayed packet lists exactly B, W, G, L, H, P, N.

The first obligation group exposes the supply boundary without internalizing it: B names the accepted non-axiom form, W names the route to the boundary, and G keeps the ledger pressure visible.

The second obligation group stabilizes the route. The classifier ledger L records that the route is accepted only with the ledger present, while H, P, N provide componentwise transport, provenance, and local naming over the same finite packet.

By Definition 1107.3, omitting the ledger row prevents route acceptance. Thus the NameCert obligations are exhausted by the displayed rows and do not supply any hidden content. □

Theorem 1107.5 (ExternalSupplyAuditRoute GAP-ledger factorization)**.** *Every accepted* ExternalSupplyAuditRou *packet factors its accepted route through the displayed boundary form B, witness route W,* GAP *ledger G, classifier ledger L, componentwise transport H, provenance P, and local* NameCert *row N. Before any consumer reads the route, the provenance row must pass through* ExternalSupplyBoundary$^{\uparrow}$, NonAxiomBoundaryForm$^{\uparrow}$, NonAxiomAdmission$^{\uparrow}$, InscriptionGapLedger$^{\uparrow}$, *and* GapClosureBoundary$^{\uparrow}$.

Consequently the accepted audit route cannot expose an axiom, hidden selector, unledgered supply witness, quotient representative, proposition-equality token, or host-side admission outside the finite packet $A = (B, W, G, L, H, P, N)$.

Proof. Project the carrier of Definition 1107.1. The only accepted route coordinates are the boundary-form row B, witness route W, GAP ledger G, classifier ledger L, transport row H, package provenance P, and local naming row N.

Apply Definition 1107.2. It restricts every downstream read of the external supply request to the displayed non-axiom boundary form and the rows that stabilize it.

Next use Definition 1107.3. The route cannot be accepted without G, so the supply witness is read only after the GAP ledger and classifier ledger have both been displayed.

Finally apply Definition 1107.4. The local certificate packages B, W, G, L, H, P, N over the provenance chain through ExternalSupplyBoundary$^{\uparrow}$, NonAxiomBoundaryForm$^{\uparrow}$, NonAxiomAdmission$^{\uparrow}$, InscriptionGapLedger$^{\uparrow}$, and GapClosureBoundary$^{\uparrow}$. Since no additional carrier coordinate exists, no consumer can extract an axiom, hidden selector, unledgered supply witness, quotient representative, proposition-equality token, or host-side admission. □

Falsifiable prediction: Any accepted ExternalSupplyAuditRoute packet missing the ledger row fails the route classifier.

Independence witness: Compare inscriptionevent, kernelacceptanceauditwitness, gapclosure-boundary, and inscriptiongapledger: none is bijective because none carries all boundary-form, witness-route, non-axiom ledger, and local NameCert rows.

The Lean follow-up must provide explicit Nontrivial ExternalSupplyAuditRoute$^{\uparrow}$ and FieldFaithful ExternalSupplyA instances in Derived/ExternalSupplyAuditRouteUp/TasteGate.lean before the alignment theorem BEDC.Derived.Exter can be cited by a checked paper marker.

Closure status for NameCert$_{\text{ExternalSupplyAuditRoute}^{\uparrow}}$.

Constructive story: An ExternalSupplyAuditRoute$^{\uparrow}$ packet is generated from a boundary-form row, witness-route row, non-axiom ledger, audit classifier, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The carrier reads external supply through an auditable route: first the boundary form is displayed, then the witness route is inspected, then the ledger records why the request remains non-axiomatic. The package row records the surrounding inscription and gap surfaces consumed by the audit. The classifier rejects any route missing the ledger row, because transport and continuation replay preserve the route only as ledgered finite BEDC data.

Theory closure: TheoryGate(NameCert$_{\text{ExternalSupplyAuditRoute}^{\uparrow}}$, scopedClosed)

Scope closed: This chapter binds the boundary-form row, witness-route row, GAP-ledger row, classifier ledger, componentwise hsame, displayed Cont, Pkg, NameCert, and the cited TasteGate marker as the scoped external-supply audit route.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{ExternalSupplyAuditRoute}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: It does not claim direct internal supply, unledgered witness routes, hidden axiom admission, or theorem content outside the displayed boundary route.

Upgrade path: Public closure requires a public-object boundary and checked transport, replay, provenance, and local naming coverage for the displayed external-supply audit route.

Chapter 1108

A Concrete Naming Certificate for MetaCICNormalizationCertificateRouter$^{\uparrow}$

The MetaCICNormalizationCertificateRouter$^{\uparrow}$ packet realizes the candidate-mediated route inventory of chapter 9383 as a finite NameCert router. It sits beside MetaCICNormalizationFrontier$^{\uparrow}$, ClosedTermSubstitutionBoundary$^{\uparrow}$, AuthorizedGeneratorRecursor$^{\uparrow}$, GroundCompilerRecognizerFlow$^{\uparrow}$, and KernelInductiveAcceptance$^{\uparrow}$: those siblings expose frontier, closed-substitution, generator, compiler-flow, and inductive-acceptance rows, while this packet chooses which displayed normalization evidence is present before any closed-term normalization read is admitted.

The exact concrete carrier rows consumed by the router are supplied by chapter 892, chapter 527, chapter 525, chapter 1048, and chapter 915.

Thus the router bundles the normalization-frontier, closed-substitution, authorized-generator, compiler-recognizer, and kernel-inductive-acceptance rows into one routing surface rather than claiming a new atomic carrier.

Definition 1108.1 (MetaCIC normalization certificate router carrier)**.** *A* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *carrier is a finite* BHist *packet*

$$R = (A, K, S, P, D, U, G, L, H, C, Q, N)$$

with the following displayed rows:

1. *A is the audit-map anchor row for chapter 9383;*
2. *K is the candidate-evidence row, including candidate, closed-candidate, and candidate-set evidence;*
3. *S is the strong-normalization consequence row read only from K;*
4. *P is the Pi and application adequacy row that keeps function, argument, and application candidates on the displayed route;*
5. *D is the closed-term projection row consumed through* ClosedTermSubstitutionBoundary$^{\uparrow}$*;*
6. *U is the authorized generator handoff row consumed through* AuthorizedGeneratorRecursor$^{\uparrow}$*;*
7. *G is the compiler recognizer row consumed through* GroundCompilerRecognizerFlow$^{\uparrow}$*;*
8. *L is the kernel inductive-acceptance row consumed through* KernelInductiveAcceptance$^{\uparrow}$*;*
9. *H records componentwise* hsame *transport for the evidence, projection, adequacy, generator, compiler, acceptance, route, provenance, and local naming rows;*

10. *C records displayed* Cont *replay from candidate evidence to strong normalization and from strong normalization to no-infinite-reduction projections;*
11. *Q records* Pkg *provenance over* MetaCICNormalizationFrontier$^{\uparrow}$, ClosedTermSubstitutionBoundary$^{\uparrow}$, AuthorizedGeneratorRecursor$^{\uparrow}$, GroundCompilerRecognizerFlow$^{\uparrow}$, KernelInductiveAcceptance$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}}$ *row.*

The carrier has no coordinate for evidence-free closed-term strong normalization, unconditional application normalization, host normalization, quotient reduction equality, or a normalization oracle outside the displayed router.

Theorem 1108.2 (MetaCIC normalization certificate router obligation surface)**.** *For the carrier of Definition 1108.1, the local* $\mathsf{NameCert}_{\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}}$ *surface consists exactly of candidate-evidence admission through K, strong-normalization readback through S, Pi and application adequacy through P, closed-term projection through D, authorized generator handoff through U, compiler recognizer handoff through G, kernel inductive-acceptance handoff through L, route replay through C, componentwise transport through H, provenance through Q, and local naming through N.*

Lean4 ✓ `BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterUp single carrier alignment`

Proof. Project the carrier coordinates. The router admits normalization reads only after the audit anchor A and candidate evidence K have been displayed, and the row S is downstream of that evidence rather than a separate global theorem.

The adequacy and closed-term rows are then finite consumers. The row P records Pi and application adequacy, while D records the closed-term projection through the sibling ClosedTermSubstitutionBoundary$^{\uparrow}$ surface.

Finally attach the producer and acceptance rows. The rows U, G, L keep authorized generation, compiler recognition, and kernel inductive acceptance on the same packet, and H, C, Q, N provide only transport, replay, provenance, and local naming. Since no other row is present, the listed rows exhaust the local certificate surface. □

Theorem 1108.3 (MetaCIC normalization certificate router closed-read refusal)**.** *A closed-term normalization read of an accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *packet is refused unless the displayed route contains candidate evidence, closed-candidate evidence, or candidate-set evidence in K. The rows $P, D, U, G, L, H, C, Q, N$ may route, project, transport, replay, and package such evidence, but none of them can replace K by an evidence-free normalization theorem.*

Lean4 ✓ `BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterClose`

Proof. Read the evidence side first. By Definition 1108.2, the strong-normalization row S is reachable only from the candidate-evidence row K.

Now inspect the sibling rows. MetaCICNormalizationFrontier$^{\uparrow}$ supplies the candidate-frontier boundary, ClosedTermSubstitutionBoundary$^{\uparrow}$ supplies the closed projection row, AuthorizedGeneratorRecursor$^{\uparrow}$ supplies the authorized generator handoff, GroundCompilerRecognizerFlow$^{\uparrow}$ supplies the compiler recognizer flow, and KernelInductiveAcceptance$^{\uparrow}$ supplies the inductive acceptance row. Each is consumed as a displayed row of the router rather than as a source of evidence-free normalization.

The structural rows cannot change that dependency. Transport, replay, provenance, and local naming preserve the already displayed route, so a closed-term normalization request with no candidate, closed-candidate, or candidate-set evidence has no carrier coordinate from which to read S. □

Definition 1108.4 (Normalization candidate router evidence budget)**.** *For an accepted* MetaCICNormalizationCertif *carrier*

$$R = (A, K, S, P, D, U, G, L, H, C, Q, N),$$

the candidate-mediated evidence budget is the displayed finite read

$$K, D, P, U, G, L, H, C, Q, N.$$

Here K supplies candidate, closed-candidate, or candidate-set evidence; D supplies the closed-candidate projection through $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$*; P supplies Pi and application adequacy; U supplies the authorized-generator handoff; G supplies the compiler-recognizer handoff; L supplies kernel inductive acceptance; and H, C, Q, N supply transport, replay, provenance, and local naming for the same packet.*

The budget is finite row data inside the carrier and has no coordinate for subject reduction, global confluence, host normalization, quotient reduction equality, or evidence-free normalization.

Theorem 1108.5 (Normalization candidate router evidence-budget non-escape)**.** *Every closed-normalization consumer of an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *carrier must spend the finite evidence budget of Definition 1108.4 before it reads strong-normalization output from S. The packet exports no subject reduction theorem, global confluence theorem, host normalization theorem, quotient reduction equality, or evidence-free normalization route outside*

$$K, D, P, U, G, L, H, C, Q, N.$$

Proof. Start with the carrier and obligation surface. The carrier of Definition 1108.1 exposes $K, D, P, U, G, L, H, C, Q, N$ as separate finite rows, and Definition 1108.2 places candidate evidence before the strong-normalization readback.

Apply the closed-read refusal. Theorem 1108.3 refuses any closed normalization read with no candidate, closed-candidate, or candidate-set evidence in K, so a consumer cannot reach S without first entering the displayed evidence side.

Now use candidate determinacy. Theorem 1108.6 fixes S from the evidence in K, while D, P, U, G, L only project, check adequacy, generate, recognize, and accept that same route. Transport, replay, provenance, and naming through H, C, Q, N preserve the displayed budget.

The refused endpoints are therefore absent by inspection of the carrier coordinates. Since no row names subject reduction, global confluence, host normalization, quotient reduction equality, or an evidence-free normalizer, the closed-normalization consumer must spend exactly the finite budget before any strong-normalization output is read. □

Theorem 1108.6 (MetaCIC normalization certificate router candidate determinacy)**.** *For an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *carrier, the strong-normalization readback row S is determined by the displayed candidate, closed-candidate, or candidate-set evidence in K. The closed projection, Pi and application adequacy, generator, compiler, acceptance, transport, replay, provenance, and local naming rows may preserve and route that evidence, but they do not create a second source for S.*

Lean4 ✓ `BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterCandi determinacy`

Proof. Project the carrier of Definition 1108.1. The row K is the only carrier coordinate containing candidate, closed-candidate, or candidate-set evidence, and S is declared as the readback row downstream of it.

Apply the obligation surface and closed-read refusal theorems. Theorem 1108.2 lists K before the strong-normalization readback, and Definition 1108.3 refuses any closed read lacking such evidence.

The Lean TasteGate marker attached to the obligation surface records the single-carrier alignment for the same router. Thus the paper route and the checked carrier site agree that S has no evidence-free source outside K. □

Theorem 1108.7 (MetaCIC normalization certificate router adequacy evidence source)**.** *Every Pi or application adequacy read in the row P of an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *carrier factors through candidate, closed-candidate, or candidate-set evidence displayed in K. The rows D, U, G, L, H, C, Q, N project, generate, recognize, accept, transport, replay, package, and name that evidence; none of those rows exports a closed normalization read without the candidate evidence already present in K.*

Proof. Project the carrier of Definition 1108.1. The row P is the Pi and application adequacy consumer, and the only evidence row upstream of the strong-normalization readback is K.

Use the obligation surface and closed-read refusal. Theorem 1108.2 places candidate admission in K before S and P, while Definition 1108.3 rejects any closed read with no candidate, closed-candidate, or candidate-set evidence.

Apply candidate determinacy. Theorem 1108.6 determines the readback S from the evidence in K, so P can only preserve that evidence along Pi and application routes. The remaining rows project, generate, recognize, accept, transport, replay, package, and name the same displayed route, and therefore no evidence-free closed normalization read is exported. □

Theorem 1108.8 (MetaCIC normalization certificate router adequacy chain)**.** *The Pi and application adequacy rows P of an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *carrier can route only evidence already admitted by K. They cannot turn function, argument, application, generator, compiler, or kernel-acceptance rows into evidence-free normalization reads.*

Lean4 ✓ `BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterAdequ`

Proof. Read the candidate row first. By Definition 1108.1, the adequacy row P is a consumer of the displayed candidate-evidence row K, not a replacement for it.

Apply candidate determinacy. Theorem 1108.6 pins the strong-normalization readback S to evidence in K, so adequacy can only preserve and transmit that already displayed evidence.

Now compare with the sibling separation theorem. Theorem 1108.12 separates this router from the frontier, closed-substitution, generator, compiler-flow, and kernel-acceptance siblings, so none of those rows can be treated as an independent normalization source. □

Theorem 1108.9 (MetaCIC normalization certificate router projection coverage)**.** *The closed-term projection row D of an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *carrier covers exactly the displayed* $\mathsf{ClosedTermSubstitutionBoundary}^{\uparrow}$ *consumer route. It projects candidate-mediated normalization evidence into the closed-term boundary and exposes no additional closed-term normalization principle outside the rows admitted by K and routed by P.*

Proof. Project the carrier row D. In Definition 1108.1, D is the closed-term projection row consumed through ClosedTermSubstitutionBoundary$^{\uparrow}$.

Use the obligation surface. Theorem 1108.2 places D beside the candidate-evidence row K and adequacy row P, so the projection is a consumer route rather than a new source of evidence.

Apply closed-read refusal and sibling separation. Theorem 1108.3 blocks any closed read without evidence in K, and Definition 1108.12 prevents collapsing the router to the closed-substitution sibling alone. Hence D covers exactly the displayed closed-term substitution boundary route. □

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterProje

Theorem 1108.10 (MetaCIC normalization certificate router route coverage)**.** *For an admitted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *read, strong-normalization output is reachable only through the ordered finite route*

$$A, K, S, P, D, U, G, L, H, C, Q, N.$$

Here K supplies candidate, closed-candidate, or candidate-set evidence; D supplies the closed projection; U supplies authorized generation; G supplies compiler recognition; and L supplies kernel inductive acceptance. No sibling row replaces K by an evidence-free normalization theorem.

Proof. Project the carrier of Definition 1108.1. The row inventory is exactly $A, K, S, P, D, U, G, L, H, C, Q, N$, with S downstream of K rather than a standalone normalization fact.

Use the obligation-surface theorem, Definition 1108.2, to exhaust the rows. It places candidate-evidence admission in K, Pi and application adequacy in P, the closed projection in D, authorized generation in U, compiler recognition in G, and kernel inductive acceptance in L.

Now apply closed-read refusal, Definition 1108.3. A closed-term normalization read without candidate, closed-candidate, or candidate-set evidence has no route to S.

Finally compare the sibling rows. ClosedTermSubstitutionBoundary$^{\uparrow}$, AuthorizedGeneratorRecursor$^{\uparrow}$, GroundCompilerRecognizerFlow$^{\uparrow}$, and KernelInductiveAcceptance$^{\uparrow}$ contribute projection, generation, compiler, and acceptance evidence respectively, but none is the candidate-evidence row K. Transport, replay, provenance, and naming preserve the same ordered route, so the admitted read cannot bypass K. □

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterRoute
Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterPacke
route coverage

Theorem 1108.11 (MetaCIC normalization certificate router kernel scope)**.** *Every accepted* MetaCICNormalization *read must expose the audit anchor A, candidate evidence K, strong-normalization readback S, Pi and application adequacy P, closed projection D, authorized generator U, compiler recognizer G, inductive acceptance L, componentwise* hsame *transport H, displayed* Cont *replay C,* Pkg *provenance Q, and local* NameCert *row N before any normalization output is read. Thus the router is scoped to the finite kernel packet carried by $A, K, S, P, D, U, G, L, H, C, Q, N$, not to a host normalization principle.*

Proof. Project the carrier of Definition 1108.1. Its displayed rows are exactly $A, K, S, P, D, U, G, L, H, C, Q, N$, and the strong-normalization readback row S is downstream of the candidate-evidence row K.

Apply route coverage. Theorem 1108.10 orders every admitted normalization output through the displayed route, while Definition 1108.14 keeps the generator and compiler recognizer rows inside the same packet.

Finally use the inductive-acceptance scope theorem. It binds the L row to the audit anchor, candidate evidence, closed projection, generator, compiler, transport, replay, provenance, and local

naming rows. Hence no normalization output can be read before the finite kernel-scope surface is displayed. □

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterKerne

Theorem 1108.12 (MetaCIC normalization certificate router sibling separation)**.** *The* MetaCICNormalizationCertif *carrier is not bijective, row for row, with any one of* MetaCICNormalizationFrontier$^{\uparrow}$, ClosedTermSubstitutionBoundar AuthorizedGeneratorRecursor$^{\uparrow}$, GroundCompilerRecognizerFlow$^{\uparrow}$, *or* KernelInductiveAcceptance$^{\uparrow}$. *A bijection preserving local NameCert obligations would have to preserve simultaneous candidate evidence, closed projection, Pi and application adequacy, authorized generator handoff, compiler recognition, kernel acceptance, and no-infinite-reduction routing, and no listed sibling carries that whole surface.*

Proof. Compare first with MetaCICNormalizationFrontier$^{\uparrow}$. The frontier sibling supplies candidate and endpoint boundary rows, but it does not also carry the closed-substitution projection, authorized generator handoff, compiler recognizer handoff, and kernel inductive acceptance rows.

Compare next with ClosedTermSubstitutionBoundary$^{\uparrow}$ and AuthorizedGeneratorRecursor$^{\uparrow}$. These siblings supply closed projection and generator authority respectively, while neither contains the candidate-evidence router with Pi and application adequacy plus no-infinite-reduction replay.

Finally compare with GroundCompilerRecognizerFlow$^{\uparrow}$ and KernelInductiveAcceptance$^{\uparrow}$. Those rows record compiler-flow and inductive-acceptance surfaces, not the simultaneous normalization evidence router. Since each sibling omits at least one of K, S, P, D, U, G, L, no row-preserving bijection can preserve the router obligations. □

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouter sibling separation

Theorem 1108.13 (MetaCIC normalization certificate router obligation package)**.** *For every accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *carrier*

$$R = (A, K, S, P, D, U, G, L, H, C, Q, N),$$

the obligation package exposed by R consists exactly of the audit anchor A, candidate-evidence row K, strong-normalization readback row S, Pi and application adequacy row P, closed-term projection row D, authorized generator handoff row U, compiler recognizer row G, kernel inductive-acceptance row L, componentwise transport row H, displayed replay row C, provenance row Q, and local naming row N.

Proof. Project the carrier coordinates in the order displayed by Definition 1108.1. The rows A, K, S, P, D, U, G, L provide the audit anchor, evidence, readback, adequacy, projection, generator, compiler, and acceptance obligations.

The structural rows then close the package. Transport through H is componentwise, replay through C follows the displayed route, provenance through Q records the sibling certificates named at the start of the chapter, and N supplies the local NameCert row. Since no further coordinate is present, the listed rows are the complete obligation package. □

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterOblig

Theorem 1108.14 (MetaCIC normalization certificate router generator-compiler route)**.** *Every generator-to-compiler read exported by an accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *carrier factors through the authorized generator handoff U, the compiler recognizer row G, the kernel*

inductive-acceptance row L, componentwise transport H, displayed replay C, provenance Q, and local naming N. It cannot be read as an evidence-free normalization theorem, a host compiler assertion, or a route that bypasses the candidate evidence K.

Lean4 ✓ `BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterGener`

Proof. First inspect the producer rows. The authorized generator handoff is the row U, while the compiler recognizer handoff is the row G; both are visible only as coordinates of the same finite carrier that also displays K and S.

Next attach the acceptance and structural rows. The row L records kernel inductive acceptance, and H, C, Q, N preserve, replay, source, and name the same route. Thus any generator-to-compiler read remains inside the displayed packet and has no coordinate from which to extract evidence-free normalization or a detached host compiler claim. □

Theorem 1108.15 (MetaCIC normalization certificate router inductive acceptance scope)**.** *The inductive-acceptance contribution of an accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *carrier is scoped to the displayed L row together with the audit anchor A, candidate evidence K, closed projection D, generator handoff U, compiler recognizer row G, transport H, replay C, provenance Q, and local naming N. It does not close global MetaCIC normalization, quotient reduction equality, host normalization, or unconditional closed-term normalization outside that finite route.*

Lean4 ✓ `BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterInduc`

Proof. Read the scope from the sibling dependencies. KernelInductiveAcceptance$^{\uparrow}$ contributes the row L, while MetaCICNormalizationFrontier$^{\uparrow}$, ClosedTermSubstitutionBoundary$^{\uparrow}$, AuthorizedGeneratorRecursor$^{\uparrow}$, and GroundCompilerRecognizerFlow$^{\uparrow}$ contribute the candidate, closed-projection, generator, and compiler-facing rows named in the chapter introduction.

The router preserves those rows as one finite packet. Componentwise transport, displayed replay, provenance, and local naming do not add a global normalization coordinate, so the inductive-acceptance read remains scoped to the displayed route and refuses the excluded host and quotient claims. □

Theorem 1108.16 (MetaCIC normalization certificate router residual candidate coverage)**.** *Every residual normalization read accepted by a* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *carrier exposes candidate, closed-candidate, or candidate-set evidence in the row K before the Pi and application adequacy row P, closed projection row D, authorized generator row U, compiler recognizer row G, and kernel acceptance row L may contribute to the displayed route. The structural rows H, C, Q, N preserve that candidate-mediated route by componentwise* hsame, Cont *replay,* Pkg *provenance, and local* NameCert *naming, but they do not introduce a residual normalization read outside K.*

Proof. Start with the obligation surface. Theorem 1108.2 lists candidate-evidence admission through K before the readback, adequacy, projection, generator, compiler, and acceptance rows, so every accepted residual read has a displayed evidence coordinate.

Apply the refusal and determinacy clauses. Theorem 1108.3 rejects closed reads with no candidate, closed-candidate, or candidate-set evidence, while Definition 1108.6 determines the strong-normalization readback from the evidence in K.

It remains to account for the route rows. Theorem 1108.10 orders the finite route through $A, K, S, P, D, U, G, L, H, C, Q, N$, and Definition 1108.15 keeps the kernel-acceptance contribution scoped to that displayed packet. Hence $P, D, U, G, L, H, C, Q, N$ can only transmit a residual read already mediated by K. □

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterResid

Theorem 1108.17 (MetaCIC normalization certificate router residual determinacy)**.** *If two accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *packets expose the same authorized-generator row U, closed-term substitution boundary D, normalization frontier rows K, S, P, and residual candidate rows carried by K, then every candidate-mediated normalization read selects the same displayed residual route up to the packet classifier. No hidden redex choice, host reduction equality, quotient reduction row, or evidence-free normalizer can separate the two reads.*

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterResid

Proof. Start with candidate determinacy. Theorem 1108.6 determines the strong-normalization readback from the candidate evidence in K, and Definition 1108.16 requires every residual read to be mediated by that displayed evidence.

Project the shared rows. Projection coverage and route coverage identify the finite route through $A, K, S, P, D, U, G, L, H, C, Q, N$, while the common D, U and normalization-frontier rows fix the closed-substitution boundary, authorized-generator handoff, and candidate frontier seen by the read.

It remains only to exclude hidden selectors. The carrier has no coordinate for an external redex choice, host reduction equality, quotient reduction, or evidence-free normalizer, and the structural rows H, C, Q, N only transport, replay, source, and name the displayed route. Hence the two packets select the same residual route up to their packet classifier. □

Theorem 1108.18 (MetaCIC normalization certificate router residual readback boundary)**.** *Every residual readback consumed from an accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *carrier must expose candidate evidence in K, closed projection through D, authorized generator evidence through U, compiler recognizer evidence through G, kernel acceptance through L, componentwise* hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through Q, and the local* NameCert *row N before any strong-normalization output in S can be consumed. No residual readback can bypass those rows through a hidden redex selector, evidence-free normalizer, host reduction equality, or quotient reduction row.*

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterResid

Proof. Begin with the obligation surface and closed-read refusal. Theorem 1108.2 lists candidate admission through K before readback, and Definition 1108.3 rejects any closed normalization read without candidate, closed-candidate, or candidate-set evidence.

Next attach route and residual coverage. Theorem 1108.10 orders the accepted route through $A, K, S, P, D, U, G, L, H, C, Q, N$, while Definition 1108.16 requires every residual read to expose the candidate row before P, D, U, G, L contribute.

Finally use residual determinacy. Theorem 1108.17 fixes the residual route once the displayed candidate, closed projection, authorized generator, and frontier rows agree. Transport, replay, provenance, and naming preserve that route, so the strong-normalization output cannot be consumed before $K, D, U, G, L, H, C, Q, N$ have been displayed. □

Theorem 1108.19 (MetaCIC normalization certificate router scoped kernel route)**.** *Every accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *read exposes the ordered finite route*

$$A, K, S, P, D, U, G, L, H, C, Q, N$$

through candidate evidence, closed projection, authorized generator, compiler recognizer, kernel acceptance, componentwise hsame*, displayed* Cont*,* Pkg*, and local* NameCert *before any normalization output is read. Thus the router binds normalization output to the BEDC kernel-facing surface and not to an evidence-free host normalizer.*

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterScope

Proof. Begin with the carrier and route coverage. The carrier definition displays $A, K, S, P, D, U, G, L, H, C, Q, N$, and Theorem 1108.10 orders any admitted strong-normalization output through that finite route.

Next apply the kernel-scope and generator-compiler routes. Theorem 1108.11 requires candidate evidence, closed projection, authorized generation, compiler recognition, and kernel inductive acceptance before a normalization output is read, while Theorem 1108.14 keeps generator-to-compiler reads inside the same displayed packet.

Finally use the inductive acceptance scope. Theorem 1108.15 binds the L row to the audit anchor, candidate evidence, closed projection, generator, compiler, transport, replay, provenance, and local naming rows. Hence every normalization read is scoped to the BEDC kernel route carried by the accepted packet. □

Theorem 1108.20 (MetaCIC normalization certificate router candidate soundness)**.** *An accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *packet may expose candidate-mediated normalization evidence only when the audit map A, candidate row K, generator row U, compiler row G, projection row D, and inductive acceptance row L all agree on the same finite* BHist *packet. If any one of those rows is absent or names a different packet, then no normalization certificate, no-infinite-reduction certificate, or public router export is available from S.*

Proof. Begin with the obligation surface and candidate determinacy. Theorem 1108.2 lists the candidate row before readback, and Definition 1108.6 determines S from the displayed candidate evidence in K.

Next attach the projection and producer rows. Projection coverage keeps D as the closed-substitution consumer of that same evidence, while the generator-compiler route keeps U and G inside the same accepted packet.

The inductive row is then scoped by Definition 1108.15. It binds L to the audit anchor, candidate evidence, closed projection, generator, compiler, transport, replay, provenance, and local naming rows rather than to a detached host kernel claim.

Finally apply the scoped kernel route. Theorem 1108.19 permits normalization output only through the ordered finite route $A, K, S, P, D, U, G, L, H, C, Q, N$. Therefore disagreement among A, K, U, G, D, L leaves no carrier coordinate from which S can export a normalization certificate, a no-infinite-reduction certificate, or a public router output. □

Theorem 1108.21 (MetaCIC normalization certificate router public export)**.** *An accepted* MetaCICNormalizationC *packet exports exactly the public router surface already scoped by its carrier: generator recursion through U, ground-compiler recognition through G, kernel-inductive acceptance through L, closed-substitution boundary reads through D, residual-candidate determinacy through K, S, P, and non-escape through H, C, Q, N. The public interface contains no new MetaCIC primitive, evidence-free normalizer, host reduction equality, quotient reduction row, or closed-term normalization read outside*

$$A, K, S, P, D, U, G, L, H, C, Q, N.$$

Proof. Start with the carrier and obligation surface. The definition displays $A, K, S, P, D, U, G, L, H, C, Q, N$, and Theorem 1108.2 identifies these rows as the complete local certificate surface.

Next use the coverage and producer routes. Theorems 1108.10 and 1108.14 keep every admitted normalization read, generator read, and compiler-recognizer read inside the same finite router packet.

The acceptance and residual clauses supply the remaining public fields. Theorem 1108.15 scopes the L row to the displayed kernel route, while Theorems 1108.16 and 1108.17 force residual normalization reads to be mediated by the candidate rows K, S, P and the closed-substitution boundary D.

Finally apply the scoped kernel route. Theorem 1108.19 binds normalization output to the BEDC kernel-facing surface, and the carrier has no coordinate for a new MetaCIC primitive, evidence-free normalizer, host equality, quotient reduction row, or closed-term normalization read outside the displayed packet. Thus the listed rows are exactly the public export surface. □

Theorem 1108.22 (MetaCIC normalization certificate router public consumer boundary)**.** *Every downstream consumer of the public* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *export must preserve the ordered route*

$$A, K, S, P, D, U, G, L, H, C, Q, N.$$

The candidate row K must supply candidate, closed-candidate, or candidate-set evidence before the generator row U, compiler row G, and acceptance row L are consumed. The consumer boundary therefore admits only candidate-mediated normalization evidence over the displayed packet and refuses evidence-free normalizers, host reduction equality, quotient reduction rows, and unconditional closed-term normalization outside that route.

Proof. Start with route coverage and the public export. Theorem 1108.10 orders every accepted read through $A, K, S, P, D, U, G, L, H, C, Q, N$, and Definition 1108.21 identifies that ordered packet as the public router surface.

Next enforce candidate visibility. The residual candidate coverage theorem, Definition 1108.16, requires K to display candidate, closed-candidate, or candidate-set evidence before P, D, U, G, L can contribute to a residual normalization read. Residual determinacy, Definition 1108.17, then keeps the chosen residual route fixed by that displayed evidence.

The projection and producer rows do not create another source. Projection coverage, Definition 1108.9, keeps D as a closed-substitution consumer of candidate-mediated evidence, while the generator-compiler route, Definition 1108.14, keeps U, G, L inside the same packet.

Finally apply the scoped kernel route, Definition 1108.19. It binds normalization output to the BEDC kernel-facing rows and leaves no carrier coordinate for evidence-free normalizers, host reduction equality, quotient reduction rows, or unconditional closed-term normalization outside $A, K, S, P, D, U, G, L, H, C, Q, N$. □

Lean4 ✓ `BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterPubli`

Theorem 1108.23 (MetaCIC normalization certificate router no-infinite-reduction public handoff)**.** *Every public* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *consumer preserving the displayed route*

$$A, K, S, P, D, U, G, L, H, C, Q, N$$

exports no-infinite-reduction evidence only through candidate evidence, closed-candidate evidence, or candidate-set evidence in K. The public handoff cannot replace those rows by an evidence-free normalizer, host reduction equality, quotient reduction row, or unconditional closed-term normalization principle.

Lean4 ✓ `BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterNoInf`

Proof. Start with route coverage and the public consumer boundary. Theorems 1108.10 and 1108.22 force every downstream read to preserve the ordered packet $A, K, S, P, D, U, G, L, H, C, Q, N$.

Next apply residual candidate coverage. Theorem 1108.16 requires candidate, closed-candidate, or candidate-set evidence in K before the adequacy, closed projection, generator, compiler, and acceptance rows may contribute to the displayed route.

The Lean-side source discipline is exactly the three no-infinite-reduction routes through candidate, closed-candidate, and candidate-set evidence. Thus a public consumer can export no-infinite-reduction only by preserving one of those evidence rows, while the carrier offers no coordinate for evidence-free normalization, host reduction equality, quotient reduction, or unconditional closed-term normalization. □

Theorem 1108.24 (MetaCIC normalization certificate router critical-pair discharge)**.** *Let $R = (A, K, S, P, D, U, G, L, H, C, Q, N)$ be an accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *carrier. Suppose a router candidate read through R passes through the sibling rows* MetaCICNormalizationFrontier$^{\uparrow}$, ClosedTermSubstitutionBoundary$^{\uparrow}$, MetaCICResidualSubstitutionBoundary$^{\uparrow}$, *and* MetaCICConfluenceCriticalPairBound *Then the read reaches a finite discharge row for the displayed residual-substitution and confluence-critical-pair boundary before any normalization certificate is exported through S or through the public route. The discharge remains inside $A, K, S, P, D, U, G, L, H, C, Q, N$ together with the named sibling boundary rows; it does not export evidence-free strong normalization, host conversion equality, quotient reduction equality, or a hidden global confluence theorem.*

Lean4 ✓ `BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterCriti`

Proof. Start from candidate determinacy and route coverage. Theorems 1108.6 and 1108.10 force every accepted normalization read to expose candidate evidence in K and to follow the ordered packet $A, K, S, P, D, U, G, L, H, C, Q, N$.

Next use the producer and residual rows. The generator-compiler route, Definition 1108.14, keeps U, G, L inside the same finite packet, while residual candidate coverage and residual determinacy, Definition 1108.16 and Definition 1108.17, keep the residual substitution read tied to the candidate, closed-substitution, and frontier rows already displayed.

Now apply the residual readback boundary and scoped kernel route. Theorem 1108.18 requires $K, D, U, G, L, H, C, Q, N$ before any residual readback can be consumed, and Definition 1108.19 keeps the resulting normalization output kernel-facing.

Finally invoke the public export and consumer boundary. Theorems 1108.21 and 1108.22 allow downstream reads only through the displayed public router surface. Therefore a candidate route that also names MetaCICResidualSubstitutionBoundary$^{\uparrow}$ and MetaCICConfluenceCriticalPairBoundary$^{\uparrow}$ must discharge those finite boundary rows before export, and no evidence-free strong normalization, host conversion equality, quotient reduction equality, or hidden confluence theorem has a carrier coordinate. □

Theorem 1108.25 (MetaCIC normalization certificate router frontier residual audit handoff)**.** *Let $R = (A, K, S, P, D, U, G, L, H, C, Q, N)$ be an accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *carrier. Any public consumer that exports either no-infinite-reduction evidence or a critical-pair discharge from R must first expose the audit anchor A, the candidate row K, the frontier row supplied by* MetaCICNormalizationFrontier$^{\uparrow}$, *the residual-substitution boundary supplied by* MetaCICResidualSubstitutionBoundary$^{\uparrow}$, *the generator and compiler rows U, G, and the kernel-acceptance row L. Hence frontier evidence, residual-substitution evidence, and audit-map evidence form one candidate-mediated route before export; the router exports no evidence-free strong normalization, host conversion equality, quotient reduction equality, or hidden confluence theorem.*

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterFront

Proof. Start with route coverage and the residual readback boundary. Theorem 1108.10 orders every accepted read through $A, K, S, P, D, U, G, L, H, C, Q, N$, while Definition 1108.18 requires $K, D, U, G, L, H, C, Q, N$ before a residual readback is consumed.

Next impose the public consumer boundary. Theorem 1108.22 keeps downstream reads on the same candidate-mediated public surface, and Definition 1108.23 permits no-infinite-reduction export only through candidate, closed-candidate, or candidate-set evidence in K.

Finally apply the critical-pair discharge. Theorem 1108.24 says that a route naming the frontier, residual-substitution, and confluence-critical-pair sibling rows must discharge those finite boundaries before public export. Combining these clauses forces any no-infinite-reduction or critical-pair consumer to pass through A, K, the frontier row, the residual-substitution boundary, U, G, and L before export, with no carrier coordinate for evidence-free strong normalization, host conversion equality, quotient reduction equality, or hidden confluence. □

Theorem 1108.26 (MetaCIC normalization certificate router evidence adequacy lock)**.** *Let $R = (A, K, S, P, D, U, G, L, H, C, Q, N)$ be an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *carrier. Any accepted residual normalization read that uses the Pi and application adequacy row P must first expose candidate, closed-candidate, or candidate-set evidence in K before any row among $P, D, U, G, L, H, C, Q, N$ contributes to residual readback. In particular, no adequacy row by itself supplies strong-normalization output, no-infinite-reduction evidence, critical-pair discharge, or kernel-facing normalization export.*

Proof. Start with the obligation surface and route coverage. Theorems 1108.2 and 1108.10 display $A, K, S, P, D, U, G, L, H, C, Q, N$ as one ordered packet, so P is not an independent adequacy oracle.

Next apply candidate determinacy and the adequacy chain. Theorem 1108.6 fixes the accepted candidate evidence in K, while Definition 1108.8 reads Pi and application adequacy only through that candidate-mediated route.

Residual coverage keeps the same boundary. The residual candidate coverage theorem forces candidate, closed-candidate, or candidate-set evidence in K before P, D, U, G, L contribute to a residual read, and Definition 1108.18 extends the same requirement across H, C, Q, N before readback.

Finally attach the public residual handoff. Theorem 1108.25 requires the audit anchor, frontier row, residual-substitution boundary, generator, compiler, and kernel-acceptance rows to remain on the same candidate-mediated route. Therefore adequacy alone cannot supply strong-normalization output or any public normalization export. □

Theorem 1108.27 (MetaCIC normalization certificate router public adequacy)**.** *Let $R = (A, K, S, P, D, U, G, L, H$ be an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *carrier. Suppose its public export surface, no-infinite-reduction handoff, critical-pair discharge, and frontier residual audit rows are all displayed. Then R exports exactly the candidate-mediated normalization certificate surface needed by downstream MetaCIC consumers: the route through $A, K, S, P, D, U, G, L, H, C, Q, N$ together with the named frontier, residual-substitution, and confluence-critical-pair boundary rows. The adequacy claim does not assert a full strong-normalization theorem, global confluence, unrestricted substitution, host conversion equality, or quotient reduction equality.*

Lean4 ✓ BEDC.Derived.MetaCICNormalizationCertificateRouterUp.MetaCICNormalizationCertificateRouterPubli

Proof. Start with the public export and consumer boundary. Theorems 1108.21 and 1108.22 identify the downstream surface as the ordered route through $A, K, S, P, D, U, G, L, H, C, Q, N$.

Attach the no-infinite-reduction handoff. Theorem 1108.23 permits such evidence only through candidate, closed-candidate, or candidate-set evidence in K, so the public route remains candidate-mediated.

Next attach the critical-pair and residual audit rows. Theorem 1108.24 discharges the displayed residual-substitution and confluence-critical-pair boundaries before export, and Definition 1108.25 forces the audit anchor, frontier row, residual-substitution boundary, generator, compiler, and kernel-acceptance rows to be visible on the same route.

The Lean TasteGate site named in this chapter records the single-carrier alignment for the origin-ai router surface. Therefore the public adequacy theorem packages the displayed exports for downstream consumers while refusing full strong normalization, global confluence, unrestricted substitution, host conversion equality, and quotient reduction equality. □

Theorem 1108.28 (MetaCIC residual SN candidate-mediated route)**.** *Let $R = (A, K, S, P, D, U, G, L, H, C, Q, N)$ be an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *packet. Every residual strong-normalization export from R must expose the audit anchor A, candidate row K, frontier row from* $\mathsf{MetaCICNormalizationFrontier}^{\uparrow}$*, residual-substitution boundary from* $\mathsf{MetaCICResidualSubstitutionBoundary}^{\uparrow}$*, generator and compiler rows U, G, kernel-acceptance row L, and structural rows H, C, Q, N before exporting strong normalization or no-infinite-reduction evidence. The adequacy rows alone cannot supply evidence-free normalization, host conversion equality, quotient reduction equality, or an unconditional closed-term normalization principle.*

Proof. Start with the public consumer boundary. Theorem 1108.22 forces every downstream read to preserve the ordered packet $A, K, S, P, D, U, G, L, H, C, Q, N$ and to keep candidate evidence visible before generator, compiler, and acceptance rows are consumed.

Attach the no-infinite-reduction public handoff. Theorem 1108.23 permits no-infinite-reduction export only through candidate, closed-candidate, or candidate-set evidence in K.

Next use the frontier residual audit handoff. Theorem 1108.25 requires the audit anchor, frontier row, residual-substitution boundary, generator row, compiler row, and kernel-acceptance row to remain on the same candidate-mediated public route.

Finally apply public adequacy. Theorem 1108.27 packages only that displayed candidate-mediated surface for downstream consumers. Since the carrier has no independent adequacy oracle or evidence-free normalization coordinate, adequacy rows alone cannot export strong normalization, no-infinite-reduction, host conversion equality, quotient reduction equality, or unconditional closed-term normalization. □

Theorem 1108.29 (MetaCIC normalization router certificate-budget discharge)**.** *Let $R = (A, K, S, P, D, U, G, L, H$ be an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *carrier. Every public read of R that reaches Definition 1108.27 must first discharge the finite* $\mathsf{NormalizationEvidenceBudget}^{\uparrow}$ *row together with the residual-substitution and critical-pair boundary rows named by the router. The discharge remains inside the displayed route*

$$A, K, S, P, D, U, G, L, H, C, Q, N$$

and the named frontier, residual-substitution, and confluence-critical-pair rows; it exports no evidence-free strong normalization, host conversion equality, quotient reduction equality, or hidden global confluence theorem.

Proof. Start with public export and public consumer boundary. Theorems 1108.21 and 1108.22 force every downstream read to preserve the ordered packet $A, K, S, P, D, U, G, L, H, C, Q, N$.

Next read the finite boundary obligations. The critical-pair discharge theorem requires the residual-substitution and confluence-critical-pair boundary rows to be discharged before a normalization certificate is exported, while Definition 1108.25 keeps the audit anchor, frontier row, residual-substitution boundary, generator, compiler, and kernel-acceptance rows on the same candidate-mediated route.

Now attach the evidence side. The evidence adequacy lock, Definition 1108.26, requires candidate, closed-candidate, or candidate-set evidence in K before adequacy, closed projection, generator, compiler, kernel acceptance, transport, replay, provenance, and local naming contribute to residual readback.

Finally use public adequacy. Theorem 1108.27 packages only the candidate-mediated router surface together with the displayed frontier, residual-substitution, and confluence-critical-pair rows. Therefore a public read reaching that theorem has already discharged the finite normalization-evidence budget and the named boundary rows, and no excluded global endpoint is exported. □

Theorem 1108.30 (MetaCIC normalization certificate router axiom-clean synchronization)**.** *Let* $R = (A, K, S, P, D, U, G, L, H, C, Q, N)$ *be an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *packet. The router's accepted packet is exhausted by the displayed candidate-evidence row* K*, closed-projection row* D*, authorized generator row* U*, compiler recognizer row* G*, kernel-acceptance row* L*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*,* Pkg *provenance* Q*, and local* $\mathsf{NameCert}$ *row* N*, together with the audit anchor* A*, readback row* S*, and adequacy row* P*. Hence the audit-clean paper route has exactly the finite surface required for axiom-clean formal-status synchronization. It does not assert full subject reduction, global confluence, or strong normalization as a host theorem.*

Proof. Project the carrier of Definition 1108.1. Its rows are exactly $A, K, S, P, D, U, G, L, H, C, Q, N$, with candidate evidence in K and all projection, generator, compiler, acceptance, replay, provenance, and naming data displayed as separate finite coordinates.

Apply route coverage and public consumer coverage. Theorems 1108.10 and 1108.22 force every accepted or public read to preserve the same candidate-mediated route before downstream consumers inspect normalization evidence.

Use public adequacy and certificate-budget discharge. Theorems 1108.27 and 1108.29 package only the displayed frontier, residual-substitution, confluence-critical-pair, generator, compiler, acceptance, replay, provenance, and local naming rows.

Therefore the finite router surface already identifies the rows relevant to axiom-clean synchronization: candidate evidence, closed projection, generator, compiler, acceptance, replay, provenance, and $\mathsf{NameCert}$ data. Since no carrier coordinate exports full subject reduction, global confluence, or host strong normalization, the synchronization is a finite-surface claim rather than a MetaCIC completeness theorem. □

Theorem 1108.31 (MetaCIC normalization router bridge-candidate surface)**.** *Let* $R = (A, K, S, P, D, U, G, L, H, C$ *be an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *packet. Any bridge-facing consumer that uses the public adequacy surface must first read candidate evidence* K*, closed projection* D*, authorized generator* U*, compiler recognizer* G*, kernel acceptance* L*, componentwise transport* H*, displayed replay* C*, provenance* Q*, and local name* N *as visible rows of the same finite packet. The bridge-candidate surface is only this displayed route through public adequacy; it refuses subject reduction, global confluence, host normalization, and quotient reduction equality.*

Proof. Start with the carrier. Definition 1108.1 displays candidate evidence, closed projection, authorized generator, compiler recognition, kernel acceptance, transport, replay, provenance, and local naming as distinct coordinates of the same packet.

Next apply public adequacy. Definition 1108.27 exports only the candidate-mediated route through $A, K, S, P, D, U, G, L, H, C, Q, N$ together with the named frontier and residual boundary rows; it does not supply a separate bridge theorem.

Finally use the axiom-clean synchronization surface. Definition 1108.30 identifies the same finite rows as the audit-clean public surface and excludes full subject reduction, global confluence, and host strong normalization. Because quotient reduction equality is also absent from the carrier, a bridge-facing consumer can treat this theorem only as a candidate surface for a later checked bridge. □

Theorem 1108.32 (MetaCIC router bridge-ready exactness)**.** *Let $R = (A, K, S, P, D, U, G, L, H, C, Q, N)$ be an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *packet. Every bridge-facing read that treats the router as bridge-ready must preserve the public adequacy target, the axiom-clean synchronization surface, and the TasteGate row before it uses the bridge-candidate route. The exact bridge-ready surface is therefore the same finite route through $A, K, S, P, D, U, G, L, H, C, Q, N$ together with the named frontier, residual-substitution, confluence-critical-pair, and TasteGate rows. It still refuses evidence-free strong normalization, unconditional application normalization, host normalization, quotient reduction equality, and bridgeChecked status.*

Proof. Start with public adequacy. Definition 1108.27 exports only the candidate-mediated route through $A, K, S, P, D, U, G, L, H, C, Q, N$ together with the named frontier and residual boundary rows.

Next preserve the axiom-clean synchronization surface. Definition 1108.30 identifies the same finite rows as the audit-clean public surface and refuses full subject reduction, global confluence, and host strong normalization.

Now attach the bridge-candidate surface and TasteGate row. Definition 1108.31 keeps bridge-facing reads behind the displayed router rows, while the existing Lean TasteGate marker records the single-carrier alignment for the same packet. Since neither row is a checked standard bridge, the read is bridge-ready only as this exact finite surface and not as bridgeChecked evidence. □

Theorem 1108.33 (MetaCIC router residual candidate coverage)**.** *Let $R = (A, K, S, P, D, U, G, L, H, C, Q, N)$ be an accepted* $\mathsf{MetaCICNormalizationCertificateRouter}^{\uparrow}$ *packet. Any residual candidate read that reaches a bridge-ready or closed-normalization-facing consumer must pass through candidate evidence in K, closed projection D, Pi and application adequacy P, authorized generator U, compiler recognizer G, kernel acceptance L, componentwise transport H, displayed replay C, provenance Q, and local naming N. The read is therefore the same candidate-mediated finite route already exposed by the router; it is not evidence-free normalization, host conversion equality, quotient reduction equality, or a hidden closed-term normalizer.*

Proof. Start with the existing residual candidate coverage theorem. Definition 1108.16 requires each residual normalization read to expose candidate, closed-candidate, or candidate-set evidence in K before the adequacy, projection, generator, compiler, acceptance, and structural rows contribute.

Next use the evidence adequacy lock and public adequacy surface. Theorems 1108.26 and 1108.27 keep $P, D, U, G, L, H, C, Q, N$ downstream of the same candidate-mediated packet.

Finally apply bridge-ready exactness. Definition 1108.32 permits a bridge-ready read only as the displayed route through $A, K, S, P, D, U, G, L, H, C, Q, N$ together with the named frontier and residual rows. Hence any closed-normalization-facing consumer sees only the listed finite coverage route and none of the excluded host endpoints. □

Theorem 1108.34 (MetaCIC router frontier audit handoff)**.** *Let $R = (A, K, S, P, D, U, G, L, H, C, Q, N)$ be an accepted* MetaCICNormalizationCertificateRouter$^{\uparrow}$ *packet. A closed-normalization consumer may read the frontier residual audit handoff only after the route has passed through the* MetaCICNormalizationFrontier *row, the candidate evidence row K, the residual-substitution boundary, generator and compiler rows U, G, kernel acceptance L, transport H, replay C, provenance Q, and local naming N. Thus the handoff is routed through the frontier row before any closed-normalization consumer receives it, and it exports no evidence-free strong normalization, host conversion equality, quotient reduction equality, or hidden confluence theorem.*

Proof. Read the verified frontier residual audit handoff first. Definition 1108.25 forces public consumers that export no-infinite-reduction evidence or critical-pair discharge to expose A, K, the frontier row, the residual-substitution boundary, U, G, and L before export.

Now attach residual candidate coverage. Definition 1108.33 keeps the candidate evidence, closed projection, adequacy, generator, compiler, acceptance, transport, replay, provenance, and naming rows on the same route.

Finally use bridge-ready exactness. A closed-normalization consumer can only read the bridge-ready surface after the frontier, residual-substitution, confluence-critical-pair, and TasteGate rows have been named with the router packet. Therefore the handoff passes through MetaCICNormalizationFrontier$^{\uparrow}$ before the consumer receives it, and no excluded host or quotient endpoint is exported. □

Falsifiable prediction: A closed-term normalization read is refused unless candidate, closed-candidate, or candidate-set evidence is present on the displayed route.

Independence witness: metacicnormalizationfrontier, closedtermsubstitutionboundary, authorizedgeneratorrecursor, groundcompilerrecognizerflow, kernelinductiveacceptance: the router has simultaneous candidate-evidence, closed projection, Pi/app adequacy, and no-infinite-reduction rows not bijective with any one sibling.

The Lean TasteGate site for MetaCICNormalizationCertificateRouter$^{\uparrow}$ must provide explicit Nontrivial MetaCICNo and FieldFaithful MetaCICNormalizationCertificateRouter$^{\uparrow}$ instances. These instances preserve candidate evidence, closed projection, Pi and application adequacy, authorized generator handoff, compiler recognition, kernel acceptance, route replay, provenance, and local naming as distinguishable fields.

Closure status for NameCert$_{\text{MetaCICNormalizationCertificateRouter}^{\uparrow}}$.

Constructive story: A MetaCICNormalizationCertificateRouter$^{\uparrow}$ packet is generated from an audit-map anchor, candidate evidence, strong-normalization readback, Pi and application adequacy, closed-term projection, authorized generator handoff, compiler recognition, kernel inductive acceptance, componentwise transport, displayed replay, provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{MetaCICNormalizationCertificateRouter}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1108.1, Definition 1108.2, Definition 1108.3, Definition 1108.12, Definition 1108.13, Definition 1108.14, Definition 1108.15, and Definition 1108.19 bind candidate-mediated normalization reads as a finite kernel-scoped router surface.

Upgrade path: No theory-axis upgrade remains; bridge checking is a separate formal-axis target.

Chapter 1109

A Concrete Naming Certificate for $\mathsf{FocusedMultiHistLedger}^{\uparrow}$

The $\mathsf{FocusedMultiHistLedger}^{\uparrow}$ packet realizes the finite closure target of chapter 9420 as a concrete NameCert carrier. It reads the current-state surface of chapter 578, the local frame surface of chapter 609, the no-subject trace surface of chapter 640, the two-history locality ledger of chapter 759, and the sealed trace boundary of chapter 1054. The packet adds no universe object, subject carrier, global clock, host equality of histories, or selected synchronization service.

Definition 1109.1 (Focused multi-Hist ledger carrier)**.** *A* $\mathsf{FocusedMultiHistLedger}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (S, F, K, T, G, R, I, D, O, H, C, P, N)$$

with the following displayed rows:

1. *S is an accepted* $\mathsf{ConsciousObserverState}^{\uparrow}$ *row naming the focused current-state surface;*
2. *F is an accepted* $\mathsf{ObserverCoordinateFrame}^{\uparrow}$ *row naming the local coordinate frame available at that state;*
3. *K is an accepted* $\mathsf{ObserverKernelTrace}^{\uparrow}$ *row exposing the focused observer trace without a subject carrier;*
4. *T is an accepted* $\mathsf{ObserverTraceSeal}^{\uparrow}$ *row sealing the focused trace and its no-subject refusal ledger;*
5. *G is the* GAP *and provenance ledger for every compressed, digested, or not-yet-fulfilled row in the finite packet;*
6. *R is the finite inter-*Hist *relation ledger, each relation being read through an* $\mathsf{InterHistLocalityLedger}^{\uparrow}$ *row;*
7. *I is the invariant-readback row for relation-stable records visible to the focused ledger;*
8. *D is the finite dependence and route row for local time slots, selector rows, and optional maximum-rate reads;*
9. *O is the audit row asserting no subject parameter, global clock, unledgered chooser, object-level* T *field, quotient history equality, or hidden choice-like service;*
10. *H records componentwise* hsame *transport for the displayed rows;*

11. *C records the displayed* Cont *replay routes by which each row is consumed from the ledger;*
12. *P is the* Pkg *provenance over* ConsciousObserverState$^{\uparrow}$, ObserverCoordinateFrame$^{\uparrow}$, ObserverKernelTrace$^{\uparrow}$, ObserverTraceSeal$^{\uparrow}$, InterHistLocalityLedger$^{\uparrow}$, BHist, hsame, Cont, *and* NameCert *rows;*
13. *N is the local* NameCert$_{\text{FocusedMultiHistLedger}^{\uparrow}}$ *row.*

The carrier is the records-side realization of the closed focused multi-Hist ledger of Definition 9420.1; it is not a carrier for a global universe, observer-substance, host spacetime, or external synchronization substrate.

Lean4 ✓ `BEDC.Derived.FocusedMultiHistLedgerUp.FocusedMultiHistLedgerUp single carrier alignment`

Theorem 1109.2 (Focused multi-Hist ledger NameCert obligations)**.** *For the carrier of Definition 1109.1, the local* NameCert$_{\text{FocusedMultiHistLedger}^{\uparrow}}$ *surface consists exactly of carrier admission for $L = (S, F, K, T, G, R, I, D, O, H, C, P, N)$, focused current-state admission through S, local frame admission through F, focused trace and trace-seal admission through K, T,* GAP *and provenance accountability through G, inter-*Hist *relation admission through R, invariant and dependence readback through I, D, audit refusal through O, componentwise* hsame *transport through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Proof. Carrier admission is projection from Definition 1109.1. The rows S, F, K, T expose the focused state, local frame, trace row, and sealed trace before the ledger reads any relation or invariant data.

The rows G, R, I, D supply the closed records-side body of the packet. The GAP ledger accounts for compressed or not-yet-fulfilled rows, the relation row consumes InterHistLocalityLedger$^{\uparrow}$, and the invariant and dependence rows record exactly the finite readback available to a focused multi-history consumer.

The audit and structural rows are O, H, C, P, N. They record the refusal of subject parameters, global clocks, hidden choosers, object-level T fields, quotient history equality, and choice-like services, while transport, replay, provenance, and local naming keep every public read inside the same displayed packet. □

Theorem 1109.3 (Focused multi-Hist ledger non-escape)**.** *Every public consumer of an accepted* FocusedMultiHistLedger$^{\uparrow}$ *carrier can read only the displayed focused state, local frame, kernel trace, trace seal,* GAP *ledger, inter-*Hist *locality ledger, invariant row, dependence row, audit row, componentwise* hsame *transport,* Cont *route,* Pkg *provenance, and local* NameCert *row*

$$S, F, K, T, G, R, I, D, O, H, C, P, N.$$

It receives no observer-substance, global observer frame, global clock, host equality of histories, quotient observer identity, unledgered compression, object-level T *field, selected limit, or choice-like synchronization service.*

Lean4 ✓ `BEDC.Derived.FocusedMultiHistLedgerUp.FocusedMultiHistLedgerCarrier nonescape`

Proof. Start with the NameCert obligations. They force every accepted read through the displayed tuple and identify $S, F, K, T, G, R, I, D, O, H, C, P, N$ as the whole local certificate surface.

The sibling rows do not widen the carrier. ConsciousObserverState$^{\uparrow}$ supplies a focused current-state surface, ObserverCoordinateFrame$^{\uparrow}$ supplies a local frame rather than a global frame, ObserverKernelTrace$^{\uparrow}$ and ObserverTraceSeal$^{\uparrow}$ supply no-subject trace exposure, and InterHistLocalityLedger$^{\uparrow}$ supplies finite two-history relation routing.

The excluded objects have no coordinate in L. A consumer requesting observer-substance, global synchronization, host equality, quotient identity, unledgered compression, an object-level T field, selected limits, or choice-like services would have to leave the displayed packet, so the accepted carrier cannot export such data. □

Theorem 1109.4 (Focused multi-Hist ledger public export)**.** *Every public consumer of an accepted* $\mathsf{FocusedMultiHistLedger}^{\uparrow}$ *carrier receives the export packet*

$$S, F, K, T, G, R, I, D, O, H, C, P, N$$

and no further row. The export surface keeps the focused current-state row, local frame row, no-subject kernel trace, trace seal, GAP *and provenance ledger, inter-*Hist *locality ledger, invariant readback, dependence route, audit refusal, componentwise transport, replay, package provenance, and local naming row visible to the public route.*

It does not export observer-substance, a global universe object, a global clock, host equality of histories, quotient observer identity, selected synchronization, unledgered compression, or an object-level T *field.*

Proof. Start with the non-escape theorem Definition 1109.3. It already identifies the displayed rows as the whole readable surface of an accepted carrier.

The public export is therefore a repackaging of those rows, not a new carrier. The focused state S, local frame F, trace rows K, T, ledger rows G, R, I, D, O, and structural rows H, C, P, N are exported together so that each public read remains tied to the same TasteGate-certified carrier surface.

The excluded objects have no coordinate in the carrier and cannot be recovered from the export packet. Hence the public route exposes exactly the focused multi-Hist ledger rows and nothing outside them. □

Falsifiable prediction: Removing either the focus row or the GAP/provenance ledger leaves a multi-Hist packet that cannot certify the closed focused ledger.

Independence witness: consciousobserverstate, observercoordinateframe, observerkerneltrace, interhistlocalityledger, and observertraceseal: none is bijective to the focused multi-Hist ledger because the ledger alone carries the focused state row, local frame row, no-subject kernel trace row, sealed trace row, GAP/provenance ledger, inter-Hist locality ledger, invariant readback, dependence route, audit refusal, transport, replay, provenance, and local NameCert rows together.

Closure status for $\mathsf{NameCert}_{\mathsf{FocusedMultiHistLedger}^{\uparrow}}$**.**

Constructive story: A $\mathsf{FocusedMultiHistLedger}^{\uparrow}$ packet is generated from focused current-state, local frame, kernel trace, trace-seal, GAP/provenance, inter-Hist locality, invariant, dependence, audit, transport, replay, package, and local NameCert rows.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FocusedMultiHistLedger}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1109.1, Definition 1109.2, Definition 1109.3, Definition 1109.4, and

Lean4 ✓ `BEDC.Derived.FocusedMultiHistLedgerUp.taste gate`

bridge the public export to the acceptance-schema route while preserving the focused state, local frame, trace seal, GAP/provenance, inter-Hist locality, invariant readback, dependence, audit, transport, replay, package, and local NameCert rows.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FocusedMultiHistLedger}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.FocusedMultiHistLedgerUp.FocusedMultiHistLedgerUp\_single\_carrier\_alignment`

Bridge status: none

Not claimed: This chapter does not close Lean verification, bridge checking, a global universe object, observer-substance, host spacetime, quotient history equality, selected synchronization, or an object-level T field.

Upgrade path: No further paper-side theory-closure upgrade is pending; machine bridge checking remains the formal-axis successor for the same public export and acceptance-schema route.

Chapter 1110

A Concrete Naming Certificate for $\mathsf{CauchyWitnessGluing}^{\uparrow}$

The $\mathsf{CauchyWitnessGluing}^{\uparrow}$ packet realizes the Real-completeness witness route of chapter 9238 as one finite NameCert surface. It sits after the witness ledger of chapter 902, the tail-witness envelope of chapter 898, the seal-budget synchronizer of chapter 886, and the completion-seal classifier of chapter 900. Those sibling packets expose the witness, tail, synchronizer, and completion-seal rows separately; this packet glues them into the single consumer surface through which a Real-completion reader may reach $\mathsf{Real}^{\uparrow}$.

Definition 1110.1 (CauchyWitnessGluing carrier)**.** *A* $\mathsf{CauchyWitnessGluing}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$G = (L, T, S, K, U, V, D, R, E, H, C, P, N)$$

with the following displayed rows:

1. *L is the* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *row recording the diagonal budget, observation-budget, seal-synchronizer, and completion-seal witness ledger;*
2. *T is the* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *row recording the finite tail envelope and its Real-facing tail agreement route;*
3. *S is the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row aligning the selector budget, observation budget, shared threshold, and seal request;*
4. *K is the* $\mathsf{RealCompletionSealClassifierUp}$ *row classifying the completion-seal read visible to the Real consumer;*
5. *U is the finite* $\mathsf{StreamName}^{\uparrow}$ *window-family row exposed by the glued route;*
6. *V is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-sequence handoff row reached after the stream windows are read;*
7. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *dyadic tolerance ledger consumed by the stream and regular-sequence rows;*
8. *R is the terminal* $\mathsf{Real}^{\uparrow}$ *seal row served to the completion-facing consumer;*
9. *E is the Real-completion witness edge stating that L, T, S, K, U, V, D, R are read as one gluing packet;*
10. *H records componentwise* hsame *transports for every displayed row;*

11. *C records the displayed* Cont *routes from the ledger to the tail envelope, from the synchronizer to the completion-seal classifier, from stream and dyadic reads to the regular handoff, and from the regular handoff to* $\mathsf{Real}^{\uparrow}$*;*
12. *P is the* Pkg *provenance over chapter 902, chapter 898, chapter 886, chapter 900, chapter 9238,* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, *and* NameCert *rows;*
13. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyWitnessGluing}^{\uparrow}}$ *row.*

The carrier exports no quotient stream equality, host real equality, selected external limit, countable-choice row, detached Cauchy witness, or ambient completeness principle beyond the displayed packet.

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingTasteGate single carrier alignment`

Theorem 1110.2 (CauchyWitnessGluing budget compatibility)**.** *Let*

$$G = (L, T, S, K, U, V, D, R, E, H, C, P, N)$$

be an accepted $\mathsf{CauchyWitnessGluing}^{\uparrow}$ *packet. Any Real-completion consumer that preserves the witness ledger L, tail envelope T, seal synchronizer S, completion-seal classifier K, stream window row U, regular handoff V, dyadic ledger D, Real seal R, witness edge E, transports H, continuations C, provenance P, and local name N preserves the same finite budget route. Replacing the synchronizer row while keeping the ledger and envelope fixed is not a refinement of this packet; it is a different candidate for acceptance.*

Proof. Begin with the witness ledger. The row L records which diagonal, observation-budget, synchronizer, and completion-seal witnesses are present before the Real-facing consumer reads the packet.

Next attach the tail and seal rows. The envelope T supplies the finite tail request seen by the Real route, while S aligns that request with the selected observation budget and shared threshold. The classifier K then reads the completion-seal side of the same synchronized route.

The lower observation rows cannot be varied independently. The stream windows U, dyadic ledger D, and regular handoff V are routed together by the displayed Cont row, and their componentwise hsame transports are recorded in H before the terminal $\mathsf{Real}^{\uparrow}$ seal R is served.

Thus a consumer preserving all displayed rows preserves the budget route as a whole. Changing S changes the coordinate that binds the ledger to the completion-seal classifier, so the resulting data may form another accepted packet, but it is not the same $\mathsf{CauchyWitnessGluing}^{\uparrow}$ carrier read. □

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingCarrier budget compatibility`

Theorem 1110.3 (CauchyWitnessGluing route obligation surface)**.** *An accepted* $\mathsf{CauchyWitnessGluing}^{\uparrow}$ *packet exposes exactly the route rows*

$$L, T, S, K, U, V, D, R, E, H, C, P, N$$

as its NameCert *obligation surface. The packet has no quotient-stream row, host-real row, selected-limit row, countable-choice row, or ambient-completeness row.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingCarrier route obligation surface`

Proof. Read the displayed carrier of Definition 1110.1. Its finite BHist data are precisely the thirteen rows $L, T, S, K, U, V, D, R, E, H, C, P, N$, with P recording the sibling provenance and N recording the local $\mathsf{NameCert}_{\mathsf{CauchyWitnessGluing}^{\uparrow}}$ row.

The exclusion clause at the end of the carrier definition removes every off-route object named in the statement. Since the consumer is accepted only as a read of that displayed packet, there is no remaining coordinate from which a quotient stream, host real, selected external limit, countable-choice principle, or ambient-completeness principle can be recovered. □

Theorem 1110.4 (CauchyWitnessGluing witness ledger exactness)**.** *In an accepted* $\mathsf{CauchyWitnessGluing}^{\uparrow}$ *packet, the witness ledger row L is exact only together with the tail envelope T, seal synchronizer S, completion classifier K, and witness edge E. The ledger read is therefore the* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *certificate of chapter 902 synchronized through the seal-budget route of chapter 886, not a detached witness row.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingCarrier witness ledger exactness`

Proof. The row L supplies the diagonal, observation-budget, synchronizer, and completion-seal witness ledger, but the gluing carrier does not expose L as an independent terminal object. Its exactness is tested inside the same packet that contains T, S, K, and E.

The tail envelope T determines the Real-facing tail request, while S aligns that request with the shared budget and seal request. The classifier K reads the completion-seal side of the synchronized route, and the edge E states that these rows are consumed as one gluing packet.

Thus a consumer that keeps L while dropping any of T, S, K, or E no longer reads the displayed $\mathsf{CauchyWitnessGluing}^{\uparrow}$ surface. It reads a detached ledger candidate, which is outside the accepted packet described here. □

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingCarrier witness ledger semantic name certificate`

Theorem 1110.5 (CauchyWitnessGluing tail envelope handoff)**.** *The handoff from the tail envelope of an accepted* $\mathsf{CauchyWitnessGluing}^{\uparrow}$ *packet to the terminal Real seal factors through* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$ *as listed in the carrier provenance. Equivalently, the route from T to R is mediated by the finite stream-window row U, the dyadic tolerance ledger D, and the regular-sequence handoff V before the* $\mathsf{Real}^{\uparrow}$ *seal is served.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingCarrier tail envelope handoff`

Proof. Start with the carrier rows named in Definition 1110.1. The tail row T is not adjacent to R by an ambient completion map; the displayed route records the stream window row U, dyadic ledger D, and regular handoff V between them.

The provenance row P names the same sibling certificates and primitive rows: $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$. The continuation row C then records the displayed path from stream and dyadic reads to the regular handoff and from the regular handoff to the terminal Real seal.

Therefore any tail-envelope handoff to R factors through those finite BEDC rows. A direct appeal to Real completeness or a hidden quotient-stream map would bypass U, D, V, and so would not be a read of this gluing packet. □

Theorem 1110.6 (CauchyWitnessGluing completion seal scope)**.** *Every completion-seal consumer of an accepted* $\mathsf{CauchyWitnessGluing}^{\uparrow}$ *packet reads the gluing data only through* BHist, hsame, Cont,

Pkg, NameCert, *and the sibling certificates named in the carrier provenance. No off-table completion principle contributes an additional primitive to the completion-seal read.*

Proof. The accepted packet is a finite BHist carrier. Componentwise equality transport is recorded by H through hsame, route transport is recorded by C through Cont, and the provenance and naming surfaces are recorded by P and N through Pkg and NameCert.

The sibling certificates listed in P supply the ledger, tail, seal-budget, completion-seal, stream, regular-sequence, dyadic, and Real rows. These are the only primitive sources available to the completion-seal consumer.

Consequently, a consumer that invokes a completion principle not present in BHist, hsame, Cont, Pkg, NameCert, or the listed sibling certificates is no longer reading the accepted CauchyWitnessGluing$^{\uparrow}$ packet. It has introduced an off-table primitive outside the chapter's scoped surface. □

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingCarrier completion seal scope`

Theorem 1110.7 (CauchyWitnessGluing Real seal nonescape)**.** *Every* Real$^{\uparrow}$ *or completion-facing read of an accepted* CauchyWitnessGluing$^{\uparrow}$ *packet factors through*

$$L \to T \to S \to K \to U \to D \to V \to R$$

with the witness edge E and the structural rows H, C, P, N visible. No consumer can reach the Real seal through an omitted ledger, hidden tail envelope, alternate seal synchronizer, detached completion-seal classifier, quotient stream, host real equality, selected external limit, countable-choice row, or ambient completeness principle.

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingCarrier real seal nonescape`

Proof. Project the carrier of Definition 1110.1. The rows $L, T, S, K, U, V, D, R, E, H, C, P, N$ are the whole finite packet, and the definition excludes the ambient Real-completion objects named in the statement.

The route first exposes the witness and tail side. A Real-facing read has to pass through the witness ledger L and tail envelope T before it can inspect the synchronized seal request.

The route then exposes the seal and observation side. The synchronizer S and completion-seal classifier K determine which completion-seal row is being read, while U, D, V supply the finite StreamName, DyadicRatCore, and RegSeqRat handoff before R is served.

Finally, the structural rows repack the result. Componentwise hsame transports, displayed Cont routes, Pkg provenance, and the local NameCert row leave no coordinate from which a consumer could extract a second Real seal or a hidden completion principle. □

Theorem 1110.8 (CauchyWitnessGluing obligation ledger)**.** *Every accepted* CauchyWitnessGluing$^{\uparrow}$ *packet exposes exactly five obligation families: witness-ledger admission through L, T, S, K, E; stream, dyadic, and* RegSeqRat$^{\uparrow}$ *handoff through U, D, V, R; componentwise* hsame *transport through H; displayed* Cont *replay through C; and* Pkg *plus local* NameCert *provenance through P, N. These families exhaust the obligation ledger and export no quotient stream equality, selected limit, countable-choice row, host real equality, or ambient* Real$^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingCarrier obligation ledger`

Proof. Start with the carrier definition and route-obligation surface. The carrier of Definition 1110.1 lists exactly $L, T, S, K, U, V, D, R, E, H, C, P, N$, and Definition 1110.3 says that these rows are the local NameCert surface.

The first family is the witness-ledger admission. By Definition 1110.4, the ledger L is exact only together with the tail envelope T, seal synchronizer S, completion classifier K, and witness edge E.

The second family is the finite handoff to the Real seal. Apply Definition 1110.5 and Definition 1110.7: the stream windows U, dyadic ledger D, regular readback V, and terminal seal R mediate every Real-facing read.

The remaining three families are structural. The row H carries componentwise hsame transport, the row C carries displayed Cont replay, and the rows P, N record package provenance and local naming. Since none of the five families contains a quotient stream, selected limit, countable-choice schedule, host real equality row, or ambient Real-completeness coordinate, the obligation ledger is exhausted by the listed rows. □

The Lean TasteGate development is expected to place the explicit Nontrivial CauchyWitnessGluing$^{\uparrow}$ and FieldFaithful CauchyWitnessGluing$^{\uparrow}$ instances in BEDC.Derived.CauchyWitnessGluingUp.TasteGate, with the single-carrier alignment target named BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingTasteGa

Theorem 1110.9 (CauchyWitnessGluing scoped primitive binding)**.** *Every accepted* CauchyWitnessGluing$^{\uparrow}$ *packet reads its witness ledger L, tail envelope T, seal synchronizer S, completion classifier K,* StreamName$^{\uparrow}$ *row U,* RegSeqRat$^{\uparrow}$ *handoff V,* DyadicRatCore$^{\uparrow}$ *ledger D,* Real$^{\uparrow}$ *seal R, witness edge E, componentwise* hsame *transports H, displayed* Cont *replays C,* Pkg *provenance P, and local* NameCert$_{\text{CauchyWitnessGluing}^{\uparrow}}$ *row N only through the displayed BEDC primitives and the sibling scope named in the carrier provenance. The scoped read exports no quotient stream equality, selected limit, countable-choice row, host real equality, or ambient* Real$^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingCarrier scoped primitive binding`

Proof. Start with the route-obligation surface. By Definition 1110.3, the local NameCert surface of an accepted packet is exactly the displayed tuple $L, T, S, K, U, V, D, R, E, H, C, P, N$, so there is no additional coordinate from which a consumer can read a hidden primitive.

Next bind the completion-facing side. Apply Definition 1110.6: completion-seal reads pass only through BHist, hsame, Cont, Pkg, NameCert, and the sibling certificates listed by the provenance row. Apply Definition 1110.7 to force every Real-facing read through the ledger, tail, synchronizer, classifier, stream, dyadic, regular, and Real rows before the terminal seal is visible.

It remains to account for the ledger boundary. By Definition 1110.8, the five obligation families are witness-ledger admission, finite handoff to Real$^{\uparrow}$, componentwise transport, displayed replay, and package plus local naming. These families include the hsame transports, Cont replays, Pkg provenance, and local NameCert row, and they exhaust the scoped primitive surface.

Combining these rows gives the claimed primitive binding. Since the cited theorems also exclude quotient streams, selected limits, countable-choice schedules, host real equality, and ambient Real-completeness coordinates, the accepted packet remains inside the displayed BEDC primitive and sibling scope. □

Theorem 1110.10 (CauchyWitnessGluing scoped route tightening)**.** *Any completion-facing read of an accepted* CauchyWitnessGluing$^{\uparrow}$ *packet must factor through the witness ledger L, tail envelope T, seal synchronizer S, completion-seal classifier K,* StreamName$^{\uparrow}$ *windows U,* DyadicRatCore$^{\uparrow}$ *ledger D,* RegSeqRat$^{\uparrow}$ *handoff V, terminal* Real$^{\uparrow}$ *seal R, witness edge E, componentwise* hsame *transports H, displayed* Cont *replays C,* Pkg *provenance P, and local* NameCert$_{\text{CauchyWitnessGluing}^{\uparrow}}$ *row N before a Real-completion consumer may inspect the route. The read exports no detached ledger, hidden tail envelope, alternate synchronizer, quotient stream equality, selected external limit, countable-choice row, host real equality, or ambient* Real$^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessGluingUp.CauchyWitnessGluingCarrier scoped route tightening`

Proof. Start with the route-obligation surface of Definition 1110.3. It identifies $L, T, S, K, U, V, D, R, E, H, C, P, N$ as the whole local NameCert surface of an accepted packet.

Bind the witness side next. Apply witness-ledger exactness, tail-envelope handoff, and completion-seal scope from Definition 1110.4, Definition 1110.5, and Definition 1110.6. These results force the ledger, tail, synchronizer, classifier, and witness edge to be read as one synchronized route before the completion-seal consumer reaches the lower observation rows.

Now bind the Real-facing side. Apply Definition 1110.7 to require the StreamName windows, DyadicRatCore ledger, RegSeqRat handoff, and terminal Real seal before any completion-facing consumer reaches R.

Finally apply the obligation ledger and scoped primitive binding of Definition 1110.8 and Definition 1110.9. The structural rows H, C, P, N transport, replay, source, and name exactly the displayed route, so the excluded ledger, quotient, choice, equality, and completeness data remain outside the scoped handoff. □

Falsifiable prediction: If the gluing packet is accepted, a Real-completion consumer that preserves the witness ledger and tail envelope but changes the seal-synchronizer row is rejected by the classifier.

Independence witness: cauchywitnessledger, cauchytailwitnessenvelope, cauchysealbudgetsynchronizer, realcompletionsealclassifier, regularcauchydiagonalmeet: none is bijective because each sibling omits at least one of the paired witness, tail, synchronizer, completion-seal, and RealUp rows required by this gluing packet.

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyWitnessGluing}^{\uparrow}}$.

Constructive story: A $\mathsf{CauchyWitnessGluing}^{\uparrow}$ packet is generated from a witness ledger, tail-envelope row, seal-synchronizer row, completion-seal classifier, StreamName, RegSeqRat, DyadicRatCore, RealUp, witness-edge, hsame, Cont, Pkg, and local NameCert rows.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyWitnessGluing}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 1110.1, Definition 1110.2, Definition 1110.3, Definition 1110.4, Definition 1110.5, Definition 1110.6, Definition 1110.7, Definition 1110.8, Definition 1110.9, Definition 1110.10, the falsifiable prediction, and the independence witness bind the displayed witness-ledger, tail-envelope, seal-synchronizer, completion-seal classifier, StreamName, RegSeqRat, DyadicRatCore, RealUp, hsame, Cont, Pkg, and NameCert rows into one scoped Real-completion witness packet.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CauchyWitnessGluing}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close quotient stream equality, selected limits, countable choice, ambient completeness, host real equality, Lean verification, or bridge checking for $\mathsf{CauchyWitnessGluing}^{\uparrow}$.

Upgrade path: The next paper step is a public Real-completion witness export, while Lean audit-token synchronization for the witness ledger, tail envelope, seal synchronizer, completion-seal classifier, and Real-facing handoff remains separate.

Chapter 1111

A Concrete Naming Certificate for $\mathsf{UnaryContinuationEndofunctor}^{\uparrow}$

The $\mathsf{UnaryContinuationEndofunctor}^{\uparrow}$ packet is the BEDC-native endofunctor surface on the unary-continuation category. In the standard category-theoretic account, as in Mac Lane's treatment of functors, an endofunctor preserves objects, arrows, identities, and composition inside one category. Here the one category is the unary-continuation reading of BHist from chapter 9363, so the carrier is finite packet data rather than a host functor object.

The packet consumes the sibling categorical surfaces chapter 480, chapter 484, chapter 62, and chapter 63. Its object and hom rows are unary BHist rows, its preservation rows are displayed Cont ledgers, and its transport, provenance, and local naming rows are the same hsame/Pkg/NameCert surface used by the unary-continuation category.

Definition 1111.1 (Unary-continuation endofunctor carrier)**.** *A* $\mathsf{UnaryContinuationEndofunctor}^{\uparrow}$ *carrier is a finite packet*

$$E = (O, H, F, I, M, T, C, P, N)$$

with the following displayed rows:

1. *O is the unary object row, accepting only unary* BHist *object histories from the unary-continuation category.*
2. *H is the displayed hom row, accepting only* $\mathsf{CategoryHomCarrier}(a, b, f)$ *rows between unary object histories.*
3. *F records the object and hom action rows of the endofunctor, sending unary objects to unary objects and displayed hom histories to displayed hom histories over the transported endpoints.*
4. *I records identity preservation: the image of an empty-tail identity row is classified with the empty-tail identity row at the image object.*
5. *M records composition preservation: the image of a displayed composite hom row is classified with the displayed composite of the two image hom rows.*
6. *T records componentwise* hsame *transport for object rows, hom rows, identity-preservation rows, and composition-preservation rows.*
7. *C stores the displayed* Cont *routes used to read the object action, hom action, identity preservation, and composition preservation.*
8. *P is the* Pkg *provenance row over* $\mathsf{KernelCategory}^{\uparrow}$, $\mathsf{FiniteKernelCategory}^{\uparrow}$, $\mathsf{Functor}^{\uparrow}$, *and* $\mathsf{NatTrans}^{\uparrow}$.

9. *N is the local* $\mathsf{NameCert}_{\mathsf{UnaryContinuationEndofunctor}^{\uparrow}}$ *row.*

The carrier has no coordinate for a host functor category, quotient morphism class, external naturality object, or equality outside the displayed BHist *rows.*

Lean4 ✓ `BEDC.Derived.UnaryContinuationEndofunctorUp.UnaryContinuationEndofunctorTasteGate single carrier alignment`

Theorem 1111.2 (Unary-continuation endofunctor NameCert obligations)**.** *The local* $\mathsf{NameCert}_{\mathsf{UnaryContinuationEndo}}$ *obligation surface for the carrier of Definition 1111.1 consists of five rows:*

1. *carrier admission by the finite packet $E = (O, H, F, I, M, T, C, P, N)$;*
2. *object and hom classifier transport by componentwise* hsame*;*
3. *identity preservation through the empty-tail identity rows of the unary-continuation category;*
4. *composition preservation through the displayed* Cont *composition rows of the unary-continuation category;*
5. *non-escape from host functor categories, quotient morphisms, external natural transformation objects, and host equality of arrows.*

Lean4 ✓ `BEDC.Derived.UnaryContinuationEndofunctorUp.UnaryContinuationEndofunctor namecert obligations`

Proof. Carrier admission is a projection of Definition 1111.1. The object, hom, action, identity, composition, transport, route, provenance, and local naming rows are all finite BHist data.

For classifier transport, use the sibling $\mathsf{KernelCategory}^{\uparrow}$ and $\mathsf{FiniteKernelCategory}^{\uparrow}$ packets. They identify the public object and hom surfaces as unary histories, displayed CategoryHomCarrier rows, and componentwise hsame transports.

Identity and composition preservation are the $\mathsf{Functor}^{\uparrow}$ rows restricted to this single unary-continuation category. The identity row I reads empty-tail continuation ledgers, while the composition row M reads displayed Cont composition ledgers before repacking the result as a displayed hom row.

The $\mathsf{NatTrans}^{\uparrow}$ sibling is consumed only as a downstream compatibility surface: it can compare components built from the same endofunctor packet, but it does not add a host naturality object. Since E has no host functor category, quotient morphism, or host arrow equality coordinate, every public read remains inside the displayed rows. □

Theorem 1111.3 (Unary-continuation endofunctor identity stability)**.** *Let $E = (O, H, F, I, M, T, C, P, N)$ be an accepted* $\mathsf{UnaryContinuationEndofunctor}^{\uparrow}$ *carrier. If $e_a : a \to a$ is the empty-tail identity hom row of the unary-continuation category, then the image of e_a under the object and hom action row F is classified with the empty-tail identity row at the image object $F(a)$. The comparison is routed only through H, I, T, C, P, N and exports no quotient morphism, host identity arrow, host arrow equality, or external functor law.*

Lean4 ✓ `BEDC.Derived.UnaryContinuationEndofunctorUp.UnaryContinuationEndofunctorCarrier identity stability`

Proof. Project the accepted carrier to its displayed hom row H, action row F, identity-preservation row I, transport row T, route row C, provenance row P, and local naming row N.

The row H reads e_a as the empty-tail identity $\mathsf{CategoryHomCarrier}(a, a, e_a)$ from the unary-continuation category surface. The action row F transports the object endpoint to $F(a)$ and the hom row to a displayed hom row over that transported endpoint.

Now apply the identity-preservation row I. It classifies the image hom row with the empty-tail identity row at $F(a)$, using the same unary-continuation identity ledger read by the sibling $\mathsf{KernelCategory}^{\uparrow}$, $\mathsf{Functor}^{\uparrow}$, and $\mathsf{NatTrans}^{\uparrow}$ surfaces referenced above.

Finally repack the comparison through T, C, P, N. Since the packet contains no quotient morphism coordinate, host identity-arrow coordinate, host arrow equality, or external functor-law object, the identity-stability statement remains a finite BEDC route through the named carrier rows. □

Theorem 1111.4 (Unary-continuation endofunctor composition stability)**.** *Let $E = (O, H, F, I, M, T, C, P, N)$ be an accepted* $\mathsf{UnaryContinuationEndofunctor}^{\uparrow}$ *carrier. If $f : a \to b$ and $g : b \to c$ are displayed unary-continuation hom rows and fg is their displayed* Cont *composite, then the image of fg under F is classified with the displayed* Cont *composite of the image of f and the image of g. The comparison is routed only through H, M, T, C, P, N and exports no quotient morphism, host function composition, host arrow equality, or external functor law.*

Lean4 ✓ `BEDC.Derived.UnaryContinuationEndofunctorUp.UnaryContinuationEndofunctorCarrier composition stability`

Proof. Start with the hom rows. The carrier reads f, g, and fg through $\mathsf{CategoryHomCarrier}$ over unary endpoints, and the route C records the displayed Cont composition producing fg.

Next apply the endofunctor action row F. It sends the three displayed hom rows to displayed hom rows over the transported endpoints, and T supplies the componentwise hsame comparisons needed to keep endpoints and hom tails aligned.

Now use the composition preservation row M. It states that the image of the displayed composite is classified with the displayed composite of the two image hom rows, all inside the same unary-continuation category surface.

Finally repack the comparison with P and N. Because the packet contains no quotient morphism class, host function-composition coordinate, host arrow equality, or external functor-law object, the stability claim is exactly the finite BEDC route through H, M, T, C, P, N. □

Closure status for $\mathsf{NameCert}_{\mathsf{UnaryContinuationEndofunctor}^{\uparrow}}$.

Constructive story: A $\mathsf{UnaryContinuationEndofunctor}^{\uparrow}$ packet is generated from unary object histories, displayed CategoryHomCarrier hom rows, object and hom action rows, identity-preservation rows, composition-preservation rows, componentwise hsame transport, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{UnaryContinuationEndofunctor}^{\uparrow}}, \mathsf{seed})$

Scope closed: The seed surface names the concrete BEDC carrier rows for unary-continuation endofunctors over objects, homs, identity preservation, composition preservation, transport, route, provenance, and local naming.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{UnaryContinuationEndofunctor}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Not claimed: This chapter does not close a Lean namespace, host functor categories, quotient morphisms, external naturality objects, arbitrary functor categories, or bridge checking.

Upgrade path: Scoped closure requires checked carrier admission, classifier transport, identity preservation, composition preservation, and non-escape over the displayed unary-continuation rows.

Chapter 1112

A Concrete Naming Certificate for $\mathsf{CrossHistCausalCone}^{\uparrow}$

The $\mathsf{CrossHistCausalCone}^{\uparrow}$ packet realizes the bounded two-history cone object in the Inter-Hist Locality chain of chapter 9419. It sits after the finite configuration surface of chapter 474, the causal witness surface of chapter 478, the maximum-rate boundary of chapter 594, the observer-locality transport surface of chapter 889, and the no-global-synchronization boundary of chapter 1003. Its role is to bind one directed affected-prefix window and its maximum-rate ledger into a finite carrier before any downstream consumer reads a causal cone as physical structure.

Definition 1112.1 (Cross-Hist causal-cone carrier)**.** *A* $\mathsf{CrossHistCausalCone}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Z = (A, B, K, W, R, M, S, H, C, P, N)$$

with the following displayed rows:

1. *A is the source-history row, read through the same finite configuration surface as* $\mathrm{MultiHistConfig}^{\uparrow}$*;*
2. *B is the target-history row whose affected prefix is inspected;*
3. *K is the unary slot or budget row selecting the bounded two-history time window;*
4. *W is the affected-prefix route, naming the finite* $\mathsf{CrossHistCausal}^{\uparrow}$ *dependence rows from A into the selected prefix of B;*
5. *R is the* $\mathsf{MaxCausalRate}^{\uparrow}$ *bound row attached to the displayed route W;*
6. *M is the observer-symmetry row, recording that the cone can be reread through the observer-locality transport of chapter 889 without changing the displayed bound;*
7. *S is the no-global-frame refusal row, inherited from chapter 1003 and excluding privileged frames, synchronized clocks, ambient metric tensors, and host-valued speed rows;*
8. *H records componentwise* hsame *and* psame *transport for the two history rows, slot row, affected-prefix route, maximum-rate bound, symmetry row, refusal row, continuation routes, provenance, and local name;*
9. *C records displayed* Cont *replay of the source row, target row, window row, affected-prefix route, maximum-rate bound, symmetry row, refusal row, and transport rows;*
10. *P is the* Pkg *provenance over* $\mathsf{CrossHistCausalCone}^{\uparrow}$, $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, $\mathsf{ObserverLocalityTransport}^{\uparrow}$, $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$, BHist, hsame, psame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*

11. *N is the local* $\mathsf{NameCert}_{\mathsf{CrossHistCausalCone}^{\uparrow}}$ *row.*

The carrier contains one bounded two-history cone packet. It contains no global frame, synchronized clock, ambient metric geometry, host real-valued speed, detached causal relation, or maximum-rate row outside the displayed cone.

Theorem 1112.2 (Cross-Hist causal-cone NameCert obligations)**.** *For the carrier of Definition 1112.1, the local* $\mathsf{NameCert}_{\mathsf{CrossHistCausalCone}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$Z = (A, B, K, W, R, M, S, H, C, P, N),$$

source and target history exactness, bounded slot/window exactness, affected-prefix route replay through W, maximum-rate attachment through R, observer-symmetry transport through M, no-global-frame refusal through S, componentwise hsame *and* psame *transport through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Proof. Carrier admission is projection from Definition 1112.1. The coordinates $A, B, K, W, R, M, S, H, C, P, N$ are the complete public inventory of the cone packet.

The source, target, and slot rows fix the bounded two-history window. The affected-prefix route W is the only causal-dependence coordinate, and the maximum-rate row R is attached to that route rather than to an unlisted family of histories.

The observer-symmetry row M and refusal row S then determine the observer-facing boundary. Transport in H and replay in C preserve the same finite cone, while P and N record provenance and local naming. Since no further coordinate is present, the listed clauses exhaust the local $\mathsf{NameCert}_{\mathsf{CrossHistCausalCone}^{\uparrow}}$ surface. □

Lean4 ✓ `BEDC.Derived.CrossHistCausalConeUp.CrossHistCausalConeNameCert obligations`

Theorem 1112.3 (Cross-Hist causal-cone zero-rate exclusion)**.** *If an accepted* $\mathsf{CrossHistCausalCone}^{\uparrow}$ *packet has a zero maximum-rate row R, then no public consumer can read a nonempty affected-prefix dependence route through the same packet. Any such route would have to be the displayed row W and hence would be bounded by the zero row attached to R.*

Proof. Project the accepted carrier. The only affected-prefix coordinate is W, and the only maximum-rate coordinate is R.

Apply Definition 1112.2. It attaches R to W inside the same local certificate, so a consumer cannot detach the route from its bound or replace the bound by an external rate row.

When R is the zero bound, an accepted public dependence read through the same cone would have to be both nonempty and zero-bounded. That violates the displayed cone packet rather than producing a second route, because the carrier has no coordinate for an alternate causal family or host-side rate comparison. □

Lean4 ✓ `BEDC.Derived.CrossHistCausalConeUp.CrossHistCausalConeUp zero rate exclusion`

Theorem 1112.4 (Cross-Hist causal-cone observer-local boundary)**.** *Every observer-local consumer of an accepted* $\mathsf{CrossHistCausalCone}^{\uparrow}$ *packet factors through the single finite tuple*

$$A, B, K, W, R, M, S, H, C, P, N.$$

The consumer reads the source and target histories through the finite configuration surface, the affected-prefix dependence through $\mathsf{CrossHistCausal}^{\uparrow}$*, the bound through* $\mathsf{MaxCausalRate}^{\uparrow}$*, the observer-symmetry transport through* $\mathsf{ObserverLocalityTransport}^{\uparrow}$*, and the refusal row through* $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$*. It receives no global frame, synchronized clock, metric tensor, Lorentz coordinate, host real-valued speed, detached rate row, or quotient of histories.*

Proof. Start with the carrier inventory in Definition 1112.1. The only public cone rows are the source, target, slot, affected-prefix route, maximum-rate bound, observer-symmetry row, refusal row, transport, replay, provenance, and local name.

Use Definition 1112.2. It routes the history rows through the finite configuration surface, the affected-prefix row through $\mathsf{CrossHistCausal}^{\uparrow}$, and the bound through $\mathsf{MaxCausalRate}^{\uparrow}$ before any observer-local consumer can read the cone.

The observer-symmetry and no-global-frame rows then close the consumer boundary. Because M and S are part of the same finite packet, observer-local transport cannot supply a privileged frame or a detached metric datum. The consumer remains inside $A, B, K, W, R, M, S, H, C, P, N$. □

Theorem 1112.5 (Cross-Hist causal-cone sibling independence)**.** *The* $\mathsf{CrossHistCausalCone}^{\uparrow}$ *carrier is not bijective to* $\mathrm{MultiHistConfig}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, $\mathsf{MaxCausalRate}^{\uparrow}$, $\mathsf{ObserverLocalityTransport}^{\uparrow}$, *or* $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$. *It carries all five sibling roles at once: source and target histories, affected-prefix causal row, maximum-rate bound, observer-symmetry transport, and no-global-frame refusal.*

Proof. Compare the carrier rows. $\mathrm{MultiHistConfig}^{\uparrow}$ supplies finite history slots but not the affected-prefix route, maximum-rate bound, observer-symmetry transport, or refusal row as one cone. $\mathsf{CrossHistCausal}^{\uparrow}$ supplies causal witness rows but not the bound and observer-local refusal ledger.

$\mathsf{MaxCausalRate}^{\uparrow}$ supplies the unary bound but not the selected affected-prefix route as a cone carrier. $\mathsf{ObserverLocalityTransport}^{\uparrow}$ supplies transport but not the bounded causal route itself. $\mathsf{NoGlobalSyncBoundary}^{\uparrow}$ supplies refusal data but not the positive causal and maximum-rate rows.

Thus each sibling omits at least one coordinate of $Z = (A, B, K, W, R, M, S, H, C, P, N)$. No projection to a single sibling can be inverted without recreating omitted cone data. □

Theorem 1112.6 (Cross-Hist causal-cone TasteGate surface)**.** *The later Lean* `TasteGate.lean` *development for* $\mathsf{CrossHistCausalCone}^{\uparrow}$ *must include explicit* Nontrivial $\mathsf{CrossHistCausalCone}^{\uparrow}$ *and* FieldFaithful $\mathsf{CrossHistCausalCone}^{\uparrow}$ *instances. These instances must preserve the source row, target row, slot/window row, affected-prefix route, maximum-rate bound, observer-symmetry row, no-global-frame refusal, transport rows, continuation replay, package provenance, and local naming row.*

Lean4 ✓ `BEDC.Derived.CrossHistCausalConeUp.CrossHistCausalConeTasteGate single carrier alignment`

Proof. Nontriviality is forced by the carrier inventory. A cone packet must distinguish at least the two history rows, selected window, affected-prefix route, maximum-rate bound, observer-symmetry row, and refusal row.

Field faithfulness is rowwise. A gate-facing instance that forgets any of $A, B, K, W, R, M, S, H, C, P, N$ would let a consumer read a collapsed object as a cone while omitting one of the local $\mathsf{NameCert}_{\mathsf{CrossHistCausalCone}^{\uparrow}}$ obligations.

Therefore the TasteGate surface must preserve exactly the finite packet named in Definition 1112.1. □

Falsifiable prediction: If the cone carrier is accepted, zero max-rate rows forbid any public affected-prefix dependence route through the same cone packet.

Independence witness: Compare multihistconfig, crosshistcausal, maxcausalrate, observerlocalitytransport, and noglobalsyncboundary: none is bijective because none carries all of causal row, max-rate bound, observer-symmetry transport, and no-global-frame refusal in one carrier.

Closure status for $\mathsf{NameCert}_{\mathsf{CrossHistCausalCone}^{\uparrow}}$.

Constructive story: A $\mathsf{CrossHistCausalCone}^{\uparrow}$ packet is generated from source and target history rows, a bounded slot/window row, an affected-prefix causal route, a maximum-rate bound, observer-symmetry transport, no-global-frame refusal, componentwise hsame and psame transport, displayed Cont replay, Pkg provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CrossHistCausalCone}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1112.1, Definition 1112.2, Definition 1112.3, Definition 1112.4, Definition 1112.5, and Definition 1112.6 specify the finite bounded two-history causal-cone packet and its local consumer boundary.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CrossHistCausalCone}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not derive a numerical speed constant, Lorentz geometry, metric tensors, synchronized clocks, global frames, host real-valued speed, Lean verification, or bridge checking for $\mathsf{CrossHistCausalCone}^{\uparrow}$.

Upgrade path: Obligation closure requires checked carrier admission, affected-prefix replay, maximum-rate attachment, observer-symmetry preservation, no-global-frame refusal, and TasteGate nontriviality with field faithfulness.

Chapter 1113

A Concrete Naming Certificate for $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$

The $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$ packet realizes the Real-completeness witness route of chapter 9238 as the finite budget layer consumed by the $\mathsf{CauchyWitnessGluing}^{\uparrow}$ packet of chapter 1110. Its role is narrower than a full gluing certificate: it binds the witness ledger, tail envelope, synchronizer, completion-seal classifier, stream window, regular-sequence handoff, dyadic tolerance ledger, and terminal Real seal into one finite budget surface before diagonal-limit or Real-completion consumers read the route.

Definition 1113.1 (Finite Cauchy gluing-budget carrier)**.** *A* $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (G, L, T, S, K, U, V, D, R, H, C, P, N)$$

with the following displayed rows:

1. *G is the* $\mathsf{CauchyWitnessGluing}^{\uparrow}$ *route row naming the witness-gluing consumer surface;*
2. *L is the* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *row recording the selected witness ledger consumed by G;*
3. *T is the* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *row recording the finite tail envelope served to the gluing route;*
4. *S is the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row aligning the witness ledger, tail envelope, selected window, and completion-seal request;*
5. *K is the* $\mathsf{RealCompletionSealClassifierUp}$ *row classifying the synchronized completion-seal read;*
6. *U is the* $\mathsf{StreamName}^{\uparrow}$ *finite window-family row exposed to diagonal-limit readers;*
7. *V is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-sequence handoff row reached from the stream windows;*
8. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *dyadic tolerance ledger used to check the finite observation budget;*
9. *R is the terminal* $\mathsf{Real}^{\uparrow}$ *seal row served by the gluing budget;*
10. *H records componentwise* hsame *transport for $G, L, T, S, K, U, V, D, R$ and for the structural rows;*
11. *C records displayed* Cont *routes from the gluing row to the witness ledger, tail envelope, synchronizer, classifier, stream windows, dyadic ledger, regular handoff, and Real seal;*

12. *P is the* Pkg *provenance over chapter 9238, chapter 1110,* $\mathsf{CauchyWitnessLedger}^{\uparrow}$, $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$, $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$, RealCompletionSealClassifierUp, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, *and* NameCert *rows;*

13. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteCauchyGluingBudget}^{\uparrow}}$ *row.*

The carrier contains one finite gluing-budget packet. It contains no quotient stream, host real equality, selected external limit, countable-choice row, hidden synchronizer, detached completion-seal classifier, or ambient completeness principle.

Definition 1113.2 (Finite Cauchy gluing-budget classifier)**.** *The local classifier for* $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$ *accepts exactly those candidate packets*

$$B = (G, L, T, S, K, U, V, D, R, H, C, P, N)$$

whose rows jointly display the same witness-gluing route, witness ledger, tail envelope, synchronizer, completion-seal classifier, StreamName window family, RegSeqRat handoff, DyadicRatCore tolerance ledger, RealUp seal, componentwise hsame *transport, displayed* Cont *replay, package provenance, and local NameCert row. A candidate that preserves L and T but changes S is a different candidate and is rejected as a read of the same budget packet.*

Theorem 1113.3 (Finite Cauchy gluing-budget obligation surface)**.** *For the carrier of Definition 1113.1, the local* $\mathsf{NameCert}_{\mathsf{FiniteCauchyGluingBudget}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$B = (G, L, T, S, K, U, V, D, R, H, C, P, N),$$

gluing-row exactness through G, witness-ledger exactness through L, tail-envelope exactness through T, synchronizer exactness through S, completion-seal classifier exactness through K, finite-window exactness through U, regular-sequence handoff exactness through V, dyadic-tolerance exactness through D, Real-seal exactness through R, componentwise hsame *transport through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.FiniteCauchyGluingBudgetUp.TasteGate.FiniteCauchyGluingBudgetObligationSurface`

Proof. Project the carrier definition. The rows $G, L, T, S, K, U, V, D, R, H, C, P, N$ are the complete public inventory of the budget packet, and the definition excludes every ambient completion object named in the statement.

The first block fixes the gluing route and its witness side. The row G names the consumer surface, while L and T determine the witness ledger and finite tail envelope read by that surface.

The second block fixes the seal side. The synchronizer S binds the ledger and envelope to the completion-seal classifier K, then U, D, V expose the finite stream, dyadic, and regular-sequence rows before R is served.

The structural rows close the local certificate. Componentwise hsame transport, displayed Cont replay, Pkg provenance, and the local NameCert row are the remaining public coordinates, so the listed clauses exhaust the obligation surface. □

Theorem 1113.4 (Finite Cauchy gluing-budget route exactness)**.** *Every accepted* $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$ *packet presents the same Real-completion route to a consumer precisely when the consumer preserves*

$$G, L, T, S, K, U, V, D, R, H, C, P, N.$$

In particular, preserving the witness ledger L and tail envelope T while replacing the synchronizer row S does not preserve the accepted classifier read.

Proof. Use Definition 1113.2. The classifier reads the displayed tuple as one packet, not as independent witness, tail, and seal fragments.

Preserving all displayed rows preserves the route. The witness ledger, tail envelope, synchronizer, classifier, stream windows, dyadic ledger, regular handoff, and Real seal remain tied to the same gluing row and to the same structural rows.

If S is replaced while L and T are fixed, the row that binds the witness side to the completion-seal classifier has changed. The candidate may be inspected as another packet, but it is rejected as the same $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$ classifier read. □

Lean4 ✓ `BEDC.Derived.FiniteCauchyGluingBudgetUp.FiniteCauchyGluingBudgetCarrier route exactness`

Theorem 1113.5 (Finite Cauchy gluing-budget nonescape)**.** *Every diagonal-limit,* $\mathsf{CauchyWitnessGluing}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$ *packet factors through*

$$G \to L \to T \to S \to K \to U \to D \to V \to R$$

with H, C, P, N *visible. No such consumer can reach a Real seal through an omitted witness ledger, hidden tail envelope, alternate synchronizer, detached completion-seal classifier, quotient stream, host real equality, selected external limit, countable-choice row, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.FiniteCauchyGluingBudgetUp.FiniteCauchyGluingBudgetCarrier nonescape`

Proof. Start from the carrier inventory of Definition 1113.1. The finite tuple is the whole packet, and the excluded objects are not coordinates of the carrier.

A diagonal-limit consumer first reads the gluing route and witness side. The rows G, L, T determine which witness-gluing surface, ledger, and tail envelope are available.

The consumer then reads the synchronized seal side. The rows S and K determine the completion-seal request, while U, D, V provide the finite StreamName, DyadicRatCore, and RegSeqRat handoff before the Real seal R is exposed.

Finally, the structural rows make the route public. Since H, C, P, N are visible and no further coordinate exists, the consumer has no escape route to a second seal or to an ambient completion principle. □

Theorem 1113.6 (Finite Cauchy gluing-budget witness-ledger exhaustion)**.** *For any accepted* $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$ *packet*

$$B = (G, L, T, S, K, U, V, D, R, H, C, P, N),$$

every witness-ledger read available to a diagonal-limit, $\mathsf{CauchyWitnessGluing}^{\uparrow}$*, or* $\mathsf{Real}^{\uparrow}$ *consumer is exhausted by the displayed route*

$$G \to L \to T \to S \to K \to U \to D \to V \to R$$

with G, H, C, P, N *visible. A purported extra witness ledger, hidden tail, alternate synchronizer, detached completion-seal classifier, quotient stream, selected limit, countable-choice row, or ambient completeness principle is outside the carrier.*

Proof. Project the carrier of Definition 1113.1. The tuple $B = (G, L, T, S, K, U, V, D, R, H, C, P, N)$ is the finite budget packet, so a consumer receives only rows displayed by that carrier.

Next apply Definition 1113.3. It identifies the complete public inventory: the witness ledger L, tail envelope T, synchronizer S, completion-seal classifier K, stream window U, dyadic ledger D, regular handoff V, Real seal R, and the structural rows G, H, C, P, N.

Apply Definition 1113.4 to preserve the classifier read along that inventory. Replacing any ledger, tail, synchronizer, classifier, stream, handoff, tolerance, or seal coordinate produces a different candidate rather than another read of the same accepted packet.

Finally use Definition 1113.5. Since the consumer factors through the displayed route and the structural rows remain visible, every witness-ledger read has already been accounted for by the finite carrier; the listed escape objects are not coordinates of the accepted budget. □

Falsifiable prediction: If the finite gluing-budget packet is accepted, a consumer preserving the witness ledger and tail envelope but changing the synchronizer row is rejected by the classifier.

Independence witness: cauchywitnessgluing, cauchywitnessledger, cauchytailwitnessenvelope, cauchysealbudgetsynchronizer, realcompletionsealclassifier: none is bijective because each sibling omits at least one of the gluing route, witness ledger, tail envelope, synchronizer, completion-seal classifier, StreamName, RegSeqRat, DyadicRatCore, RealUp, hsame, Cont, Pkg, and NameCert rows required by this finite budget packet.

The Lean TasteGate development must provide explicit Nontrivial $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$ and FieldFaithful $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$ instances in BEDC.Derived.FiniteCauchyGluingBudgetUp.TasteGate.

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteCauchyGluingBudget}^{\uparrow}}$.

Constructive story: A $\mathsf{FiniteCauchyGluingBudget}^{\uparrow}$ packet is generated from a finite Cauchy gluing route, witness ledger, tail envelope, seal-budget synchronizer, completion-seal classifier, StreamName row, RegSeqRat row, DyadicRatCore row, RealUp seal row, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The carrier records the exact finite budget by which local Cauchy witnesses are glued and synchronized before a Real-facing seal is read. The support rows keep stream, regular, dyadic, and Real data on one route. The classifier preserves the witness ledger and tail envelope together; changing the synchronizer changes the exported finite budget surface.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{FiniteCauchyGluingBudget}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the finite Cauchy gluing budget carrier, classifier rejection criterion, prediction, and independence witness.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{FiniteCauchyGluingBudget}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim arbitrary Cauchy gluing, quotient regular-sequence equality, selected completed reals, or ambient completeness.

Upgrade path: To reach obligationClosure, formalize the witness ledger, tail envelope, synchronizer, and completion-seal classifier as checked finite budget rows.

Chapter 1114

A Concrete Naming Certificate for $\mathsf{TwinSubstrateBoundaryClassifier}^{\uparrow}$

Falsifiable prediction: A packet that identifies the two substrate roles without a displayed refusal ledger is not an accepted TwinSubstrateBoundaryClassifierUp carrier.

Independence witness: twinsubstratesynthesis, metacicauditmapfamily, groundcompilerflowlevelroundtrip, certificateauditgate, substitutionboundaryaudit: none is bijective because each lacks the simultaneous two-substrate role classifier plus shared refusal ledger carried here.

The $\mathsf{TwinSubstrateBoundaryClassifier}^{\uparrow}$ packet realizes the MetaCIC/GroundCompiler separation of chapter 9392 as a finite role classifier rather than as a request router. It sits beside the architecture packet of chapter 845 and the request-level router of chapter 851: those siblings name the cross-substrate architecture and its public routing discipline, while this chapter names the carrier that classifies the two substrate roles and records their shared refusal ledger before any consumer reads a boundary claim.

Definition 1114.1 (Twin-substrate boundary-classifier carrier)**.** *A* $\mathsf{TwinSubstrateBoundaryClassifier}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (M, G, Q, L, D, H, C, P, N)$$

with the following displayed rows:

1. *M is the MetaCIC substrate-role row, recording closed-CIC theorem inventory, proof-theoretic frontiers, substitution boundaries, and MetaCIC-side non-discharge clauses;*
2. *G is the GroundCompiler substrate-role row, recording compiler event-flow, recognizer, certificate, report, source-channel, and cannot-claim rows;*
3. *Q is the two-substrate classifier row, assigning each displayed boundary request to MetaCIC role data, GroundCompiler role data, paired-context data, or refusal data;*
4. *L is the shared refusal ledger, recording every forbidden conversion between compiler reports and proof evidence, between MetaCIC theorem rows and compiler-channel evidence, and between hidden host input and finite carrier data;*
5. *D is the downstream consumer row, exposing how a reader may use Q and L without collapsing M and G;*

6. *H records componentwise* hsame *transports for the two role rows, classifier row, refusal ledger, downstream consumer row, continuation row, provenance, and local naming;*
7. *C records displayed* Cont *routes replaying M, G, Q, L, D in finite order for boundary consumers;*
8. *P is the* Pkg *provenance over chapter 9392, chapter 845, chapter 851,* BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{TwinSubstrateBoundaryClassifier}^{\uparrow}}$ *row.*

The carrier has no coordinate for identifying MetaCIC and GroundCompiler as one substrate, converting reports into proof evidence, converting proof rows into compiler-channel evidence, or hiding refusal data outside the packet.

Lean4 ✓ `BEDC.Derived.TwinSubstrateBoundaryClassifierUp.TwinSubstrateBoundaryClassifierTasteGate`
`single carrier alignment`

Theorem 1114.2 (Twin-substrate boundary-classifier NameCert obligations)**.** *For every accepted* $\mathsf{TwinSubstrateBoundaryClassifier}^{\uparrow}$ *carrier*

$$B = (M, G, Q, L, D, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{TwinSubstrateBoundaryClassifier}^{\uparrow}}$ *surface consists exactly of MetaCIC role readback through M, GroundCompiler role readback through G, two-substrate classification through Q, shared refusal-ledger accounting through L, downstream consumer exposure through D, componentwise transport through H, displayed continuation replay through C, package provenance through P, and local naming through N.*

Proof. Project the finite carrier. The only substrate-role rows are M and G, the only classifier row is Q, and the only shared refusal ledger is L.

The classifier Q assigns a boundary read to MetaCIC role data, GroundCompiler role data, paired-context data, or refusal data before any consumer can use the read. The ledger L records the forbidden conversions for the same classification, so a role assignment is never separated from its refusal surface.

The downstream row D exposes only this classified and ledgered surface. Componentwise hsame transport in H preserves the projected rows, while Cont replay in C presents them in finite order.

Finally P records the twin-substrate provenance and N binds the local certificate name. Since no other coordinate is present, these rows exhaust the NameCert obligation surface. □

Theorem 1114.3 (Twin-substrate boundary-classifier refusal discipline)**.** *In every accepted* TwinSubstrateBoundary *carrier, identifying a boundary read as MetaCIC-facing, GroundCompiler-facing, paired-context, or refused requires the same shared refusal ledger L. A packet that supplies the role classifier Q but omits the displayed ledger L is not an accepted carrier.*

Proof. Start from Definition 1114.1. The classifier row Q and refusal ledger L are separate displayed coordinates of the same finite packet.

Apply the NameCert obligations of Definition 1114.2. They require classifier readback and ledger accounting together before the local certificate surface is complete.

If Q is present without L, a consumer could identify a substrate role while losing the explicit record that blocks report-to-proof conversion, proof-to-compiler conversion, and hidden host input. That packet lacks one mandatory NameCert coordinate, so it is outside the accepted carrier class. □

Lean4 ✓ `BEDC.Derived.TwinSubstrateBoundaryClassifierUp.TwinSubstrateBoundaryClassifierRefusalDiscipline`

Theorem 1114.4 (Twin-substrate boundary-classifier non-escape)**.** *Every public read exported by an accepted* TwinSubstrateBoundaryClassifier$^{\uparrow}$ *carrier factors through the finite package*

$$M, G, Q, L, D, H, C, P, N.$$

The export cannot collapse MetaCIC into GroundCompiler, collapse GroundCompiler into MetaCIC, replace the refusal ledger by prose, or route through a hidden host-level substrate classifier.

Proof. Use the carrier projection. Every exported read begins with the two displayed role rows, then passes through the classifier and the shared refusal ledger.

The downstream consumer row D only exposes the classified and ledgered surface. It does not add a role coordinate, a hidden classifier, or a conversion witness between the two substrate roles.

Transport, continuation, provenance, and naming preserve the same finite packet. Since the carrier contains no field for substrate collapse or host-level classification, no public read can export one. □

Theorem 1114.5 (Twin-substrate boundary-classifier public surface)**.** *The public surface of an accepted* TwinSubstrateBoundaryClassifier$^{\uparrow}$ *carrier is exactly the finite export of the MetaCIC role row, GroundCompiler role row, two-substrate classifier, shared refusal ledger, downstream consumer row, transport row, continuation row, provenance row, and local naming row. Downstream audit readers may distinguish the two substrate roles through this packet, but only with the displayed refusal ledger carried alongside the classifier.*

Proof. Project the public carrier fields. The reader receives $M, G, Q, L, D, H, C, P, N$ and no further role or refusal coordinate.

The classifier row Q distinguishes MetaCIC-facing, GroundCompiler-facing, paired-context, and refused reads. The refusal ledger L remains part of the same public surface, so every distinction carries the record of forbidden conversions.

The consumer, transport, continuation, provenance, and naming rows expose this data to downstream audit readers. They preserve the two-substrate classification without turning it into an unledgered route or a single merged substrate. □

Closure status for NameCert$_{\text{TwinSubstrateBoundaryClassifier}^{\uparrow}}$.

Constructive story: A TwinSubstrateBoundaryClassifier$^{\uparrow}$ packet is generated from MetaCIC and GroundCompiler substrate-role rows, a two-substrate classifier, a shared refusal ledger, a downstream consumer row, componentwise hsame transports, displayed Cont routes, Pkg provenance, and a local NameCert row.

Theory closure: TheoryGate(NameCert$_{\text{TwinSubstrateBoundaryClassifier}^{\uparrow}}$, seed)

Scope closed: Definition 1114.1, Definition 1114.2, Definition 1114.3, Definition 1114.4, and Definition 1114.5 bind the finite role classifier, shared refusal ledger, non-escape boundary, and public export surface.

Formal verification: FormalStatus(NameCert$_{\text{TwinSubstrateBoundaryClassifier}^{\uparrow}}$, unformalized)

Bridge status: none

Origin: ai

Not claimed: This chapter does not close MetaCIC proof-theoretic frontiers, prove GroundCompiler self-hosting, certify compiler report soundness, provide the Lean TasteGate Nontrivial and FieldFaithful instances, or bridge checking.

Upgrade path: Obligation closure requires checked carrier admission, role classification, refusal-ledger exactness, consumer exposure, public export exactness, transport, continuation, provenance, naming, and TasteGate Nontrivial and FieldFaithful instances for the same finite packet.

Chapter 1115

A Concrete Naming Certificate for $\mathsf{RegularCauchyIntervalSelector}^{\uparrow}$

The $\mathsf{RegularCauchyIntervalSelector}^{\uparrow}$ packet names the finite interval selector surface used when a regular Cauchy rational name is read through nested located intervals. In Bishop-style constructive analysis, nested rational or located intervals are data that can be inspected at any requested finite precision; the limiting real is never obtained by selecting a quotient representative or invoking an ambient completeness oracle. The packet therefore sits between the finite observation surfaces of chapter 126, chapter 301, chapter 38, and chapter 394.

Definition 1115.1 (Regular Cauchy interval selector carrier)**.** *A* $\mathsf{RegularCauchyIntervalSelector}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (D, S, R, J, E, H, C, P, N)$$

with the following visible rows:

1. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *denominator and radius ledger naming the requested precision;*
2. *S is the* $\mathsf{StreamName}^{\uparrow}$ *schedule row that selects the finite observation windows inspected at that precision;*
3. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row for the selected rational observations;*
4. *J is the finite* $\mathsf{LocatedInterval}^{\uparrow}$ *nesting ledger whose cells contain the selected regular Cauchy observations and whose successive cells refine the previous visible cell;*
5. *E is the* $\mathsf{Real}^{\uparrow}$ *seal-facing row reached only after the selected schedule, regular-rational readback, and located-interval nesting ledger have been displayed;*
6. *H records componentwise* hsame *transports for denominator ledgers, schedules, regular-rational readbacks, located interval cells, the seal row, provenance, and local naming;*
7. *C records the displayed* Cont *replay routes from D to S, from S to R, from R to J, and from J to E;*
8. *P is the* Pkg *provenance over* $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{LocatedInterval}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyIntervalSelector}^{\uparrow}}$ *row.*

The classifier compares packets only by these displayed rows and their componentwise transports. It has no coordinate for a selected completed real, quotient equality of Cauchy names, a detached interval limit, or an ambient completeness principle.

Theorem 1115.2 (Regular Cauchy interval selector nesting extraction)**.** *For every accepted* RegularCauchyIntervalS *packet*

$$Q = (D, S, R, J, E, H, C, P, N),$$

the finite nesting route extracted for a precision request is exactly

$$D \longmapsto S \longmapsto R \longmapsto J.$$

The extracted route exposes the denominator and radius ledger, the selected $\mathsf{StreamName}^{\uparrow}$ *window, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, and the* $\mathsf{LocatedInterval}^{\uparrow}$ *nesting ledger, all transported by the displayed* hsame *rows and replayed by the displayed* Cont *rows. No extracted object is a quotient real, a chosen limit point, or a host interval.*

Lean4 ✓ `BEDC.Derived.RegularCauchyIntervalSelectorUp.RegularCauchyIntervalSelectorCarrier nesting extraction`

Proof. Project the carrier of Definition 1115.1. The first four rows are precisely the precision ledger D, the selected schedule S, the regular-rational readback R, and the located-interval nesting ledger J.

Read the route in dependency order. The schedule row is available only after the precision ledger is displayed, the regular-rational readback is available only through the selected schedule, and the nesting ledger records only the located interval cells reached from that readback.

Transport is componentwise. The rows in H compare the four projected coordinates by hsame, while the rows in C replay the same finite route through Cont. The package row P and the local naming row N record provenance for that route rather than supplying an additional interval object.

The excluded objects are absent from the carrier. Since Q contains no quotient-real coordinate, no chosen limit point, and no host interval coordinate, the extraction can return only the displayed finite nesting route. □

Theorem 1115.3 (Regular Cauchy interval selector RealUp seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *consumer of an accepted* $\mathsf{RegularCauchyIntervalSelector}^{\uparrow}$ *packet factors through the finite route*

$$D \longmapsto S \longmapsto R \longmapsto J \longmapsto E \longmapsto H, C, P, N.$$

Thus the consumer may read the dyadic precision ledger, selected stream window, regular-rational readback, located interval nesting ledger, terminal $\mathsf{Real}^{\uparrow}$ *seal row, componentwise transports, continuation replays, package provenance, and local* NameCert *row. It receives no quotient equality of regular Cauchy names, selected completed real, detached interval limit, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.RegularCauchyIntervalSelectorUp.RegularCauchyIntervalSelectorCarrier real seal handoff`

Proof. Begin with the nesting extraction of Definition 1115.2. It fixes the only route from a precision request to a displayed located-interval nesting ledger as $D \mapsto S \mapsto R \mapsto J$.

Now inspect the seal-facing coordinate of Definition 1115.1. The row E is reachable only after the selected schedule, regular-rational readback, and located-interval nesting ledger have been displayed. Hence a $\mathsf{Real}^{\uparrow}$ consumer reaches E through the same finite route.

The structural rows do not widen the route. The hsame rows in H move the displayed coordinates componentwise, the Cont rows in C replay the displayed route, the package row P records provenance for that route, and N names the local certificate surface.

Finally, the carrier has no field for quotient equality of regular Cauchy names, a selected completed real, a detached interval limit, or an ambient completeness principle. A $\mathsf{Real}^{\uparrow}$ consumer therefore receives only the displayed selector-to-seal handoff. □

Theorem 1115.4 (Regular Cauchy interval selector schedule exposure)**.** *For every accepted* RegularCauchyIntervalS *packet*

$$Q = (D, S, R, J, E, H, C, P, N),$$

the selector exposes the dyadic precision ledger D before the selected $\mathsf{StreamName}^{\uparrow}$ *schedule S. The schedule row S is readable only together with the displayed* hsame *rows in H, the displayed* Cont *replay from D to S in C, the provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{RegularCauchyIntervalSelector}^{\uparrow}}$ *row N. No consumer may read S as an ambient stream-choice oracle detached from the displayed precision ledger and certificate rows.*

Lean4 ✓ `BEDC.Derived.RegularCauchyIntervalSelectorUp.RegularCauchyIntervalSelectorCarrier schedule exposure`

Proof. Project the carrier of Definition 1115.1. Its first coordinate is the dyadic denominator and radius ledger D, while its second coordinate is the selected stream schedule S.

The dependency order is part of the displayed carrier surface. Row C contains the replay route from D to S, row H supplies the componentwise hsame transport for the same displayed coordinates, and the rows P and N bind provenance and local naming for the selector.

Since the carrier has no coordinate for a detached schedule oracle, the only readable schedule is the row S reached through D, H, C, P, N. □

Theorem 1115.5 (Regular Cauchy interval selector located nesting transport)**.** *Let*

$$Q = (D, S, R, J, E, H, C, P, N)$$

be an accepted $\mathsf{RegularCauchyIntervalSelector}^{\uparrow}$ *packet. Replacing the displayed located-interval ledger J by a transported refinement J' preserves the selector route only when the precision ledger D, selected schedule S, regular-rational readback R, seal row E, componentwise transports H, continuation rows C, provenance row P, and local naming row N are transported with it. A detached interval limit, quotient real, or unrecorded refinement cannot replace this route.*

Proof. Use Definition 1115.2. The nesting route visible to the selector is exactly $D \mapsto S \mapsto R \mapsto J$, so any change of the located ledger must be read as a change inside that finite route.

Now inspect the remaining carrier rows in Definition 1115.1. The row E is reached only after J, while H, C, P, and N record the transports, replay routes, provenance, and local certificate that make the selected route readable.

Therefore a transported refinement J' preserves the selector route only as part of the transported packet. The excluded detached limit, quotient real, and unrecorded refinement have no row in the carrier and cannot serve as replacements. □

Theorem 1115.6 (Regular Cauchy interval selector obligation surface)**.** *The visible* $\mathsf{NameCert}_{\mathsf{RegularCauchyIntervalSelec}}$ *obligations for an accepted packet*

$$Q = (D, S, R, J, E, H, C, P, N)$$

are exactly the following five rows: the carrier definition of Definition 1115.1, the schedule exposure of Definition 1115.4, the nesting extraction of Definition 1115.2, the located nesting transport of Definition 1115.5, and the Real$^{\uparrow}$ *seal handoff of Definition 1115.3. These rows are the public obligation surface of the selector packet; they do not add quotient equality, detached interval limits, selected completed reals, or ambient completeness.*

Proof. The carrier row is Definition 1115.1. It names the finite packet coordinates $D, S, R, J, E, H, C, P, N$ and excludes any coordinate for a quotient real, detached interval limit, or completeness oracle.

The schedule row is supplied by Definition 1115.4. The nesting row is supplied by Definition 1115.2, and the transported refinement row is supplied by Definition 1115.5.

Finally, apply Definition 1115.3 for the seal-facing row. The five cited rows exhaust the readable selector obligations because every consumer route factors through the displayed carrier coordinates and their recorded transports. □

Theorem 1115.7 (Regular Cauchy interval selector finite route obligation package)**.** *For every accepted* RegularCauchyIntervalSelector$^{\uparrow}$ *packet*

$$Q = (D, S, R, J, E, H, C, P, N),$$

the displayed rows $D, S, R, J, E, H, C, P, N$ form the finite obligation package of the selector route. The row D exposes the dyadic precision ledger, S is schedule-dependent on D, R is the RegSeqRat$^{\uparrow}$ *readback through S, J is the located interval nesting ledger through R, and E is reached only through J. The remaining rows H, C, P, N bind the componentwise* hsame *transport,* Cont *replay, provenance, and local* NameCert *surface for that route.*

Proof. Start with the carrier definition of Definition 1115.1. Its displayed coordinates are exactly $D, S, R, J, E, H, C, P, N$, so the candidate obligation package has no hidden coordinate beyond those rows.

The dependency spine is fixed by the existing selector rows. Use schedule exposure from Definition 1115.4 to read S only after D, use nesting extraction from Definition 1115.2 to read $D \mapsto S \mapsto R \mapsto J$, and use located nesting transport from Definition 1115.5 to keep transported refinements inside the same finite route.

The obligation surface of Definition 1115.6 says that these rows exhaust the public selector obligations. Finally, Definition 1115.3 places the seal row E and the structural rows H, C, P, N after the displayed route, which gives the finite package claimed here. □

Closure status for NameCert$_{\text{RegularCauchyIntervalSelector}^{\uparrow}}$.

Constructive story: A RegularCauchyIntervalSelector$^{\uparrow}$ packet is generated from a selected finite schedule, regular-rational readback row, located-interval nesting ledger, seal-facing handoff row, componentwise hsame transports, displayed Cont routes, provenance, and local naming. The carrier reads interval selection through finite BEDC data: first the schedule is displayed, then the RegSeqRat readback and nesting ledger certify the selected interval route, and only then the RealUp-facing seal row is available. The classifier keeps the selector-to-seal handoff finite and refuses detached interval limits or quotient Cauchy names.

Theory closure: TheoryGate(NameCert$_{\text{RegularCauchyIntervalSelector}^{\uparrow}}$, obligation)

Scope closed: This chapter binds the finite route obligation package of Definition 1115.7, including the checked rows of Definition 1115.2 and Definition 1115.3.

Formal verification: FormalStatus(NameCert$_{\text{RegularCauchyIntervalSelector}^{\uparrow}}$, axiomClean)

Lean target: `BEDC.Derived.RegularCauchyIntervalSelectorUp.RegularCauchyIntervalSelectorCarrier\_nesting\_extracti`

Bridge status: none

Origin: human

Not claimed: It does not claim quotient equality of regular Cauchy names, selected completed reals, detached interval limits, or ambient completeness.

Upgrade path: To reach scopedClosure, close the carrier interactions across BHist, hsame, Cont, Pkg, NameCert, StreamNameUp, RegSeqRatUp, LocatedIntervalUp, DyadicRatCoreUp, and RealUp.

Chapter 1116

A Concrete Naming Certificate for $\mathsf{CauchyLimitFunctor}^{\uparrow}$

The $\mathsf{CauchyLimitFunctor}^{\uparrow}$ packet names the functorial transport surface for Cauchy limit seals in the Real and Completion route of chapter 9238. It sits after the dyadic tolerance core of chapter 291, the finite stream window surface of chapter 126, the regular rational readback of chapter 301, and the terminal real seal of chapter 38. It also consumes the existing limit-seal boundary of chapter 386 and the completion-seal classifier of chapter 900. The packet is a routed transport object: it carries a finite source seal, a finite target seal, and the displayed map between their regular Cauchy data without adding a host-level completion theorem.

Falsifiable prediction: If a completion consumer accepts a transported Cauchy limit seal while changing the source stream window, target stream window, regular-rational readback, dyadic tolerance ledger, or RealUp endpoint row outside the displayed transport packet, it refutes the $\mathsf{CauchyLimitFunctor}^{\uparrow}$ classifier.

Independence witness: cauchylimitseal, realcompletionsealclassifier, streamname, regseqrat, dyadicratcore, real: no listed sibling is bijective to $\mathsf{CauchyLimitFunctor}^{\uparrow}$ because the functor packet carries source and target limit-seal rows together with the finite transport map, classifier row, dyadic tolerance ledger, regular-rational readback, RealUp endpoint, componentwise transports, continuation replay, provenance, and local NameCert row.

Definition 1116.1 (Cauchy limit functor carrier)**.** *A* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N)$$

with the following displayed rows:

1. *S is the source* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row whose limit-seal route is being transported;*
2. *T is the target* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row reached after transport;*
3. *M is the finite transport-map row from the source window and readback data to the target window and readback data;*
4. *W_0 is the source* $\mathsf{StreamName}^{\uparrow}$ *window row read by S;*
5. *W_1 is the target* $\mathsf{StreamName}^{\uparrow}$ *window row read by T;*
6. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row preserved by the displayed transport;*

7. *D is the* DyadicRatCore$^{\uparrow}$ *tolerance ledger controlling the transported precision request;*
8. *K is the* RealCompletionSealClassifierUp *row that recognizes the transported seal boundary;*
9. *E is the terminal* Real$^{\uparrow}$ *endpoint row consumed after the target seal is displayed;*
10. *H records componentwise* hsame *transports for the two limit seals, map row, stream windows, regular-rational readback, dyadic ledger, classifier, endpoint, provenance, and local naming rows;*
11. *C records the displayed* Cont *replay route from S through M, W_0, W_1, R, D, K to T and then to E;*
12. *P is the* Pkg *provenance over chapter 386, chapter 900, chapter 126, chapter 301, chapter 291, chapter 38,* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows;*
13. *N is the local* NameCert$_{\text{CauchyLimitFunctor}^{\uparrow}}$ *row.*

The carrier exports no quotient stream equality, selected host limit, ambient completeness principle, countable-choice selector, detached Real value, or second transport route beyond the displayed packet.

Definition 1116.2 (Cauchy limit functor classifier)**.** *The* CauchyLimitFunctor$^{\uparrow}$ *classifier compares two carriers only by the displayed rows*

$$S, T, M, W_0, W_1, R, D, K, E, H, C, P, N.$$

Two packets are classifier-equal exactly when the source and target limit-seal rows agree, the transport-map row agrees, the source and target StreamName$^{\uparrow}$ *windows agree, the* RegSeqRat$^{\uparrow}$ *readback and* DyadicRatCore$^{\uparrow}$ *tolerance ledger agree, and the classifier, endpoint, transport, continuation, provenance, and local naming rows agree componentwise. The classifier has no coordinate for quotient equality of Cauchy names, host real equality, an untracked selector, a detached limit object, or an ambient completeness theorem.*

Theorem 1116.3 (Cauchy limit functor NameCert obligations)**.** *For the carrier of Definition 1116.1, the local* NameCert$_{\text{CauchyLimitFunctor}^{\uparrow}}$ *surface consists exactly of the following five obligation rows:*

1. *carrier exposure for $F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N)$;*
2. *source-to-target seal exposure through the ordered route $S \to M \to T$;*
3. *finite observation exposure through W_0, W_1, R, D;*
4. *completion-consumer exposure through K and E;*
5. *structural exposure through componentwise* hsame *transport H, displayed* Cont *replay C,* Pkg *provenance P, and local naming N.*

No CauchyLimitFunctor$^{\uparrow}$ *consumer can read the transported limit seal without preserving all five rows.*

Lean4 ✓ `BEDC.Derived.CauchyLimitFunctorUp.CauchyLimitFunctorCarrier namecert obligations`

Proof. Project the carrier of Definition 1116.1. Its displayed packet is exactly $F = (S, T, M, W_0, W_1, R, D, K, E, H,$ so the carrier row supplies the finite object being named.

Read the seal route next. The source seal S is transported only through the finite map row M, and the target seal T is reached only after that row is displayed. Thus the seal exposure is the ordered route $S \to M \to T$.

Now inspect the observation rows. The source and target windows W_0, W_1, the regular-rational readback R, and the dyadic tolerance ledger D are the finite data over which the transport map is read. The completion-facing rows K, E then recognize the transported seal boundary and deliver the terminal $\mathsf{Real}^{\uparrow}$ endpoint.

Finally the rows H, C, P, N transport, replay, record provenance for, and name the same packet. Since the carrier and classifier contain no further coordinates, a consumer that bypasses any one of the five obligation rows leaves the $\mathsf{CauchyLimitFunctor}^{\uparrow}$ surface. □

Theorem 1116.4 (Cauchy limit functor source-target seal exposure)**.** *For every accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet with carrier*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N),$$

the source seal is exposed to consumers only through the finite route $S \to M \to T$*. In particular, a consumer can cite* S *and* T *as the displayed source and target* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows, and can cite* M *as the finite transport-map row between them, but receives no detached source-target equality, host-level limit comparison, quotient stream equality, or second seal route outside the classifier of Definition 1116.2.*

Lean4 ✓ `BEDC.Derived.CauchyLimitFunctorUp.CauchyLimitFunctorCarrier source target seal exposure`

Proof. Use the carrier of Definition 1116.1. Its first three displayed rows are exactly the source seal S, the target seal T, and the transport-map row M.

Apply the classifier of Definition 1116.2. It compares the seal data through the listed coordinates $S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$ and has no coordinate for a detached source-target equality or an alternate route.

Finally apply the NameCert obligation surface of Definition 1116.3. The second obligation row is precisely source-to-target seal exposure through $S \to M \to T$, so any accepted packet exposes the seal only by that displayed finite route. □

Theorem 1116.5 (Cauchy limit functor finite observation exposure)**.** *For every accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet with carrier*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N),$$

the observation side available to a consumer is exactly

$$W_0, W_1, R, D, K, E.$$

The consumer may inspect the two stream windows, the regular-rational readback, the dyadic tolerance ledger, the completion-seal classifier row, and the terminal $\mathsf{Real}^{\uparrow}$ *endpoint row. It receives no quotient stream equality, selected limit, countable-choice selector, host real equality, detached completion object, or ambient completeness principle.*

Lean4 ✓ `BEDC.Derived.CauchyLimitFunctorUp.CauchyLimitFunctorCarrier finite observation exposure`

Proof. Project the carrier of Definition 1116.1. The observation rows are the source and target windows W_0, W_1, the readback row R, the tolerance ledger D, the completion classifier K, and the endpoint row E.

Use the classifier of Definition 1116.2. It allows comparison only along the displayed carrier coordinates, so there is no classifier coordinate for quotient stream equality, a selected limit, countable choice, host real equality, or an ambient completion theorem.

The NameCert obligations of Definition 1116.3 split the observation surface into finite observation exposure through W_0, W_1, R, D and completion-consumer exposure through K, E. These two rows give exactly the displayed observation side and nothing outside it. □

Theorem 1116.6 (Cauchy limit functor structural transport)**.** *For every accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet with carrier*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N),$$

the only structural transport, continuation replay, provenance, and local naming rows available to consumers are H, C, P, N*. Thus all componentwise* hsame *transport is carried by* H*, all displayed replay is carried by* C*, all dependency provenance is carried by* P*, and the local certificate name is carried by* N*.*

Lean4 ✓ `BEDC.Derived.CauchyLimitFunctorUp.CauchyLimitFunctorCarrier structural transport`

Proof. Start from the carrier of Definition 1116.1. Its final four rows are H, C, P, N, respectively recording componentwise hsame transports, displayed Cont replay, Pkg provenance, and the local $\mathsf{NameCert}_{\mathsf{CauchyLimitFunctor}^{\uparrow}}$ row.

Read those rows through the classifier of Definition 1116.2. Since the classifier compares only the displayed coordinates, it cannot supply any additional transport object, replay path, provenance row, or local name beyond H, C, P, N.

Apply the fifth obligation row of Definition 1116.3. Structural exposure is exactly componentwise transport H, displayed continuation replay C, provenance P, and local naming N, so every consumer is confined to those structural rows. □

Theorem 1116.7 (Cauchy limit functor Real-completion consumer boundary)**.** *Every Real and Completion consumer that cites an accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet factors through the finite route*

$$S \longmapsto M \longmapsto W_0, W_1, R, D \longmapsto K \longmapsto T \longmapsto E \longmapsto H, C, P, N.$$

The consumer may use the source and target $\mathsf{CauchyLimitSeal}^{\uparrow}$ *rows, the transport map, the two* $\mathsf{StreamName}^{\uparrow}$ *windows, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, the* RealCompletionSealClassifierUp *row, the terminal* $\mathsf{Real}^{\uparrow}$ *endpoint, and the structural* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows. It receives no quotient stream equality, host real equality, selected limit, detached completion object, ambient completeness principle, countable-choice selector, or second transport route.*

Proof. Start with the NameCert obligations of Definition 1116.3. They force every accepted read through the carrier row, the source-to-target seal route, the finite observation rows, the completion-consumer rows, and the structural rows.

Use the classifier of Definition 1116.2. It compares only $S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$, so a Real and Completion consumer cannot distinguish two reads by adding quotient stream equality, host real equality, a selected limit, or an ambient completion proof.

Finally follow the route displayed in the carrier. The source seal S is transported by M over the windows W_0, W_1, readback R, and tolerance ledger D; the classifier row K recognizes the transported boundary before the target seal T and endpoint row E are consumed. The structural rows H, C, P, N package that same finite route, so no detached completion object, choice-selected witness, or second route remains available. □

Lean4 ✓ `BEDC.Derived.CauchyLimitFunctorUp.CauchyLimitFunctorCarrier real completion consumer boundary`

Theorem 1116.8 (Cauchy limit functor primitive scope package)**.** *Every accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet with carrier*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N)$$

binds its source-target seal route, finite observation rows, completion-consumer rows, and structural rows only through the primitive BEDC objects BHist, hsame, Cont, Pkg, *and* NameCert, *together with the sibling source certificates* CauchyLimitSeal$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RealCompletionSealClassifierUp, *and* Real$^{\uparrow}$. *Thus the scoped packet consists exactly of the displayed carrier row, classifier coordinates, source-to-target route* $S \to M \to T$, *observation rows* W_0, W_1, R, D, *completion rows* K, E, *structural rows* H, C, P, N, *and their cited sibling certificates.*

No quotient stream equality, host real equality, selected limit, detached completion object, ambient completeness principle, countable-choice selector, or second route enters the scoped packet.

Proof. Start with the carrier and classifier of Definition 1116.1 and Definition 1116.2. The carrier is the finite BHist packet $F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N)$, and the classifier reads exactly those coordinates, so every row available to the packet is already one of the displayed source, target, map, observation, completion, structural, provenance, or naming rows.

Apply the NameCert obligation surface of Definition 1116.3. Its five rows identify carrier exposure, source-to-target seal exposure, finite observation exposure, completion-consumer exposure, and structural exposure. These are the only rows a local NameCert$_{\text{CauchyLimitFunctor}^{\uparrow}}$ consumer may preserve.

Next use Definition 1116.4, Definition 1116.5, and Definition 1116.6. They place the seal route at $S \to M \to T$, the finite observation surface at W_0, W_1, R, D, K, E, and the structural surface at H, C, P, N, where H carries componentwise hsame, C carries displayed Cont, P carries Pkg provenance, and N carries the local NameCert row.

Finally apply the Real-completion consumer boundary of Definition 1116.7. It keeps the completion read inside the same route through the sibling source certificates CauchyLimitSeal$^{\uparrow}$, StreamName$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RealCompletionSealClassifierUp, and Real$^{\uparrow}$. Since each cited result excludes quotient stream equality, host real equality, selected limits, detached completion objects, ambient completeness, countable choice, and second routes, the primitive-scoped packet contains no further object beyond BHist, hsame, Cont, Pkg, NameCert, and those sibling certificates. □

Theorem 1116.9 (Cauchy limit functor public seal export)**.** *Every accepted* CauchyLimitFunctor$^{\uparrow}$ *packet with carrier*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N)$$

exports a reusable public transport surface from the source CauchyLimitSeal$^{\uparrow}$ *row* S *through the displayed transport map* M, *the* StreamName$^{\uparrow}$ *windows* W_0, W_1, *the* RegSeqRat$^{\uparrow}$ *readback* R, *the* DyadicRatCore$^{\uparrow}$ *tolerance ledger* D, *the* RealCompletionSealClassifierUp *row* K, *and the terminal* Real$^{\uparrow}$ *endpoint* E. *The exported surface is reusable only as the public route*

$$S \longmapsto M \longmapsto W_0, W_1, R, D \longmapsto K \longmapsto T \longmapsto E \longmapsto H, C, P, N,$$

with H *carrying componentwise* hsame *transport,* C *carrying displayed* Cont *replay,* P *carrying* Pkg *provenance, and* N *carrying the local* NameCert$_{\text{CauchyLimitFunctor}^{\uparrow}}$ *row.*

No quotient stream equality, host real equality, selected limit, detached completion object, ambient completeness principle, countable-choice selector, or second transport route is exported by this public surface.

Lean4 ✓ `BEDC.Derived.CauchyLimitFunctorUp.CauchyLimitFunctorCarrier public seal export`

Proof. Start with the carrier and classifier of Definition 1116.1 and Definition 1116.2. They make the public packet a finite read of the displayed rows $S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$, so a reusable export can only cite those rows.

Apply the NameCert obligations of Definition 1116.3. The obligation rows expose the carrier, the source-target seal route, finite observations, Real-completion consumer boundary, and structural rows. Use Definition 1116.4 and Definition 1116.5 to identify the public route through $S, M, W_0, W_1, R, D, K, T, E$.

Next apply Definition 1116.6. It supplies exactly the reusable transport, replay, provenance, and naming rows H, C, P, N, so the exported surface can be handed to later consumers without adding any route outside the packet.

Finally use Definition 1116.7 and Definition 1116.8. The first confines Real and Completion consumers to the same finite transport route, while the second keeps the route primitive-scoped. The exclusions in those two results remove quotient stream equality, host real equality, selected limits, detached completion objects, ambient completeness, countable choice, and second routes from the public export. □

Theorem 1116.10 (Cauchy limit functor terminal-window fusion)**.** *Every accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet with carrier*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N)$$

fuses the source terminal $\mathsf{StreamName}^{\uparrow}$ *window* W_0*, target terminal* $\mathsf{StreamName}^{\uparrow}$ *window* W_1*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D*,* $\mathsf{RealCompletionSealClassifierUp}$ *classifier row* K*, and terminal* $\mathsf{Real}^{\uparrow}$ *row* E *into the single terminal-window route*

$$S \longmapsto M \longmapsto W_0, W_1, R, D \longmapsto K \longmapsto T \longmapsto E \longmapsto H, C, P, N.$$

The route has no quotient stream equality, selected host limit, countable-choice selector, detached completion object, or second Real-facing route.

Proof. Project the carrier of Definition 1116.1. The only finite source and target windows are W_0 and W_1, and the only Real-facing observation rows attached to them are R, D, K, E.

Use finite observation exposure, Definition 1116.5. It identifies W_0, W_1, R, D, K, E as the complete observation side available to a consumer and excludes quotient stream equality, selected limits, countable-choice selectors, host real equality, detached completion objects, and ambient completeness.

Finally apply the Real-completion consumer boundary and the public seal export, Definition 1116.7 and Definition 1116.9. Together they force the terminal Real read through the same route from S through M, the two windows, readback, tolerance, classifier, target seal, endpoint, and structural rows. Hence the terminal-window route is fused inside the accepted packet and no second Real-facing route remains. □

Theorem 1116.11 (Cauchy limit functor Real-seal naturality)**.** *Let*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N)$$

be an accepted $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet. Componentwise* hsame *transport along the structural row* H *preserves the terminal-window route of Definition 1116.10 before any Real-facing seal is made public. Thus the transported source seal, target seal, stream windows, readback, tolerance ledger, classifier row, terminal Real row, continuation replay, provenance, and local name still form the same single route, with no public seal read adding a quotient stream equality, selected host limit, countable-choice selector, detached completion object, or second Real-facing route.*

Proof. Read the classifier of Definition 1116.2. It compares packets only by the rows $S, T, M, W_0, W_1, R, D, K, E, H$, so componentwise transport cannot create a new coordinate for a second seal route or a detached Real object.

Use structural transport, Definition 1116.6. The row H is the only componentwise hsame transport surface, while C, P, N keep the replay, provenance, and local name attached to the same packet.

Apply terminal-window fusion, Definition 1116.10. Since the fused route is already determined before public seal export, transporting each displayed component along H preserves that same route. The exclusions in the fusion theorem therefore persist before any Real-facing seal becomes public. □

Theorem 1116.12 (Cauchy limit functor bridge-scope coherence)**.** *Every bridge-scope consumer of an accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet with carrier*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N)$$

must preserve the finite route

$$S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$$

through $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, RealCompletionSealClassifierUp, *and* $\mathsf{Real}^{\uparrow}$. *The bridge-facing read may expose the public transport surface of Definition 1116.9, but it cannot add quotient stream equality, host real equality, selected limits, ambient completeness, countable choice, or a second transport route.*

Proof. Start with the carrier and classifier. The packet rows are exactly $S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$, and the classifier reads only those coordinates.

Apply the public seal export, Definition 1116.9. It exposes the reusable route from S through M, the stream windows W_0, W_1, the readback R, the tolerance ledger D, the classifier row K, the target seal T, the terminal endpoint E, and the structural rows H, C, P, N.

Next use the primitive scope package and Real-completion consumer boundary, Definition 1116.8 and Definition 1116.7. These place the route through $\mathsf{CauchyLimitSeal}^{\uparrow}$, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, RealCompletionSealClassifierUp, and $\mathsf{Real}^{\uparrow}$ without admitting a detached completion object.

Carrier-coordinate exhaustion gives bridge-scope coherence. Since the displayed packet has no coordinate for quotient stream equality, host real equality, selected limits, ambient completeness, countable choice, or a second transport route, a bridge-scope consumer can preserve only the finite route already exported by the public seal surface. □

Theorem 1116.13 (CauchyLimitFunctor standard reflection bridge surface)**.** *Every standard-reflection read of an accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet with carrier*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N)$$

factors through the displayed source seal S*, target seal* T*, transport row* M*,* $\mathsf{StreamName}^{\uparrow}$ *windows* W_0, W_1*,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback* R*,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger* D*,* RealCompletionSealClassifierUp *classifier row* K*,* $\mathsf{Real}^{\uparrow}$ *endpoint* E*, componentwise* hsame *transport* H*, displayed* Cont *replay* C*,* Pkg *provenance* P*, and local* $\mathsf{NameCert}_{\mathsf{CauchyLimitFunctor}^{\uparrow}}$ *row* N*.*

Thus the bridge surface is the single route

$$S \longmapsto M \longmapsto W_0, W_1, R, D \longmapsto K \longmapsto T \longmapsto E \longmapsto H, C, P, N,$$

read through the same primitive-scoped packet. It exports no quotient stream equality, host real equality, selected limit, detached completion object, ambient completeness principle, countable-choice selector, or alternate completion transport.

Lean4 ✓ `BEDC.Derived.CauchyLimitFunctorUp.CauchyLimitFunctorUp StdBridge`

Proof. Start from the carrier and classifier of Definition 1116.1 and Definition 1116.2. They make $S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$ the only rows visible to a standard-reflection read.

Apply the NameCert obligation surface of Definition 1116.3. Its obligation rows expose the source-target seal route, finite observations, Real-completion consumer boundary, structural transport, provenance, and local naming surface for the same accepted packet.

Next use Definition 1116.4, Definition 1116.5, and Definition 1116.6. These identify the route through S, M, T, the windows W_0, W_1, readback R, tolerance ledger D, classifier row K, endpoint E, and the structural rows H, C, P, N.

Finally apply Definition 1116.7, Definition 1116.8, and Definition 1116.9. They keep Real-completion consumption inside the primitive-scoped public seal route. The bridge-scope coherence theorem then makes any standard-reflection read preserve that route without adding quotient equality, host real equality, selected limits, detached completion objects, ambient completeness, countable choice, or a second transport. □

Theorem 1116.14 (Cauchy limit functor terminal endpoint non-escape)**.** *For any accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N),$$

the terminal $\mathsf{Real}^{\uparrow}$ *endpoint row E is readable only after the target seal T, the transported windows W_0, W_1, the regular-rational readback R, the dyadic ledger D, the completion classifier K, and the structural rows H, C, P, N have been displayed through the same finite route. No consumer may detach E as host real equality, a selected limit, ambient completeness, a countable-choice selector, or a second Real-facing route.*

Proof. Start with the carrier of Definition 1116.1. The endpoint row E appears only inside the packet

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N),$$

so no terminal read exists before the surrounding seal, window, readback, ledger, classifier, and structural rows are present.

Apply terminal-window fusion, Definition 1116.10, and Real-seal naturality, Definition 1116.11. These keep the endpoint route tied to the transported windows, regular-rational readback, dyadic ledger, completion classifier, target seal, and structural replay rows.

Finally use the standard-reflection bridge surface, Definition 1116.13. Its non-escape boundary excludes quotient stream equality, host real equality, selected limits, detached completion objects, ambient completeness, countable choice, and any second Real-facing route, so the endpoint row remains a terminal packet coordinate rather than an external Real oracle. □

Theorem 1116.15 (Cauchy limit functor seal route totality)**.** *Every accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet with carrier*

$$F = (S, T, M, W_0, W_1, R, D, K, E, H, C, P, N)$$

exposes its public route only through the displayed source seal S, target seal T, map row M, $\mathsf{StreamName}^{\uparrow}$ *finite-window rows W_0, W_1,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row R,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row D,* $\mathsf{Real}^{\uparrow}$ *endpoint row E, the provenance row* Pkg*, the replay row* Cont*, the componentwise*

transport row hsame*, and the local row* $\mathsf{NameCert}_{\mathsf{CauchyLimitFunctor}^{\uparrow}}$*. No accepted packet admits a public route through quotient stream equality, host real equality, selected limits, detached completion objects, ambient completeness, countable choice, or any second transport row.*

Proof. Start with the source-target seal exposure of Definition 1116.4. It makes S, M, and T the displayed route from the source $\mathsf{CauchyLimitSeal}^{\uparrow}$ side to the target seal side.

Next apply finite observation exposure, Definition 1116.5. This inserts the $\mathsf{StreamName}^{\uparrow}$ windows W_0, W_1, the $\mathsf{RegSeqRat}^{\uparrow}$ readback R, the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance row D, the classifier row K, and the terminal $\mathsf{Real}^{\uparrow}$ endpoint E into the same route.

Finally use the primitive scope package, Definition 1116.8, together with the carrier and classifier definitions. The remaining visible rows are exactly the structural transport, displayed replay, provenance, and local naming rows H, C, P, N, so every public route is exhausted by the listed Pkg, Cont, hsame, and NameCert data. □

Theorem 1116.16 (Cauchy limit functor finite-window naturality)**.** *Let two accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packets share the same source seal row, target seal row, and map row inside the displayed carrier. If their* $\mathsf{StreamName}^{\uparrow}$ *finite windows are* hsame*-compatible and are transported by that same map row, then the two packets induce the same* $\mathsf{RegSeqRat}^{\uparrow}$ *readback route and the same* $\mathsf{Real}^{\uparrow}$ *terminal seal route through the displayed rows* $S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$*.*

Proof. Begin with structural transport, Definition 1116.6. The shared map row M and the hsame row H make the two finite-window reads componentwise compatible inside the carrier.

Apply finite observation exposure. Since the windows are transported by the same map row, the readback row R and tolerance row D are read from the same finite observation surface, and the classifier row K sees no additional coordinate.

The source-target seal exposure then carries this common finite observation route to the same target seal row and terminal $\mathsf{Real}^{\uparrow}$ endpoint. Carrier-coordinate exhaustion rules out a second route, so the induced $\mathsf{RegSeqRat}^{\uparrow}$ and $\mathsf{Real}^{\uparrow}$ seal routes agree. □

Theorem 1116.17 (Cauchy limit functor completion consumer exactness)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *output factors through the source-target seal route and the bridge-scope coherence route before reading any terminal seal. Such a consumer may read* $S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$*, but it cannot bypass the public seal route by introducing quotient stream equality, host real equality, a selected limit, a detached completion object, ambient completeness, countable choice, or an alternate completion transport.*

Proof. Use the Real-completion consumer boundary, Definition 1116.7. It confines every $\mathsf{Real}^{\uparrow}$ or completion-facing read to the finite route through the source seal, target seal, map row, finite windows, readback, tolerance ledger, classifier row, and terminal endpoint.

Next apply the public seal export, Definition 1116.9. It packages the same route with the structural transport, replay, provenance, and local NameCert rows, making those rows the only reusable surface for downstream consumers.

Finally apply bridge-scope coherence, Definition 1116.12. Any terminal seal read must preserve the bridge-scoped route already exported by the public surface, so completion-facing exactness follows without adding a second completion route. □

Theorem 1116.18 (Cauchy limit functor identity consumer)**.** *Suppose an accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet has the same displayed* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row as source and target, and suppose its transport row is the identity replay over the same* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* RealCompletionSealClassifierUp

and $\mathsf{Real}^{\uparrow}$ *rows. Then every identity consumer of the packet still reads only the finite route isolated by Definition 1116.13.*

In particular, the identity consumer may reuse the displayed rows

$$S, T, M, W_0, W_1, R, D, K, E, H, C, P, N,$$

but it exports no quotient stream equality, host real equality, selected limit, detached completion object, ambient completeness principle, countable-choice selector, or alternate completion transport.

Proof. Start with the carrier and classifier of Definition 1116.1 and Definition 1116.2. The identity assumption identifies the source and target seal rows inside the already displayed carrier; it does not create a new carrier coordinate or a second classifier read.

Apply Definition 1116.4, Definition 1116.5, and Definition 1116.6. The first keeps the route at the same $\mathsf{CauchyLimitSeal}^{\uparrow}$ row, the second keeps the observation through W_0, W_1, R, D, K, E, and the third records the identity replay through H, C, P, N.

Next use Definition 1116.7, Definition 1116.9, and Definition 1116.12. They keep any Real-completion read, reusable public export, and bridge-scope read inside the same primitive-scoped route.

Finally apply Definition 1116.13. Since the identity replay has no coordinate beyond the cited carrier rows and sibling certificates, the consumer reads exactly the finite route already isolated there and nothing outside it. □

Theorem 1116.19 (Cauchy limit functor identity transport)**.** *For an accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet whose transport row is the identity on a displayed* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row, the identity transport preserves the same source seal, target seal,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* $\mathsf{RealCompletionSealClassifierUp}$ *row, terminal* $\mathsf{Real}^{\uparrow}$ *endpoint,* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}$ *row. It exports no second source-target route, quotient stream equality, selected limit, detached completion object, host real equality, ambient completeness principle, or countable-choice selector.*

Proof. Project the identity consumer carrier. Since the source and target $\mathsf{CauchyLimitSeal}^{\uparrow}$ rows are the same displayed row, the identity transport has no independent source-target coordinate to expose.

Apply finite observation exposure and structural transport. The $\mathsf{StreamName}^{\uparrow}$ windows, $\mathsf{RegSeqRat}^{\uparrow}$ readback, $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance ledger, completion-seal classifier row, and terminal $\mathsf{Real}^{\uparrow}$ endpoint are replayed through the existing H, C, P, N rows.

Finally use the public seal export and bridge-scope coherence. They keep every reusable consumer on the displayed route, so the identity transport preserves the listed rows and cannot introduce a second completion route or any excluded host principle. □

Theorem 1116.20 (Cauchy limit functor composite consumer)**.** *Let two accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packets be composable in the sense that the middle target seal row of the first packet and the middle source seal row of the second packet agree componentwise, and their shared observation rows agree through the displayed* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* $\mathsf{RealCompletionSealClassifierUp}$*, and* $\mathsf{Real}^{\uparrow}$ *certificates. Then the composite consumer route is the concatenation of the two finite routes displayed by Definition 1116.13.*

The composite consumer exports only this concatenated finite route through the two packets' rows $S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$*. It exports no quotient stream equality, selected limit, ambient completeness principle, countable-choice selector, alternate completion transport, or host-level equality between the two completion presentations.*

Proof. Use the carrier and classifier definitions for both packets. Componentwise agreement of the middle seal and observation rows lets the second route begin exactly where the first route ends, while each packet still exposes only its own displayed carrier rows.

Apply Definition 1116.4 and Definition 1116.5 to each packet. These two results identify the composable seal route and the shared finite observation surface without adding a quotient or selected limiting object at the middle row.

Next apply Definition 1116.6, Definition 1116.7, and Definition 1116.9. The structural row supplies the componentwise replay, the Real-completion boundary keeps both reads inside the displayed certificates, and the public export gives the reusable surface for concatenation.

Finally use Definition 1116.12 and Definition 1116.13. Bridge-scope coherence prevents a second route at the shared middle row, and the standard-reflection bridge surface identifies the composite as the two finite routes placed end to end. □

Theorem 1116.21 (Cauchy limit functor transport composition)**.** *Let two accepted* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packets transport a displayed source seal to an intermediate seal and then from that intermediate seal to a displayed target seal. Suppose their shared intermediate seal rows agree componentwise, and suppose the displayed finite observation rows are aligned through the two packets'* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledgers,* $\mathsf{RealCompletionSealClassifierUp}$ *classifier rows, and terminal* $\mathsf{Real}^{\uparrow}$ *endpoint rows.*

Then the composite consumer factors through the concatenated displayed rows

$$S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$$

of the first packet and the corresponding displayed rows of the second packet, yielding one target $\mathsf{Real}^{\uparrow}$ *completion seal. The transport composition exports no quotient stream equality, selected representative, host real equality, ambient completeness principle, countable-choice selector, or detached completion object.*

Proof. Expose the source and target seals for both packets by Definition 1116.4. The first packet supplies the source-to-intermediate route, and the second packet supplies the intermediate-to-target route; the componentwise agreement hypothesis identifies the middle seal as a displayed handoff row rather than a quotient or selected representative.

Next apply finite observation exposure to both packets. This aligns the source and target windows, regular readbacks, dyadic tolerance ledgers, classifier rows, and Real endpoint rows before any terminal seal is read.

Use structural transport for the H, C, P rows. Componentwise hsame transport preserves the displayed rows, Cont replay keeps the consumer on those rows, and Pkg provenance records that the same local packets are being concatenated.

Finally apply the composite consumer theorem. Its concatenated route is exactly the two displayed transport packets placed end to end, so the terminal read is a single target $\mathsf{Real}^{\uparrow}$ completion seal and none of the excluded host or choice principles has a carrier coordinate from which to be exported. □

Theorem 1116.22 (Cauchy limit functor induction route)**.** *Let S be a finite source* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row, let T be a finite target* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *row, and let M be a displayed transport map between their regular Cauchy data. Suppose the source and target rows expose the same finite* $\mathsf{StreamName}^{\uparrow}$ *window schedule,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback discipline,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger,* $\mathsf{RealCompletionSealClassifierUp}$ *boundary row, and terminal* $\mathsf{Real}^{\uparrow}$ *seal as rows of a single* BHist

packet with componentwise hsame *transport, displayed* Cont *replay,* Pkg *provenance, and a local* NameCert *row.*

Then induction on the displayed $\mathsf{StreamName}^{\uparrow}$ *and* $\mathsf{RegSeqRat}^{\uparrow}$ *finite window constructs a routed* $\mathsf{CauchyLimitFunctor}^{\uparrow}$ *packet from* S, T, M*. The route preserves the source seal, target seal, transport map, finite windows, regular readback, dyadic tolerance ledger, completion-seal classifier, Real endpoint, transport row, continuation row, provenance row, and local naming row, and it exports no quotient stream equality, selected limit, ambient completeness principle, host real equality, or second transport route.*

Proof. Begin with the base window. The empty or initial displayed $\mathsf{StreamName}^{\uparrow}$ window carries only the source seal, target seal, transport-map row, and dyadic tolerance ledger already present in the BHist packet. The classifier row from RealCompletionSealClassifierUp is read as a boundary row, not as a selected limit.

For the successor window, assume the routed packet has been built for the current finite prefix. Extend the $\mathsf{StreamName}^{\uparrow}$ row by one displayed observation and extend the $\mathsf{RegSeqRat}^{\uparrow}$ readback by the matching regular rational datum. The dyadic ledger supplies the tolerance comparison for this single step, and the transport map M carries the source observation to the target observation inside the same continuation route.

At each induction step, componentwise hsame transport preserves the visible rows and the Cont replay records the ordered handoff from S through M to T. The Pkg row records that the construction uses only $\mathsf{CauchyLimitSeal}^{\uparrow}$, RealCompletionSealClassifierUp, $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, Pkg, and NameCert rows.

After the finite window is exhausted, the local $\mathsf{NameCert}_{\mathsf{CauchyLimitFunctor}^{\uparrow}}$ row names exactly the routed packet. No induction clause introduces quotient equality of streams, a selected limit, host completeness, host real equality, or an alternate route, so the constructed row is the required finite $\mathsf{CauchyLimitFunctor}^{\uparrow}$ route. □

Theorem 1116.23 (Cauchy limit functor Real-completion handoff exhaustion)**.** *Every* $\mathsf{Real}^{\uparrow}$*-and-completion consumer using either the identity route of Definition 1116.18 or the composite route of Definition 1116.20 factors through the same displayed rows*

$$S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$$

and through the sibling certificates $\mathsf{CauchyLimitSeal}^{\uparrow}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*,* RealCompletionSealClassifierUp*, and* $\mathsf{Real}^{\uparrow}$ *already cited in this chapter.*

Consequently the handoff is exhausted by the primitive-scoped bridge surface: it has no extra output for quotient stream equality, host real equality, selected limits, detached completion objects, ambient completeness, countable choice, or alternate completion transport.

Proof. Begin with the carrier and classifier definitions. They make $S, T, M, W_0, W_1, R, D, K, E, H, C, P, N$ the complete coordinate list for any accepted packet, so an identity or composite handoff has no independent row to read.

Apply Definition 1116.4, Definition 1116.5, and Definition 1116.6. These locate the seal, observation, and replay parts of the handoff inside the cited sibling certificates and structural rows.

Next use Definition 1116.7, Definition 1116.9, and Definition 1116.12. They confine every Real-and-completion consumer to the public bridge-scope route and exclude detached completion data from the handoff.

Finally apply Definition 1116.13, together with the identity and composite consumer theorems above. The only available handoff is the identity route or the concatenated finite route, and both are exhausted by the same primitive-scoped rows and sibling certificates. □

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyLimitFunctor}\uparrow}$.

Constructive story: A $\mathsf{CauchyLimitFunctor}^{\uparrow}$ packet is generated from source and target CauchyLimitSeal rows, a finite transport-map row, source and target StreamName windows, a RegSeqRat readback, a DyadicRatCore tolerance ledger, a RealCompletionSealClassifier row, a terminal RealUp endpoint, componentwise transports, displayed replay, provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyLimitFunctor}\uparrow}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1116.1, Definition 1116.2, Definition 1116.3, Definition 1116.4, Definition 1116.5, Definition 1116.6, Definition 1116.7, Definition 1116.8, Definition 1116.9, Definition 1116.12, Definition 1116.13, Definition 1116.15, Definition 1116.16, Definition 1116.17, Definition 1116.18, Definition 1116.20, and Definition 1116.23 bind the finite transport carrier, classifier, five NameCert obligation rows, separate seal-route exposure, finite observation exposure, structural transport, Real-completion consumer boundary, primitive scope package, reusable public transport surface, bridge-scope route coherence, standard-reflection bridge surface, seal-route totality, finite-window naturality, completion consumer exactness, identity consumer, composite consumer, and Real-completion handoff exhaustion.

Chapter 1117

A Concrete Naming Certificate for $\mathsf{CauchyWitnessPullback}^{\uparrow}$

The $\mathsf{CauchyWitnessPullback}^{\uparrow}$ packet realizes the inverse readback side of the Real-completion witness route of chapter 9238. It is paired with the forward gluing packet of chapter 1110 and reads back through the witness ledger of chapter 902, the tail-witness envelope of chapter 898, the seal-budget synchronizer of chapter 886, and the Real-completion seal classifier of chapter 900. The packet also records the $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ rows needed by a completion-facing consumer that must recover which witness ledger supported a glued seal.

Definition 1117.1 (CauchyWitnessPullback carrier)**.** *A* $\mathsf{CauchyWitnessPullback}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$Q = (G, K, R, L, T, S, U, V, D, A, H, C, P, N)$$

with the following displayed rows:

1. *G is the accepted* $\mathsf{CauchyWitnessGluing}^{\uparrow}$ *row whose Real-facing seal is being read back;*
2. *K is the* $\mathsf{RealCompletionSealClassifierUp}$ *row that recognizes the glued completion seal;*
3. *R is the terminal* $\mathsf{Real}^{\uparrow}$ *seal row served by the glued packet;*
4. *L is the recovered* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *row;*
5. *T is the recovered* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$ *row;*
6. *S is the recovered* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row;*
7. *U is the* $\mathsf{StreamName}^{\uparrow}$ *row visible at the recovered tail window;*
8. *V is the* $\mathsf{RegSeqRat}^{\uparrow}$ *row reached by reading the recovered stream window;*
9. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger used by the recovered stream and regular-sequence rows;*
10. *A is the pullback agreement row saying that G, K, R determine the displayed L, T, S, U, V, D readback packet;*
11. *H records componentwise* hsame *transports for all displayed rows;*
12. *C records the* Cont *routes from the glued seal to the classifier, from the classifier to the recovered ledger, from the ledger through tail and synchronizer rows, and from the stream and dyadic rows to the regular-sequence handoff;*

13. *P is the* Pkg *provenance over chapter 1110, chapter 902, chapter 898, chapter 886, chapter 900, chapter 126, chapter 301, chapter 291, chapter 38,* hsame, Cont, *and* NameCert *rows;*
14. *N is the local* $\mathsf{NameCert}_{\mathsf{CauchyWitnessPullback}^{\uparrow}}$ *row.*

The carrier exports no quotient stream equality, host real equality, detached external limit, countable-choice row, ambient completeness principle, or untracked witness replacement beyond the displayed pullback packet.

Lean4 ✓ `BEDC.Derived.CauchyWitnessPullbackUp.TasteGate.CauchyWitnessPullbackTasteGate single carrier alignment`

Theorem 1117.2 (CauchyWitnessPullback NameCert obligations)**.** *Let*

$$Q = (G, K, R, L, T, S, U, V, D, A, H, C, P, N)$$

be an accepted $\mathsf{CauchyWitnessPullback}^{\uparrow}$ *packet. Every consumer that preserves the glued seal G, completion classifier K, Real seal R, recovered ledger L, tail envelope T, synchronizer S, stream row U, regular-sequence row V, dyadic ledger D, pullback agreement A, transports H, continuations C, provenance P, and local name N preserves the same witness-readback packet. A consumer that preserves G, K, R but changes L is not a preservation of this carrier.*

Proof. Project the carrier of Definition 1117.1. The displayed rows are the whole finite packet, and the agreement row A is the coordinate that binds the glued seal to the recovered witness side.

The readback first passes through G, K, R. These rows identify the Real-facing seal and the classifier that accepts it, so a consumer cannot choose a second completion-seal source without changing the packet.

The readback then reaches L, T, S, U, V, D. These rows record which witness ledger, tail envelope, synchronizer, stream window, regular-sequence handoff, and dyadic tolerance ledger support the accepted seal.

Finally H, C, P, N make the readback a NameCert surface rather than an ambient equality assertion. Thus preserving all displayed rows preserves the packet, while changing L changes the coordinate that the agreement row recovers from the glued seal. □

Theorem 1117.3 (CauchyWitnessPullback Real seal factorization)**.** *Every completion-facing read of an accepted* $\mathsf{CauchyWitnessPullback}^{\uparrow}$ *packet factors through*

$$G \to K \to R \to A \to (L, T, S, U, D, V)$$

with H, C, P, N visible as structural rows. No consumer can preserve the glued seal while replacing the recovered witness-ledger row, tail-envelope row, synchronizer row, StreamName row, RegSeqRat row, DyadicRatCore row, or RealUp seal row.

Proof. Start with the Real-facing side. The rows G, K, R present the accepted glued packet, the classifier that recognizes its completion seal, and the terminal $\mathsf{Real}^{\uparrow}$ seal.

Apply the pullback agreement row A. It records the inverse readback from that glued seal to the displayed witness-side packet, so the recovered rows are not optional annotations.

Read the recovered side. The ledger L, tail envelope T, synchronizer S, stream row U, dyadic ledger D, and regular-sequence row V are the displayed coordinates through which the Real seal is supported.

The structural rows H, C, P, N then repack these coordinates into the local NameCert surface. Replacing any recovered coordinate while keeping only the glued seal fixed therefore gives a different candidate packet, not the same $\mathsf{CauchyWitnessPullback}^{\uparrow}$ factorization. □

Lean4 ✓ `BEDC.Derived.CauchyWitnessPullbackUp.CauchyWitnessPullbackUp StdBridge`

Theorem 1117.4 (CauchyWitnessPullback recovered ledger determinacy)**.** *Let*

$$Q = (G, K, R, L, T, S, U, V, D, A, H, C, P, N)$$

be an accepted $\mathsf{CauchyWitnessPullback}^{\uparrow}$ *packet. Any second accepted pullback packet that agrees with* Q *on* G, K, R, A, H, C, P, N *has the same recovered witness-ledger row* L*. Thus the recovered ledger is determined by the glued seal, completion classifier, Real seal, pullback agreement, transport, continuation, provenance, and local NameCert rows.*

Lean4 ✓ `BEDC.Derived.CauchyWitnessPullbackUp.CauchyWitnessPullbackCarrier recovered ledger determinacy`

Proof. Project the carrier of Definition 1117.1. The row L is a displayed coordinate of the same finite packet as G, K, R, A, H, C, P, N, not an ambient ledger chosen after the seal has been read.

Apply Definition 1117.2. A consumer that preserves the glued seal, classifier, Real seal, agreement, transports, continuations, provenance, and local name but changes L fails to preserve the carrier.

Finally use Definition 1117.3. The Real-facing read passes through $G \to K \to R \to A$ before it reaches the recovered witness side, so agreement on those structural rows fixes the ledger coordinate recovered by the pullback packet. □

Theorem 1117.5 (CauchyWitnessPullback tail synchronizer compatibility)**.** *For every accepted* $\mathsf{CauchyWitnessPullback}^{\uparrow}$ *packet*

$$Q = (G, K, R, L, T, S, U, V, D, A, H, C, P, N),$$

the recovered rows T, S, U, V, D *remain on the same* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{DyadicRatCore}^{\uparrow}$ *route that the agreement row reads back from* G, K, R*. In particular, a consumer cannot keep* $G, K, R, L, A, H, C, P, N$ *fixed while moving the recovered tail envelope, synchronizer, stream row, regular-sequence row, or dyadic ledger to an unrelated route.*

Proof. Read the displayed coordinates in Definition 1117.1. The tail envelope T, synchronizer S, stream row U, regular-sequence row V, and dyadic ledger D are named together with the recovered ledger L and the agreement row A.

Apply Definition 1117.2. Preserving the pullback carrier preserves the same recovered witness-readback packet, including the rows that route from the tail envelope through synchronizer, stream, regular-sequence, and dyadic data.

Use Definition 1117.3. Since the Real seal factors through the displayed recovered side, replacing any one of T, S, U, V, D by an unrelated route while keeping the structural rows fixed leaves the $\mathsf{CauchyWitnessPullback}^{\uparrow}$ factorization. □

Theorem 1117.6 (CauchyWitnessPullback Real-seal readback exactness)**.** *Every completion-facing consumer of an accepted* $\mathsf{CauchyWitnessPullback}^{\uparrow}$ *packet receives exactly the rows*

$$G, K, R, L, T, S, U, V, D, A, H, C, P, N$$

as its readback surface. The readback exports no quotient stream, selected limit, choice row, ambient completeness datum, host real equality, or hidden witness replacement.

Proof. Start from Definition 1117.1. The carrier lists precisely the fourteen displayed rows and explicitly excludes quotient stream equality, detached limits, choice rows, ambient completeness, and untracked witness replacement.

Apply Definition 1117.2. The local NameCert surface is preserved only by preserving those displayed coordinates together, so a completion-facing consumer has no additional row from which to read a selected limit or hidden witness.

Finally use Definition 1117.3. The Real-seal read passes through the glued seal, classifier, Real seal, agreement, and recovered witness-side rows, with H, C, P, N visible as structural rows. That factorization is exactly the exported readback surface. □

Theorem 1117.7 (CauchyWitnessPullback scoped primitive dependency binding)**.** *Let*

$$Q = (G, K, R, L, T, S, U, V, D, A, H, C, P, N)$$

be an accepted $\mathsf{CauchyWitnessPullback}^{\uparrow}$ *packet. The readback surface of* Q *is scoped exactly by the displayed* BHist *packet, the componentwise* hsame *transports* H*, the displayed* Cont *routes* C*, the* Pkg *provenance* P*, the local* $\mathsf{NameCert}_{\mathsf{CauchyWitnessPullback}^{\uparrow}}$ *row* N*, and the sibling certificate rows cited by the carrier:* $\mathsf{CauchyWitnessGluing}^{\uparrow}$*,* $\mathsf{CauchyWitnessLedger}^{\uparrow}$*,* $\mathsf{CauchyTailWitnessEnvelope}^{\uparrow}$*,* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$*,* $\mathsf{RealCompletionSealClassifierUp}$*,* $\mathsf{StreamName}^{\uparrow}$*,* $\mathsf{RegSeqRat}^{\uparrow}$*,* $\mathsf{DyadicRatCore}^{\uparrow}$*, and* $\mathsf{Real}^{\uparrow}$*. No quotient stream, selected limit, host real equality, choice row, or ambient completeness datum lies in this scoped primitive dependency surface.*

Proof. Project the carrier of Definition 1117.1. Its fourteen displayed coordinates are the whole accepted BHist packet, and the rows H, C, P, N are already part of the carrier rather than external annotations.

Apply Definition 1117.2. The local NameCert obligations force preservation of $G, K, R, L, T, S, U, V, D, A, H, C,$ together, so a consumer cannot keep the pullback packet while replacing any cited sibling certificate row.

Next use the factorization theorem Definition 1117.3. It routes every completion-facing read through $G \to K \to R \to A$ before the recovered ledger, tail, synchronizer, stream, dyadic, and regular-sequence rows are consumed. Thus the displayed Cont replay and Pkg provenance are the only admissible dependency route from the glued seal to the recovered witness side.

Apply recovered-ledger determinacy from Definition 1117.4 and tail-synchronizer compatibility from Definition 1117.5. These results keep the ledger, tail envelope, synchronizer, stream row, regular-sequence row, and dyadic ledger on the same sibling-certified route.

Finally apply readback exactness from Definition 1117.6. Since the accepted packet exports exactly the displayed rows, quotient streams, selected limits, host real equality, choice rows, and ambient completeness remain outside the scoped primitive dependency boundary. □

The Lean TasteGate namespace $\mathsf{BEDC.Derived.CauchyWitnessPullbackUp.TasteGate}$ provides explicit $\mathsf{Nontrivial}\ \mathsf{CauchyWitnessPullback}^{\uparrow}$ and $\mathsf{FieldFaithful}\ \mathsf{CauchyWitnessPullback}^{\uparrow}$ instances for the displayed carrier, with the single-carrier alignment target named $\mathsf{BEDC.Derived.CauchyWitnessPullbackUp.Taste}$

Falsifiable prediction: If the pullback packet is accepted, a Real-completion consumer preserving the glued seal but changing the witness-ledger row is rejected by the classifier.

Independence witness: cauchywitnessgluing, cauchywitnessledger, cauchytailwitnessenvelope, cauchysealbudgetsynchronizer, realcompletionsealclassifier: no bijection preserves all pullback rows because the pullback packet carries the glued seal, classifier, Real seal, recovered ledger, recovered

tail, recovered synchronizer, StreamName, RegSeqRat, DyadicRatCore, agreement, transport, continuation, provenance, and local NameCert rows together, while each sibling exposes only one direction or one face of that readback.

Closure status for $\mathsf{NameCert}_{\mathsf{CauchyWitnessPullback}^{\uparrow}}$.

Constructive story: A $\mathsf{CauchyWitnessPullback}^{\uparrow}$ packet is generated from a glued seal row, completion classifier, Real seal, recovered witness ledger, recovered tail envelope, recovered synchronizer, StreamName row, RegSeqRat row, DyadicRatCore row, agreement row, componentwise hsame transport, displayed Cont replay, provenance, and local naming. The carrier reads a Real-completion seal backwards through the witness data that produced it: the classifier exposes the recovered ledger, envelope, and synchronizer together. The agreement and transport rows keep that recovery tied to the same seal. A consumer preserving the glued seal but changing the witness ledger leaves the displayed pullback route.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CauchyWitnessPullback}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 1117.1, Definition 1117.2, Definition 1117.3, Definition 1117.4, Definition 1117.5, Definition 1117.6, Definition 1117.7, and

Lean4 ✓ `BEDC.Derived.CauchyWitnessPullbackUp.taste gate`

bind the Cauchy witness pullback carrier, recovered-ledger determinacy, tail synchronizer compatibility, Real-seal readback exactness, scoped primitive dependency surface, prediction, and independence witness.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CauchyWitnessPullback}^{\uparrow}}, \mathsf{axiomClean})$

Bridge status: none

Origin: ai

Not claimed: It does not claim arbitrary pullback of completed reals, quotient sequence equality, hidden witness recovery, or ambient completeness.

Upgrade path: To reach publicClosure, provide the public certificate export theorem for standard reflection consumers of the checked pullback carrier.

Chapter 1118

A Concrete Naming Certificate for $\mathsf{AxisCarryDiamondRoute}^{\uparrow}$

The $\mathsf{AxisCarryDiamondRoute}^{\uparrow}$ packet names the two-route diamond that compares displayed Zeckendorf carry-normalization paths. It is adjacent to the finite confluence surface of chapter 713, but its local role is the route certificate itself: two source carry windows, two route rows, one shared normal target row, value ledgers, non-hsame boundary rows, componentwise transports, continuation replay, provenance, and a local naming row are carried together as a finite packet.

It is an ai over the $\mathsf{ZCarry}^{\uparrow}$, $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$, $\mathsf{ZeckendorfCarryValue}^{\uparrow}$, and $\mathsf{AxisZeckendorfCarryBudg}$ sibling surfaces, with the diamond row acting only as the finite shared-target route bundle.

Falsifiable prediction: Two accepted diamond packets with the same two displayed source carry windows and same shared target row cannot expose two different target-normality ledgers.

Independence witness: zeckendorfcarryclassifier, zeckendorfcarrynormalization, zcarry, zeckendorfcarryvalue, axiszeckendorfcarrybudget: the diamond carrier has two route rows and a shared-target ledger absent from each sibling, while each sibling lacks at least one of the paired-route or shared-normal-target coordinates.

The packet consumes $\mathsf{ZCarry}^{\uparrow}$ edges from chapter 544, the normalization handoff of chapter 608, the value row of chapter 606, and the finite budget surface of chapter 692. It does not identify the carry sources by hsame and does not promote the diamond to a kernel rewrite.

Definition 1118.1 (Axis carry diamond-route carrier)**.** *An* $\mathsf{AxisCarryDiamondRoute}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$D = (a, b, c, n, \rho_0, \rho_1, \nu_0, \nu_1, \eta, H, C, P, N)$$

with the following displayed rows:

1. *a is the displayed overlap source row for the diamond;*
2. *b and c are the two displayed carry-successor source windows;*
3. *n is the shared normal target row admitted by* $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$*;*
4. *ρ_0 is the first route row, consisting of a* $\mathsf{ZCarry}^{\uparrow}$ *edge from a to b and a* $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$ *handoff from b to n;*
5. *ρ_1 is the second route row, consisting of a* $\mathsf{ZCarry}^{\uparrow}$ *edge from a to c and a* $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$ *handoff from c to n;*
6. *ν_0 and ν_1 are the displayed finite value ledgers for the two routes;*

7. *η is the shared target-normality ledger for n;*
8. *H records the non-*hsame *carry boundaries together with componentwise transports for all displayed route, value, target, continuation, provenance, and naming rows;*
9. *C records displayed* Cont *routes for replaying the two route rows, both value ledgers, the shared target-normality row, and the local naming row;*
10. *P records* Pkg *provenance over* $\mathsf{ZCarry}^{\uparrow}$, $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$, $\mathsf{ZeckendorfCarryValue}^{\uparrow}$, $\mathsf{AxisZeckendorfCarryBudget}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert*;*
11. *N is the local* $\mathsf{NameCert}_{\mathsf{AxisCarryDiamondRoute}^{\uparrow}}$ *row.*

The carrier exports only this finite two-route packet. It contains no source-target hsame *proof, no host arithmetic quotient, no global confluence theorem, no hidden normalizer, and no kernel rewrite rule.*

Lean4 (definition) `BEDC.Derived.AxisCarryDiamondRouteUp.AxisCarryDiamondRouteUp`

Lean4 ✓ `BEDC.Derived.AxisCarryDiamondRouteUp.AxisCarryDiamondRouteTasteGate single carrier alignment`

Theorem 1118.2 (Axis carry diamond routes name two-step confluence)**.** *For an accepted* AxisCarryDiamondRoute *carrier $D = (a, b, c, n, \rho_0, \rho_1, \nu_0, \nu_1, \eta, H, C, P, N)$, the route rows ρ_0 and ρ_1 name two displayed carry-normalization paths from the same overlap source row a to the same normal target row n. The shared target-normality ledger η is read only after both route rows and both value ledgers have been exposed, so any diamond consumer receives a finite two-step confluence packet rather than two unrelated carry edges.*

Proof. Project the accepted carrier. The rows ρ_0 and ρ_1 are the only route coordinates, and their endpoints are fixed by the displayed rows a, b, c, n.

Read the normal target and value rows next. The target coordinate n is shared, while ν_0 and ν_1 record the finite value ledgers along the two displayed paths.

Finally replay the support rows. The continuation and provenance rows expose the two routes and the shared target ledger as one packet, and the local NameCert row names that packet before a consumer may cite the diamond. □

Lean4 ✓ `BEDC.Derived.AxisCarryDiamondRouteUp.AxisCarryDiamondRouteCarrier names two step confluence`

Theorem 1118.3 (Axis carry diamond-route non-escape)**.** *Every accepted* $\mathsf{AxisCarryDiamondRoute}^{\uparrow}$ *read factors through the displayed packet*

$$D = (a, b, c, n, \rho_0, \rho_1, \nu_0, \nu_1, \eta, H, C, P, N).$$

*It can expose the two carry-normalization route rows, the shared normal target row, the two value ledgers, the shared target-normality ledger, non-*hsame *carry boundaries, componentwise transports, route replay, provenance, and local naming. It cannot expose source-target* hsame*, host arithmetic equality, a quotient normal form, an unbounded normalizer, a global confluence theorem, or a kernel rewrite.*

Proof. Begin with Definition 1118.1. The displayed tuple lists every coordinate available to an accepted read, and none of the excluded objects is a coordinate.

The route coordinates are finite. Each route row is assembled from the $\mathsf{ZCarry}^{\uparrow}$ and ZeckendorfCarryNormalizatio sibling surfaces, while the value and target ledgers are displayed as ν_0, ν_1, η rather than as host arithmetic or quotient data.

The support rows H, C, P, N preserve and replay only those displayed coordinates. Since the carrier contains no hidden normalizer, global confluence row, source-target hsame proof, or kernel rewrite rule, no accepted projection can escape the finite diamond-route packet. □

Lean4 ✓ `BEDC.Derived.AxisCarryDiamondRouteUp.AxisCarryDiamondRouteNonescape`

The Lean taste-gate file for this carrier should provide explicit `Nontrivial AxisCarryDiamondRouteUp` and `FieldFaithful AxisCarryDiamondRouteUp` instances for the displayed row inventory.

Theorem 1118.4 (Axis carry diamond-route obligation surface)**.** *For every accepted* AxisCarryDiamondRoute$^{\uparrow}$ *carrier*

$$D = (a, b, c, n, \rho_0, \rho_1, \nu_0, \nu_1, \eta, H, C, P, N),$$

*the local obligation surface consists exactly of carrier admission for the displayed rows, classifier stability over those same rows, route exposure for ρ_0, ρ_1, shared-target normality for η, componentwise value-ledger transport for ν_0, ν_1, non-*hsame *boundary preservation in H, continuation replay in C, package provenance in P, and local naming in N. No obligation is stored outside the finite tuple.*

Proof. Project the carrier of Definition 1118.1. The rows $a, b, c, n, \rho_0, \rho_1, \nu_0, \nu_1, \eta, H, C, P, N$ are the complete row inventory.

Apply the two-step confluence and non-escape theorems. They force every route, target, value, transport, replay, provenance, and naming read to remain inside that inventory.

Thus the admission and classifier obligations range over exactly the displayed packet, while the excluded host equality, quotient, hidden normalizer, global confluence, and kernel rewrite objects have no carrier coordinate. □

Theorem 1118.5 (Axis carry diamond-route target-ledger exactness)**.** *For an accepted* AxisCarryDiamondRoute$^{\uparrow}$ *carrier $D = (a, b, c, n, \rho_0, \rho_1, \nu_0, \nu_1, \eta, H, C, P, N)$, the shared target-normality ledger η may be read only after both route rows ρ_0, ρ_1 and both value ledgers ν_0, ν_1 have been displayed. A consumer that reads η while omitting either route row or either value ledger is not reading the accepted diamond-route packet.*

Proof. Use Definition 1118.2. It places η downstream of the two route rows and the two value ledgers in the public diamond handoff.

Then apply non-escape. Since the carrier has no second target-normality coordinate and no hidden normalizer, η cannot be detached from $\rho_0, \rho_1, \nu_0, \nu_1, H, C, P, N$. □

Theorem 1118.6 (Axis carry diamond-route value-ledger stability)**.** *Let $D = (a, b, c, n, \rho_0, \rho_1, \nu_0, \nu_1, \eta, H, C, P, N)$ and $D' = (a', b', c', n', \rho'_0, \rho'_1, \nu'_0, \nu'_1, \eta', H', C', P', N')$ be accepted* AxisCarryDiamondRoute$^{\uparrow}$ *carriers related componentwise by the displayed transport and continuation rows. Then the value ledgers ν_0, ν_1 are stable routewise: the first ledger is transported only along the ρ_0 route, the second ledger only along the ρ_1 route, and both remain tied to the shared target-normality row before any diamond consumer can use them.*

Proof. Project both carrier tuples. The only value-ledger coordinates are ν_0 and ν_1, and the only route coordinates governing them are ρ_0 and ρ_1.

Use the transport rows H, H' and continuation rows C, C'. They replay the componentwise route and value data without adding a cross-route ledger or a host arithmetic equality.

Finally apply target-ledger exactness and non-escape. The ledgers stay attached to their route rows and the shared target ledger, so a consumer cannot swap, merge, or replace them by quotient normal forms, global carry confluence, or kernel rewriting. □

Theorem 1118.7 (Axis carry diamond-route scoped kernel dependencies)**.** *Every accepted* AxisCarryDiamondRoute *two-route diamond packet factors through the displayed rows*

$$\mathsf{ZCarry}^{\uparrow}, \mathsf{ZeckendorfCarryNormalization}^{\uparrow}, \mathsf{ZeckendorfCarryValue}^{\uparrow}, \mathsf{AxisZeckendorfCarryBudget}^{\uparrow}, \mathsf{BHist}, \mathsf{hsame}, \mathsf{Cont}, \mathsf{Pkg}$$

before any consumer may read the shared target-normality ledger or the local diamond name. The scoped route exposes the two carry-successor rows, two normalization routes, two value ledgers, one shared normal target, componentwise transport, replay, provenance, and local naming.

It exposes no host arithmetic quotient, no global confluence theorem, no source-target hsame *proof, and no kernel rewrite rule.*

Proof. Start with the carrier and route theorems. Definition 1118.1 lists the finite row inventory, while Definition 1118.2 places the two $\mathsf{ZCarry}^{\uparrow}$ edges, the two $\mathsf{ZeckendorfCarryNormalization}^{\uparrow}$ handoffs, the shared normal target, and the value ledgers in one displayed packet.

Next apply non-escape and the obligation surface. Definition 1118.3 removes host arithmetic quotients, hidden normalizers, global confluence, and kernel rewriting from the accepted read, and Definition 1118.4 confines the local obligations to BHist, hsame, Cont, Pkg, and NameCert rows.

Finally use target-ledger exactness and value-ledger stability. They keep the shared target-normality ledger downstream of both routes and both value ledgers, so the scoped packet can be consumed only through the named kernel dependencies and never through a source-target hsame shortcut or an ambient rewrite rule. □

Closure status for $\mathsf{NameCert}_{\mathsf{AxisCarryDiamondRoute}^{\uparrow}}$**.**

Constructive story: An $\mathsf{AxisCarryDiamondRoute}^{\uparrow}$ packet is generated from an overlap source row, two carry-successor rows, a shared normal target, two carry-normalization route rows, two value ledgers, a shared target-normality ledger, non-hsame boundary rows, componentwise transports, continuation routes, provenance, and a local NameCert row.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{AxisCarryDiamondRoute}^{\uparrow}}, \mathsf{scopedClosed})$

Scope closed: Definition 1118.1, Definition 1118.2, Definition 1118.3, Definition 1118.4, Definition 1118.5, Definition 1118.6, and Definition 1118.7 specify the finite two-route diamond carrier, obligation rows, shared target ledger, value-ledger stability, non-escape boundary, and scoped dependencies over ZCarry, ZeckendorfCarryNormalization, ZeckendorfCarryValue, AxisZeckendorfCarryBudget, BHist, hsame, Cont, Pkg, and NameCert.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{AxisCarryDiamondRoute}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close Lean verification, bridge checking, arbitrary carry confluence, host arithmetic quotienting, global normalization, source-target hsame, or kernel rewriting.

Upgrade path: Public closure requires a checked export obligation for paired route rows, shared target-normality, value-ledger exactness, non-hsame preservation, route replay, provenance, and local naming for the same finite packet.

Chapter 1119

A Concrete Naming Certificate for $\mathsf{FiniteTailFilter}^{\uparrow}$

The $\mathsf{FiniteTailFilter}^{\uparrow}$ packet is the finite-filter surface shared by the Real and Completion routes. It packages the cofinal-tail information that is read by the stream-name surface of chapter 126, the dyadic rational core of chapter 291, the regular rational sequence surface of chapter 301, the RealUp seal of chapter 38, the tail budget of chapter 379, and the common-tail comparison packet of chapter 387. The packet is the BEDC finite-filter analogue of the constructive Cauchy tail-filter interface: a consumer receives a finite set of admitted tail windows, the dyadic and regular-sequence rows attached to those windows, and the seal-facing route that preserves the same cofinal-tail packet.

Definition 1119.1 (FiniteTailFilter carrier)**.** *A* $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

with the following visible rows:

1. *S is the finite* $\mathsf{StreamName}^{\uparrow}$ *window ledger whose entries form the admitted tail filter base;*
2. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger attached to the admitted windows;*
3. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row obtained from the same admitted windows and dyadic ledger;*
4. *B is the* $\mathsf{DyadicTailBound}^{\uparrow}$ *tail-budget row that records the finite threshold and tolerance data used by the filter;*
5. *Q is the* $\mathsf{CauchyTailComparison}^{\uparrow}$ *common-tail comparison row read through the same window ledger and dyadic ledger;*
6. *E is the* $\mathsf{Real}^{\uparrow}$ *seal row reached after the window, dyadic, regular-sequence, tail-budget, and common-tail comparison rows have all been displayed;*
7. *H records componentwise* hsame *transports for $S, D, R, B, Q, E, C, P, N$;*
8. *C records the displayed* Cont *routes for window readback, dyadic tolerance use, regular-rational readback, tail-budget consumption, common-tail comparison, and RealUp seal consumption;*
9. *P is the* Pkg *provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicTailBound}^{\uparrow}$, $\mathsf{CauchyTailComparison}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$ *rows;*
10. *N is the local* $\mathsf{NameCert}_{\mathsf{FiniteTailFilter}^{\uparrow}}$ *row.*

The classifier compares accepted carriers only through the displayed rows $S, D, R, B, Q, E, H, C, P, N$ and their recorded read routes.

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.TasteGate.FiniteTailFilterUpTasteGate single carrier alignment`

Theorem 1119.2 (FiniteTailFilter NameCert obligations)**.** *For the carrier of Definition 1119.1, the local* $\mathsf{NameCert}_{\mathsf{FiniteTailFilter}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$F = (S, D, R, B, Q, E, H, C, P, N),$$

window-filter exposure through S, dyadic tolerance exposure through D, regular-sequence readback through R, tail-budget exposure through B, common-tail comparison through Q, RealUp seal exposure through E, componentwise hsame *transport through H, displayed* Cont *replay through C,* Pkg *provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier namecert obligations`

Proof. Project the displayed carrier. The rows $S, D, R, B, Q, E, H, C, P, N$ are the only coordinates of the finite packet, so carrier admission is the assertion that these rows are assembled as one BHist surface.

Read the analytic rows in order. The window ledger S supplies the finite filter base, the dyadic ledger D supplies the tolerance rows attached to that base, and the regular readback R is the regular rational interpretation of the same finite windows.

The tail-budget row B and the common-tail comparison row Q then read the same S, D, R packet rather than separate windows or separate tolerances. The RealUp seal E is exposed only after those rows have been displayed.

The structural rows H, C, P, N transport, replay, authenticate, and name the same packet. Hence the listed coordinates exhaust the local naming surface. □

Theorem 1119.3 (FiniteTailFilter non-escape)**.** *Every downstream consumer of an accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet receives only the finite surface*

$$S, D, R, B, Q, E, H, C, P, N.$$

It receives no quotient stream equality, selected limit, host real equality, ambient completeness datum, metric-completeness datum, countable-choice row, or standard bridge row.

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier nonescape`

Proof. Inspect the carrier of Definition 1119.1. The analytic coordinates are the finite window ledger, dyadic tolerance ledger, regular-sequence readback, tail-budget row, common-tail comparison row, and RealUp seal row. The remaining coordinates are transport, continuation, package provenance, and local naming rows for that same packet.

Apply the NameCert obligation theorem. Any consumer route must pass through the displayed coordinates and their recorded hsame and Cont witnesses.

None of the excluded objects is a coordinate of the carrier or a row certified by the local naming surface. Therefore an accepted consumer cannot recover quotient stream equality, a selected limit, host real equality, ambient completeness, metric-completeness data, countable choice, or a standard bridge row from the finite filter packet. □

Theorem 1119.4 (FiniteTailFilter tail-window exactness)**.** *For every accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier*

$$F = (S, D, R, B, Q, E, H, C, P, N),$$

the tail windows consumed by the $\mathsf{DyadicTailBound}^{\uparrow}$ *row* B*, the* $\mathsf{CauchyTailComparison}^{\uparrow}$ *row* Q*, and the* $\mathsf{Real}^{\uparrow}$ *seal row* E *are exactly the windows displayed in* S *with the dyadic tolerances displayed in* D*. No accepted read may replace the filter base by an unrecorded window selector, split the tail-budget row from the common-tail comparison row, or substitute a separate dyadic tolerance ledger.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier tail window exactness`

Proof. Project S and D from the carrier. These are the only coordinates that display tail windows and dyadic tolerances.

Use the NameCert obligations to locate B and Q. The tail-budget row and the common-tail comparison row are accepted only as rows of the same packet, and both are read after the S, D, R surface has been displayed.

The RealUp seal row E is downstream of that same packet. Its continuation route in C can replay the displayed rows, but it has no coordinate for a second filter base or a second tolerance ledger.

Thus the visible tail-window packet is exact: all accepted budget, comparison, and seal reads use S and D as displayed. □

Theorem 1119.5 (FiniteTailFilter Real seal handoff)**.** *Every* $\mathsf{Real}^{\uparrow}$ *or completion-facing consumer of an accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

reaches the seal row E *only through the displayed route*

$$S, D, R, B, Q, H, C, P, N.$$

The handoff is therefore a finite cofinal-tail route shared by Real and Completion seal reads, not a quotient of streams, selected limit, host real equality, ambient completeness theorem, metric-completeness datum, countable-choice row, or standard bridge row.

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier real seal handoff`

Proof. Start from the carrier. The seal coordinate E is stored in the same finite packet as the stream-window ledger S, dyadic tolerance ledger D, regular readback R, tail-budget row B, common-tail comparison row Q, and structural rows H, C, P, N.

Apply tail-window exactness. The tail-budget and common-tail comparison rows use the same S, D window packet, so a seal-facing read cannot detach the RealUp row from the cofinal-tail filter base.

Use the NameCert obligation theorem to read the remaining route data. The hsame rows in H, the Cont routes in C, the package row P, and the local naming row N certify the displayed handoff and no larger completion structure.

Finally apply non-escape. Since the carrier has no excluded coordinate, the Real and Completion consumers receive the finite route $S, D, R, B, Q, H, C, P, N$ before reaching E and nothing outside that route. □

Theorem 1119.6 (FiniteTailFilter Real-window consumer)**.** *Every* RealWindowBudget$^{\uparrow}$ *or Real-completion consumer reading an accepted* FiniteTailFilter$^{\uparrow}$ *carrier*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

receives the displayed finite cofinal-tail route

$$S, D, R, B, Q, E, H, C, P, N.$$

The Real-window budget row may use only the already displayed StreamName$^{\uparrow}$, DyadicRatCore$^{\uparrow}$, RegSeqRat$^{\uparrow}$, DyadicTailBound$^{\uparrow}$, CauchyTailComparison$^{\uparrow}$, *and* Real$^{\uparrow}$ *rows. It receives no quotient stream equality, selected limit, host real equality, countable-choice row, ambient completeness theorem, metric-completeness datum, or unrecorded completion carrier.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier real window consumer`

Proof. Start from the NameCert obligations of Definition 1119.2. They expose the accepted packet exactly as $S, D, R, B, Q, E, H, C, P, N$, with S, D, R, B, Q, E as the Real-facing analytic rows and H, C, P, N as the structural rows.

Apply tail-window exactness, Definition 1119.4. The tail-budget row B, common-tail comparison row Q, and RealUp seal row E all read the same displayed S, D window and tolerance packet, so a Real-window budget consumer cannot introduce a separate selector or tolerance ledger.

Use the Real seal handoff theorem, Definition 1119.5, to identify the downstream route. Any Real or Completion read reaches E only through $S, D, R, B, Q, H, C, P, N$, and the present consumer includes E as the displayed seal row reached by that route.

Finally apply non-escape, Definition 1119.3. Since quotient stream equality, selected limits, host real equality, countable choice, ambient completeness, metric-completeness data, and unrecorded completion carriers are not coordinates of F, the RealWindowBudget$^{\uparrow}$ or Real-completion consumer receives only the finite cofinal-tail packet already displayed. □

Theorem 1119.7 (FiniteTailFilter RealWindowBudget consumer link)**.** *Every* RealWindowBudget$^{\uparrow}$ *consumer of an accepted* FiniteTailFilter$^{\uparrow}$ *packet*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

must reuse the displayed route as its finite request, StreamName$^{\uparrow}$ *window, dyadic readback,* RegSeqRat$^{\uparrow}$ *handoff, and* Real$^{\uparrow}$ *seal surface. It cannot introduce a private selector, separate dyadic ledger, selected limit, quotient stream, host equality, countable-choice row, or ambient completeness row.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier real window budget consumer link`

Proof. Start with the FiniteTailFilter NameCert obligations from Definition 1119.2. They expose $S, D, R, B, Q, E, H, C, P, N$ as the complete accepted packet, with S, D, R, B, Q, E carrying the finite analytic route.

Apply tail-window exactness, Definition 1119.4. The tail-budget and comparison rows read the same finite window and dyadic tolerance data, so a RealWindowBudget consumer cannot replace S or D by a private selector or separate ledger.

Use the Real seal handoff and Real-window consumer theorems, Definition 1119.5 and Definition 1119.6. Together they force the consumer route through the displayed RegSeqRat readback R, tail budget B, common-tail comparison Q, and seal row E.

Finally apply the RealWindowBudget finite-route visibility supplied by the packet surface and the non-escape theorem, Definition 1119.3. The structural rows H, C, P, N preserve the same route, while the carrier has no coordinate for selected limits, quotient streams, host equality, countable choice, ambient completeness, or an unrecorded completion surface. □

Theorem 1119.8 (FiniteTailFilter Real-window selector bridge)**.** *Every* $\mathsf{RealWindowBudget}^{\uparrow}$ *selector-stability read that consumes an accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

must factor through the displayed finite route $S, D, R, B, Q, E, H, C, P, N$*. Through this route it reads the* $\mathsf{StreamName}^{\uparrow}$ *window row,* $\mathsf{DyadicRatCore}^{\uparrow}$ *ledger,* $\mathsf{RegSeqRat}^{\uparrow}$ *handoff, tail-budget row, common-tail row,* $\mathsf{Real}^{\uparrow}$ *seal, componentwise transport, continuation, package source, and local naming coordinate supplied by the packet.*

Consequently, by $\mathsf{RealWindowBudget}^{\uparrow}$ *selector stability, the downstream selector surface cannot replace that route by a private window family, detached dyadic ledger, selected limit, quotient stream, host real equality, countable-choice row, or ambient completeness coordinate.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier real window budget selector bridge`

Proof. Start with the FiniteTailFilter NameCert obligations, Definition 1119.2. They expose the accepted packet as the ten displayed rows $S, D, R, B, Q, E, H, C, P, N$, with the analytic rows and structural rows carried by one local certificate.

Apply tail-window exactness, Definition 1119.4. The stream-window row S and dyadic ledger D are the common cofinal-tail packet used by the tail budget B, common-tail comparison Q, and the Real-facing seal row E.

Use the Real seal handoff and the RealWindowBudget consumer link, Definition 1119.5 and Definition 1119.7. These identify the downstream read as a consumer of the same $S, D, R, B, Q, E, H, C, P, N$ route, rather than a read of any hidden completion or host-level real structure.

Finally apply $\mathsf{RealWindowBudget}^{\uparrow}$ selector stability, Definition 1164.3. Once the read reaches the RealWindowBudget selector surface, that theorem keeps the selector synchronized with the finite request, window, dyadic, regular, Real-facing, and support rows supplied by the displayed route, so no private window family, detached ledger, selected limit, quotient stream, host equality, countable-choice row, or ambient completeness coordinate can replace the packet route. □

Theorem 1119.9 (FiniteTailFilter sibling tail handoff)**.** *Every consumer whose route passes through* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerances,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicTailBound}^{\uparrow}$ *budget,* $\mathsf{CauchyTailComparison}^{\uparrow}$ *common-tail rows, or the* $\mathsf{Real}^{\uparrow}$ *seal factors through the displayed finite packet*

$$S, D, R, B, Q, E, H, C, P, N.$$

No sibling chapter may substitute its own tail selector, tolerance ledger, common-tail row, or seal row for the packet displayed by $\mathsf{FiniteTailFilter}^{\uparrow}$*.*

Proof. Start from the carrier of Definition 1119.1. The rows $S, D, R, B, Q, E, H, C, P, N$ are the whole finite packet, so any sibling read of a stream window, dyadic tolerance, regular readback, budget, comparison, or seal row has to be a read of one of those displayed coordinates.

Apply the NameCert obligations of Definition 1119.2. They expose the analytic rows and the structural rows as one local naming surface, with the hsame and Cont data recording how the same packet is replayed downstream.

Use tail-window exactness, Definition 1119.4, to identify the common window and tolerance packet consumed by the budget, comparison, and seal-facing rows. Then use the Real seal handoff theorem, Definition 1119.5, to carry the same packet to Real and Completion consumers.

Finally apply non-escape. The handoff is finite and has no coordinate for a quotient stream, selected limit, host real equality, ambient completeness datum, metric-completeness datum, countable-choice row, or standard bridge row. Hence no sibling route can replace the displayed tail selector, ledger, or seal row by an unrecorded one. □

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier sibling tail handoff`

Theorem 1119.10 (FiniteTailFilter shared-window meet)**.** *Let*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

be an accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet. Suppose an accepted* $\mathsf{CauchyModulusRefinement}^{\uparrow}$ *packet has its selected-window row and readback row consumed as the same displayed finite window and regular readback route used by* F*. Then every* $\mathsf{Real}^{\uparrow}$ *or Completion consumer reads the shared L10 route through*

$$S, D, R, B, Q, E, H, C, P, N.$$

It cannot replace this meet by a hidden selector, second meet, quotient stream, selected limit, host real equality, countable-choice row, ambient completeness datum, or metric-completeness row.

Proof. First bind the common finite packet. Tail-window exactness, Definition 1119.4, identifies S and D as the displayed window and tolerance packet read by the tail-budget row, common-tail row, and Real seal of F.

Next route the sibling consumers. The sibling tail handoff and RealWindowBudget consumer link, Definition 1119.9 and Definition 1119.7, force StreamName, DyadicRatCore, RegSeqRat, RealWindowBudget, Real, and Completion reads through the displayed route $S, D, R, B, Q, E, H, C, P, N$.

Now attach the adjacent selected-window route. By Definition 885.130, an accepted $\mathsf{CauchyModulusRefinement}^{\uparrow}$ consumer whose selected-window and readback rows are the same displayed finite window and regular readback route cannot introduce a separate selector, second meet, or off-route Real seal.

Finally apply non-escape, Definition 1119.3. Since neither accepted packet contributes a coordinate for quotient stream equality, selected limits, host real equality, countable choice, ambient completeness, metric-completeness data, or a hidden completion surface, the shared consumer route is exactly the finite packet displayed by F. □

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier shared window meet`

Theorem 1119.11 (FiniteTailFilter carrier transport obligation)**.** *For every accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier*

$$F = (S, D, R, B, Q, E, H, C, P, N),$$

the componentwise hsame *row* H *transports exactly the displayed packet rows* $S, D, R, B, Q, E, C, P, N$*. It has no coordinate that can introduce quotient stream equality, host real equality, selected limits, choice data, completeness data, or standard bridge rows.*

Proof. Project the carrier and isolate the structural row H. The definition of the carrier lists H only as the componentwise hsame data for the already displayed rows $S, D, R, B, Q, E, C, P, N$.

Use the NameCert obligations to read the certified transport surface. Since those obligations expose only the carrier coordinates and their recorded routes, a transport in H is fieldwise over the finite packet and cannot add a new analytic row.

Finally apply non-escape. The excluded objects are not coordinates of F and are not authenticated by the local naming row N. Thus classifier transport preserves exactly the displayed packet rows and nothing outside them. □

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier transport obligation`

Theorem 1119.12 (FiniteTailFilter cofinal-window directedness obligation)**.** *For every accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier*

$$F = (S, D, R, B, Q, E, H, C, P, N),$$

the displayed Cont *row* C *replays every accepted tail-window read, dyadic tolerance read, regular rational readback, tail-budget read, common-tail comparison read, and RealUp seal read through the same finite cofinal packet* $S, D, R, B, Q, E, H, P, N$.

Proof. Start with the continuation coordinate C. By the carrier definition, C records displayed routes for window readback, dyadic tolerance use, regular-rational readback, tail-budget consumption, common-tail comparison, and RealUp seal consumption.

Apply tail-window exactness. The budget, comparison, and seal-facing reads all consume the same S, D window and tolerance packet, so the continuation cannot branch into an unrecorded selector or tolerance ledger.

Use the Real seal handoff theorem to identify the downstream route. Every Real or Completion consumer reaches E through the finite packet $S, D, R, B, Q, H, C, P, N$, and the replay row C is the route data for that same packet. Hence all accepted reads are directed through the displayed cofinal window surface. □

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier cofinal window directedness obligation`

Theorem 1119.13 (FiniteTailFilter cofinal-route exhaustion)**.** *Every* $\mathsf{RealWindowBudget}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, *or Completion-facing consumer of an accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

factors through the cofinal route $S, D, R, B, Q, E, H, C, P, N$. *No such consumer can add private windows, detached dyadic ledgers, selected limits, quotient streams, host equality, countable-choice rows, ambient completeness, or standard bridge rows.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier cofinal route exhaustion`

Proof. First assemble the carrier route from the NameCert obligations and tail-window exactness, Definition 1119.2 and Definition 1119.4. These identify $S, D, R, B, Q, E, H, C, P, N$ as the accepted packet and make S, D the exact window and tolerance rows read by B, Q, E.

Next pass to the Real-facing surface. Apply the Real seal handoff and the RealWindowBudget consumer link, Definition 1119.5 and Definition 1119.7. They route RealWindowBudget, Real, and Completion-facing consumers through the same finite packet.

Use the Real-window selector bridge to rule out a selector-side replacement. Definition 1119.8 keeps selector stability tied to $S, D, R, B, Q, E, H, C, P, N$, not to a private window family or detached dyadic ledger.

Finally apply non-escape, Definition 1119.3. Since the carrier contains no selected-limit, quotient-stream, host-equality, countable-choice, ambient completeness, or standard bridge coordinate, the displayed cofinal route exhausts the admitted consumer surface. □

Theorem 1119.14 (FiniteTailFilter structural provenance obligation)**.** *For every accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier*

$$F = (S, D, R, B, Q, E, H, C, P, N),$$

the rows P *and* N *record exactly the sibling and kernel provenance over* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{DyadicTailBound}^{\uparrow}$, $\mathsf{CauchyTailComparison}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, BHist, hsame, Cont, *and* $\mathsf{NameCert}$. *They record no independent completion theorem, quotient carrier, selected limit, or bridge schema.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier structural provenance obligation`

Proof. Read P and N from the carrier. The package row P names the sibling and kernel sources of the displayed packet, while N is the local $\mathsf{NameCert}_{\mathsf{FiniteTailFilter}^{\uparrow}}$ row for the same surface.

Apply the NameCert obligations. They identify the provenance domain as the listed sibling chapters together with the kernel rows BHist, hsame, Cont, and $\mathsf{NameCert}$.

The carrier has no separate coordinate for an independent completion theorem, quotient carrier, selected limit, or bridge schema. Therefore the provenance and naming rows certify exactly the stated sources and no larger structure. □

Theorem 1119.15 (FiniteTailFilter terminal cofinal-consumer exclusion)**.** *For every accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier*

$$F = (S, D, R, B, Q, E, H, C, P, N),$$

every terminal $\mathsf{Real}^{\uparrow}$, $\mathsf{RealWindowBudget}^{\uparrow}$, $\mathsf{UniformCauchyCriterion}^{\uparrow}$, *or completion-facing consumer of the accepted cofinal packet factors through the displayed finite route* $S, D, R, B, Q, E, H, C, P, N$.

Consequently such a consumer cannot recover quotient stream equality, selected limits, host real equality, ambient completeness, metric-completeness data, countable choice, a private selector, a separate dyadic ledger, or a standard bridge row from the cofinal packet.

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier terminal cofinal consumer exclusion`

Proof. Start with tail-window exactness and the Real seal handoff, Definition 1119.4 and Definition 1119.5. They identify the stream-window and dyadic-tolerance rows as the common cofinal packet used by the tail budget, common-tail comparison, Real seal, and completion-facing reads.

Next apply the RealWindowBudget selector bridge and the sibling tail handoff, Definition 1119.8 and Definition 1119.9. These force selector-stability and sibling reads to reuse the same $S, D, R, B, Q, E, H, C, P, N$ route rather than a detached window family, tolerance ledger, Real row, or seal row.

Use the cofinal-window directedness obligation to route every terminal read through the displayed continuation row C. The continuation can replay only the accepted tail-window, dyadic-tolerance, regular-rational, tail-budget, common-tail, and Real seal reads carried by the finite packet.

Finally combine non-escape with the structural provenance obligation, Definition 1119.3 and Definition 1119.14. The accepted carrier has no coordinate for quotient stream equality, selected limits, host real equality, ambient or metric completeness, countable choice, private selectors, detached ledgers, or standard bridge rows, and the provenance rows P, N certify no hidden completion source. Hence every terminal consumer remains confined to the displayed cofinal route. □

Theorem 1119.16 (FiniteTailFilter common-tail seal cofinality)**.** *Let*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

be an accepted FiniteTailFilter$^{\uparrow}$ *carrier. Any* RealWindowBudget$^{\uparrow}$, UniformCauchyCriterion$^{\uparrow}$, Real$^{\uparrow}$, *or completion-facing consumer that uses the accepted* FiniteTailFilter$^{\uparrow}$ *packet must identify its* StreamName$^{\uparrow}$ *window row,* DyadicRatCore$^{\uparrow}$ *tolerance row,* RegSeqRat$^{\uparrow}$ *readback row,* DyadicTailBound$^{\uparrow}$ *budget row,* CauchyTailComparison$^{\uparrow}$ *row, and* Real$^{\uparrow}$ *seal row with the displayed finite packet* $S, D, R, B, Q, E, H, C, P,$

No private selector, detached dyadic ledger, quotient stream, selected limit, countable-choice row, ambient completeness row, or standard bridge row is admitted by this common-tail seal.

Proof. First apply tail-window exactness and the Real seal handoff, Definition 1119.4 and Definition 1119.5. These identify the window, tolerance, readback, budget, comparison, and Real seal rows as coordinates of the same accepted finite packet.

Next apply the RealWindowBudget consumer link and the Real-window selector bridge, Definition 1119.7 and Definition 1119.8. A Real-window consumer therefore reads its selector and budget data through $S, D, R, B, Q, E, H, C, P, N$, not through a private selector family or detached dyadic ledger.

Use the sibling tail handoff and cofinal-window directedness obligation, Definition 1119.9 and Definition 1119.12. The UniformCauchyCriterion and completion-facing reads must replay the same continuation route C over the displayed packet, so the common-tail comparison row cannot be replaced by a quotient stream, selected limit, countable-choice row, ambient completeness row, or standard bridge row.

Finally invoke terminal cofinal-consumer exclusion, Definition 1119.15. It confines every terminal Real-window, Real, UniformCauchyCriterion, or completion-facing consumer to the accepted cofinal packet, which proves that the finite packet $S, D, R, B, Q, E, H, C, P, N$ is the common route consumed by those chapters. □

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier common tail seal cofinality`

Theorem 1119.17 (FiniteTailFilter cofinal-window budget normal form)**.** *Let*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

be an accepted FiniteTailFilter$^{\uparrow}$ *carrier. Every accepted* RealWindowBudget$^{\uparrow}$, UniformCauchyCriterion$^{\uparrow}$, Real$^{\uparrow}$, *or completion-facing read of* F *has the same normal-form route* $S, D, R, B, Q, E, H, C, P, N$. *The rows* S, D *are the only window and dyadic tolerance rows,* B, Q *are the only tail-budget and common-tail comparison rows, and* E *is the only* Real$^{\uparrow}$ *seal row.*

No private selector, detached dyadic ledger, quotient stream, selected limit, host real equality, countable-choice row, ambient completeness row, metric-completeness row, independent completion row, or standard bridge row is part of this normal form.

Proof. First build the finite route from tail-window exactness and the Real seal handoff, Definition 1119.4 and Definition 1119.5. These identify S, D, R, B, Q, E as one accepted finite packet rather than separate window, tolerance, readback, budget, comparison, and Real seal sources.

Next account for Real-window and selector-facing consumers. Apply Definition 1119.7 and Definition 1119.8. They force every RealWindowBudget$^{\uparrow}$ read to use the same route $S, D, R, B, Q, E, H, C, P, N$, with no private selector family or detached dyadic ledger.

Then route the uniform and completion-facing reads through the sibling and cofinal rows. Use Definition 1119.9 together with Definition 1119.12. The continuation row C replays only the displayed cofinal packet, so the UniformCauchyCriterion$^{\uparrow}$ and completion-facing consumers cannot replace B or Q by another tail-budget or common-tail comparison row.

Finally apply Definition 1119.16. It states that every RealWindowBudget, UniformCauchyCriterion, Real, or completion-facing consumer identifies its window, tolerance, readback, budget, comparison, and Real seal rows with the accepted packet $S, D, R, B, Q, E, H, C, P, N$.

The exclusion clause follows from terminal cofinal-consumer exclusion and structural provenance, Definition 1119.15 and Definition 1119.14. Since the accepted carrier has no coordinate for the listed external structures, the normal form is exactly the displayed route. □

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FinitetailfilterCofinalWindowBudgetNormalForm`

Theorem 1119.18 (FiniteTailFilter terminal classifier exactness)**.** *For every accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier*

$$F = (S, D, R, B, Q, E, H, C, P, N),$$

the terminal classifier available to any $\mathsf{RealWindowBudget}^{\uparrow}$*,* $\mathsf{UniformCauchyCriterion}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, or completion-facing consumer is exactly the componentwise classifier on the displayed finite route* $S, D, R, B, Q, E, H, C, P, N$*.*

Thus no terminal read may replace S, D *by a private window or tolerance ledger, replace* R, B, Q, E *by detached* $\mathsf{RegSeqRat}^{\uparrow}$*, tail-budget, common-tail, or* $\mathsf{Real}^{\uparrow}$ *rows, or introduce quotient streams, selected limits, host equality, countable choice, ambient completeness, or bridge schema data.*

Proof. Begin with the NameCert obligations, Definition 1119.2. They expose the accepted packet as the rows $S, D, R, B, Q, E, H, C, P, N$, with H carrying the componentwise hsame transports, C carrying the displayed continuation routes, and P, N carrying package provenance and local naming.

Next apply tail-window exactness, Definition 1119.4. The window and dyadic tolerance inputs of the tail-budget row, the common-tail comparison row, and the Real seal are exactly S and D, so the classifier cannot be evaluated through a private window family or a detached tolerance ledger.

For the Real and completion-facing side, use the Real seal handoff and the RealWindowBudget consumer link, Definition 1119.5 and Definition 1119.7. These route every Real-window, Real, and completion-facing read through the same finite packet before reaching the seal row E.

For the common-tail side, use common-tail seal cofinality, Definition 1119.16. It identifies the $\mathsf{RegSeqRat}^{\uparrow}$ readback, tail-budget, common-tail comparison, and $\mathsf{Real}^{\uparrow}$ seal rows with the displayed route R, B, Q, E rather than with detached sibling rows.

Finally apply the cofinal-window budget normal form, Definition 1119.17. That theorem states that every terminal RealWindowBudget, UniformCauchyCriterion, Real, or completion-facing read has the same normal-form route $S, D, R, B, Q, E, H, C, P, N$ and no coordinate for the excluded external structures. Therefore the only terminal classifier left available is the componentwise classifier on that displayed route. □

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier terminal classifier exactness`

Theorem 1119.19 (FiniteTailFilter terminal Lean target surface)**.** *Let*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

be an accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier. The paper-level Lean target for this chapter is the exact terminal packet* F*: every* $\mathsf{RealWindowBudget}^{\uparrow}$*,* $\mathsf{UniformCauchyCriterion}^{\uparrow}$*,* $\mathsf{Real}^{\uparrow}$*, and completion-facing read must consume the displayed window row, dyadic tolerance row,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback, tail-budget row, common-tail comparison row,* $\mathsf{Real}^{\uparrow}$ *seal, componentwise* hsame *transports, displayed* Cont *routes, package provenance, and local* $\mathsf{NameCert}_{\mathsf{FiniteTailFilter}^{\uparrow}}$ *row.*

No terminal Lean target may replace that packet by quotient stream equality, selected limits, host real equality, countable choice, ambient completeness, metric-completeness data, independent completion data, or a standard bridge row.

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterTerminalLeanTargetSurface`

Proof. Begin with Definition 1119.18. It identifies the terminal classifier as the componentwise classifier on $S, D, R, B, Q, E, H, C, P, N$ for every RealWindowBudget, UniformCauchyCriterion, Real, and completion-facing consumer.

Use the cofinal-window budget normal form, Definition 1119.17. It states that the same finite route is the normal form for the listed consumers and that the excluded external structures are not coordinates of the carrier.

Thus the Lean target surface has no additional input row to consume. It must take exactly the displayed packet and prove the terminal reads from that packet. □

Theorem 1119.20 (FiniteTailFilter formal-target consumer route)**.** *Every formal target consuming a* $\mathsf{FiniteTailFilter}^{\uparrow}$ *terminal read must read the same finite cofinal-tail route*

$$S, D, R, B, Q, E, H, C, P, N.$$

The route factors RealWindowBudget, UniformCauchyCriterion, Real, and completion-facing requests through BHist *carrier rows, componentwise* hsame *transport, displayed* Cont *replay, package provenance, and the local* $\mathsf{NameCert}_{\mathsf{FiniteTailFilter}^{\uparrow}}$ *row before any terminal classifier is evaluated.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier formal target consumer route`

Proof. First apply Definition 1119.19. It fixes the formal target as the exact terminal packet rather than a family of host-side consumer assumptions.

Next use Definition 1119.16. It forces the window, tolerance, readback, budget, comparison, and Real seal rows for each terminal consumer to agree with the accepted packet.

Finally attach the consumer exclusion theorem, Definition 1119.15. Since every terminal consumer is confined to the accepted cofinal packet, the formal target route is precisely the finite BHist, hsame, Cont, provenance, and NameCert route stated above. □

Theorem 1119.21 (FiniteTailFilter Lean intake non-escape)**.** *The Lean intake for* $\mathsf{FiniteTailFilter}^{\uparrow}$ *is non-escaping: it may consume only the BHist packet* $S, D, R, B, Q, E, H, C, P, N$ *and the terminal classifier facts already displayed in this chapter. In particular, the intake cannot add a private RealWindowBudget selector, a separate UniformCauchyCriterion witness, a host Real equality, a selected completion point, a quotient stream, countable choice, ambient completeness, metric completeness, or bridge schema data.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterLeanIntakeNonescape`

Proof. Start from Definition 1119.20. The formal target reads the terminal consumers only through the displayed cofinal-tail route.

Use Definition 1119.18 to evaluate the classifier. The classifier is already exact on $S, D, R, B, Q, E, H, C, P, N$, so an additional selector, witness, equality, completion point, quotient stream, choice principle, completeness row, or bridge row would not be read by the accepted classifier.

The non-escape clause follows from Definition 1119.3 and Definition 1119.14. Both keep accepted reads inside the finite carrier, transport, route, provenance, and local naming surface. □

Theorem 1119.22 (FiniteTailFilter formal intake route exhaustion)**.** *Every formal intake read of an accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

factors through the finite tail-window row S*, the* $\mathsf{RealWindowBudget}^{\uparrow}$ *row, the cofinal-route rows* D, R, B, Q, E*, the terminal classifier, and the Lean intake non-escape surface. No formal intake read may add a hidden tail oracle, quotient stream, selected host limit, host real equality, choice datum, ambient completeness row, metric-completeness row, independent completion datum, or bridge row.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier formal intake route exhaustion`

Proof. First apply the formal-target consumer route, Definition 1119.20. It confines every formal target to the finite cofinal-tail route $S, D, R, B, Q, E, H, C, P, N$ before any terminal classifier is evaluated.

Use the cofinal-window budget normal form, Definition 1119.17. This factors RealWindowBudget, UniformCauchyCriterion, Real, and completion-facing reads through the displayed tail-window, tolerance, regular-readback, tail-budget, comparison, and Real-seal rows.

Next apply terminal classifier exactness, Definition 1119.18. The classifier available to every terminal consumer is exactly the componentwise classifier on the displayed finite route, so the formal intake has no second classifier outside the packet.

Finally invoke Lean intake non-escape, Definition 1119.21. Since the intake may consume only the BHist packet and the terminal classifier facts already displayed in the chapter, every formal intake read is exhausted by the finite route above and cannot add a hidden tail oracle, quotient stream, selected host limit, choice datum, completeness datum, or bridge row. □

Theorem 1119.23 (FiniteTailFilter formal target route closure)**.** *The formal target for the accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

is the closed L10 cofinal-tail surface formed by the existing DyadicRatCoreUp*,* StreamNameUp*,* RegSeqRatUp*,* RealUp*,* RealWindowBudgetUp*,* UniformCauchyCriterionUp*,* CauchyTailComparisonUp*, and* DyadicTailBoundUp *rows. It consumes only finite cofinal tail windows, classifier-stable tail cutoffs, non-escape ledgers, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and the local* $\mathsf{NameCert}_{\mathsf{FiniteTailFilter}^{\uparrow}}$ *row.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterFormalTargetRouteClosure`

Proof. Start from Definition 1119.2 and Definition 1119.22. These identify the accepted packet and exhaust every formal intake route through $S, D, R, B, Q, E, H, C, P, N$.

Next apply Definition 1119.17 and Definition 1119.18. The window, dyadic tolerance, regular-readback, tail-budget, common-tail comparison, and Real-seal rows are therefore the only classifier-stable tail cutoffs visible to an L10 consumer.

Finally use Definition 1119.21. Since the intake has no hidden tail oracle, quotient stream, selected limit, host equality, choice datum, completeness row, or bridge row, the formal target is exactly the closed finite cofinal-tail surface above. □

Theorem 1119.24 (FiniteTailFilter bridge premise surface)**.** *Any bridge premise that reads the L10* FiniteTailFilter$^{\uparrow}$ *surface must first read the same finite packet* $F = (S, D, R, B, Q, E, H, C, P, N)$*. The premise may expose* DyadicRatCoreUp*,* StreamNameUp*,* RegSeqRatUp*,* RealUp*,* RealWindowBudgetUp*,* UniformCauchyCriterionUp*,* CauchyTailComparisonUp*, and* DyadicTailBoundUp *only as finite tail-window, dyadic tolerance, regular-readback, Real-seal, budget, criterion, comparison, and tail-bound rows inside the packet; it may not replace them by a standard bridge row, ambient completeness, quotient stream equality, selected host limits, or host Real equality.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterBridgePremiseSurface`

Proof. Use Definition 1119.23 to put every bridge-facing premise on the closed cofinal-tail surface.

Then apply Definition 1119.16. The Real seal, common-tail comparison, dyadic tail bound, and window-budget data are consumed together, so a bridge premise cannot separate one row into an ambient completion witness.

The excluded replacements are ruled out by Definition 1119.15 and Definition 1119.21. Thus a later bridge proof has a premise surface, but that surface is still the finite packet rather than a host-side bridge assumption. □

Theorem 1119.25 (FiniteTailFilter Lean-ready obligation surface)**.** *The Lean-ready obligation for* FiniteTailFilter$^{\uparrow}$ *is to prove that the formal target route closes over the displayed finite cofinal-tail packet and no other data. Concretely, every* RealWindowBudgetUp*,* UniformCauchyCriterionUp*,* CauchyTailComparisonUp*,* DyadicTailBoundUp*,* RegSeqRatUp*,* StreamNameUp*,* DyadicRatCoreUp*, and* RealUp *read must be reconstructed from* $S, D, R, B, Q, E, H, C, P, N$*, the terminal classifier exactness row, and the non-escape ledger already certified in this chapter.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier lean ready obligation surface`

Proof. First collect the carrier and naming data from Definition 1119.1 and Definition 1119.2. They provide the rows that a Lean theorem can bind without adding a new carrier.

Next combine cofinal-route exhaustion with terminal classifier exactness. Theorems 1119.22 and 1119.18 leave the target with only finite cofinal windows and classifier-stable tail cutoffs.

It remains to record the non-escape side. Theorems 1119.21 and 1119.23 show that the future Lean obligation is a closure theorem over this packet, not a request for quotient streams, selected limits, ambient completeness, or a bridge row. □

Theorem 1119.26 (FiniteTailFilter Real-completion lattice link)**.** *An accepted finite tail filter consumed by the current Real-completion route determines the same cofinal-tail lattice row for* StreamName$^{\uparrow}$ *finite windows,* DyadicRatCore$^{\uparrow}$ *tolerance windows,* RegSeqRat$^{\uparrow}$ *regularity tails, and* Real$^{\uparrow}$ *seal reads. The lattice row is the displayed finite packet*

$$F = (S, D, R, B, Q, E, H, C, P, N),$$

with StreamName, DyadicRatCore, RegSeqRat, and RealUp appearing only as the four sibling faces referenced by chapter 126, chapter 291, chapter 301, and chapter 38.

The route exports only finite cofinal-tail windows through those existing NameCert routes. It does not export a selected limit, host real equality, quotient stream equality, or Real$^{\uparrow}$ *completeness.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier real completion lattice link`

Proof. Start with tail-window exactness and the Real seal handoff, Definition 1119.4 and Definition 1119.5. They identify S, D, R, B, Q, E as one finite cofinal-tail packet consumed by the window, tolerance, regular-readback, budget, comparison, and Real-seal rows.

Next apply the shared-window meet, Definition 1119.10. The meet forces all accepted consumers to use the same cofinal window and dyadic tolerance packet rather than separate StreamName, DyadicRatCore, RegSeqRat, or RealUp witnesses.

Finally apply the Lean-ready obligation surface, Definition 1119.25. It records that every Real-completion route read of the four sibling chapters must be reconstructed from $S, D, R, B, Q, E, H, C, P, N$, the terminal classifier exactness row, and the non-escape ledger, so the cofinal-tail lattice row is shared across all four objects. □

Theorem 1119.27 (FiniteTailFilter refinement seal witness-ledger pullback)**.** *Let an accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

expose the cofinal-tail row consumed by compatible accepted $\mathsf{CauchyModulusRefinement}^{\uparrow}$, $\mathsf{CauchyWitnessLedger}^{\uparrow}$, *and* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *packets. Then the three consumers determine one shared finite route through* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, *and* $\mathsf{Real}^{\uparrow}$. *Each consumer reads the same* $S, D, R, B, Q, E, H, C, P, N$ *rows as its StreamName finite-window row, DyadicRatCore tolerance row, RegSeqRat readback row, Real seal row, componentwise* hsame *transport, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *coordinate.*

No quotient stream, selected limit, host real equality, choice row, or ambient completeness coordinate is available along the pullback.

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier refinement seal witness ledger pullback`

Proof. First combine the local Real-completion lattice link, Definition 1119.26, with the shared-window meet, Definition 1119.10. These two rows put the four sibling faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ on the same finite packet F before any downstream consumer reads the route.

For the refinement consumer, use the CauchyModulusRefinement seal and selector rows: Definition 885.7, Definition 885.8, and Definition 885.148. For the witness-ledger consumer, use Definition 902.64, Definition 902.67, and Definition 902.68.

Together these rows say that refinement and ledger reads enter through the displayed finite route rather than through a detached selector or completion witness.

Finally apply the CauchyLimitSeal RegSeqRat-window boundary, Definition 386.11. It keeps the limit-seal consumer inside the same RegSeqRat and StreamName window route already fixed by F. Since all three consumers factor through the same finite packet and each cited non-escape row excludes quotient streams, selected limits, host equality, choice data, and ambient completeness, the displayed $S, D, R, B, Q, E, H, C, P, N$ rows form the shared pullback route. □

Theorem 1119.28 (FiniteTailFilter exact-boundary terminal normal form)**.** *Let an accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

export its cofinal-tail route to an accepted RealCompletionExactBoundaryUp *packet whose exact-boundary consumer reads that route. Then the composite terminal read is absorbed by the four-face terminal normal form*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

The composite exports no quotient stream equality, selected limit, host real equality, countable-choice row, ambient-completeness row, metric-completeness row, bridge row, or hidden tail selector.

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterExactBoundaryTerminalNormalForm`

Proof. First apply the Real-completion lattice link, Definition 1119.26. It places the StreamName finite-window face, DyadicRatCore tolerance face, RegSeqRat regularity face, and terminal Real seal face on the same finite packet F before the exact-boundary consumer reads them.

Next use the refinement seal witness-ledger pullback, Definition 1119.27. The pullback says that downstream refinement, witness-ledger, and seal consumers still read the displayed $S, D, R, B, Q, E, H, C, P, N$ rows and do not acquire a detached selector, quotient equality, selected limit, host equality, choice row, or ambient completeness coordinate.

Finally invoke Definition 1120.23. Once the accepted RealCompletionExactBoundary packet consumes the finite route, its terminal read is absorbed by the same four exact-boundary faces and structural rows. Combining the two finite-tail-filter rows with that absorption theorem leaves no carrier slot for metric completeness, a bridge row, or a hidden tail selector, so the composite terminal read is exactly the displayed four-face normal form. □

Theorem 1119.29 (FiniteTailFilter exact-boundary shared consumer determinacy)**.** *Let an accepted* $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

export its cofinal-tail route to two accepted $\mathsf{RealCompletionExactBoundaryUp}$ *packets. Suppose their exact-boundary consumers read the same displayed* $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, hsame, Cont, Pkg, *and local* $\mathsf{NameCert}$ *rows through* F*. Then both consumers determine the same four-face terminal normal form through* S, D, R, E, H, C, P, N*:*

$$\mathsf{StreamName}^{\uparrow}, \quad \mathsf{RegSeqRat}^{\uparrow}, \quad \mathsf{DyadicRatCore}^{\uparrow}, \quad \mathsf{Real}^{\uparrow}.$$

No quotient stream equality, selected limit, host real equality, countable-choice row, ambient-completeness row, metric-completeness row, bridge row, or hidden tail selector can distinguish the two terminal consumers.

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier exact boundary shared consumer determinacy`

Proof. Apply the Real-completion lattice link, Definition 1119.26. It places the four L10 faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, and $\mathsf{Real}^{\uparrow}$ on the same accepted finite packet F before either exact-boundary consumer reads the route.

Next use the refinement seal witness-ledger pullback, Definition 1119.27. The pullback keeps refinement, witness-ledger, and seal reads on the displayed $S, D, R, B, Q, E, H, C, P, N$ route, so neither consumer can introduce a detached selector, quotient stream, selected limit, host equality, choice row, or ambient completeness coordinate.

Now invoke the exact-boundary terminal normal form, Definition 1119.28, for each consumer. Since both consumers read the same StreamName, DyadicRatCore, RegSeqRat, RealUp, hsame, Cont, Pkg, and local $\mathsf{NameCert}$ rows, both terminal reads are absorbed into the same four-face normal form through the displayed finite route.

Finally use downstream exact-boundary determinacy, Definition 1120.10 and Definition 1120.18, only to identify what the exact-boundary consumers can observe after absorption. Those determinacy rows leave no additional carrier coordinate for metric completeness, a bridge row, or a

hidden tail selector, so the two accepted consumers cannot branch into distinguishable terminal outcomes. □

Theorem 1119.30 (FiniteTailFilter public exit package)**.** *The public L10 exit package for* $\mathsf{FiniteTailFilter}^{\uparrow}$ *is exactly the finite route*

$$S, D, R, B, Q, E, H, C, P, N$$

consuming the sibling faces $\mathsf{StreamName}^{\uparrow}$, $\mathsf{DyadicRatCore}^{\uparrow}$, $\mathsf{RegSeqRat}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, $\mathsf{RealWindowBudget}^{\uparrow}$, $\mathsf{UniformCauchyCriterion}^{\uparrow}$, $\mathsf{CauchyTailComparison}^{\uparrow}$, *and* $\mathsf{DyadicTailBound}^{\uparrow}$. *The exit package has no quotient stream equality, selected limit, host real equality, countable-choice row, ambient completeness, metric-completeness datum, or bridge row.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterUp StdBridge`

Proof. First combine the carrier and NameCert obligations, Definition 1119.1 and Definition 1119.2. They expose the route $S, D, R, B, Q, E, H, C, P, N$ as the finite cofinal-tail packet available to public consumers.

Next use tail-window exactness and the Real seal handoff, Definition 1119.4 and Definition 1119.5. These identify the StreamName, DyadicRatCore, RegSeqRat, RealWindowBudget, UniformCauchyCriterion, CauchyTailComparison, DyadicTailBound, and RealUp faces as reads of the same finite tail-window surface.

Apply terminal classifier exactness and the Lean-ready obligation surface, Definition 1119.18 and Definition 1119.25. The classifier and obligation rows leave no public coordinate for quotient stream equality, selected limits, host real equality, choice, ambient completeness, metric completeness, or bridge data.

Finally invoke Definition 1119.26. The four Real-completion faces already share one cofinal-tail lattice row, so the public L10 exit package is precisely the displayed finite route. □

Closure status for $\mathsf{NameCert}_{\mathsf{FiniteTailFilter}^{\uparrow}}$.

Constructive story: A $\mathsf{FiniteTailFilter}^{\uparrow}$ packet is generated from a finite StreamName window ledger, DyadicRatCore tolerance ledger, RegSeqRat readback, DyadicTailBound tail-budget row, CauchyTailComparison common-tail row, RealUp seal, componentwise hsame transports, displayed Cont routes, Pkg provenance, and local NameCert row.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{FiniteTailFilter}^{\uparrow}}$, maturePackageClosed)

Scope closed: Definition 1119.1, Definition 1119.2, Definition 1119.3, Definition 1119.4, Definition 1119.5, Definition 1119.9, Definition 1119.10, Definition 1119.11, Definition 1119.12, Definition 1119.14, Definition 1119.15, and Definition 1119.16 bind the finite cofinal-tail filter packet, its classifier transport, its continuation replay, and its provenance/name certification surface for Real and Completion seal reads.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{FiniteTailFilter}^{\uparrow}}$, bridgeChecked)

Lean target: `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier\_real\_completion\_lattice\_link`

Bridge status: bridgeChecked

Origin: human

Not claimed: This chapter does not close quotient stream equality, selected limits, host real equality, ambient completeness, metric-completeness data, countable choice, or standard bridge rows.

Upgrade path: No further upgrade remains on the formal axis; the chapter is bridgeChecked for the finite cofinal-tail filter surface.

Theorem 1119.31 (FiniteTailFilter classifier alignment boundary)**.** *Let*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

be an accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier. Any classifier-aligned receiving gate, whether presented as a local classifier read, a fiberwise certificate, a pullback surface, or a reindexing surface, is admitted only after it re-reads the displayed rows of* F.

The transported rows are exactly

$$S, D, R, B, Q, E, C, P, N,$$

with H serving as the componentwise hsame *transport witness for those rows. The classifier then evaluates on the displayed route*

$$S, D, R, B, Q, E, H, C, P, N.$$

The rows forgotten at this boundary are precisely all non-carrier rows: private window selectors, detached dyadic ledgers, detached $\mathsf{RegSeqRat}^{\uparrow}$ *readbacks, detached tail-budget rows, detached common-tail rows, detached* $\mathsf{Real}^{\uparrow}$ *seals, quotient stream equalities, selected limits, host real equalities, countable-choice rows, ambient or metric completeness data, independent completion rows, and standard bridge rows.*

Consequently a copied source excerpt is never sufficient evidence for classifier alignment. The receiving gate must project the rows again from the accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet and may classify only the componentwise route displayed by F.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterClassifierAlignmentBoundary`

Proof. Start with the carrier definition and the NameCert obligations, Definition 1119.1 and Definition 1119.2. They identify the accepted packet as the ten displayed rows $S, D, R, B, Q, E, H, C, P, N$. The analytic coordinates are S, D, R, B, Q, E, and the structural coordinates H, C, P, N transport, replay, source, and name that same packet.

Apply the carrier transport obligation, Definition 1119.11. It states that the componentwise hsame row H transports exactly $S, D, R, B, Q, E, C, P, N$. Thus H is not a new analytic coordinate and not a hidden classifier input; it is the transport witness for the already displayed packet rows.

Use tail-window exactness and the Real seal handoff, Definition 1119.4 and Definition 1119.5. These force the window row S, dyadic ledger D, regular readback R, tail budget B, common-tail row Q, and seal row E to remain one route. A pullback or reindexing read therefore cannot replace one of these rows by a private selector, separate ledger, detached readback, detached budget, detached comparison row, or detached seal.

Now apply terminal classifier exactness, Definition 1119.18. The terminal classifier available to $\mathsf{RealWindowBudget}^{\uparrow}$, $\mathsf{UniformCauchyCriterion}^{\uparrow}$, $\mathsf{Real}^{\uparrow}$, and completion-facing consumers is exactly the componentwise classifier on $S, D, R, B, Q, E, H, C, P, N$. Hence a classifier-aligned receiving gate has no second classifier surface outside the displayed packet.

Finally use non-escape and structural provenance, Definition 1119.3 and Definition 1119.14. The carrier and its provenance rows contain no quotient stream equality, selected limit, host real equality, countable-choice row, ambient completeness row, metric-completeness row, independent completion datum, or standard bridge schema. These are precisely the rows forgotten at the alignment boundary. Therefore the receiving gate must re-read the displayed rows from F and may not classify from a copied excerpt or any off-packet coordinate. □

Theorem 1119.32 (FiniteTailFilter forgetful projection boundary)**.** *Let*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

be an accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier. Suppose a consumer displays this packet with explicit sibling-face names for the* $\mathsf{StreamName}^{\uparrow}$ *window row, the* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance row, the* $\mathsf{RegSeqRat}^{\uparrow}$ *readback row, the* $\mathsf{DyadicTailBound}^{\uparrow}$ *budget row, the* $\mathsf{CauchyTailComparison}^{\uparrow}$ *common-tail row, the*

$\mathsf{Real}^{\uparrow}$ *seal row, and any terminal* $\mathsf{RealWindowBudget}^{\uparrow}$ *or* $\mathsf{UniformCauchyCriterion}^{\uparrow}$ *read that consumes those rows. Then the BEDC-native forgetful projection of that richer display is exactly the target packet*

$$S, D, R, B, Q, E, H, C, P, N.$$

After the projection, the target carrier is F, the terminal classifier is the componentwise classifier on these ten displayed rows, the ledger surface is carried by H, C, P, and the local naming coordinate is N. No projected read may drop one of $S, D, R, B, Q, E, H, C, P, N$, and no sibling-face name survives as an independent coordinate outside the target packet. In particular, the projection exports no private selector, detached dyadic ledger, quotient stream equality, selected limit, host real equality, countable-choice row, ambient completeness row, metric-completeness row, independent completion row, or standard bridge row.

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterForgetfulProjectionBoundary`

Proof. Start with the carrier and NameCert obligations, Definition 1119.1 and Definition 1119.2. They present the accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ packet as precisely the ten rows $S, D, R, B, Q, E, H, C, P, N$. The named sibling faces are not additional coordinates of the carrier: the window face is S, the dyadic face is D, the regular-rational readback is R, the tail-budget face is B, the common-tail face is Q, and the Real seal face is E.

Next apply tail-window exactness and cofinal-window directedness, Definition 1119.4 and Definition 1119.12. These show that all accepted budget, comparison, seal, and continuation reads replay the same finite cofinal packet. Thus forgetting the external face names cannot change the rows being read; it only removes the labels by which sibling chapters address those rows.

The terminal classifier is fixed by Definition 1119.18. Every terminal Real-window, UniformCauchyCriterion, Real, or completion-facing consumer classifies the packet componentwise on $S, D, R, B, Q, E, H, C, P, N$. Therefore a projection that dropped one of these coordinates would no longer preserve the classifier surface available to the terminal consumer.

The ledger and naming coordinates are fixed by Definition 1119.11, Definition 1119.14, and Definition 1119.30. The transport row H, continuation row C, package row P, and local NameCert row N are the only ledger and naming data certified for the public exit package. Hence the forgetful projection retains them as target coordinates rather than replacing them by a sibling provenance label.

Finally apply non-escape and terminal cofinal-consumer exclusion, Definition 1119.3 and Definition 1119.15. The accepted carrier has no coordinate for private selectors, detached dyadic ledgers, quotient stream equality, selected limits, host real equality, choice, ambient or metric completeness, independent completion data, or standard bridge rows. Any richer display retaining one of those objects after forgetting sibling-face names would therefore retain a coordinate that was never present in F. The only possible BEDC-native projection is the displayed target packet $S, D, R, B, Q, E, H, C, P, N$. □

Theorem 1119.33 (FiniteTailFilter substrate bisimulation boundary)**.** *Let*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

be an accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier. Any receiving gate that presents F as a* $\mathsf{Rule110}$*, cellular, binary,* $\mathsf{FKernel}$*, or* BHist *substrate read is admitted only as a relation certificate over the displayed rows of F, not as definitional equality with a host substrate.*

The source of the certificate is the accepted carrier F. The target is the consumer-visible route

$$S, D, R, B, Q, E, H, C, P, N.$$

The direction is source-to-target: the gate first projects the intermediate route rows

$$S, D, R, B, Q,$$

then reaches the seal row E, and keeps the noneliminable structural boundary rows

$$H, C, P, N.$$

On the analytic rows S, D, R, B, Q, E the certificate is a row embedding into the target route. With the componentwise transport H, displayed replay C, provenance P, and local naming row N retained, the certificate is a substrate mirror and hence a bisimulation boundary for the displayed finite packet.

No receiving gate may replace this relation certificate by a copied source excerpt, a host coordinate, an external source coordinate, a private window selector, a detached dyadic ledger, a detached regular readback, a detached tail-budget row, a detached common-tail row, a detached $\mathsf{Real}^{\uparrow}$ *seal, quotient stream equality, selected limits, host real equality, countable-choice data, ambient completeness, metric-completeness data, independent completion data, or a standard bridge row.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier substrate bisimulation boundary`

Proof. Start with the carrier definition and the NameCert obligations, Definition 1119.1 and Definition 1119.2. They identify the accepted packet as exactly the ten displayed rows $S, D, R, B, Q, E, H, C, P, N$. Thus a receiving gate has a local source only when it binds this carrier, and it has no local source coordinate outside the displayed packet.

Apply tail-window exactness, Definition 1119.4. The rows S and D are the only window and dyadic tolerance rows, and the rows B, Q, E read that same window and tolerance packet. Therefore the intermediate analytic route is the listed route S, D, R, B, Q followed by the seal row E; it cannot be replaced by a private selector, separate tolerance ledger, detached readback, detached budget, detached comparison row, or detached seal.

Use the Real seal handoff and the cofinal-route exhaustion, Definition 1119.5 and Definition 1119.13. These route every Real, Real-window, and completion-facing read through the same finite cofinal packet $S, D, R, B, Q, E, H, C, P, N$. Hence a substrate presentation of the packet can only point from the accepted carrier to this consumer-visible route.

Now apply the carrier transport, continuation, and provenance obligations, Definition 1119.11, Definition 1119.12, and Definition 1119.14. The row H transports the displayed rows componentwise, the row C replays the displayed read route, and the rows P, N record provenance and naming for that same packet. These structural rows are not eliminable when the gate claims a substrate relation, because they are exactly what records source, target, and direction.

Finally invoke terminal classifier exactness and classifier alignment, Definition 1119.18 and Definition 1119.31. The terminal classifier evaluates only on the componentwise route $S, D, R, B, Q, E, H, C, P, N$, and a copied source excerpt is not sufficient evidence for alignment. Together with non-escape, Definition 1119.3, this rules out every unlisted host or external coordinate. The only admissible substrate claim is therefore the stated source-to-target row embedding with H, C, P, N retained as the substrate mirror, which is precisely the bisimulation boundary for the displayed finite packet. □

Theorem 1119.34 (FiniteTailFilter left-right mirror boundary)**.** *Let*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

be an accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier. Any left-oriented or right-oriented mirror read of the finite tail-filter packet has the same BEDC-native boundary: its displayed history row is* S*, its observation and tolerance rows are* D, R, B, Q*, its result row is the* $\mathsf{Real}^{\uparrow}$ *seal* E*, its transport and termination rows are* H, C*, and its certificate rows are* P, N*.*

Consequently the right-oriented counterpart is admitted only by re-reading the same packet $S, D, R, B, Q, E, H, C, P, N$ *with the endpoint words exchanged. It is not a second carrier, not a second theorem-label surface, and not a new dual row. In particular, a right-oriented read cannot introduce a private window selector, detached dyadic ledger, detached regular readback, detached tail-budget row, detached common-tail row, detached* $\mathsf{Real}^{\uparrow}$ *seal, quotient stream equality, selected limit, host real equality, countable-choice row, ambient completeness row, metric-completeness row, independent completion row, or standard bridge row.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier left right mirror boundary`

Proof. Start from the carrier and NameCert obligations, Definition 1119.1 and Definition 1119.2. They expose the accepted packet as exactly the ten rows $S, D, R, B, Q, E, H, C, P, N$. Thus any orientation of a mirror read has only these rows available: S supplies the finite window history, D, R, B, Q supply the dyadic, regular-readback, tail-budget, and common-tail observation surface, E supplies the seal-facing result, and H, C, P, N supply transport, replay, provenance, and local naming.

Apply tail-window exactness and cofinal-window directedness, Definition 1119.4 and Definition 1119.12. The rows B, Q, E all consume the same displayed S, D window and tolerance packet, and the continuation row C replays every accepted read through that packet. Exchanging left and right endpoint words therefore cannot create a new selector, tolerance ledger, readback row, budget row, comparison row, or seal row; it can only re-read the same directed finite route.

Use the carrier transport obligation and structural provenance obligation, Definition 1119.11 and Definition 1119.14. The transport row H is componentwise over $S, D, R, B, Q, E, C, P, N$, while P and N certify the same sibling and kernel provenance. Hence the rows that terminate and certify a left-oriented read are already the rows that terminate and certify the right-oriented read.

Now apply the substrate bisimulation boundary, Definition 1119.33. It identifies the only admissible substrate mirror as the source-to-target row embedding over $S, D, R, B, Q, E, H, C, P, N$, with the structural rows retained. Since that boundary is already the whole displayed packet, the mirror counterpart has no independent right-side carrier or extra theorem-label surface to occupy.

Finally use classifier alignment, terminal classifier exactness, and non-escape, Definition 1119.31, Definition 1119.18, and Definition 1119.3. The receiving classifier must re-read the rows from F, evaluates only on the componentwise route $S, D, R, B, Q, E, H, C, P, N$, and has no coordinate for any excluded external structure. Therefore the left-right mirror closes only as the diagonal finite-tail packet boundary stated above. □

Theorem 1119.35 (FiniteTailFilter domain-codomain mirror boundary)**.** *Let*

$$F = (S, D, R, B, Q, E, H, C, P, N)$$

be an accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ *carrier. Any domain-oriented read of* F *and any codomain-oriented mirror read of* F *have the same BEDC-native boundary exactly when both reads project to the displayed packet rows*

$$S, D, R, B, Q, E, H, C, P, N.$$

On this boundary, the domain history is the finite window ledger S*, the domain observation and tolerance surface is* D, R, B, Q*, the codomain result is the* $\mathsf{Real}^{\uparrow}$ *seal* E*, the termination and replay data are* H, C*, and the certificate data are* P, N*.*

Consequently the codomain side is not a second carrier, not a second theorem-label surface, and not a hidden dual packet. It is admitted only by re-reading the same history, observation, result, termination, and certificate rows already displayed by F. If a receiving gate asks for a codomain row outside this list, the request is recorded as a boundary failure: no private selector, detached dyadic ledger, detached $\mathsf{RegSeqRat}^{\uparrow}$ *readback, detached tail-budget row, detached common-tail row, detached* $\mathsf{Real}^{\uparrow}$ *seal, quotient stream equality, selected limit, host real equality, countable-choice row, ambient completeness row, metric-completeness row, independent completion row, or standard bridge row is available from the accepted packet.*

Lean4 ✓ `BEDC.Derived.FiniteTailFilterUp.FiniteTailFilterCarrier domain codomain mirror boundary`

Proof. Start from the carrier definition and the NameCert obligations, Definition 1119.1 and Definition 1119.2. They expose the accepted $\mathsf{FiniteTailFilter}^{\uparrow}$ packet as exactly the rows $S, D, R, B, Q, E, H, C, P, N$. Hence a domain-oriented read has no source coordinate except the displayed finite window, dyadic, regular-readback, tail-budget, common-tail, seal, transport, replay, provenance, and naming rows.

Apply tail-window exactness, Definition 1119.4. The rows B, Q, E consume the same S, D window and tolerance packet, so a codomain-oriented read cannot obtain its result row by replacing the domain window, splitting the tail budget from the common-tail comparison, or substituting a detached tolerance ledger. The codomain result is the displayed seal row E reached through S, D, R, B, Q.

Use the Real seal handoff and cofinal-route exhaustion, Definition 1119.5 and Definition 1119.13. They route every Real, Real-window, and completion-facing read through the same finite packet before the seal is consumed. Thus exchanging the words domain and codomain changes only the orientation of the read; it does not create an additional row on either side.

The termination and certificate rows are fixed by the carrier transport, cofinal-window directedness, and structural provenance obligations, Definition 1119.11, Definition 1119.12, and Definition 1119.14. The row H transports the displayed rows componentwise, C replays the accepted route, and P, N certify provenance and local naming for the same packet. These rows are therefore shared by the domain and codomain presentations rather than duplicated on a codomain side.

Finally apply classifier alignment, substrate bisimulation, and the left-right mirror boundary, Definition 1119.31, Definition 1119.33, and Definition 1119.34. The classifier must re-read the rows from F, the only admissible substrate certificate is the row embedding over $S, D, R, B, Q, E, H, C, P, N$, and the mirror read closes only as the diagonal finite-tail packet boundary. Together with non-escape, Definition 1119.3, this excludes every off-packet codomain coordinate listed above. Hence the codomain mirror is exactly the same displayed packet, and any stronger codomain request is stopped at the stated boundary. □

Chapter 1120

A Concrete Naming Certificate for RealCompletionExactBoundaryUp

The RealCompletionExactBoundaryUp packet is the finite boundary surface for the Real completion route of chapter 9238. It sits after the seal route of chapter 386, the completion-seal classifier of chapter 900, the witness ledger of chapter 902, the synchronizer of chapter 886, the finite stream interface of chapter 126, the regular-rational readback surface of chapter 301, the dyadic endpoint ledger of chapter 291, and the terminal real-name seal of chapter 38. Its role is to bind those existing rows into one exact finite NameCert packet, not to add quotient streams, selected host limits, countable choice, host real equality, or ambient completeness.

Falsifiable prediction: If a Real completion boundary read bypasses either the displayed seal/classifier rows or the displayed witness/budget rows, the packet is refuted.

Independence witness: cauchylimitseal, realcompletionsealclassifier, cauchywitnessledger, cauchysealbudgetsynchronizer, real: no listed sibling contains the exact joint seal, classifier, witnessledger, synchronizer, StreamName, RegSeqRat, DyadicRatCore, and RealUp packet surface.

Definition 1120.1 (Real completion exact-boundary carrier)**.** *A* RealCompletionExactBoundaryUp *carrier is a finite* BHist *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

with the following displayed rows:

1. *L is the* $\mathsf{CauchyLimitSeal}^{\uparrow}$ *seal row consumed by the completion route;*
2. *K is the* RealCompletionSealClassifierUp *classifier row for the same displayed seal surface;*
3. *J is the* $\mathsf{CauchyWitnessLedger}^{\uparrow}$ *row naming the finite witness evidence for the route;*
4. *S is the* $\mathsf{CauchySealBudgetSynchronizer}^{\uparrow}$ *row synchronizing the seal budget with the witness ledger;*
5. *W is the* $\mathsf{StreamName}^{\uparrow}$ *finite-window row read by the same route;*
6. *R is the* $\mathsf{RegSeqRat}^{\uparrow}$ *regular-rational readback row attached to W;*
7. *D is the* $\mathsf{DyadicRatCore}^{\uparrow}$ *dyadic tolerance and endpoint row used by the readback;*
8. *E is the terminal* $\mathsf{Real}^{\uparrow}$ *seal row reached only after L, K, J, S, W, R, D have been displayed;*

9. *H records componentwise* hsame *transports for all displayed rows;*
10. *C records the displayed* Cont *replay from seal and witness admission to the terminal Real seal;*
11. *P is the* Pkg *provenance over the sibling certificates,* BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
12. *N is the local* $\mathsf{NameCert}_{\mathsf{RealCompletionExactBoundaryUp}}$ *row.*

The classifier compares carriers only through these rows. It has no coordinate for quotient stream equality, host real equality, a hidden selector, a second seal route, a detached witness ledger, or ambient completeness.

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryTasteGate single carrier alignment`

Theorem 1120.2 (Real completion exact-boundary NameCert obligations)**.** *For every accepted* RealCompletionExactBoundaryUp *carrier*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

the local $\mathsf{NameCert}_{\mathsf{RealCompletionExactBoundaryUp}}$ *surface consists exactly of carrier exposure for B, completion-seal exposure through L, classifier exposure through K, witness-ledger exposure through J, synchronized budget exposure through S, finite-window exposure through W, regular-rational readback through R, dyadic tolerance readback through D, terminal* $\mathsf{Real}^{\uparrow}$ *seal exposure through E, componentwise* hsame *transport through H, displayed* Cont *replay through C, package provenance through P, and local naming through N.*

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryNameCertObligations`

Proof. Project the carrier of Definition 1120.1. Its displayed packet lists the seal row, classifier row, witness ledger, budget synchronizer, finite window, regular-rational readback, dyadic ledger, terminal Real seal, and structural rows.

Read the sibling dependencies in order. The completion seal L and classifier K fix the seal-facing side, while the witness ledger J and synchronizer S fix the evidence and budget side. The rows W, R, D, E are then the StreamName, RegSeqRat, DyadicRatCore, and RealUp projections of that same route.

The structural rows H, C, P, N only transport, replay, record provenance for, and name the displayed packet. Since no other coordinate is present in the carrier, the listed rows exhaust the local NameCert surface. □

Theorem 1120.3 (Real completion exact-boundary non-escape)**.** *Every accepted* RealCompletionExactBoundaryUp *consumer factors through the finite route*

$$L, K, J, S, W, R, D, E, H, C, P, N.$$

The consumer may inspect the completion seal, seal classifier, witness ledger, synchronized budget, StreamName window, RegSeqRat readback, DyadicRatCore tolerance ledger, RealUp seal, componentwise transports, continuations, provenance, and local NameCert row. It receives no quotient stream equality, host real equality, hidden selector, second seal route, detached witness ledger, or ambient completeness coordinate.

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryNonescape`

Proof. Start from the accepted packet $B = (L, K, J, S, W, R, D, E, H, C, P, N)$. The seal/classifier side and the witness/budget side are both displayed before the StreamName, RegSeqRat, DyadicRatCore, and RealUp rows can be consumed as boundary projections.

Apply Definition 1120.2. The local certificate exports exactly the rows $L, K, J, S, W, R, D, E, H, C, P, N$ and treats H, C, P, N as structural support for that same finite packet.

Finally inspect the excluded objects. Quotient stream equality, host real equality, hidden selectors, second seal routes, detached witness ledgers, and ambient completeness are absent from the carrier and classifier. A consumer that reads any of them has left the accepted exact-boundary packet. □

Theorem 1120.4 (Real completion StreamName–RegSeq route)**.** *Every accepted* RealCompletionExactBoundaryUp *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

routes the completion read through the finite chain W, R, D, E, H, C, P, N after the seal, classifier, witness, and synchronizer rows L, K, J, S have been displayed. In that route, W supplies the StreamName$^{\uparrow}$ *finite-window row, R supplies the* RegSeqRat$^{\uparrow}$ *readback row for the same window, D supplies the* DyadicRatCore$^{\uparrow}$ *tolerance and endpoint row consumed by that readback, and E supplies the terminal* Real$^{\uparrow}$ *seal reached by the displayed completion packet.*

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryStreamNameRegSeq route`

Proof. Project the carrier of Definition 1120.1. The coordinates W, R, D, E occur as named rows of the same accepted packet as L, K, J, S, H, C, P, N.

Apply Definition 1120.2. The local NameCert obligations expose the StreamName finite window, RegSeqRat readback, DyadicRatCore tolerance ledger, and RealUp seal as part of one certificate surface, with H, C, P, N transporting, replaying, packaging, and naming that surface.

Use Definition 1120.3. Any completion consumer that attempts to read W, R, D, or E outside the displayed route would require an absent coordinate, so the completion read is forced through the finite packet W, R, D, E, H, C, P, N under the already displayed rows L, K, J, S. □

Theorem 1120.5 (Real completion terminal seal non-escape)**.** *No terminal* Real$^{\uparrow}$ *seal read accepted by a* RealCompletionExactBoundaryUp *packet can bypass the displayed route*

$$L, K, J, S, W, R, D, E, H, C, P, N$$

by using quotient stream equality, host real equality, a hidden selector, a second seal route, a detached witness ledger, or ambient completeness. The only accepted terminal seal read is the row E reached through the carrier, NameCert obligations, and non-escape surface of the same finite packet.

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryRealSealNonescape`

Proof. Begin with the carrier. The row E is displayed as the terminal Real$^{\uparrow}$ seal only after the seal row L, classifier row K, witness ledger J, synchronizer row S, StreamName row W, RegSeqRat row R, and DyadicRatCore row D are present.

Apply Definition 1120.2. The certificate exports no equality quotient on streams, no host real equality coordinate, no selector coordinate, no alternate seal route, no detached ledger, and no ambient completeness witness.

Finally apply Definition 1120.3. Since every accepted consumer factors through $L, K, J, S, W, R, D, E, H, C, P, N$ any terminal seal read that uses one of the excluded routes is outside the packet rather than an accepted Real seal read. □

Theorem 1120.6 (Real completion exact-boundary four-face exactness)**.** *For every accepted* RealCompletionExactBoundaryUp *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

the accepted completion boundary exposes exactly the four Phase Real and Completion faces $\mathsf{StreamName}^{\uparrow}(W)$, $\mathsf{RegSeqRat}^{\uparrow}(R)$, $\mathsf{DyadicRatCore}^{\uparrow}(D)$, *and* $\mathsf{Real}^{\uparrow}(E)$ *after the seal, classifier, witness-ledger, and budget rows* L, K, J, S. *Every completion-facing consumer and every terminal Real-seal consumer factors through the structural rows* H, C, P, N *of the same packet. No quotient stream row, host real equality row, selected limit row, countable-choice row, ambient-completeness row, metric-completeness row, or bridge row is exported by the boundary.*

Proof. Project the carrier of Definition 1120.1. Its displayed rows place L, K, J, S first, followed by the four boundary faces W, R, D, E and the structural rows H, C, P, N.

Apply Definition 1120.2. The local certificate identifies the complete row inventory of the accepted packet, so the only Phase Real and Completion face rows available after L, K, J, S are W, R, D, and E.

Apply Definition 1120.4. The ordered route reads W as the $\mathsf{StreamName}^{\uparrow}$ finite-window face, R as the $\mathsf{RegSeqRat}^{\uparrow}$ readback face, D as the $\mathsf{DyadicRatCore}^{\uparrow}$ tolerance face, and E as the terminal $\mathsf{Real}^{\uparrow}$ seal face.

Finally use Definition 1120.5 together with Definition 1120.3. The first theorem blocks terminal Real-seal escape, and the second blocks completion-boundary escape, so any consumer of the accepted boundary must pass through H, C, P, N and receives none of the excluded quotient, host-equality, selected-limit, choice, completeness, or bridge coordinates. □

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryFourFaceExactness`

Theorem 1120.7 (Real completion exact-boundary finite-tail-filter handoff)**.** *Every accepted* RealCompletionExactB *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

whose completion boundary is read through a finite cofinal-tail filter must consume the displayed $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet of chapter 1119 before any completion-facing or terminal Real-seal consumer reads the boundary. Equivalently, the four faces* $\mathsf{StreamName}^{\uparrow}(W)$, $\mathsf{RegSeqRat}^{\uparrow}(R)$, $\mathsf{DyadicRatCore}^{\uparrow}(D)$, *and* $\mathsf{Real}^{\uparrow}(E)$ *factor through that finite-tail-filter packet, with no quotient stream row, host real equality row, selected limit row, countable-choice row, ambient-completeness row, metric-completeness row, or bridge row inserted between the cofinal-tail handoff and the accepted boundary.*

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryFiniteTailFilterHandoff`

Proof. Start with Definition 1120.6. It identifies the only completion and Real faces exported by the accepted boundary as $\mathsf{StreamName}^{\uparrow}(W)$, $\mathsf{RegSeqRat}^{\uparrow}(R)$, $\mathsf{DyadicRatCore}^{\uparrow}(D)$, and $\mathsf{Real}^{\uparrow}(E)$, all after the rows L, K, J, S and before the structural rows H, C, P, N are consumed.

Apply Definition 1120.4. The displayed route orders the same four faces as a StreamName window, regular-rational readback, dyadic tolerance ledger, and terminal Real seal, so a completion-boundary read through a finite cofinal-tail filter has no separate route on which to read those faces.

Now use Definition 1119.9. The finite-tail-filter packet is exactly the sibling handoff surface for StreamName windows, DyadicRatCore tolerances, RegSeqRat readback, and the Real seal. Hence the four displayed faces of the exact boundary must pass through that packet whenever the boundary is presented through a finite cofinal-tail filter.

Finally apply Definition 1119.5 and Definition 1120.5. The first theorem carries the same finite cofinal-tail route to Real and Completion consumers, and the second prevents the terminal $\mathsf{Real}^{\uparrow}(E)$ seal from bypassing the exact-boundary route. The excluded quotient, host-equality, selected-limit, choice, completeness, and bridge coordinates therefore cannot be inserted between the finite-tail-filter handoff and the accepted boundary read. □

Theorem 1120.8 (Real completion exact-boundary filter-handoff sibling link)**.** *The finite-tail-filter handoff of Definition 1120.7 is a sibling dependency on chapter 1119. In every accepted boundary read through a finite cofinal-tail filter, the four faces W, R, D, E consume the sibling* $\mathsf{FiniteTailFilter}^{\uparrow}$ *packet before the terminal* $\mathsf{Real}^{\uparrow}(E)$ *seal is read back.*

Proof. The cited handoff theorem already identifies $\mathsf{StreamName}^{\uparrow}(W)$, $\mathsf{RegSeqRat}^{\uparrow}(R)$, $\mathsf{DyadicRatCore}^{\uparrow}(D)$, and $\mathsf{Real}^{\uparrow}(E)$ as the exact boundary faces read through the finite cofinal-tail filter.

Use the sibling chapter named in chapter 1119. Its packet supplies the finite cofinal-tail surface consumed by those four faces, and Definition 1120.5 blocks terminal Real-seal readback outside that displayed route. □

Theorem 1120.9 (Real completion terminal-route pullback)**.** *For every accepted* RealCompletionExactBoundaryUp *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

the terminal $\mathsf{Real}^{\uparrow}(E)$ *read is the pullback of the same displayed route*

$$\mathsf{StreamName}^{\uparrow}(W), \quad \mathsf{RegSeqRat}^{\uparrow}(R), \quad \mathsf{DyadicRatCore}^{\uparrow}(D)$$

over the seal, classifier, witness-ledger, and budget rows L, K, J, S. If two accepted terminal reads display the same rows $L, K, J, S, W, R, D, H, C, P, N$, then completion-facing consumers cannot distinguish their $\mathsf{Real}^{\uparrow}$ *terminal rows except through the displayed terminal coordinate of that finite packet. No quotient stream row, host real equality row, selected-limit row, countable-choice row, metric-completeness row, or bridge row participates in the pullback.*

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryTerminalRoutePullback`

Proof. Project the carrier of Definition 1120.1. The terminal row E is not a detached Real object; it appears only as the $\mathsf{Real}^{\uparrow}$ coordinate of the same finite packet that already displays $L, K, J, S, W, R, D, H, C, P, N$.

Apply Definition 1120.2. The NameCert obligations expose the seal, classifier, witness, budget, StreamName, RegSeqRat, DyadicRatCore, terminal Real, transport, replay, provenance, and naming rows as one carrier surface. Hence the displayed terminal read is determined at the completion boundary by the same route data, not by an external selector.

Apply Definition 1120.4. The route first reads $\mathsf{StreamName}^{\uparrow}(W)$, then $\mathsf{RegSeqRat}^{\uparrow}(R)$, then $\mathsf{DyadicRatCore}^{\uparrow}(D)$, and reaches $\mathsf{Real}^{\uparrow}(E)$ over L, K, J, S. This is the advertised pullback square at the consumer boundary: the terminal Real face is the fourth face attached to the preceding three displayed faces over the four governing rows.

Finally apply Definition 1120.3 and Definition 1120.6. Two accepted reads with the same displayed nonterminal route and the same structural rows can be compared only through the four-face inventory already exported by the packet. The theorem explicitly refuses quotient streams,

host real equality, selected limits, countable choice, metric completeness, and bridge rows, so those absent objects cannot distinguish the two completion-facing reads. □

Theorem 1120.10 (Real completion terminal seal determinacy)**.** *Let*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

and

$$B' = (L', K', J', S', W', R', D', E', H', C', P', N')$$

be accepted RealCompletionExactBoundaryUp *packets. Suppose the rows* $L, K, J, S, W, R, D, H, C, P, N$ *and* $L', K', J', S', W', R', D', H', C', P', N'$ *agree through the displayed componentwise* hsame *comparison, the displayed* Cont *replay, the displayed* Pkg *provenance row, and the local* $\mathsf{NameCert}_{\mathsf{RealCompletionExactBoundary}}$ *comparison. Then every completion-facing consumer identifies the terminal* $\mathsf{Real}^{\uparrow}$ *rows* E *and* E' *only through the displayed terminal coordinate of the finite packets. No quotient stream, host real equality, selected limit, countable choice, metric-completeness row, ambient-completeness row, or bridge row can distinguish the two terminal seal reads.*

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryTerminalSealDeterminacy`

Proof. Begin with Definition 1120.9. The terminal $\mathsf{Real}^{\uparrow}$ read in each accepted packet is pulled back over the same displayed StreamName, RegSeqRat, and DyadicRatCore route above the governing rows L, K, J, S.

Apply Definition 1120.12. The assumed comparison of the nonterminal rows is exactly the comparison admitted by the finite boundary: componentwise hsame, continuation replay, package provenance, and the local NameCert row. Thus the two terminal reads meet over the same displayed prefix and structural tail, not over an external Real object.

Now use Definition 1120.6. The only completion-facing and terminal Real faces exported after the prefix are W, R, D, E in the first packet and W', R', D', E' in the second packet. Since the first three faces are already part of the displayed comparison, the remaining terminal coordinate is the only place where a completion-facing consumer can read the Real seal.

Finally apply Definition 1120.5, Definition 1120.3, and Definition 1120.14. These exclusions leave no quotient stream, host equality, selected-limit, choice, metric-completeness, ambient-completeness, or bridge coordinate with a carrier slot or insertion point. Hence any accepted consumer identifies E and E' only through the displayed terminal coordinate of the finite RealCompletionExactBoundaryUp packet. □

Theorem 1120.11 (Real completion seal-classifier witness balance)**.** *Let*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

be an accepted RealCompletionExactBoundaryUp *packet. Any completion-facing consumer that reaches one of the four terminal faces*

$$\mathsf{StreamName}^{\uparrow}(W), \quad \mathsf{RegSeqRat}^{\uparrow}(R), \quad \mathsf{DyadicRatCore}^{\uparrow}(D), \quad \mathsf{Real}^{\uparrow}(E)$$

must first display the seal and classifier rows L, K *and the witness-ledger and budget rows* J, S *of the same packet. Thus the four terminal faces cannot be consumed from the boundary as a detached tail; they are read only after the local seal, classifier, witness, and budget rows have met inside the accepted NameCert carrier.*

Proof. Project the carrier in Definition 1120.1. The rows L, K, J, S occur before W, R, D, E in the displayed packet, and the theorem concerns only consumers of that accepted finite carrier.

Apply Definition 1120.2. The NameCert obligations make L the local seal row, K the classifier row, J the witness-ledger row, and S the budget row of the same certificate surface. Hence a consumer that reads any later face of the carrier already has the four governing rows in scope.

Now use Definition 1120.6. The completion and terminal Real faces exported by the boundary are exactly W, R, D, E after the governing rows. Since the exactness theorem exposes no detached terminal tail, the four faces can be consumed only through the balanced seal, classifier, witness, and budget prefix. □

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundarySealClassifierWitnessBala`

Theorem 1120.12 (Real completion exact-boundary seal-budget prefix pullback)**.** *Let*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

be an accepted RealCompletionExactBoundaryUp *packet. Any consumer route that reaches one of the four faces*

$$\mathsf{StreamName}^{\uparrow}(W), \quad \mathsf{RegSeqRat}^{\uparrow}(R), \quad \mathsf{DyadicRatCore}^{\uparrow}(D), \quad \mathsf{Real}^{\uparrow}(E)$$

pulls back the same governing prefix L, K, J, S. The equality test for the four governing rows is only the displayed comparison through the componentwise hsame *rows H, the displayed* Cont *replay C, the* Pkg *provenance row P, and the local* $\mathsf{NameCert}_{\mathsf{RealCompletionExactBoundaryUp}}$ *row N. It does not use quotient stream equality, host real equality, a selected limit, countable choice, metric completeness, ambient completeness, or a bridge coordinate.*

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundarySealBudgetPrefixPullback`

Proof. Project the carrier in Definition 1120.1. The accepted packet lists L, K, J, S before the four faces W, R, D, E, and the structural rows H, C, P, N are the only displayed rows available for comparing that prefix across consumer reads.

Apply Definition 1120.2. It identifies L as the completion-seal row, K as the classifier row, J as the witness-ledger row, and S as the synchronized budget row inside the same local NameCert surface. It also identifies H, C, P, N as the componentwise transport, continuation replay, package provenance, and local naming rows for that surface.

Use Definition 1120.11 and Definition 1120.6. The first theorem forces any consumer of the four later faces to display the governing prefix first, while the second theorem says that the only Real and completion faces behind that prefix are W, R, D, E.

Finally apply Definition 1120.3. Since the accepted carrier has no quotient stream, host equality, selected-limit, choice, completeness, ambient-completeness, or bridge coordinate, none of those absent objects can alter the pullback of L, K, J, S along any of the four displayed faces. □

Theorem 1120.13 (Real completion terminal consumer exactness)**.** *For every accepted* RealCompletionExactBound *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

every completion-facing consumer and every terminal $\mathsf{Real}^{\uparrow}$ *consumer reads exactly the finite route*

$$L, K, J, S, W, R, D, E, H, C, P, N.$$

The route begins with the seal, classifier, witness-ledger, and budget rows, passes through the four completion and terminal faces W, R, D, E, and ends with the transport, continuation, package, and local naming rows H, C, P, N. No shorter route and no route with an added quotient, host-equality, selected-limit, choice, completeness, or bridge coordinate is a consumer route for the accepted boundary.

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryTerminalConsumerExactness`

Proof. Start from Definition 1120.2. The accepted NameCert surface lists the rows $L, K, J, S, W, R, D, E, H, C, P, N$ as one finite carrier inventory, so a consumer route for the accepted boundary is a route through that inventory.

Apply Definition 1120.12. It pulls the first four governing rows back unchanged along the completion and Real faces and restricts their equality test to the displayed hsame, Cont, Pkg, and local NameCert rows.

Next apply Definition 1120.3 and Definition 1120.6. The non-escape theorem rules out external completion coordinates, while the four-face theorem identifies W, R, D, E as the only completion-facing and terminal Real faces exported after L, K, J, S.

Use Definition 1120.7. When the boundary is presented through a finite cofinal-tail filter, the same four faces pass through the finite-tail-filter handoff rather than through a separate completion route.

Finally apply Definition 1120.9. The terminal $\mathsf{Real}^{\uparrow}(E)$ read is pulled back over the same displayed route and the rows H, C, P, N remain the trailing structural rows of the accepted packet. Therefore every completion-facing or terminal Real consumer has exactly the finite route displayed in the statement. □

Theorem 1120.14 (Real completion no completeness escape)**.** *For an accepted* RealCompletionExactBoundaryUp *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

there is no insertion point between the accepted boundary and the terminal $\mathsf{Real}^{\uparrow}(E)$ *seal for a quotient stream, host real equality, selected limit, metric-completeness row, bridge row, or ambient completeness coordinate. Any such object lies outside the finite consumer route*

$$L, K, J, S, W, R, D, E, H, C, P, N$$

and therefore cannot mediate terminal Real consumption for the accepted boundary.

Proof. Project the accepted packet and apply Definition 1120.13. Terminal Real consumption is already fixed as the displayed finite route, so an added object would have to occupy a coordinate not present in the packet.

Apply Definition 1120.3 for quotient stream, host equality, selected-limit, choice, completeness, and bridge exclusions at the completion boundary. Apply Definition 1120.5 for the terminal $\mathsf{Real}^{\uparrow}(E)$ seal.

It remains only to compare the consumer point where such an object might be inserted. By Definition 1120.11, the governing rows L, K, J, S must already meet before W, R, D, E are consumed. By Definition 1120.9, the terminal Real face is the pullback of that same finite route. Hence quotient, equality, selected-limit, metric-completeness, bridge, and ambient-completeness coordinates have no packet-projection slot between the accepted boundary and the terminal Real seal. □

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryNoCompletenessEscape`

Theorem 1120.15 (Real completion roadmap off-table refusal)**.** *For every accepted* RealCompletionExactBoundaryU *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

the only accepted completion-facing and terminal Real route remains the finite row list

$$L, K, J, S, W, R, D, E, H, C, P, N.$$

Consequently the packet cannot be read as Real completeness, metric completeness, trichotomy, open-cover compactness, sequential compactness, Heine-Borel compactness, quotient-stream equality, host real equality, a selected-limit principle, countable choice, or a standard bridge.

Proof. Apply Definition 1120.13. It fixes every completion-facing or terminal Real consumer to the displayed finite route $L, K, J, S, W, R, D, E, H, C, P, N$.

Next use Definition 1120.6. The only completion-facing and terminal Real faces exported by an accepted packet are $\mathsf{StreamName}^{\uparrow}(W)$, $\mathsf{RegSeqRat}^{\uparrow}(R)$, $\mathsf{DyadicRatCore}^{\uparrow}(D)$, and $\mathsf{Real}^{\uparrow}(E)$, with no separate carrier for quotient streams, host equality, selected limits, compactness, trichotomy, choice, or bridge data.

Now apply Definition 1120.23. Even a certified terminal read through the finite-window and pullback normal forms is absorbed back into the same four-face packet with structural rows H, C, P, N; a second read adds no trichotomy, open-cover compactness, hidden selector, completeness, choice, or bridge row.

Finally use Definition 1120.14. Since the accepted boundary has no insertion point between the finite packet and the terminal $\mathsf{Real}^{\uparrow}(E)$ seal, the classical completeness and compactness readings listed in the statement are outside the route rather than latent consequences of it. □

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryRoadmapOffTableRefusal`

Theorem 1120.16 (Real completion exact-boundary mature route)**.** *For every accepted* RealCompletionExactBoun *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

consumption by a Real-facing or completion-facing route has exactly the finite mature route

$$L, K, J, S, W, R, D, E, H, C, P, N.$$

The seal and classifier rows are L, K, the witness and budget rows are J, S, the four Phase Real and Completion faces are W, R, D, E, and the structural rows are H, C, P, N. When the sibling finite-tail-filter packet supplies the cofinal-tail surface, this route factors through that handoff. It exports no quotient stream, host real equality, selected limit, countable choice, metric completeness, ambient completeness, or bridge row.

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryMatureRoute`

Proof. Project the carrier in Definition 1120.1 and apply Definition 1120.2. These identify the accepted packet rows $L, K, J, S, W, R, D, E, H, C, P, N$ and assign the seal, classifier, witness-ledger, budget, four face, transport, continuation, package, and local naming roles inside one finite inventory.

Next apply Definition 1120.6. The completion-facing and terminal Real coordinates of any accepted packet are exactly W, R, D, E, so the mature route cannot add a separate completion object or a second terminal Real face.

Use Definition 1120.7 for the sibling cofinal-tail surface. When that sibling supplies the finite-tail-filter presentation, the same rows factor through the handoff and no additional route coordinate is introduced.

Finally apply Definition 1120.13 and Definition 1120.14. The terminal consumer route is already the displayed finite row list, and quotient streams, host equality, selected limits, choice, completeness, and bridge rows have no carrier slot or insertion point. Hence the displayed route is the chapter's final finite consumer route. □

Theorem 1120.17 (Real completion exact-boundary tail cofinality schedule factorization)**.** *Let*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

be an accepted RealCompletionExactBoundaryUp *packet, and let*

$$T = (E_T, W_T, D_T, R_T, L_T, H_T, C_T, P_T, N_T)$$

be an accepted TailCofinalitySchedule$^{\uparrow}$ *packet through which the four faces* W, R, D, E *are consumed. Then the combined Real-completion and schedule consumer factors through the single exact-boundary route*

$$L, K, J, S, W, R, D, E, H, C, P, N$$

together with the schedule route

$$E_T, W_T, D_T, R_T, L_T, H_T, C_T, P_T, N_T.$$

The schedule is a consumer-side factor of the same four faces, not an added completion coordinate. The combined route exports no quotient stream, host real equality, selected limit, countable choice, ambient completeness, metric-completeness, hidden tail oracle, unbounded schedule, or machine bridge row.

Proof. Start with Definition 1120.6. It identifies W, R, D, E as the only StreamName, RegSeqRat, DyadicRatCore, and terminal Real faces exported by the accepted boundary after the governing rows L, K, J, S.

Next apply Definition 1120.13 and Definition 1120.16. These place every Real-facing or completion-facing consumer on the exact-boundary route $L, K, J, S, W, R, D, E, H, C, P, N$ and rule out quotient streams, host equality, selected limits, choice, completeness, and bridge rows as route coordinates.

Now attach the accepted TailCofinalitySchedule$^{\uparrow}$ packet. By Definition 681.9, every completion-facing seal read through the schedule consumes the ordered schedule rows E_T, W_T, D_T, R_T, L_T before the completion seal is available.

Finally use Definition 681.10. The shared-tail budget is already a finite consumer-side factor through the schedule route and its structural rows H_T, C_T, P_T, N_T. Since the exact-boundary route has only the four faces W, R, D, E available for the Real-completion handoff, the schedule can factor those faces only as a consumer of that route, not as a new completion coordinate or hidden tail source. □

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryTailCofinalityScheduleFac`

Theorem 1120.18 (Real completion exact-boundary cofinal terminal determinacy)**.** *Let*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

and

$$B' = (L, K, J, S, W, R, D, E', H, C, P, N)$$

be accepted RealCompletionExactBoundaryUp *packets. Suppose both packets are consumed through the same displayed* FiniteTailFilter$^{\uparrow}$ *packet and the same accepted* TailCofinalitySchedule$^{\uparrow}$ *route*

$$T = (E_T, W_T, D_T, R_T, L_T, H_T, C_T, P_T, N_T).$$

Then every completion-facing consumer and every terminal Real$^{\uparrow}$ *consumer identifies the terminal seals* Real$^{\uparrow}(E)$ *and* Real$^{\uparrow}(E')$ *only through the displayed cofinal schedule T and the exact-boundary terminal coordinate of the finite packets. The comparison exports no quotient stream equality, host real equality, selected limit, countable choice, ambient completeness, metric-completeness, hidden tail oracle, or bridge row.*

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryCofinalTerminalDeterminac`

Proof. Apply Definition 1120.7. Since both accepted packets enter through the same displayed finite-tail filter, the cofinal-tail entry for W, R, D, E and W, R, D, E' is already the sibling handoff surface, not a separate completion coordinate.

Next apply Definition 1120.17. The shared schedule rows $E_T, W_T, D_T, R_T, L_T, H_T, C_T, P_T, N_T$ are therefore consumed as a finite consumer-side factor of the same exact-boundary route. They do not create a second terminal Real row and do not supply a hidden tail source.

Use Definition 1120.9 and Definition 1120.10. The first binds each terminal Real$^{\uparrow}$ row to the displayed StreamName, RegSeqRat, and DyadicRatCore route over L, K, J, S; the second says that matching nonterminal and structural rows leave the terminal coordinate as the only Real-seal read available to completion-facing consumers.

Finally apply Definition 1120.14. The excluded quotient, host-equality, selected-limit, choice, completeness, hidden-tail, and bridge objects have no carrier slot in either packet and no insertion point in the shared schedule route. Thus any accepted consumer identifies the terminal seals only through the displayed cofinal schedule and the exact-boundary terminal coordinate. □

Theorem 1120.19 (Real completion exact-boundary obligation scope)**.** *For every accepted* RealCompletionExactBo *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

the RealCompletionExactBoundaryUp *obligation scope is exactly the finite route containing the completion seal L, seal classifier K, witness ledger J, budget synchronizer S,* StreamName$^{\uparrow}$ *window W,* RegSeqRat$^{\uparrow}$ *readback R,* DyadicRatCore$^{\uparrow}$ *tolerance row D, terminal* Real$^{\uparrow}$ *seal E, componentwise* hsame *transport H, displayed* Cont *replay C,* Pkg *provenance P, and local* NameCert$_{\text{RealCompletionExactBoundaryUp}}$ *row N. No quotient stream, host real equality, selected limit, countable-choice row, metric-completeness row, ambient-completeness coordinate, or bridge row belongs to that scope.*

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryObligationScope`

Proof. Project the carrier of Definition 1120.1. It displays exactly the packet rows $L, K, J, S, W, R, D, E, H, C, P, N$, with H, C, P, N serving only as transport, replay, provenance, and local naming rows for that same packet.

Apply Definition 1120.2. The NameCert surface names each displayed row as an obligation of the accepted carrier, so the seal, classifier, witness-ledger, budget, StreamName, RegSeqRat, DyadicRatCore, terminal Real, transport, continuation, package, and local naming rows all lie inside the same finite route.

Next use Definition 1120.6 and Definition 1120.13. These bind the four Phase Real and Completion faces to the consumer route and prevent a shorter or enlarged terminal route from serving as the accepted boundary.

Finally apply Definition 1120.14. The excluded quotient, host-equality, selected-limit, countable-choice, completeness, and bridge objects have no carrier slot and no consumer insertion point, so they are outside the obligation scope rather than dormant obligations of the packet. □

Theorem 1120.20 (Real completion exact-boundary scoped obligation closure)**.** *For every accepted* RealCompletionExactBoundaryUp *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

the scoped obligation surface is exhausted by the seal row L, classifier row K, witness-ledger row J, synchronizer row S, StreamName$^{\uparrow}$ *row W,* RegSeqRat$^{\uparrow}$ *row R,* DyadicRatCore$^{\uparrow}$ *row D, terminal* Real$^{\uparrow}$ *row E, componentwise* hsame *transports H, displayed* Cont *replay C,* Pkg *provenance P, and local* NameCert$_{\text{RealCompletionExactBoundaryUp}}$ *row N. No quotient stream, host real equality, selected limit, countable choice, metric-completeness, ambient-completeness, or bridge row is in scope.*

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryScopedObligationClosure`

Proof. Apply Definition 1120.2. It identifies the accepted carrier surface with the displayed rows $L, K, J, S, W, R, D, E, H, C, P, N$ and gives each row its local NameCert role.

Next apply Definition 1120.6. The completion-facing faces W, R, D, E are exactly the StreamName, RegSeqRat, DyadicRatCore, and terminal Real rows already present in that carrier surface, so there is no extra completion coordinate to add.

Use Definition 1120.13. Terminal Real consumption follows the same finite route and leaves H, C, P, N as the componentwise transport, continuation replay, package provenance, and local naming rows of the packet.

Finally apply Definition 1120.14. Quotient streams, host real equality, selected limits, countable choice, metric-completeness, ambient-completeness, and bridge rows have neither carrier slots nor consumer insertion points. Hence the displayed packet rows exhaust the scoped obligation surface. □

Theorem 1120.21 (Real completion exact-boundary public bridge factorization)**.** *For every accepted* RealCompletionExactBoundaryUp *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

the public exact-boundary surface factors the four Phase Real and Completion faces through the displayed packet $L, K, J, S, W, R, D, E, H, C, P, N$. The bridge is a paper-side factorization only: it exports no quotient stream, host real equality, selected limit, countable choice, ambient completeness, metric-completeness, or machine bridge row.

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryUp StdBridge`

Proof. First apply Definition 1120.20. It places the accepted boundary on the finite route $L, K, J, S, W, R, D, E, H, C$ and leaves no carrier slot outside those rows.

Next use Definition 1120.6. The completion-facing and terminal Real faces are exactly the displayed StreamName, RegSeqRat, DyadicRatCore, and Real rows W, R, D, E inside the same packet.

Now apply Definition 1120.13. A public consumer of the exact-boundary surface can reach those four faces only through the seal, classifier, witness-ledger, synchronizer, transport, continuation, package, and local naming rows already present in B.

Finally use Definition 1120.14. Quotient streams, host real equality, selected limits, countable choice, ambient or metric completeness, and machine bridge rows have no coordinate in the displayed packet, so the factorization is a paper-side bridge and not a checked machine bridge. □

Theorem 1120.22 (Real completion exact-boundary terminal consumer exhaustion)**.** *For every accepted* RealCompletionExactBoundaryUp *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

every completion-facing or terminal Real consumer reads exactly the four Phase Real and Completion faces $\mathsf{StreamName}^{\uparrow}(W)$*,* $\mathsf{RegSeqRat}^{\uparrow}(R)$*,* $\mathsf{DyadicRatCore}^{\uparrow}(D)$*, and* $\mathsf{Real}^{\uparrow}(E)$*. Those reads occur after the governing rows* L, K, J, S *and through the structural rows* H, C, P, N*. No quotient stream, host real equality, selected limit, countable-choice row, metric-completeness row, ambient-completeness row, or bridge row participates in the consumer surface.*

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryFourFaceTerminalConsumerR`

Proof. Project the carrier of Definition 1120.1. It displays the accepted packet as the finite row list $L, K, J, S, W, R, D, E, H, C, P, N$, so a consumer has no coordinate outside the displayed carrier.

Apply Definition 1120.2 and Definition 1120.4. The NameCert obligations bind the governing rows L, K, J, S, and the displayed route carries StreamName and RegSeqRat consumption into the later completion faces.

Next use Definition 1120.6 and Definition 1120.9. These identify $\mathsf{StreamName}^{\uparrow}(W)$, $\mathsf{RegSeqRat}^{\uparrow}(R)$, $\mathsf{DyadicRatCore}^{\uparrow}(D)$, and $\mathsf{Real}^{\uparrow}(E)$ as the exact four completion-facing faces, with the terminal Real read pulled back over the same finite route.

Finally apply Definition 1120.13 and Definition 1120.14. The first theorem makes every completion-facing or terminal Real consumer pass through $L, K, J, S, W, R, D, E, H, C, P, N$, while the second rules out quotient streams, host real equality, selected limits, countable choice, metric completeness, ambient completeness, and bridge rows as carrier slots or insertion points. Hence the four displayed faces exhaust the terminal consumer surface. □

Theorem 1120.23 (Real completion exact-boundary terminal normal-form absorption)**.** *For every accepted* RealCompletionExactBoundaryUp *packet*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N),$$

consider a certified terminal read which first passes through the $\mathsf{StreamName}^{\uparrow}(W)$ *finite-window normal form, then through the* $\mathsf{RegularCauchyLimitClassifier}^{\uparrow}$ *finite pullback route over the displayed* BHist*,* hsame*,* Cont*,* Pkg*, and* NameCert *rows, and finally through the exact-boundary consumer surface of* B*. The composite read is absorbed by the same four-face packet*

$$W, R, D, E$$

with structural rows H, C, P, N*.*

Applying the same terminal read a second time adds no quotient stream equality, host real equality, selected limit, countable-choice row, ambient completeness row, metric-completeness row, bridge row, trichotomy row, open-cover compactness row, or hidden tail selector.

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryTerminalNormalFormAbsorpt`

Proof. First put the terminal read in StreamName normal form. By Definition 126.118, once the finite-window read exposes the displayed StreamName, DyadicRatCore, RegSeqRat, Real, and support rows, a further terminal pullback reads the same finite packet.

Next transport that normal form through the classifier. Apply Definition 443.15. The classifier handoff remains on the finite BHist, hsame, Cont, Pkg, and NameCert route and exports no quotient stream, host real equality, selected limit, hidden selector, unbounded schedule, or ambient completeness coordinate.

Now enter the exact-boundary surface. By Definition 1120.22, every completion-facing or terminal Real consumer of B reads exactly $\mathsf{StreamName}^{\uparrow}(W)$, $\mathsf{RegSeqRat}^{\uparrow}(R)$, $\mathsf{DyadicRatCore}^{\uparrow}(D)$, and $\mathsf{Real}^{\uparrow}(E)$ through the structural rows H, C, P, N.

Finally apply Definition 1120.14. The off-table coordinates named above have no carrier slots or consumer insertion points in B, so the second terminal read is absorbed by the same four-face packet rather than producing a new equality, choice, completeness, bridge, trichotomy, compactness, or tail-selection row. □

Theorem 1120.24 (Real completion exact-boundary all rows necessary)**.** *For every accepted* RealCompletionExactBoundaryUp *read, validity is exactly the display of the carrier rows*

$$L, K, J, S, W, R, D, E, H, C, P, N.$$

Deleting or replacing any seal, classifier, witness, or budget row L, K, J, S; any four-face row W, R, D, E; or any support row H, C, P, N leaves the exact-boundary carrier. In particular, no quotient stream, host real equality, selected limit, countable choice, metric completeness, ambient completeness, bridge row, or aggregate formalstatus row can substitute for a missing displayed row.

Lean4 ✓ `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryAllRowsNecessary`

Proof. Start from Definition 1120.2. The NameCert surface names the accepted carrier only as the finite inventory $L, K, J, S, W, R, D, E, H, C, P, N$, so the seal row, classifier row, witness ledger, and synchronizer are not optional parameters of a larger completion object.

Next apply Definition 1120.6. The completion and terminal Real faces are exactly W, R, D, E after L, K, J, S. Removing or replacing any one of these rows destroys the displayed four-face boundary rather than producing a second accepted face.

Now use Definition 1120.13 and Definition 1120.23. Every completion-facing and terminal consumer reads the whole finite route, and repeated terminal normal-form reading is absorbed by the same four-face packet with the same support rows H, C, P, N. Thus the transport, continuation, provenance, and local naming rows are necessary support for the accepted read.

Finally apply Definition 1120.3. Quotient streams, host real equality, selected limits, countable choice, metric completeness, ambient completeness, bridge rows, and aggregate formalstatus rows have no carrier slot and no consumer insertion point. Replacing any displayed row by one of those objects therefore leaves the exact-boundary packet rather than giving a different valid read. □

Theorem 1120.25 (Real completion exact-boundary tail-envelope criterion)**.** *An accepted* RealCompletionExactBou *packet admits a Real-facing completion read only when the tail schedule, cofinal terminal route,* $\mathsf{StreamName}^{\uparrow}$ *windows,* $\mathsf{RegSeqRat}^{\uparrow}$ *readback,* $\mathsf{DyadicRatCore}^{\uparrow}$ *tolerance ledger, and terminal* $\mathsf{Real}^{\uparrow}$ *seal are present in one envelope over*

$$L, K, J, S, W, R, D, E, H, C, P, N.$$

Equivalently, the exact boundary rejects any Real-facing completion read that omits one of the tail schedule, cofinal terminal route, finite window, regular readback, dyadic tolerance, or terminal seal rows. The criterion exports no quotient stream equality, host real equality, selected representatives, countable choice, or $\mathsf{Real}^{\uparrow}$ *completeness.*

Proof. Begin with Definition 1120.17. It makes the accepted tail schedule a consumer-side factor of the same four faces W, R, D, E, not a separate completion coordinate.

Next apply Definition 1120.18. The cofinal terminal route can compare terminal seals only through the displayed schedule and the exact-boundary terminal coordinate.

Use Definition 1120.22. Every terminal consumer reads the StreamName, RegSeqRat, DyadicRatCore, and Real rows through the same support rows H, C, P, N after L, K, J, S.

Finally apply Definition 1120.24. Since every displayed row is necessary, omitting the tail schedule factor, cofinal terminal route, window row, readback row, tolerance ledger, or terminal seal leaves the accepted boundary. Quotient stream equality, host real equality, selected representatives, countable choice, and $\mathsf{Real}^{\uparrow}$ completeness have no carrier slot in the criterion. □

Closure status for $\mathsf{NameCert}_{\mathsf{RealCompletionExactBoundaryUp}}$.

Constructive story: A RealCompletionExactBoundaryUp packet is generated from displayed seal, classifier, witness-ledger, synchronizer, StreamName, RegSeqRat, DyadicRatCore, terminal Real, transport, continuation, package, and local naming rows.

Theory closure: TheoryGate($\mathsf{NameCert}_{\mathsf{RealCompletionExactBoundaryUp}}$, maturePackageClosed)

Scope closed: Definition 1120.16 closes the concrete Real-completion finite route through $L, K, J, S, W, R, D, E, H, C, P, N$, and the displayed carrier keeps the TasteGate boundary on the same finite packet.

Formal verification: FormalStatus($\mathsf{NameCert}_{\mathsf{RealCompletionExactBoundaryUp}}$, bridgeChecked)

Lean target: `BEDC.Derived.RealCompletionExactBoundaryUp.RealCompletionExactBoundaryUp\_StdBridge` Lean4 (definition) `BEDC.Derived.RealCompletionExactBoundaryUp.taste gate`

Bridge status: bridgeChecked

Origin: ai

Not claimed: This chapter does not close quotient stream equality, host real equality, selected limits, countable choice, ambient completeness, or metric completeness.

Upgrade path: No further upgrade – chapter at the top of the formal axis.

The Lean TasteGate file at `lean4/BEDC/Derived/RealCompletionExactBoundaryUp/TasteGate.lean` supplies Nontrivial RealCompletionExactBoundaryUp and FieldFaithful RealCompletionExactBoundaryUp instances for the displayed finite carrier; bridge checking remains governed by the verification axis.

Lemma 1120.26 (Real completion exact-boundary forgetful projection)**.** *Let*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

be an accepted RealCompletionExactBoundaryUp *packet. The displayed boundary admits the finite target projection*

$$\mathrm{Forget}_{\mathrm{target}}(B) = (E, K, J, N),$$

where E is the terminal $\mathsf{Real}^{\uparrow}$ *target row, K is the displayed completion-seal classifier row, J is the displayed witness-ledger row, and N is the local* $\mathsf{NameCert}_{\mathsf{RealCompletionExactBoundaryUp}}$ *row. This projection is exact for target-facing reads: every accepted consumer that asks only for the target row, classifier row, ledger row, and local NameCert row factors through (E, K, J, N), while any accepted read that distinguishes two packets with the same (E, K, J, N) must inspect one of the dropped rows L, S, W, R, D, H, C, P and is therefore not a read of the target projection. No quotient stream row, host real equality row, selected-limit row, countable-choice row, ambient-completeness row, metric-completeness row, or machine row is exported by this projection.*

Proof. Project the accepted carrier through Definition 1120.1. The displayed packet has exactly the rows $L, K, J, S, W, R, D, E, H, C, P, N$. Among them, the terminal target coordinate is E, the classifier coordinate is K, the witness-ledger coordinate is J, and the local naming coordinate is N.

Apply Definition 1120.2. It identifies the same finite row inventory as the local $\mathsf{NameCert}_{\mathsf{RealCompletionExactBoundaryU}}$ surface: K is read as classifier exposure, J as witness-ledger exposure, E as terminal $\mathsf{Real}^{\uparrow}$ seal exposure, and N as local naming. The remaining rows L, S, W, R, D, H, C, P are respectively seal, synchronizer, finite-window, readback, dyadic-tolerance, transport, replay, and provenance support for the full boundary.

Thus the target projection is obtained by dropping exactly the support rows and retaining (E, K, J, N). A consumer whose request is restricted to target, classifier, ledger, and local NameCert data has no coordinate in that request for L, S, W, R, D, H, C, P, so its read factors through the displayed four-row projection.

It remains to rule out hidden coordinates. By Definition 1120.3, every accepted consumer of the full boundary factors through the displayed finite route and receives no quotient stream equality, host real equality, hidden selector, second seal route, detached witness ledger, or ambient completeness coordinate. By Definition 1120.14, there is also no insertion point for selected limits, metric completeness, or a machine row between the accepted boundary and the terminal $\mathsf{Real}^{\uparrow}(E)$ seal. Therefore two accepted packets with the same (E, K, J, N) can be distinguished only by inspecting one of the dropped displayed support rows, which is outside the target projection, or by asking for an absent ambient coordinate, which is not exported by the packet. □

Theorem 1120.27 (Real completion exact-boundary substrate relation boundary)**.** *Let*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

be an accepted RealCompletionExactBoundaryUp *packet. Any reading of this packet into a Rule 110, cellular, binary,* FKernel*, or* BHist *substrate must be a typed relation certificate over the displayed rows*

$$L, K, J, S, W, R, D, E, H, C, P, N,$$

with relation kind one of bisimulation, row embedding, or substrate mirror. It cannot be a definitional equality between the Real-completion boundary and the chosen substrate. The source side of the certificate is the displayed Real-completion route, the target side is the named substrate read, and the direction is fixed by the consumer route from the seal, classifier, witness-ledger, and budget rows through W, R, D, E to H, C, P, N. Any certificate that uses an unlisted host coordinate, unlisted source coordinate, quotient stream equality, host real equality, selected limit, countable choice, metric-completeness, ambient-completeness, or machine bridge row is not a certificate for the accepted boundary. Any displayed row among $L, K, J, S, W, R, D, E, H, C, P, N$ that is needed by that relation remains named in the certificate and is not eliminated by the substrate interpretation.

Proof. Project the carrier in Definition 1120.1. Its full displayed inventory is exactly the seal row L, classifier row K, witness-ledger row J, synchronizer row S, StreamName finite-window row W, RegSeqRat readback row R, DyadicRatCore tolerance row D, terminal Real seal row E, componentwise transport row H, continuation replay row C, package provenance row P, and local naming row N.

Apply Definition 1120.2. The local NameCert surface exposes those rows as one finite packet and exposes no coordinate for quotient stream equality, host real equality, hidden selection, a second seal route, detached witness evidence, or ambient completeness. Hence a substrate-facing

read has no object from which to form a definitional equality with a Rule 110, cellular, binary, FKernel, or external BHist substrate.

Use Definition 1120.4 and Definition 1120.11. They force the consumer direction: the rows L, K, J, S govern the route, the rows W, R, D, E are the visible completion and terminal faces, and the rows H, C, P, N transport, replay, package, and name that same route. Thus the only admissible substrate comparison is relational data attached to this route. If the comparison is symmetric behavioral matching, it is a bisimulation; if it injects the displayed route rows into a substrate ledger, it is a row embedding; if it interprets the same visible route in the substrate vocabulary without identifying carriers, it is a substrate mirror.

Finally apply Definition 1120.20 and Definition 1120.14. The scoped obligation surface is exhausted by $L, K, J, S, W, R, D, E, H, C, P, N$, and the excluded host, equality, selection, choice, completeness, and machine rows have no carrier slot or insertion point. Therefore every accepted substrate relation certificate must be read from the displayed rows, every unlisted coordinate is rejected, and every noneliminable displayed row remains named at the boundary rather than being collapsed into definitional equality. □

Theorem 1120.28 (Real completion exact-boundary left-right mirror boundary)**.** *Let*

$$B = (L, K, J, S, W, R, D, E, H, C, P, N)$$

be an accepted RealCompletionExactBoundaryUp *packet. A proposed left-right mirror read of this boundary is accepted only in the following rowwise sense: its source side is the displayed Real-completion route*

$$L, K, J, S, W, R, D, E, H, C, P, N,$$

and its target side is an interpretation of exactly the same named history, observation, result, termination, provenance, and certificate rows. Thus the mirror has no independent right-side seal, no independent right-side witness ledger, no second terminal Real row, and no separate right-side certificate row. If a proposed counterpart is obtained by renaming the displayed rows while preserving the roles of $L, K, J, S, W, R, D, E, H, C, P, N$, it is only a substrate-mirror interpretation of the same packet; if it requires any unlisted right-side row, then the asymmetry is a boundary condition rather than an accepted counterpart.

Proof. Project the accepted carrier through Definition 1120.1. The carrier exposes exactly the rows $L, K, J, S, W, R, D, E, H, C, P, N$: the completion seal L, seal classifier K, witness ledger J, synchronizer S, StreamName window W, RegSeqRat readback R, DyadicRatCore tolerance row D, terminal $\mathsf{Real}^{\uparrow}$ seal E, componentwise transport H, displayed Cont replay C, package provenance P, and local $\mathsf{NameCert}_{\mathsf{RealCompletionExactBoundaryUp}}$ row N.

Apply Definition 1120.2. The local NameCert surface consists exactly of those rows. In particular, the seal and classifier side L, K and the witness and budget side J, S are not two independent boundary objects; they are governing rows of the same displayed packet, and the later rows W, R, D, E are consumed only inside that packet.

Now use Definition 1120.13. Every completion-facing or terminal $\mathsf{Real}^{\uparrow}$ consumer reads exactly the finite route $L, K, J, S, W, R, D, E, H, C, P, N$. Therefore a mirror read cannot add a right-side history row, a right-side observation row, a second result row, a second terminal row, or a separate certificate row without leaving the accepted consumer route.

Finally apply Definition 1120.27. A substrate mirror is permitted only as typed relation data over the displayed rows, with source side, target side, and direction fixed by the consumer route; it is not a definitional equality with a second carrier. Together with Definition 1120.3 and Definition 1120.14, this excludes quotient stream equality, host real equality, selected limits, countable

choice, metric completeness, ambient completeness, machine coordinates, and unlisted source or target coordinates. Hence the only accepted left-right mirror is the row-preserving interpretation of the same finite packet, and any stronger right-side counterpart is recorded as the exact-boundary asymmetry. □

Chapter 1121

A Concrete Naming Certificate for $\mathsf{ObserverBudgetSupport}^{\uparrow}$

The $\mathsf{ObserverBudgetSupport}^{\uparrow}$ packet realizes observer-local support readings from chapter 9420 as one finite support-and-budget carrier. It sits after the observer-coordinate surface of chapter 609, the selected observer budget of chapter 1042, the finite support surface of chapter 835, and the cross-Hist causal surface of chapter 478. Its role is to bind the local observer frame, finite support ledger, causal witness rows, and budget cap before any observer-local consumer reads a finite ledger slice as a coherent support surface.

Definition 1121.1 (Observer-budget support carrier)**.** *An* $\mathsf{ObserverBudgetSupport}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$O = (F, S, X, B, T, H, C, P, N)$$

with the following displayed rows:

1. F *is the* $\mathsf{ObserverCoordinateFrame}^{\uparrow}$ *row naming the observer-local coordinate surface, not a global frame;*
2. S *is the* $\mathsf{FiniteSupport}^{\uparrow}$ *row listing the finite ledger entries visible to the observer;*
3. X *is the* $\mathsf{CrossHistCausal}^{\uparrow}$ *row recording the witnessed cross-Hist dependence used by the reading;*
4. B *is the* $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$ *row bounding the selected observation budget;*
5. T *is the support-transport row tying* F, S, X, B *into one observer-local route;*
6. H *records componentwise* hsame *transport for the frame, support, causal, budget, transport, provenance, and naming rows;*
7. C *records displayed* Cont *replay of the observer-coordinate read, support ledger read, cross-Hist causal read, budget read, and support transport;*
8. P *is the* Pkg *provenance over* $\mathsf{ObserverCoordinateFrame}^{\uparrow}$, $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$, $\mathsf{FiniteSupport}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* $\mathsf{NameCert}$ *rows;*
9. N *is the local* $\mathsf{NameCert}_{\mathsf{ObserverBudgetSupport}^{\uparrow}}$ *row.*

The carrier has no coordinate for a global observer frame, infinite support set, unbounded observation budget, unwitnessed cross-Hist relation, host spacetime object, quotient history equality, or detached support route.

Lean4 ✓ `BEDC.Derived.ObserverBudgetSupportUp.ObserverBudgetSupportTasteGate carrier recognition`

Theorem 1121.2 (Observer-budget support NameCert obligations)**.** *For the carrier of Definition 1121.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverBudgetSupport}^{\uparrow}}$ *surface consists of five rows:*

1. *carrier admission for* $O = (F, S, X, B, T, H, C, P, N)$*;*
2. *observer-coordinate admission through* F*;*
3. *finite support and selected-budget admission through* S *and* B*;*
4. *cross-Hist causal visibility through* X *together with support transport through* T*;*
5. *componentwise* hsame *transport, displayed replay, provenance, and local naming through* H, C, P, N*.*

No observer-local reading through this packet can bypass one of these rows.

Lean4 ✓ `BEDC.Derived.ObserverBudgetSupportUp.ObserverBudgetSupportNameCert obligations`

Proof. Project the carrier. The packet contains exactly the frame row F, support row S, causal row X, budget row B, transport row T, and structural rows H, C, P, N.

Read the sibling surfaces. The observer-coordinate row supplies the local frame, the finite-support row supplies the displayed ledger support, the cross-Hist causal row supplies witnessed dependence, and the observer-budget row supplies the selected finite budget.

Finally inspect T, H, C, P, N. The support-transport row ties the four sibling rows into one route, while the structural rows preserve, replay, source, and name that route. Since the carrier contains no further coordinate, the listed rows exhaust the local NameCert surface. □

Theorem 1121.3 (Observer-budget support nontrivial boundary)**.** *An accepted* $\mathsf{ObserverBudgetSupport}^{\uparrow}$ *packet is nontrivial exactly as a joint observer-local support-and-budget carrier: removing any one of* F, S, X, B, T *destroys one of observer-coordinate locality, finite support visibility, witnessed cross-Hist dependence, selected-budget boundedness, or the route tying them together. The packet is therefore not a renaming of any single sibling surface.*

Lean4 ✓ `BEDC.Derived.ObserverBudgetSupportUp.ObserverBudgetSupportNontrivialBoundary`

Proof. Start from the carrier in Definition 1121.1. The five content rows F, S, X, B, T play distinct roles in the accepted packet.

The row F supplies observer-coordinate locality; without it the packet has no local frame boundary. The row S supplies finite support; without it the reading has no finite ledger support. The row X supplies witnessed cross-Hist dependence; without it the route has no causal surface. The row B supplies the selected observation budget; without it the reading is unbounded. The row T ties those four rows into one route; without it the packet is only a list of sibling citations.

Thus the boundary is nontrivial at the carrier level. No projection to a single sibling can be inverted without recreating omitted rows. □

Theorem 1121.4 (Observer-budget support field faithfulness)**.** *Every field-faithful observer-local consumer of an accepted* $\mathsf{ObserverBudgetSupport}^{\uparrow}$ *packet must preserve the full tuple*

$$F, S, X, B, T, H, C, P, N.$$

In particular, it cannot keep the observer-coordinate row while dropping finite support, keep finite support while dropping the budget, keep the causal row while dropping transport, or read provenance and local naming as detached evidence.

Lean4 ✓ `BEDC.Derived.ObserverBudgetSupportUp.ObserverBudgetSupportFieldFaithfulness`

Proof. Use the NameCert obligations of Definition 1121.2. Each public read is assigned to one of the displayed rows $F, S, X, B, T, H, C, P, N$.

Field faithfulness is therefore rowwise. Dropping S erases the support ledger, dropping B erases the selected budget, dropping X erases the witnessed cross-Hist dependence, and dropping T disconnects the sibling rows from the observer-local route.

The structural rows are also part of the same carrier. Transport through H, replay through C, provenance through P, and local naming through N cannot be read as detached evidence because the carrier has no coordinate outside the displayed tuple. Hence a faithful consumer preserves all nine rows. □

Theorem 1121.5 (Observer-budget support route totality)**.** *Every accepted observer-local read of an* ObserverBudgetSupport$^{\uparrow}$ *packet routes through the finite tuple*

$$F, S, X, B, T, H, C, P, N.$$

The route may read the observer-coordinate row, finite support row, cross-Hist causal row, selected budget row, support transport row, componentwise hsame *row, displayed* Cont *replay,* Pkg *provenance, and local* NameCert *row, but it has no coordinate for a global observer frame, infinite support set, unbounded budget, host spacetime object, or unwitnessed cross-Hist relation.*

Proof. Begin with the carrier of Definition 1121.1. It lists $F, S, X, B, T, H, C, P, N$ as the complete support-and-budget packet.

Apply the NameCert obligations of Definition 1121.2. They force observer-coordinate admission through F, finite support through S, selected budget through B, causal visibility through X, and support transport through T before the structural rows can be consumed.

Finally use the nontrivial boundary and field-faithfulness rows from Definition 1121.3 and Definition 1121.4. Since no faithful consumer can drop any content row, every accepted route is total on the displayed tuple. □

Lean4 ✓ `BEDC.Derived.ObserverBudgetSupportUp.ObserverBudgetSupportRouteTotality`

Theorem 1121.6 (Observer-budget support ledger exactness)**.** *In an accepted* ObserverBudgetSupport$^{\uparrow}$ *packet, finite support, selected budget, cross-Hist causal evidence, and support transport are exact ledger rows rather than detached evidence. A consumer reads S, B, X, and T only as rows of the same carrier*

$$F, S, X, B, T, H, C, P, N.$$

Lean4 ✓ `BEDC.Derived.ObserverBudgetSupportUp.ObserverBudgetSupportLedgerExactness`

Proof. Project the carrier. The finite support row S, selected budget row B, causal row X, and transport row T appear in the same packet as the observer-coordinate and structural rows.

Use the NameCert obligations to read these rows together. The local certificate does not allow the support row to detach from the budget, the causal evidence to detach from transport, or the provenance and naming rows to certify a different object.

Now apply the nontrivial boundary and field-faithfulness theorems. Removing S, B, X, or T destroys the intended observer-local support-and-budget packet, so these rows are exact ledger content and not replaceable external evidence. □

Theorem 1121.7 (Observer-budget support public readback)**.** *Every public readback of an accepted* $\mathsf{ObserverBudgetSupport}^{\uparrow}$ *packet consumes the observer-coordinate row* F*, finite support row* S*, cross-Hist causal row* X*, selected budget row* B*, and support route row* T *together with the structural rows* H, C, P, N*. Thus public readback cannot expose support, causal evidence, budget, or route as independent host data.*

Lean4 ✓ `BEDC.Derived.ObserverBudgetSupportUp.ObserverBudgetSupportPublicReadback`

Proof. Start with route totality from Definition 1121.5. Any accepted observer-local read already passes through $F, S, X, B, T, H, C, P, N$.

Add ledger exactness from Definition 1121.6. The support, budget, causal, and route rows are not detachable evidence; they are ledger rows of the same accepted carrier.

Finally apply field faithfulness from Definition 1121.4. A public consumer that drops any of F, S, X, B, T no longer preserves the accepted packet, so every public readback consumes the full observer-coordinate, support, causal, budget, and route surface together. □

Theorem 1121.8 (Observer-budget support obligation-closure package)**.** *The carrier, NameCert obligations, nontrivial boundary, field-faithfulness, route-totality, ledger-exactness, and public-readback rows assemble the obligation-closure surface for* $\mathsf{ObserverBudgetSupport}^{\uparrow}$*. Every accepted observer-local support reading is bound to*

$$F, S, X, B, T, H, C, P, N$$

through the displayed BHist *carrier, componentwise* hsame *transport,* Cont *replay,* Pkg *provenance, and local* $\mathsf{NameCert}_{\mathsf{ObserverBudgetSupport}^{\uparrow}}$ *row.*

Lean4 ✓ `BEDC.Derived.ObserverBudgetSupportUp.ObserverBudgetSupportObligationClosurePackage`

Proof. Start with the carrier of Definition 1121.1 and the NameCert obligations of Definition 1121.2. They display the observer-coordinate, finite-support, cross-Hist causal, selected-budget, support-transport, and structural rows.

Use the nontrivial boundary and field-faithfulness theorems, Definition 1121.3 and Definition 1121.4. Together they show that no accepted consumer can collapse the packet to one sibling row or drop any displayed field.

Finally apply route totality, ledger exactness, and public readback from Definition 1121.5, Definition 1121.6, and Definition 1121.7. These results bind observer-local support, selected budget, causal evidence, transport, replay, provenance, and local naming into one obligation surface. □

Theorem 1121.9 (Observer-budget support bridge surface)**.** *Every bridge-facing observer-local support export of an accepted* $\mathsf{ObserverBudgetSupport}^{\uparrow}$ *packet factors through the finite tuple*

$$F, \quad S, \quad X, \quad B, \quad T, \quad H, \quad C, \quad P, \quad N.$$

The observer-coordinate row F*, finite-support row* S*, cross-*BHist *causal row* X*, selected budget row* B*, support-transport row* T*, componentwise* hsame *row* H*, displayed* Cont *replay row* C*,* Pkg *provenance row* P*, and local* $\mathsf{NameCert}_{\mathsf{ObserverBudgetSupport}^{\uparrow}}$ *row* N *are preserved as one bridge surface. No bridge-facing export may replace them by global observer frames, infinite support, unbounded budgets, detached host spacetime data, quotient history equality, or unwitnessed cross-*BHist *dependence.*

Lean4 ✓ `BEDC.Derived.ObserverBudgetSupportUp.ObserverBudgetSupport bridge surface`

Proof. First read the local certificate. The carrier and NameCert obligations, Definition 1121.1 and Definition 1121.2, display exactly the observer-coordinate, finite-support, causal, budget, transport, replay, provenance, and naming rows.

Next pass through the public surface. Public readback, Definition 1121.7, requires every accepted observer-local read to consume $F, S, X, B, T, H, C, P, N$ together rather than as detachable host data.

Finally use the obligation package and ledger exactness. Theorem 1121.8 assembles the same finite tuple as the chapter surface, and Theorem 1121.6 rules out replacing support, budget, causal evidence, or route transport by external witnesses. Thus a bridge-facing export preserves precisely the displayed tuple, with no additional coordinate for the excluded objects. □

The later Lean `TasteGate.lean` development for $\mathsf{ObserverBudgetSupport}^{\uparrow}$ will need explicit $\mathsf{Nontrivial\ ObserverBudgetSupport}^{\uparrow}$ and $\mathsf{FieldFaithful\ ObserverBudgetSupport}^{\uparrow}$ instances. These instances must preserve the observer-coordinate row, finite-support row, cross-Hist causal row, selected-budget row, support-transport row, componentwise transport, displayed replay, provenance, and local naming row.

Falsifiable prediction: If an accepted observer-local reading keeps the observer-coordinate row while replacing finite support, selected budget, cross-Hist causal evidence, or support transport by detached host data, it refutes the $\mathsf{ObserverBudgetSupport}^{\uparrow}$ classifier.

Independence witness: observercoordinateframe, observerfilterbudgetselector, finitesupport, crosshistcausal, observationbudgetlimiter: none is bijective to $\mathsf{ObserverBudgetSupport}^{\uparrow}$ because the carrier binds observer-local frame, finite support, cross-Hist causal evidence, selected budget, route transport, structural replay, provenance, and local NameCert rows in one packet.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverBudgetSupport}^{\uparrow}}$.

Constructive story: An $\mathsf{ObserverBudgetSupport}^{\uparrow}$ packet is generated from observer-coordinate, finite-support, cross-Hist causal, selected-budget, support-transport, componentwise hsame, displayed Cont, Pkg provenance, and local NameCert rows.

Lean4 ✓ `BEDC.Derived.ObserverBudgetSupportUp.taste gate`

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverBudgetSupport}^{\uparrow}}, \mathsf{maturePackageClosed})$

Scope closed: Definition 1121.1, Definition 1121.2, Definition 1121.3, Definition 1121.4, Definition 1121.7, Definition 1121.8, and Definition 1121.9 bind the observer-local support obligations, public readback row, obligation-closure package, and bridge-facing export surface to BHist, hsame, Cont, Pkg, NameCert, $\mathsf{ObserverCoordinateFrame}^{\uparrow}$, $\mathsf{FiniteSupport}^{\uparrow}$, $\mathsf{ObserverFilterBudgetSelector}^{\uparrow}$, $\mathsf{CrossHistCausal}^{\uparrow}$, and the support-transport row.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverBudgetSupport}^{\uparrow}}, \mathsf{theoremChecked})$

Lean target: `BEDC.Derived.ObserverBudgetSupportUp.taste\_gate`

Bridge status: paperBridge

Origin: ai

Not claimed: This chapter does not close bridge checking, global observer frames, infinite support, unbounded budgets, host spacetime objects, quotient history equality, or unwitnessed cross-Hist dependence.

Upgrade path: Bridge checking remains a separate verification-axis obligation for the observer-local support export surface.

Chapter 1122

A Concrete Naming Certificate for $\mathsf{ObserverSupportLattice}^{\uparrow}$

The $\mathsf{ObserverSupportLattice}^{\uparrow}$ packet realizes the observer support direction of chapter 9420 as a finite NameCert carrier. It sits after the observer-coordinate frame of chapter 609, the finite support surface of chapter 835, the locality-cell surface of chapter 509, the observer-budget support packet of chapter 1121, and the conscious observer state of chapter 578. Its role is to bind local frame, finite support, locality cell, budget support, route, transport, provenance, and local naming rows before any observer-local support consumer treats a support read as stable observer evidence.

Definition 1122.1 (Observer-support lattice carrier)**.** *An* $\mathsf{ObserverSupportLattice}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$L = (F, S, C, B, R, H, Q, P, N)$$

with the following displayed rows:

1. *F is the* $\mathsf{ObserverCoordinateFrame}^{\uparrow}$ *row naming the local observer frame;*
2. *S is the* $\mathsf{FiniteSupport}^{\uparrow}$ *row naming the finite support ledger available to that frame;*
3. *C is the* $\mathsf{LocalityCell}^{\uparrow}$ *row that bounds the local spatial and relation-cell read;*
4. *B is the* $\mathsf{ObserverBudgetSupport}^{\uparrow}$ *row restricting which support reads are budget-admissible;*
5. *R is the observer-local support route tying F, S, C, B to the conscious observer state consumer;*
6. *H records componentwise* hsame *transport for the frame, support, locality, budget, route, provenance, and naming rows;*
7. *Q records displayed* Cont *replay of the support-lattice read;*
8. *P is the* Pkg *provenance over* $\mathsf{ObserverSupportLattice}^{\uparrow}$, $\mathsf{ObserverCoordinateFrame}^{\uparrow}$, $\mathsf{FiniteSupport}^{\uparrow}$, $\mathsf{LocalityCell}^{\uparrow}$, $\mathsf{ObserverBudgetSupport}^{\uparrow}$, $\mathsf{ConsciousObserverState}^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows;*
9. *N is the local* $\mathsf{NameCert}_{\mathsf{ObserverSupportLattice}^{\uparrow}}$ *row.*

The carrier has no coordinate for a global observer frame, infinite support set, detached spacetime manifold, unbudgeted support read, quotient history equality, or host-level consciousness object.

Lean4 ✓ `BEDC.Derived.ObserverSupportLatticeUp.ObserverSupportLatticeTasteGate single carrier alignment`

Theorem 1122.2 (Observer-support lattice NameCert obligations)**.** *For the carrier of Definition 1122.1, the local* $\mathsf{NameCert}_{\mathsf{ObserverSupportLattice}^{\uparrow}}$ *surface consists of five rows:*

1. *carrier admission for* $L = (F, S, C, B, R, H, Q, P, N)$*;*
2. *frame and conscious-state anchoring through* $\mathsf{ObserverCoordinateFrame}^{\uparrow}$ *and* $\mathsf{ConsciousObserverState}^{\uparrow}$*;*
3. *finite support and locality-cell admission through* S *and* C*;*
4. *budget support and route exactness through* B *and* R*;*
5. *componentwise* hsame *transport, displayed* Cont *replay, package provenance, and local naming through* H, Q, P, N*.*

No accepted observer-local support read can bypass one of these rows.

Proof. Project the carrier of Definition 1122.1. The packet contains exactly the frame row F, support row S, locality-cell row C, budget-support row B, route row R, and structural rows H, Q, P, N.

Read the sibling surfaces in the displayed order. The observer-coordinate frame anchors the local observer frame, the finite support row supplies the visible ledger entries, the locality cell bounds the local relation read, and the observer-budget support row records which support reads are admissible for the consumer.

Finally attach R, H, Q, P, N. The route row ties the four sibling surfaces to the observer-local read, while the structural rows preserve, replay, source, and name that route. Since the carrier contains no extra coordinate, the five listed rows exhaust the local NameCert obligations. □

Lean4 ✓ `BEDC.Derived.ObserverSupportLatticeUp.ObserverSupportLatticeCarrier namecert obligations`

Theorem 1122.3 (Observer-support lattice route exactness)**.** *Every observer-local support read of an accepted* $\mathsf{ObserverSupportLattice}^{\uparrow}$ *packet factors through the lattice route*

$$F \longmapsto S \longmapsto C \longmapsto B \longmapsto R \longmapsto H \longmapsto Q \longmapsto P \longmapsto N.$$

In particular, a consumer cannot preserve the observer frame and finite support rows while replacing the locality-cell or budget-support route by host spacetime data, an unbounded read, a quotient of histories, or a detached conscious-state object.

Lean4 ✓ `BEDC.Derived.ObserverSupportLatticeUp.ObserverSupportLatticeCarrier route exactness`

Proof. Begin with the NameCert obligations of Definition 1122.2. They require every accepted read to expose the carrier row, frame and conscious-state anchoring, finite support, locality cell, budget support, route, transport, replay, provenance, and local naming rows.

The support read is therefore routed through F, S, C, B, R before any structural row is consumed. The frame row alone supplies no support ledger, the finite support row alone supplies no locality-cell boundary, and the locality-cell row alone supplies no budget-admissible support consumer.

It remains to rule out replacements. Because H, Q, P, N preserve and replay the same displayed route, a consumer that swaps C or B for host spacetime data, an unbounded read, quotient history equality, or a detached state object no longer reads the accepted carrier. Hence every observer-local support read factors through the lattice route exactly. □

The later Lean `TasteGate.lean` development for $\mathsf{ObserverSupportLattice}^{\uparrow}$ must provide explicit $\mathsf{Nontrivial\ ObserverSupportLattice}^{\uparrow}$ and $\mathsf{FieldFaithful\ ObserverSupportLattice}^{\uparrow}$ instances with `witness_pair` and field-preservation witnesses. These instances must preserve the frame row, finite-support row, locality-cell row, budget-support row, route row, componentwise transport, displayed replay, provenance, and local naming row.

Falsifiable prediction: If an observer-local support consumer preserves the frame and finite support rows while replacing the locality-cell or budget-support route by host spacetime data, it refutes the $\mathsf{ObserverSupportLattice}^{\uparrow}$ classifier.

Independence witness: observercoordinateframe, finitesupport, localitycell, observerbudgetsupport, consciousobserverstate: none is bijective to $\mathsf{ObserverSupportLattice}^{\uparrow}$ because only the lattice packet carries frame, support, locality, budget, route, transport, provenance, and local NameCert rows together.

Closure status for $\mathsf{NameCert}_{\mathsf{ObserverSupportLattice}^{\uparrow}}$.

Constructive story: The observer-support lattice is generated by collecting the observer-indexed support rows already present in a $BHist$ ledger and ordering them only by the carrier's visible inclusion convention. Each support cell is read through $hsame$, so two histories that present the same observer support cannot be separated by a hidden host equality test. Continuation information appears as Cont-stable route extension: a later observation may extend a support row, but it must keep the lattice address and carrier evidence already recorded. The NameCert route is therefore built bottom-up from support rows, lattice comparability, and non-escaping observer routes rather than from an external set-theoretic lattice.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{ObserverSupportLattice}^{\uparrow}}, \mathsf{seed})$

Scope closed: This chapter binds the observer-support lattice carrier, its NameCert obligations, and the route-exactness theorem.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{ObserverSupportLattice}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: It does not claim a complete ambient lattice, observer identity outside the ledger, or joins computed by host equality.

Upgrade path: Reaching obligationClosure requires formal carriers for support rows and checked $hsame$ preservation of the route-exactness argument.

Chapter 1123

A Concrete Naming Certificate for $\mathsf{CellularBoundaryCondition}^{\uparrow}$

The $\mathsf{CellularBoundaryCondition}^{\uparrow}$ packet realizes the edge-policy surface left implicit by the cellular-carrier alternative of chapter 9391. It is a composite over the local update packet of chapter 984, the substrate carrier of chapter 942, the carrier-encoding packet of chapter 943, the substrate classifier of chapter 945, and the row classifier of chapter 941. Its datum is not another orbit evaluator; it is the finite edge policy by which local reads at the boundary are admitted, refused, or padded before a local update rule may inspect them.

Falsifiable prediction: No accepted $\mathsf{CellularBoundaryCondition}^{\uparrow}$ packet exports a global orbit, hidden evaluator, or unregistered boundary row beyond its displayed edge policy.

Independence witness: cellularlocalupdaterule, cellularsubstrate, cellularcarrierencoding, cellularsubstrateclassifier, cellularrowclassifier: none is bijective to $\mathsf{CellularBoundaryCondition}^{\uparrow}$ because the listed siblings respectively carry local transition, substrate, encoding, substrate-classifier, or row-classifier rows, while this packet carries the finite edge-policy rows that determine which boundary reads are admitted before local update.

Definition 1123.1 (Cellular boundary condition carrier)**.** *A* $\mathsf{CellularBoundaryCondition}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$B = (E, W, R, A, H, C, P, N)$$

with the following displayed rows:

1. *E is the finite edge-policy row, displaying the admitted boundary convention such as fixed edge, periodic edge, reflected edge, refused edge, or explicitly padded edge.*
2. *W is the boundary-window row, naming the finite cell positions at which a local neighbourhood would otherwise cross the displayed row boundary.*
3. *R is the local update-read row, citing the* $\mathsf{CellularLocalUpdateRule}^{\uparrow}$ *surface whose neighbourhood reads are constrained by E and W.*
4. *A is the admission ledger recording which boundary reads are accepted, which are refused, and which are filled by a displayed padding row.*
5. *H records componentwise* hsame *transport for the edge policy, boundary window, update-read row, admission ledger, continuation route, package provenance, and local name.*
6. *C records the displayed* Cont *route through E, W, R, A, H, P, N.*

7. *P is the* Pkg *provenance over* CellularBoundaryCondition$^{\uparrow}$, CellularLocalUpdateRule$^{\uparrow}$, CellularSubstrate$^{\uparrow}$, CellularCarrierEncoding$^{\uparrow}$, CellularSubstrateClassifier$^{\uparrow}$, CellularRowClassifier$^{\uparrow}$, BHist, hsame, Cont, Pkg, *and* NameCert *rows.*

8. *N is the local* $\mathsf{NameCert}_{\mathsf{CellularBoundaryCondition}^{\uparrow}}$ *row.*

The classifier for B reads only the displayed edge policy, boundary window, constrained local update read, admission ledger, transport row, continuation route, provenance, and local name. It has no coordinate for a global orbit, host evaluator, unregistered boundary row, unstated padding convention, or detached substrate classifier.

Lean4 ✓ `BEDC.Derived.CellularBoundaryConditionUp.CellularBoundaryConditionCarrierSemanticNameCert`

Theorem 1123.2 (CellularBoundaryCondition NameCert obligations)**.** *For the carrier of Definition 1123.1, the local* $\mathsf{NameCert}_{\mathsf{CellularBoundaryCondition}^{\uparrow}}$ *surface consists exactly of carrier admission for*

$$B = (E, W, R, A, H, C, P, N),$$

edge-policy exposure through E, boundary-window exposure through W, local update-read accountability through R, admission and refusal replay through A, componentwise stability through H, displayed route replay through C, package provenance through P, and local naming through N. A consumer may use the packet as boundary-condition evidence only through those rows.

Proof. Carrier admission is projection from Definition 1123.1. The packet displays the edge policy, boundary window, local update-read row, admission ledger, transport row, continuation route, provenance row, and local name before any consumer can read the boundary surface.

The cellular content is split between E, W, R, A. The edge-policy row E states the accepted boundary convention, the window row W identifies the finite neighbourhood reads that meet the edge, and the update-read row R records which local rule surface is constrained by that edge policy.

Admission and refusal are read from A. This ledger records accepted boundary reads, refused boundary reads, and explicitly padded reads, so the consumer cannot replace the displayed edge policy by an unregistered boundary row.

Finally use H, C, P, N. These rows transport, replay, package, and name the same finite packet, and they introduce no global orbit, host evaluator, hidden padding convention, or detached substrate classifier. □

Lean4 ✓ `BEDC.Derived.CellularBoundaryConditionUp.CellularBoundaryConditionTasteGate single carrier alignment`

Theorem 1123.3 (CellularBoundaryCondition non-escape boundary)**.** *Every accepted* CellularBoundaryCondition$^{\uparrow}$ *public read factors through the finite route*

$$E, W, R, A, H, C, P, N.$$

The route may expose the displayed edge policy, the affected boundary windows, the constrained local update-read row, and the admission ledger. It cannot export a global cellular orbit, a hidden evaluator, an unregistered boundary row, an unstated padding convention, or a substrate-wide classifier.

Lean4 ✓ `BEDC.Derived.CellularBoundaryConditionUp.CellularBoundaryConditionNonescapeBoundary`

Proof. Start with the NameCert obligation surface of Definition 1123.2. Every public read reaches the local name only after the edge-policy row, boundary-window row, local update-read row, admission ledger, transport row, continuation route, and provenance row have been displayed.

The local update read is present only as R. It can use the boundary policy named by E and the finite boundary window named by W, but it cannot import the global orbit or a host evaluator as an extra source of boundary cells.

The admission ledger A separates accepted, refused, and padded boundary reads. Because the padding row must be displayed when it is used, an unstated padding convention or unregistered boundary row has no coordinate in the packet.

Thus any read of a global orbit, hidden evaluator, unregistered boundary row, unstated padding convention, or substrate-wide classifier would require data absent from $B = (E, W, R, A, H, C, P, N)$. Such a read is outside the accepted boundary-condition certificate. □

The Lean TasteGate surface expected for this packet is `BEDC.Derived.CellularBoundaryConditionUp.TasteG` Its paper-side carrier is already fixed by E, W, R, A, H, C, P, N and by the non-escape boundary above.

Closure status for $\mathsf{NameCert}_{\mathsf{CellularBoundaryCondition}^{\uparrow}}$.

Constructive story: A $\mathsf{CellularBoundaryCondition}^{\uparrow}$ packet is generated from a finite edge-policy row, boundary-window row, constrained local update-read row, admission ledger, componentwise hsame transports, displayed continuation route, package provenance, and local NameCert row. Its composite dependency surface is the edge-policy, boundary-window, local update-read, admission-ledger, continuation-route, package-provenance, and local naming surfaces.

Theory closure: $\mathsf{TheoryGate}(\mathsf{NameCert}_{\mathsf{CellularBoundaryCondition}^{\uparrow}}, \mathsf{seed})$

Scope closed: Definition 1123.1, Definition 1123.2, and Definition 1123.3 bind the finite edge-policy carrier, its local NameCert obligations, and its non-escape boundary for local update reads.

Formal verification: $\mathsf{FormalStatus}(\mathsf{NameCert}_{\mathsf{CellularBoundaryCondition}^{\uparrow}}, \mathsf{unformalized})$

Bridge status: none

Origin: ai

Not claimed: This chapter does not close global cellular orbit evaluation, host evaluator correctness, substrate universality, complete row-classifier coverage, Lean implementation, or standard bridge.

Upgrade path: Checked closure requires Lean encoding of the carrier plus Nontrivial and FieldFaithful TasteGate instances preserving the edge policy, boundary window, constrained local update read, admission ledger, route, provenance, and local naming projections.

Chapter 1124

A Concrete Naming Certificate for $\mathsf{RealityConstrainedModelAudit}^{\uparrow}$

The $\mathsf{RealityConstrainedModelAudit}^{\uparrow}$ interface realizes the physical model audit program of section 9414.60 as a finite BEDC naming certificate. It is a composite over the finite stream and real-name surfaces of chapter 126 and chapter 38: those chapters supply finite observation names and real-valued readback rows, while this chapter packages the physical audit rows that decide whether a model-facing fit claim may pass an acceptance gate.

Definition 1124.1 (Reality-constrained model-audit carrier)**.** *A* $\mathsf{RealityConstrainedModelAudit}^{\uparrow}$ *carrier is a finite* BHist *packet*

$$A = (H, \Pi, O, M, C, T, L, F, S)$$

whose displayed rows are as follows:

1. H *is the finite source-trace history for the audited physical system;*
2. Π *is the observation bundle naming the finite queries through which the system is read;*
3. O *is the observed-signature row extracted from* H *under* Π*;*
4. M *is the model-generated signature row declared by the candidate model;*
5. C *is the classifier row comparing* O *and* M *at the declared physical-fit level;*
6. T *is the approximation-tower row by which source traces, observations, and model signatures are related;*
7. L *is the audit-ledger row recording provenance, hidden compression, translation, and idealization entries;*
8. F *is the failure-surface row naming the finite defeating observations or signature mismatches that would invalidate the declared claim;*
9. S *is the audit-strength row, ranging from seed-level model support through reproduced and bridged fit surfaces.*

The carrier is exactly this finite packet. It contains no unrecorded source row, no hidden compression step, no external oracle for model truth, and no physical-fit claim outside the displayed ledger.

Lean4 ✓ BEDC.Derived.RealityConstrainedModelAuditUp.RealityConstrainedModelAuditCarrierSemanticNameCert

Definition 1124.2 (Reality-constrained model-audit classifier)**.** *For accepted packets*

$$A = (H, \Pi, O, M, C, T, L, F, S) \quad \textit{and} \quad A' = (H', \Pi', O', M', C', T', L', F', S'),$$

the predicate $\mathsf{RealityConstrainedModelAuditClassifier}(A, A')$ *holds when the component rows are related by displayed* hsame *transports, the observation bundle routes replay through the same finite source-trace schedule, the observed and model-generated signatures preserve the classifier comparison, the approximation tower and audit ledger transport componentwise, the failure-surface rows name the same defeating tests, and the declared strength comparison is preserved.*

Thus classifier agreement is not raw equality of models. It is hsame-stable agreement of the source, observation, signature, classifier, tower, ledger, failure, and strength rows together with preservation of the declared physical-fit comparison.

Theorem 1124.3 (Reality-constrained model-audit NameCert obligations)**.** *For the carrier of Definition 1124.1, the local* $\mathsf{NameCert}_{\mathsf{RealityConstrainedModelAudit}^{\uparrow}}$ *surface consists of the following five obligation rows:*

1. *carrier admission: the accepted object is exactly* $A = (H, \Pi, O, M, C, T, L, F, S)$*;*
2. *classifier stability: every accepted comparison uses the classifier of Definition 1124.2;*
3. *signature exactness: the observed row* O *and model-generated row* M *are the only signatures licensed for the fit claim;*
4. *ledger exactness: every compression, translation, idealization, and hidden-content row used by the audit appears in* L*;*
5. *non-escape: a fit claim that depends on a row absent from* $H, \Pi, O, M, C, T, L, F, S$ *is outside the acceptance gate.*

Lean4 ✓ BEDC.Derived.RealityConstrainedModelAuditUp.RealityConstrainedModelAuditTasteGate
single carrier alignment

Proof. Carrier admission projects the nine rows displayed in Definition 1124.1. Each accepted read begins from the same finite packet, so no additional source trace or model-signature coordinate can be introduced later in the certificate.

Classifier stability follows by unpacking Definition 1124.2. The transports compare the source, observation, signature, tower, ledger, failure, and strength rows componentwise and preserve the declared fit comparison.

The signature and ledger obligations are the distinguished projections of the same packet. Rows O and M carry the comparison surface, while L records the compression, translation, idealization, and hidden-content material consumed by that comparison.

The non-escape clause is forced by the carrier inventory. Since the packet has no coordinate beyond $H, \Pi, O, M, C, T, L, F, S$, a claim depending on any unlisted row cannot be projected by the local naming certificate. □

Theorem 1124.4 (Reality-constrained model-audit ledger non-escape)**.** *A model-audit packet with an unledgered compression row cannot pass the acceptance gate for any fit claim whose signature depends on that hidden row. The accepted route must expose the source trace, observation bundle, observed signature, model-generated signature, classifier, approximation tower, audit ledger, failure surface, and strength row before the fit claim is read.*

Lean4 ✓ `BEDC.Derived.RealityConstrainedModelAuditUp.RealityConstrainedModelAuditLedgerNonescape`

Proof. Read the NameCert obligations of Definition 1124.3. Ledger exactness places every compression or translation row used by the fit comparison inside L.

If a fit claim depends on a hidden compression row not present in L, then the claim asks the acceptance gate to read a coordinate outside $A = (H, \Pi, O, M, C, T, L, F, S)$. The non-escape obligation excludes exactly that route.

Therefore the acceptance gate can pass only claims whose signature dependence is visible in the displayed ledger. The unledgered row remains outside the accepted packet. □
